Contents

Contributors XVii
Preface to the 1st Edition: *Abba J. Kastin* li
Preface to the 2nd Edition: *Abba J. Kastin* liii

Section I
Plant Peptides
Yoshikatsu Matsubayashi

1. **CLAVATA3** 1
Shinichiro Sawa

2. **Defense Signal Peptides** 5
Yube Yamaguchi, Gregory Pearce and Alisa Huffaker

3. **DVL/RTFL** 15
Elene R. Valdivia, Kate L. Hertweck, Sung Ki Cho and John C Walker

4. **EPF** 20
Tatsuo Kakimoto

5. **IDA/IDL** 24
Melinka A. Butenko, Robert Kumpf and Reidunn B. Aalen

6. **LUREs** 31
Tetsuya Higashiyama

7. **Phytosulfokine** 35
Yoshikatsu Matsubayashi

8. **POLARIS** 40
Keith Lindsey, Saher Mehdi, Stuart A. Casson, Anna J. Mudge, Jennifer F. Topping and Junli Liu

9. **RALF Peptides** 46
Juliano R. Guerreiro, Gregory Pearce, Marcio C. Silva-Filho and Daniel S. Moura

10. **Root Meristem Growth Factor** 50
Yoshikatsu Matsubayashi

11. **ROTUNDIFOLIA4** 53
Takahiro Yamaguchi, Momoko Ikeuchi and Hirokazu Tsukaya

12. **SCR** 58
Sushma Naithani, Palitha Dharmawardhana and June B. Nasrallah

13. **Stomagen/EPFL9** 67
Tomoo Shimada, Shigeo S. Sugano and Ikuko Hara-Nishimura

14. **TDIF** 71
Yuki Kondo, Yuki Hirakawa and Hiroo Fukuda

Section II
Bacterial/Antibiotic Peptides
Robert E.W. Hancock

15. **Cathelicidins** 77
Neeloffer Mookherjee, Kelly L. Brown and Robert E.W. Hancock

16. **Class II Non-Lantibiotic Bacteriocins** 85
Ingolf F. Nes, Dag A. Brede and Dzung B. Diep

17. **Colicins** 93
O. Sharma, S.D. Zakharov, M.V. Zhalnina, E. Yamashita and W.A. Cramer

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY
Copyright Elsevier 2024

18. Defensins 101
Nikolinka Antcheva, Filomena Guida and Alessandro Tossi

19. Lantibiotics 119
Jasmin Dischinger, Imke Wiedemann, Gabriele Bierbaum and Hans-Georg Sahl

20. Microcins 129
Sylvie Rebuffat

21. Nonribosomal Peptide Synthesis 138
Jan Grünewald and Mohamed A. Marahiel

22. Peptaibols 150
César de la Fuente-Núñez, L. Whitmore and B.A. Wallace

Section III
Fungal Peptides
Tzi Bun Ng

23. Antifungal and Antibacterial Peptides of Fungal Origin 157
Tzi Bun Ng

24. Fungal Peptides with Ribonuclease and Ribosome Inactivating Activities 162
Tzi Bun Ng

25. Fungal Toxins 166
Jack Ho Wong

26. Plant Antifungal Peptides 169
Suzana Meira Ribeiro, William Farias Porto, Osmar Nascimento Silva, Marcelo de Oliveira Santos, Simoni Campos Dias and Octávio Luiz Franco

27. Polysaccaride Krestin (PSK) and Polysaccharopeptide PSP 180
Jennifer Man-Fan Wan

Section IV
Invertebrate Peptides
Ronald J. Nachman

28. AKH/RPCH Peptides 185
Gerd Gäde and Heather G. Marco

29. Allatostatins 191
Stephen S. Tobe and William G. Bendena

30. Allatotropin 197
Frank M. Horodyski

31. B-Type Allatostatins and Sex Peptides 203
Hans Peter Vandersmissen, Ronald J. Nachman and Jozef Vanden Broeck

32. Crustacean Bioactive Peptides 209
H. Dircksen

33. Developmental Peptides: ETH, Corazonin, and PTTH 222
Michael E. Adams, Young-Joon Kim, Yoonseong Park and Dusan Zitnan

34. Diuretic/Antidiuretic 229
Geoffrey M. Coast and David A. Schooley

35. FMRFamide-Like Peptides (FLPs) 237
Ian Orchard and Angela B. Lange

36. Free-Living Nematodes 247
E.P. Masler

37. FXPRLamide (Pyrokinin/PBAN) Family 255
Miriam Altstein, Aliza Hariton and Ronald J. Nachman

38. Insulin-Like Peptides 267
Yevgeniya Antonova-Koch, Michael A. Riehle, Anam J. Arik and Mark R. Brown

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

39. Molluscan Bioactive Peptides 276
Anna Di Cosmo and Gianluca Polese

40. Parasitic Nematode Peptides 287
Nikki J. Marks and Aaron G. Maule

41. Pigment Dispersing Factor 298
Liesbet Temmerman, Ellen Meelkop and Liliane Schoofs

42. Proctolin 304
Angela B. Lange and Ian Orchard

43. Sulfakinins 310
Liliane Schoofs, Tom Janssen and Ronald J. Nachman

44. Tachykinin Peptides 315
Dick R. Nässel

Section V
Amphibian/Skin Peptides
J. Michael Conlon

45. Bradykinin Peptides 321
J. Michael Conlon

46. Bombesin Peptides 326
Eliot R. Spindel

47. Bombinins 331
Vincenzo Luca, Donatella Barra and Maria Luisa Mangoni

48. Caeruleins 338
John H. Bowie

49. Chromogranins/Secretogranins 342
Maité Montero-Hadjadje, Charlène Delestre, Maité Courel and Youssef Anouar

50. Dermaseptins 350
Pierre Nicolas and Ali Ladram

51. Insulin-Releasing Peptides 364
Opeolu O. Ojo, Peter R Flatt, Yasser H.A. Abdel-Wahab and J. Michael Conlon

52. Neurohypophysial Peptides 371
Sunny K. Boyd

53. Opioid and Bv8 Peptides 376
Lucia Negri, Pietro Melchiorri and Roberta Lattanzi

54. Sodefrin and Related Pheromones 384
Sakae Kikuyama, Fumiyo Toyoda, Kazutoshi Yamamoto, Takeo Iwata, Tomoaki Nakada and Itaru Hasunuma

55. Tachykinins 391
Cinzia Severini and Giovanna Improta

56. Temporins 400
Andrea C. Rinaldi and J. Michael Conlon

Section VI
Venom Peptides
Jean-Marc Sabatier

57. Animal Toxins 407
Jean-Marc Sabatier and Michel De Waard

58. Hymenoptera Insect Peptides 416
Mario Sergio Palma

59. Scorpion Peptides 423
Ricardo C. Rodríguez de la Vega, Nicolas Vidal and Lourival D. Possani

60. Sea Anemone Peptides 430
Raymond S. Norton

61. Snail Peptides 437
Baldomero M. Olivera, Julita S. Imperial and Gisela P. Concepcion

62. Snake Peptides 451
Alan L. Harvey

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

63. Spider Peptides 461
Graham M. Nicholson

64. Targets and Therapeutic Properties 473
Christine Beeton

65. Worm Peptides 483
William R. Kem

Section VII
Cancer/Anticancer Peptides
Terry Moody

66. Adrenomedullin 489
Frank Cuttitta and Alfredo Martínez

67. Angiotensin II/Angiotensin-(1–7) 494
Patricia E. Gallagher, Alison L. Arter, Bhavani Krishnan, Maria A. Garcia-Espinosa and E. Ann Tallant

68. Apelin 502
Frank Cuttitta and David S. Salomon

69. Bombesin Peptides 506
Robert T. Jensen and Terry W. Moody

70. Endothelin-1 512
Samer-ul Haque, Hazel Welch and Marilena Loizidou

71. Gastrin 519
Jens F. Rehfeld and Jens P. Goetze

72. Leptin/Adiponectin 524
Hong Tu

73. LHRH Analogs 531
Andrew V. Schally, Jorg B. Engel, Jacek Pinski and Norman L. Block

74. Orexins (Hypocretins) 541
Marc Laburthe and Thierry Voisin

75. Somatostatin/NPY 548
Meike Körner and Jean Claude Reubi

76. VIP/PACAP Receptors 556
Terry W. Moody and Robert T. Jensen

Section VIII
Vaccine Peptides
Pravin T.P. Kaumaya

77. Antiadhesin Peptide-Based Vaccines for *Pseudomonas aeruginosa* 563
Wendy J. Hartsock, Clifton Hackbarth and Robert S. Hodges

78. Lipo-Peptides/Saccharides for Peptide Vaccine Delivery 571
Mariusz Skwarczynski, Mehfuz Zaman and IstvanToth

79. Novel Tumor Derived Peptides in Vaccines 580
Anthony W. Purcell, Nathan P. Croft and Nadine L. Dudek

80. Peptide Vaccine for Alzheimer's Disease 590
Beka Solomon

81. Peptide Vaccines for Myeloid Leukemias 596
Pratap Neelakantan and Katayoun Rezvani

82. Peptide Vaccines for Otitis Media 603
Laura A. Novotny and Lauren O. Bakaletz

83. Therapeutic Peptides Targeting HER-2/*neu* and VEGF Signaling Pathways in Breast Cancer 612
Kevin Chu Foy, Daniele Vicari and Pravin T.P. Kaumaya

84. Use of Positional Scanning Libraries to Identify Immunologically Relevant Peptides 617
Mireia Sospedra, Valeria Judkowski, Jon R. Appel and Clemencia Pinilla

Section IX
Immune/Inflammatory Peptides
Joost Oppenheim

85. Anaphylatoxins 625
De Yang

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

86. Annexin-A1 Peptide Ac2–26 631
M Perretti, F D'Acquisto and R.J. Flower

87. Immunoregulatory Neuropeptides 640
Mario Delgado

88. Chemerin 649
Marc Parmentier

89. Chemokines 656
Sunny C. Yung and Joshua M. Farber

90. DP IV/CD26 Effector Peptides 664
Siegfried Ansorge and Dirk Reinhold

91. FPR Ligands 671
Ying Liu, Keqiang Chen and Ji Ming Wang

92. Neuroimmune Peptides 681
Ning Zhang, Hua Geng and Joost J. Oppenheim

93. Peptide Loading of MHC 687
Melissa J. Call

94. Peptide Recognition by T Cells 697
Malte Mohme and Roland Martin

95. RGD Peptides 705
Ignacy Z. Siemion, Alicja Kluczyk and Marek Cebrat

Section X
Brain Peptides
Hubert Vaudry

96. Apelin 715
Xavier Iturrioz and Catherine Llorens-Cortes

97. BNP/CNP 724
Yoshio Takei

98. CART 732
Csaba Fekete and Ronald M. Lechan

99. CCK 738
Margery C. Beinfeld

100. CGRP/Adrenomedullin 744
Denise Wootten, Nanda Tilakaratne, Arthur Christopoulos and Patrick M. Sexton

101. CRH Family 752
David A. Lovejoy

102. Endozepines 760
Marie-Christine Tonon, Jerome Leprince, Fabrice Morin, Pierrick Gandolfo, Vincent Compere, Georges Pelletier, Maria M. Malagon and Hubert Vaudry

103. Galanin and GALP 766
Andrew L. Gundlach and Philip J. Ryan

104. Ghrelin 776
Masayasu Kojima, Yuki Nakamura, Takahiro Sato and Kenji Kangawa

105. GHRH 784
Maria M. Malagon, Rafael Vazquez-Martinez, Antonio J. Martinez-Fuentes, Francisco Gracia-Navarro and Justo P. Castaño

106. GnRH (LHRH) 792
R.P. Millar

107. Gonadotropin-Inhibitory Hormone 802
Kazuyoshi Tsutsui and Takayoshi Ubuka

108. Hypocretins (Orexins) 812
Luis de Lecea and J. Gregor Sutcliffe

109. Kisspeptins 819
Manuel Tena-Sempere

110. MCH 828
Françoise Presse and Jean-Louis Nahon

111. Melanocortins 838
Sylvie Jégou, Roger D. Cone, Alex N. Eberlé and Hubert Vaudry

112. MIF-1/Tyr-MIF-1 845
Abba J. Kastin and Weihong Pan

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

113. Nesfatin-1 850
Andreas Stengel and Yvette Taché

114. Neuromedin U 856
Preeti H. Jethwa, Caroline J. Small, Michael Patterson and Stephen R. Bloom

115. Neuropeptide B/W 863
Fumiko Takenoya, Haruaki Kageyama, Ki Sung Kang and Seiji Shioda

116. Neuropeptide S 869
Rainer K. Reinscheid

117. Neurotensin/Neuromedin N 875
Paul R. Dobner and Robert E. Carraway

118. NPY 883
Yvan Dumont and Rémi Quirion

119. PACAP 889
David Vaudry, Tomoya Nakamachi, Magali Basille, Olivier Wurtz, Alain Fournier, Hubert Vaudry and Seiji Shoida

120. Prolactin-Releasing Peptide 898
Shuji Hinuma and Norio Iijima

121. Relaxin 907
Andrew L. Gundlach, Craig M. Smith, Philip J. Ryan, Anna Blasiak, Francisco E. Olucha-Bordonau and Sherie Ma

122. 26RFa 917
Jérôme Leprince, Cindy Neveu, Benjamin Lefranc, Laure Guilhaudis, Isabelle Segalas-Milazzo, Jean-Claude do Rego, Manuel Tena-Sempere, Kazuyoshi Tsutsui and Hubert Vaudry

123. Secretin 924
Stephanie Y.L. Ng, Carrie Y.Y. Cheng and Billy K.C. Chow

124. Somatostatin/Cortistatin 933
Jacques Epelbaum, Cécile Viollet and Raphaelle Winsky-Sommerer

125. Tachykinins 943
Nigel M. Page

126. TRH 951
A. Eugene Pekary

127. Urotensin II Peptides 957
Isabelle Lihrmann, Hervé Tostivint, Howard Bern and Hubert Vaudry

128. VIP 966
Sandrine Passemard, Catalina Abad Rabat, Pierre Gressens and Vincent Lelièvre

129. VP/OT 975
John F. Morris

Section XI
Endocrine Peptides
Ludwik Malendowicz

130. Adiponectin 983
Frederik J. Steyn and Chen Chen

131. Adrenomedullin Peptides 990
Josune García-Sanmartín, Ignacio M. Larráyoz, Laura Ochoa-Callejero and Alfredo Martínez

132. Ghrelin 996
Marcos C. Carreira, Ana B. Crujeiras and Felipe F. Casanueva

133. Leptin 1005
Krzysztof W. Nowak, Przemyslaw Kaczmarek, Tatiana Wojciechowicz and Mathias Z. Strowski

134. ANP 1011
Jolanta Gutkowska

135. Neuromedins U/S 1019
Ludwik K. Malendowicz, Marcin Rucinski and Agnieszka Ziolkowska

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

136. Neuropeptide B/W 1025
Fumiko Takenoya, Haruaki Kageyama, Ki Sung Kang and Seiji Shioda

137. Orexins 1032
Naima Ahmed, Harman S. Mattu and Harpal S. Randeva

138. PACAP 1038
David Vaudry, Delphine Burel, Ludovic Galas, Hélène Lacaille, Dominique Duterte-Boucher, David Chatenet, Alain Fournier and Hubert Vaudry

Section XII
Ingestive Peptides
Stephen C. Woods

139. Adiponectin/Resistin 1045
Rexford S. Ahima

140. Amylin/CGRP 1049
Thomas A. Lutz

141. Apolipoprotein (apo) A-IV/apoE 1057
Patrick Tso and Min Liu

142. Bombesin 1064
Ellen E. Ladenheim

143. CART 1071
Graham J. Dockray and Guillaume de Lartigue

144. CCK 1077
Claire Barbier de La Serre and Timothy H. Moran

145. CRH 1084
D. Richard and C. Lopez

146. Enterostatin 1089
Charlotte Erlanson-Albertsson

147. Galanin 1097
Jessica R. Barson, Irene Morganstern and Sarah F. Leibowitz

148. Ghrelin 1104
Omar Al-massadi, Kristy M. Heppner, Rubén Nogueiras, Diego Pérez-Tilve and Matthias H. Tschöp

149. GLP-1 1111
Gustavo Pacheco-López and Wolfgang Langhans

150. Glucagon 1118
Nori Geary

151. Insulin 1123
Bernadette E. Grayson and Stephen C. Woods

152. Leptin 1129
Martin G. Myers Jr. and Megan Greenwald-Yarnell

153. Melanocortins 1135
Joram D. Mul and Roger A.H. Adan

154. NPY 1143
Simona Perboni, Marzia Vignoni and Akio Inui

155. Opioids 1149
Blake A. Gosnell, Catherine M. Kotz, Charles J. Billington and Allen S. Levine

156. Orexin 1154
Jon F. Davis and Stephen C. Benoit

157. PYY 1160
Rachel Troke, Tricia Tan and Stephen R. Bloom

Section XIII
Gastrointestinal Peptides
Yvette Taché

158. Adrenomedullin 1167
Mitchell L. Schubert and Shijian Chu

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

159. Angiogenic Growth Factors 1172
Sandor Szabo, Xiaoming Deng, Tetyana Khomenko, Ganna Tolstanova, Brankica Paunovic, Longchuan Chen, Ximing Xiong and Zsuzsanna Sandor

160. Apelin 1182
Song Han, George H. Greeley Jr. and Ella W. Englander

161. Bombesin-Related Peptides 1188
Robert T. Jensen and Terry W. Moody

162. CCK 1197
Travis E. Solomon, Ayman I. Sayegh and Joseph R. Reeve, Jr

163. CGRP 1204
S. Evangelista

164. Galanin 1210
Duan Chen, Yosuke Kodama, Bård Kulseng, Helene Johannessen and Chun-Mei Zhao

165. Gastrin 1219
Arthur Shulkes and Graham S. Baldwin

166. GIP 1227
Nigel Irwin and Peter R. Flatt

167. Ghrelin 1236
Theo L. Peeters

168. GLP 1/2, Enteroglucagon, Glicentin, and Oxyntomodulin 1241
Jens Juul Holst, Carolyn F. Deacon Bolette Hartmann and Jens Pedersen

169. Leptin 1251
Sandra Guilmeau, Robert Ducroc and André Bado

170. Motilin 1257
Pierre Poitras

171. Neurotensin 1265
James M. Bugni and Charalabos Pothoulakis

172. Nesfatin-1 1271
Shinsuke Oh-I, Hiroyuki Shimizu and Masatomo Mori

173. Obestatin 1275
Guillaume Gourcerol

174. Opioids 1283
Catia Sternini, Celine Duraffourd and Laura Anselmi

175. PACAP 1289
John P. Vu, Patrizia M. Germano and Joseph R. Pisegna

176. Pancreatic Polypeptide 1294
Tricia M. Tan and Stephen R. Bloom

177. Paneth Cell α-Defensins 1300
André J. Ouellette and Michael E. Selsted

178. PYY 1307
Louise Purtell and Herbert Herzog

179. Secretin 1314
Laurence J. Miller

180. Somatostatin 1320
Vicente Martinez

181. Tachykinins 1330
Peter Holzer

182. TFF Peptides 1338
Werner Hoffmann

183. Urocortins 1346
Vincent Wu, Pu-Qing Yuan, Muriel Larauche, Lixin Wang and Mulugeta Million

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

184. VIP 1354
Karnam S. Murthy and John R. Grider

Section XIV
Cardiovascular Peptides
Kazuhiro Takahashi

185. Adrenomedullin Peptides 1361
Johji Kato and Kazuo Kitamura

186. Angiotensin II Peptides 1369
Yasukatsu Izumi and Hiroshi Iwao

187. Apelin 1377
Ábel Perjés, Klára Farkasfalvi, Heikki Ruskoaho and István Szokodi

188. Bradykinin Peptides 1386
Duncan John Campbell

189. CGRP 1394
Ross King and Susan D. Brain

190. Endothelins 1402
Takashi Miyauchi and Katsutoshi Goto

191. Ghrelin 1408
Ichiro Kishimoto, Takeshi Tokudome, Hiroshi Hosoda, Mikiya Miyazato and Kenji Kangawa

192. Natriuretic Peptides 1415
Naoto Minamino and Toshio Nishikimi

193. Salusins 1423
Masayoshi Shichiri, Hajime Izumiyama and Takuya Watanabe

194. Urocortins 1428
Mark Richards and Miriam Rademaker

195. Urotensin Peptides 1437
Kazuhiro Takahashi and Kazuhito Totsune

196. VIP 1443
Robert J. Henning

197. VP/OT 1450
Jolanta Gutkowska and Marek Jankowski

Section XV
Renal Peptides
Willis K. Samson

198. Adrenomedullin 2/Intermedin 1459
Yoshio Takei

199. ANP 1467
Jochen R. Hirsch and Wolf-Georg Forssmann

200. Endothelin 1473
David M. Pollock

201. Neurohypophyseal Peptides 1481
Joseph G. Verbalis

202. Peptides, Sex, Diabetes, and the Kidney 1487
Michaele B. Manigrasso and Christine Maric-Bilkan

203. Prolactin 1494
Willis K. Samson

204. Renin–Angiotensin System 1499
Minolfa C. Prieto, Alexis A Gonzalez, Ryousuke Satou, Hiroyuki Kobori and L. Gabriel Navar

Section XVI
Respiratory Peptides
Sami Said

205. Adrenomedullin 1507
Stefan Hippenstiel, Andreas C. Hocke, Norbert Suttorp and Bettina Temmesfeld-Wollbrück

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

206. Endothelin-1 1513
Karen A. Fagan, Natalie N. Bauer and Ivan F. McMurtry

207. Kinin Receptors 1519
Sébastien Talbot, James Chi-Jen Lin and Réjean Couture

208. PACAP 1527
Mario Delgado

209. VIP 1535
Sami I. Said, Valerie Chappe and Sayyed A. Hamidi

Section XVII
Opiate Peptides
Fred Nyberg

210. Antiopioid Peptides 1543
Ji-Sheng Han

211. Casomorphins/Hemorphins 1550
Fred Nyberg, Anna Carlsson and Mathias Hallberg

212. Endomorphins 1556
Hirokazu Mizoguchi, Tsukasa Sakurada and Shinobu Sakurada

213. Evolution of the Opioid System 1562
Dan Larhammar, Görel Sundström and Robert M. Dores

214. Exorphins 1570
Masaaki Yoshikawa

215. Nociceptin/Orphanin FQ 1577
Girolamo Calò, David G. Lambert and Remo Guerrini

216. Opioid-Substance P Chimeric Peptides 1586
Andrzej W. Lipkowski, Daniel B. Carr, Iwona Bonney and Piotr Kosson

217. POMC-Derived Opioid Peptides 1592
Patricia J. McLaughlin and Ian S. Zagon

218. Prodynorphin-Derived Peptides 1596
Santi Spampinato, Andrea Bedini and Monica Baiula

219. Proenkephalin-Derived Peptides 1602
Patricia J. McLaughlin

Section XVIII
Neurotrophic Peptides
Illana Gozes

220. Activity-Dependent Neuroprotective Protein (ADNP) and Davunetide (NAP) 1611
I. Gozes and P.W. Baas

221. Erythropoietin 1619
Y. Haim Ohana, T. Liron, S. Prutchi-Sagiv, M. Mittelman, M.C. Souroujon and D. Neumann

222. Insulin-Like Growth Factor-1 1627
Itay Bentov and Haim Werner

223. Neuregulins 1633
Kim B. Seroogy, Jonathan W. Dickerson, Sarah N. Cassella and Lixin Zhang-Auberson

224. Neurotrophins 1639
Ljubica Ivanisevic and H. Uri Saragovi

225. TGF-β 1647
Veronica Lifshitz and Dan Frenkel

Section XIX
Blood–Brain Peptides
Weihong Pan

226. Augurin and *Ecrg4*-derived Neuropeptides 1655
Conrad Johanson, Ana Gonzalez, Miles Miller, Sonia Podvin, Edward Stopa and Andrew Baird

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

227. Diseases Mediated by the BBB: Alzheimer's, Obesity, and Beyond 1667
William A. Banks

228. Hypothalamic Neuropeptides 1672
David J. Begley

229. Ingestive Peptides 1677
William A. Banks

230. Neurotrophic Peptides 1682
Weihong Pan and Abba J. Kastin

231. Oligopeptide and Peptide-Like Drug Transport 1688
Richard F. Keep and David E. Smith

232. Opioid Peptides 1696
Richard D. Egleton, Ken A. Witt and Thomas P. Davis

233. Peptide Delivery 1702
Paul Kiptoo, Marlyn D. Laksitorini and Teruna J. Siahaan

Section XX
Peptide Biosynthesis/Processing
Naoto Minamino

234. Acetylation 1711
Qun Li, Iain J. Clarke and A. Ian Smith

235. Carboxypeptidases E and D 1715
Lloyd D. Fricker

236. Disulfide Bond Formation 1721
Gautam Rajpal and Peter Arvan

237. Ghrelin *O*-Acyltransferase (GOAT) 1730
Masayasu Kojima and Hideko Ohgusu

238. Glutaminyl Cyclases 1736
Holger Cynis, Stephan Schilling and Hans-Ulrich Demuth

239. In Silico Search for Biologically Active Peptides 1743
Mariko Nishiyama, Munehiro Ishii, Shuichi Hirose, Hiroyuki Yamazaki and Sadao Kimura

240. New Mass Spectrometric Approaches for Uncovering Neuropeptides 1749
Xiaowen Hou and Jonathan V. Sweedler

241. Peptide Degradation (Neprilysin and Other Regulatory Peptidases) 1757
Anthony J. Turner and Natalia N. Nalivaeva

242. Peptidomics of Mice Lacking Peptide Processing Enzymes 1765
Jonathan H. Wardman and Lloyd D. Fricker

243. Peptidomics Strategy for Discovering Endogenous Biologically Active Peptides 1772
Kazuki Sasaki and Naoto Minamino

244. Peptidylglycine-Amidating Monoxygenase (PAM) 1780
KS Vishwanatha, Richard E. Mains and Betty A. Eipper

245. Prohormone Convertase 1/3 1789
Mirella Vivoli and Iris Lindberg

246. Prohormone Convertase 2 1797
Mirella Vivoli and Iris Lindberg

247. Proprotein Convertase Furin and Proprotein Convertase PC5/6 1803
Nabil G. Seidah

248. Proprotein Convertases PC4, PACE4, and PC7 1812
Nabil G. Seidah

249. Proprotein Convertases SKI-1/S1P and PCSK9 1821
Nabil G. Seidah

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

250. Tyrosylprotein Sulfotransferases 1829
Jens R. Bundgaard and Jens F. Rehfeld

Section XXI
General Peptide Topics
Abba J. Kastin

251. Classical Neurotransmitters and Neuropeptides 1835
Tomas Hökfelt, Sven Ove Ögren and Zhi-Qing David Xu

252. Evolution in Action: Skin Peptides 1842
J.M. Conlon

253. Peptide Chronomics 1850
Franz Halberg, Weihong Pan, Earl E. Bakken and Germaine Cornélissen

254. Peptides and Behavior 1858
Susan Rotzinger

255. Peptides and Sleep 1884
A. Steiger

256. Peptides and Stress 1872
Annika Thorsell

257. Peptides and Temperature 1880
Miklós Székely, Márta Balaskó and Erika Pétervári

258. Pheromone Peptides 1889
Miriam Altstein

259. Prebiotic Peptides 1899
Bernd M. Rode and Kristof Plankensteiner

260. Viral Fusion Peptides 1904
Avraham Ashkenazi and Yechiel Shai

Index 1913

Color Plates 1943

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Contributors

Reidunn B. Aalen
Department of Molecular Biosciences, University of Oslo, Oslo, Norway
Chapter 5 *IDA/IDL*

Yasser H.A. Abdel-Wahab
School of Biomedical Sciences, University of Ulster, Coleraine, Northern Ireland, UK
Chapter 51 *Insulin-Releasing Peptides*

Michael E. Adams
Departments of Entomology and Cell Biology and Neuroscience, University of California, Riverside, CA, USA
Chapter 33 *Developmental Peptides: ETH, Corazonin, and PTTH*

Roger A.H. Adan
Rudolf Magnus Institute of Neuroscience, Department of Neuroscience and Pharmacology, University Medical Center Utrecht, Utrecht, The Netherlands
Chapter 153 *Melanocortins*

Rexford S. Ahima
Perelman School of Medicine, Division of Endocrinology, Diabetes and Metabolism, Philadelphia, PA, USA
Chapter 139 *Adiponectin/Resistin*

Naima Ahmed
Division of Metabolic and Vascular Health, Warwick Medical School, University of Warwick, Gibbet Hill, Coventry, UK
Chapter 137 *Orexins*

Omar Al-Massadi
Metabolic Disease Institute, Department of Internal Medicine, University of Cincinnati-College of Medicine, OH, USA. Department of Physiology, School of Medicine, University of Santiago de Compostela-Instituto de Investigación Sanitaria, Santiago de Compostela, Spain
Chapter 148 *Ghrelin*

Miriam Altstein
Department of Entomology, the Volcani Center, Bet Dagan, Israel
Chapter 37 *FXPRLamide (Pyrokinin/PBAN) Family*
Chapter 258 *Pheromone Peptides*

Youssef Anouar
INSERM U982, Laboratory of Neuronal and Neuroendocrine Communication and Differentiation, Institute for Biomedical Research and Inovation (IRIB), University of Rouen, Mont-Saint-Aignan, France
Chapter 49 *Chromogranins/Secretogranins*

Laura Anselmi
CURE Digestive Diseases Research Center, Division of Digestive Diseases, Departments of Medicine, University of California, Los Angeles, CA, USA
Chapter 174 *Opioids*

Siegfried Ansorge
IMTM GmbH, Magdeburg, Germany
Chapter 90 *DP IV/CD26 Effector Peptides*

Nikolinka Antcheva
Department of Life Sciences, University of Trieste, Trieste, Italy
Chapter 18 *Defensins*

Yevgeniya Antonova-Koch
Department of Entomology, University of Arizona, Tucson, AZ, USA
Chapter 38 *Insulin-Like Peptides*

Jon R. Appel
Torrey Pines Institute for Molecular Studies, San Diego, CA, USA
Chapter 84 *The Use of Positional Scanning Libraries to Identify Immunologically Relevant Peptides*

Anam J. Arik
Department of Entomology, University of Arizona, Tucson, AZ
Chapter 38 *Insulin-Like Peptides*

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY
Copyright Elsevier 2024

Alison L. Arter
Hypertension and Vascular Disease Center, Wake Forest School of Medicine, Winston-Salem, NC, USA
Chapter 67 *Angiotensin II/Angiotensin-(1–7)*

Peter Arvan
Division of Metabolism, Endocrinology and Diabetes, University of Michigan Medical School, Ann Arbor, MI, USA
Chapter 236 *Disulfide Bond Formation*

Avraham Ashkenazi
Department of Biological Chemistry, The Weizmann Institute of Science, Israel
Chapter 260 *Viral Fusion Peptides*

P.W. Baas
Department of Neurobiology and Anatomy, Graduate Program in Neuroscience, Drexel University College of Medicine, Philadelphia, PA, USA
Chapter 220 *Activity-Dependent Neuroprotective Protein (ADNP) and Davunetide (NAP)*

André Bado
Institut National de la Santé et de la Recherche Médicale INSERM U773, UFR de Médecine Paris Diderot, Université Paris Diderot, Sorbonne Paris Cité, Paris, France
Chapter 169 *Leptin*

Andrew Baird
Molecular Neuroscience Group, School of Medicine, University of Birmingham, Edgbaston, UK., Department of Surgery, University of California, San Diego, USA
Chapter 226 *Augurin and* Ecrg4*-derived Neuropeptides*

Monica Baiula
Department of Pharmacology, University of Bologna, Bologna, Italy
Chapter 218 *Prodynorphin-Derived Peptides*

Lauren O. Bakaletz
Center for Microbial Pathogenesis, The Research Institute at Nationwide Children's Hospital, Department of Pediatrics and The Ohio State University College of Medicine, Columbus, OH, USA
Chapter 82 *Peptide Vaccines for Otitis Media*

Earl E. Bakken
North Hawaii Community Hospital Inc., Kamuela, HI, USA
Chapter 253 *Peptide Chronomics*

Márta Balaskó
Department of Pathophysiology and Gerontology, Medical School, University of Pécs, Pécs, Hungary
Chapter 257 *Peptides and Temperature*

Graham S. Baldwin
The University of Melbourne, Department of Surgery, Victoria, Australia
Chapter 165 *Gastrin*

William A. Banks
GRECC, Veterans Affairs Puget Sound Health Care System, WA, USA. Division of Gerontology and Geriatric Medicine, Department of Internal Medicine, University of Washington School of Medicine, WA, USA
Chapter 227 *Diseases Mediated by the BBB: Alzheimer's, Obesity, and Beyond*
Chapter 229 *Ingestive Peptides*

Donatella Barra
Istituto Pasteur-Fondazione Cenci Bolognetti, Dipartimento di Scienze Biochimiche "A. Rossi Fanelli" and CNR Istituto di Biologia e Patologia Molecolari Università "La Sapienza", Roma, Italy
Chapter 47 *Bombinins*

Jessica R. Barson
The Rockefeller University, New York, NY, USA
Chapter 147 *Galanin*

Magali Basille
INSERM U982, University of Rouen, Mont-Saint-Aignan, France. International Laboratory Samuel de Champlain, France
Chapter 119 *PACAP*

Natalie N. Bauer
Center for Lung Biology, Departments of Medicine and Pharmacology, University of South Alabama, Mobile, AL, USA
Chapter 206 *Endothelin-1*

Andrea Bedini
Department of Pharmacology, University of Bologna, Bologna, Italy
Chapter 218 *Prodynorphin-Derived Peptides*

Christine Beeton
Department of Molecular Physiology and Biophysics, Baylor College of Medicine, TX, USA
Chapter 64 *Targets and Therapeutic Properties*

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

David J. Begley
Kings College London Institute of Pharmaceutical Science, Blood-Brain Barrier Group, London, UK
Chapter 228 *Hypothalamic Neuropeptides*

Margery C. Beinfeld
Department of Molecular Physiology and Pharmacology, Tufts University School of Medicine, Boston, MA, USA
Chapter 99 *CCK*

William G. Bendena
Department of Biology, Queen's University, Kingston, Ontario, Canada
Chapter 29 *Allatostatins*

Stephen C. Benoit
Department of Psychiatry, Metabolic Diseases Institute, University of Cincinnati, Cincinnati, OH, USA
Chapter 156 *Orexin*

Itay Bentov
Department of Anesthesia and Pain Medicine, University of Washington, Seattle, WA, USA
Chapter 222 *Insulin-like Growth Factor-1*

Howard Bern†
Department of Integrative Biology, University of California, Berkeley, CA, USA
Chapter 127 *Urotensin II Peptides*

Gabriele Bierbaum
Institute of Medical Microbiology, Parasitology and Immunology, Bonn, Germany Gabriele Bierbaum, Institute of Medical Microbiology, Parasitology and Immunology, Bonn, Germany
Chapter 19 *Lantibiotics*

Charles J. Billington
Veterans Affairs Medical Center, Minneapolis, MN, USA
Chapter 155 *Opioids*

Anna Blasiak
Department of Neurophysiology and Chronobiology, Jagiellonian University, Krakow, Poland
Chapter 121 *Relaxin*

Norman L. Block
Endocrine, Polypeptide and Cancer Institute, Veterans Affairs Medical Center and Departments of Pathology, Urology, Oncology and Biomedical Engineering at the University of Miami Miller School of Medicine, Miami, FL, USA
Chapter 73 *LHRH Analogs*

†deceased

Stephen. R. Bloom
Division of Diabetes Endocrinology and Metabolism, Section of Investigative Medicine, Imperial College London, London, UK
Chapter 114 *Neuromedin U*
Chapter 157 *PYY*
Chapter 176 *Pancreatic Polypeptide*

Iwona Bonney
Department of Anesthesiology, Tufts Medical Center, Tufts University School of Medicine, Boston, MA, USA
Chapter 216 *Opioid-Substance P Chimeric Peptides*

John H. Bowie
Department of Chemistry, The University of Adelaide, South Australia
Chapter 48 *Caeruleins*

Sunny K. Boyd
Department of Biological Sciences, University of Notre Dame, Notre Dame, IN, USA
Chapter 52 *Neurohypophysial Peptides*

Susan D. Brain
BHF Centre of Cardiovascular Excellence Cardiovascular Division, King's College London, London, UK
Chapter 189 *CGRP*

Dag A. Brede
Department of Chemistry, Biotechnology and Food Science Laboratory of Microbial Gene Technology, Norwegian University of Life Sciences, Norway
Chapter 16 *Class II Nonlantibiotic Bacteriocins*

Jozef Vanden Broeck
Animal Physiology and Neurobiology, Katholieke Universiteit Leuven, NaamsestraatLeuven, Belgium
Chapter 31 *B-Type Allatostatins and Sex Peptides*

Kelly L. Brown
Child and Family Research Institute, Vancouver, British Columbia, Canada
Chapter 15 *Cathelicidins*

Mark R. Brown
Department of Entomology, University of Georgia, Athens, GA, Center for Tropical and Emerging Global Diseases, University of Georgia, Athens, GA
Chapter 38 *Insulin-Like Peptides*

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

James M. Bugni
Inflammatory Bowel Disease Center, Division of Digestive Diseases, David Geffen School of Medicine, University of California at Los Angeles, CA, USA
Chapter 171 *Neurotensin*

Jens R. Bundgaard
Department of Clinical Biochemistry, University of Copenhagen, Copenhagen, Denmark
Chapter 250 *Tyrosylprotein Sulfotransferases*

Delphine Burel
INSERM U982, Mont-Saint-Aignan, France. PRIMACEN, University of Rouen, Mont-Saint-Aignan, France
Chapter 138 *PACAP*

Melinka A. Butenko
Department of Molecular Biosciences, University of Oslo, Oslo, Norway
Chapter 5 *IDA/IDL*

Melissa J. Call
Walter and Eliza Hall Institute, Department of Structural Biology, Parkville, VIC, Australia
Chapter 93 *Peptide Loading of MHC*

Girolamo Calò
Department of Medicine, Section of Pharmacology, University of Ferrara and National Institute of Neuroscience, Italy
Chapter 215 *Nociceptin/Orphanin FQ*

Duncan John Campbell
St. Vincent's Institute of Medical Research and Department of Medicine, The University of Melbourne, Fitzroy, Victoria, Australia
Chapter 188 *Bradykinin and Related Peptides*

Anna Carlsson
Department of Pharmaceutical Biosciences, Uppsala University, Uppsala, Sweden
Chapter 211 *Casomorphins/Hemorphins*

Daniel B. Carr
Department of Anesthesiology, Tufts Medical Center, Boston, MA, USA
Chapter 216 *Opioid-Substance P Chimeric Peptides*

Robert E. Carraway
Department of Microbiology and Physiological Systems, University of Massachusetts Medical School, Worcester, MA, USA
Chapter 117 *Neurotensin/Neuromedin N*

Marcos C. Carreira
Molecular and Cellular Endocrinology Laboratory, Department of Medicine, Instituto de Investigación Sanitaria (IDIS), Complejo Hospitalario Universitario de Santiago (CHUS), Universidad de Santiago de Compostela (USC), Santiago de Compostela, Spain; CIBER de Fisiopatología de la Obesidad y Nutrición (CB06/03), Instituto de Salud Carlos III, Madrid, Spain
Chapter 132 *Ghrelin*

Felipe F. Casanueva
Molecular and Cellular Endocrinology Laboratory, Department of Medicine, Instituto de Investigación Sanitaria (IDIS), Complejo Hospitalario Universitario de Santiago (CHUS), Universidad de Santiago de Compostela (USC), Santiago de Compostela, Spain; CIBER de Fisiopatología de la Obesidad y Nutrición (CB06/03), Instituto de Salud Carlos III, Madrid, Spain; Departamento de Medicina, Universidade de Santiago de Compostela, Santiago de Compostela, Spain
Chapter 132 *Ghrelin*

Sarah N. Cassella
Department of Neurology and Neuroscience Graduate Program, University of Cincinnati, Cincinnati, OH, USA
Chapter 223 *Neuregulins*

Stuart A. Casson
School of Biological Sciences, University of Bristol, Bristol, UK
Chapter 8 *POLARIS*

Justo P. Castaño
Department of Cell Biology, Physiology and Immunology, Instituto Maimónides de Investigaciones Biomédicas (IMIBIC), University of Córdoba, Córdoba, Spain; CIBER Fisiopatologia de la obesidad y Nutricion (CIBERobn) Institute de Salud Carlos III, Spain
Chapter 105 *GHRH*

Marek Cebrat
Faculty of Chemistry, University of Wrocław, F. Joliot-Curie 14, Wroclaw, Poland
Chapter 95 *RGD Peptides*

Valerie Chappe
Dalhousie University – Physiology and Biophysics Department, Halifax, NS, Canada
Chapter 209 *VIP*

David Chatenet
INRS-Institut Armand Frappier, University of Québec, Québec, Canada
Chapter 138 *PACAP*

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Keqiang Chen
Laboratory of Molecular Immunoregulation, Cancer and Inflammation Program, Center for Cancer Research, National Cancer Institute at Frederick, MD, USA
Chapter 91 *FPR Ligands*

Chen Chen
School of Biomedical Sciences, University of Queensland, St Lucia, Brisbane, Australia
Chapter 130 *Adiponectin*

Longchuan Chen
Diagnostic and Molecular Medicine, Medical Healthcare Groups, VA Medical Center, Long Beach, CA, USA; Departments of Pathology, Pharmacology, and Medicine, University of California-Irvine, CA, USA
Chapter 159 *Angiogenic Growth Factors*

Duan Chen
Department of Cancer Research and Molecular Medicine, Norwegian University of Science and Technology, Trondheim NO, Norway
Chapter 164 *Galanin*

Carrie Y.Y. Cheng
School of Biological Sciences, The University of Hong Kong, Hong Kong SAR, China
Chapter 123 *Secretin*

Sung Ki Cho
Department of Horticulture, Iowa State University, Ames, IA, USA
Chapter 3 *DVL/RTFL*

Billy K.C. Chow
School of Biological Sciences, The University of Hong Kong, Hong Kong SAR, China
Chapter 123 *Secretin*

Arthur Christopoulos
Drug Discovery Biology, Monash Institute of Pharmaceutical Sciences, Parkville, Victoria, Australia; Department of Pharmacology, Monash University, Parkville, Victoria, Australia
Chapter 100 *CGRP/Adrenomedullin*

Shijian Chu
Department of Medicine, Virginia Commonwealth University's Medical College of Virginia and McGuire Veterans Affairs Medical Center, Richmond, Virginia, USA
Chapter 158 *Adrenomedullin*

Iain J. Clarke
Department of Physiology, Faculty of Medicine, Nursing and Health Sciences, Monash University, Clayton, Victoria, Australia
Chapter 234 *Acetylation*

Geoffrey M. Coast
Department of Biological Sciences, Birkbeck, London, UK
Chapter 34 *Diuretic/Antidiuretic*

Vincent Compere
INSERM U982, Laboratory of Neuronal and Neuroendocrine Cell Differentiation and Communication, European Institute for Peptide Research (IFRMP 23), Regional Platform for Cell Imaging (PRIMACEN), University of Rouen, Mont-Saint-Aignan, France; Department of Anaesthesiology and Critical Care, Rouen University Hospital, France
Chapter 102 *Endozepines*

Gisela P. Concepcion
Marine Science Institute, University of the Philippines, Diliman, Quezon City, Philippines
Chapter 61 *Snail Peptides*

Roger D. Cone
Department of Molecular Physiology and Biophysics, The Vanderbilt University School of Medicine, Nashville, TN, USA
Chapter 111 *Melanocortins*

J. Michael Conlon
Department of Biochemistry, Faculty of Medicine and Health Sciences, United Arab Emirates University, Al Ain, United Arab Emirates
Chapter 45 *Bradykinin-Related Peptides*
Chapter 51 *Insulin-Releasing Peptides*
Chapter 252 *Evolution in Action: Skin Peptides*

Germaine Cornélissen
Halberg Chronobiology Center, University of Minnesota, Minneapolis, MN, USA
Chapter 253 *Peptide Chronomics*

Maité Courel
INSERM, U982, Laboratory of Neuronal and Neuroendocrine Communication and Differentiation, Institute for Biomedical Research and Inovation (IRIB), University of Rouen, Mont-Saint-Aignan, France
Chapter 49 *Chromogranins/Secretogranins*

Réjean Couture
Department of Physiology, Faculty of Medicine, Université de Montréal, Montréal, QC, Canada
Chapter 207 *Kinin Receptors*

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY
Copyright Elsevier 2024

W.A. Cramer
Department of Biological Sciences, Hockmeyer Hall of Structural Biology, Purdue University, West Lafayette, IN, USA
Chapter 17 *Colicins*

Nathan P. Croft
Department of Biochemistry and Molecular Biology, Monash University, VIC, Australia
Chapter 79 *Novel Tumor Derived Peptides in Vaccines*

Ana B. Crujeiras
Molecular and Cellular Endocrinology Laboratory, Department of Medicine, Instituto de Investigación Sanitaria (IDIS), Complejo Hospitalario Universitario de Santiago (CHUS), Universidad de Santiago de Compostela (USC), Santiago de Compostela, Spain; CIBER de Fisiopatología de la Obesidad y Nutrición (CB06/03), Instituto de Salud Carlos III, Madrid, Spain.
Chapter 132 *Ghrelin*

Frank Cuttitta
Angiogenesis Core Facility, Radiation Oncology Branch, Center for Cancer Research, National Cancer Institute, Gaithersburg, MD, USA
Chapter 66 *Adrenomedullin*
Chapter 68 *Apelin*

Holger Cynis
Probiodrug AG, Halle, Germany
Chapter 238 *Glutaminyl Cyclases*

F. D'Acquisto
Centre for Biochemical Pharmacology, William Harvey Research Institute, Barts and the London School of Medicine and Dentistry, London, UK

Chapter 14 *TDIF*

Gerd Gäde
Zoology Department, University of Cape Town, Private Bag, ZA-7700 Rondebosch, South Africa
Chapter 28 *AKH/RPCH Peptides*

Ludovic Galas
PRIMACEN, University of Rouen, Mont-Saint-Aignan, France
Chapter 138 *PACAP*

Patricia E. Gallagher
Hypertension and Vascular Disease Center, Wake Forest School of Medicine, Winston-Salem, NC
Chapter 67 *Angiotensin II/Angiotensin-(1–7)*

Pierrick Gandolfo
INSERM U982, Laboratory of Neuronal and Neuroendocrine Cell Differentiation and Communication, European Institute for Peptide Research (IFRMP 23), Regional Platform for Cell Imaging (PRIMACEN), University of Rouen, Mont-Saint-Aignan, France
Chapter 102 *Endozepines*

Maria A. Garcia-Espinosa
Hypertension and Vascular Disease Center, Wake Forest School of Medicine, Winston-Salem, NC
Chapter 67 *Angiotensin II/Angiotensin-(1–7)*

Josune García-Sanmartín
Oncology Area, Center for Biomedical Research of La Rioja (CIBIR), Logroño, Spain
Chapter 131 *Adrenomedullin Peptides*

Nori Geary
Zielackerstrasse 10, Schwerzenbach, Switzerland
Chapter 150 *Glucagon*

Hua Geng
From the Laboratory of Molecular Immunoregulation, Center for Cancer Research, National Cancer Institute at Frederick, Frederick, MD, USA. Research Center of Basic Medical Sciences, Cancer Institute and Hospital, Tianjin Medical University, Tianjin, People's Republic of China
Chapter 92 *Neuroimmune Peptides*

Patrizia M. Germano
CURE: VA/UCLA Digestive Diseases Research Center, VA Greater Los Angeles Heath Care System at West LA and Department of Medicine, University of California, Los Angeles, CA, USA
Chapter 175 *PACAP*

Jens P. Goetze
Department of Clinical Biochemistry, Rigshospitalet, University of Copenhagen, Copenhagen, Denmark
Chapter 71 *Gastrin in Cancer*

Alexis A. Gonzalez
Department of Physiology and the Renal and Hypertension Center of Excellence, Tulane University School of Medicine, New Orleans, USA
Chapter 204 *Renin–Angiotensin System*

Ana Gonzalez
Molecular Neuroscience Group, School of Medicine, University of Birmingham, Edgbaston, UK
Chapter 226 *Augurin and* Ecrg4*-derived Neuropeptides*

Blake A. Gosnell
Department of Food Science and Nutrition, University of Minnesota, St. Paul, MN, USA
Chapter 155 *Opioids*

Katsutoshi Goto
Life Science Center for Tsukuba Advanced Research Alliance (TARA), University of Tsukuba, Tsukuba, Ibaraki, Japan
Chapter 190 *Endothelins*

Guillaume Gourcerol
INSERM 1073 and Physiology Department, University of Rouen, Rouen, France
Chapter 173 *Obestatin*

I. Gozes
The Adams Super Center for Brain Research, The Lily and Avraham Gildor Chair for the Investigation of Growth Factors, The Elton Laboratory for Molecular Neuroendocrinology, Department of Human Molecular Biology and Biochemistry, School of Neuroscience, Sackler Faculty of Medicine, Tel-Aviv University, Tel Aviv, Israel
Chapter 220 *Activity-Dependent Neuroprotective Protein (ADNP) and Davunetide (NAP)*

Francisco Gracia-Navarro
Department of Cell Biology, Physiology and Immunology, Instituto Maimónides de Investigaciones Biomédicas (IMIBIC), University of Córdoba, Córdoba, Spain.
Chapter 105 *Growth Hormone-releasing Hormone (GHRH)*

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY
Copyright Elsevier 2024

Bernadette E. Grayson
Department of Internal Medicine, Division of Endocrinology, Diabetes and Metabolism, The University of Cincinnati College of Medicine, Cincinnati, OH, USA
Chapter 151 *Insulin*

George H. Greeley Jr.
Department of Surgery University of Texas Medical Branch, Galveston, TX, USA
Chapter 160 *Apelin*

Megan Greenwald-Yarnell
Division of Metabolism, Endocrinology, and Diabetes, Department of Internal Medicine. University of Michigan Medical School, Ann Arbor, MI, USA
Chapter 152 *Leptin*

Pierre Gressens
INSERM U676, Paris, France. Université Paris 7, Faculté de Médecine Denis Diderot, Paris, France; Institute for Reproductive and Developmental Biology, Centre for the Developing Brain, Imperial College, London, UK
Chapter 128 *VIP*

John R. Grider
Department of Physiology and Biophysics, Virginia Commonwealth University, Richmond, VA, USA
Chapter 184 *Vasoactive Intestinal Peptide*

Jan Grünewald
Genomics Institute of the Novartis Research Foundation, San Diego, CA, USA
Chapter 21 *Nonribosomal Peptide Synthesis*

Juliano R. Guerreiro
Laboratório de Bioquímica de Proteínas, Departamento de Ciências Biológicas, Escola Superior de Agricultura "Luiz de Queiroz", Universidade de São Paulo, Piracicaba, São Paulo, Brazil
Chapter 9 *RALF Peptides*

Remo Guerrini
Department of Pharmaceutical Sciences and LTTA (Laboratorio per le Tecnologie delle Terapie Avanzate), University of Ferrara, Italy
Chapter 215 *Nociceptin/Orphanin FQ*

Filomena Guida
Department of Life Sciences, University of Trieste, Trieste, Italy
Chapter 18 *Defensins*

Laure Guilhaudis
Behavioral Analysis Facility, European Institute for Peptide Research (IFRMP 23), University of Rouen, Rouen, France
Chapter 122 *26RFa*

Sandra Guilmeau
Institut National de la Santé et de la Recherche Médicale INSERM U773, UFR de Médecine Paris Diderot, Université Paris Diderot, Sorbonne Paris Cité, Paris, France
Chapter 169 *Leptin*

Andrew L. Gundlach
Florey Neuroscience Institutes, The University of Melbourne, VC, Australia; Department of Anatomy and Cell Biology, The University of Melbourne, VIC, Australia; Centre for Neuroscience, The University of Melbourne, VC, Australia
Chapter 103 *Galanin and GALP*
Chapter 121 *Relaxin*

Jolanta Gutkowska
Centre Hospitalier de l'Université de Montréal, Montréal, QC, Canada
Chapter 134 *Natriuretic Peptides*

Centre Hospitalier de l'Université de Montréal, Hôtel-Dieu, Montréal, QC, Canada
Chapter 197 *VP/OT*

Clifton Hackbarth
Department of Biochemistry and Molecular Genetics, University of Colorado, School of Medicine, Aurora, CO, USA
Chapter 77 *Antiadhesin Synthetic Consensus Sequence Peptide-Based Vaccines for* Pseudomonas aeruginosa

Y. Haim Ohana
Department of Cell and Developmental Biology, Sackler Faculty of Medicine, Tel-Aviv University, Tel Aviv, Israel
Chapter 221 *Erythropoietin*

Franz Halberg
Halberg Chronobiology Center, University of Minnesota, Minneapolis, MN, USA
Chapter 253 *Peptide Chronomics*

Mathias Hallberg
Department of Pharmaceutical Biosciences, Division of Biological Research on Drug Dependence, Uppsala University, Uppsala, Sweden
Chapter 211 *Casomorphins/Hemorphins*

Sayyed A. Hamidi
Department of Medicine, State University of New York, NY, USA
Chapter 209 *VIP*

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Song Han
Department of Surgery University of Texas Medical Branch, Galveston, TX, USA
Chapter 160 *Apelin*

Ji-Sheng Han
Neuroscience Research Institute, Peking University, Beijing, People's Republic of China
Chapter 210 *Antiopioid Peptides*

Robert E.W. Hancock
Centre for Microbial Diseases and Immunity Research, University of British Columbia, Vancouver, BC, Canada
Chapter 15 *Cathelicidins*

Samer-ul Haque
Division of Surgery and Interventional Science, UCL Medical School, London, UK
Chapter 70 *Endothelin-1*

Ikuko Hara-Nishimura
Department of Botany, Graduate School of Science, Kyoto University, Sakyo-ku, Kyoto, Japan
Chapter 13 *Stomagen/EPFL9*

Aliza Hariton
Department of Entomology, The Volcani Center, Bet Dagan, Israel
Chapter 37 *The FXPRLamide (Pyrokinin/PBAN) Family*

Wendy J. Hartsock
Department of Biochemistry and Molecular Genetics, University of Colorado, School of Medicine, Aurora, CO, USA
Chapter 77 *Antiadhesin Synthetic Consensus Sequence Peptide-Based Vaccines for* Pseudomonas aeruginosa

Alan L. Harvey
Strathclyde Institute for Drug Research, and Department of Physiology and Pharmacology, University of Strathclyde, Glasgow, UK
Chapter 62 *Snake Venom Peptides*

Itaru Hasunuma
Department of Biology, Faculty of Science, Toho University, Funabashi, Chiba, Japan
Chapter 54 *Sodefrin and Related Pheromones*

Robert J. Henning
The Center for Cardiovascular Research and the James A. Haley Hospital, Tampa, FL, USA
Chapter 196 *Vasoactive Intestinal Peptide (VIP)*

Kristy M. Heppner
Metabolic Disease Institute, Department of Internal Medicine, University of Cincinnati-College of Medicine, OH, USA
Chapter 148 *Ghrelin*

Kate L. Hertweck
National Evolutionary Synthesis Center (NESCent), Durham, NC, USA
Chapter 3 *DVL/RTFL*

Herbert Herzog
Neuroscience Research Program, Garvan Institute of Medical Research, Darlinghurst, Sydney, NSW, Australia
Chapter 178 *PYY*

Tetsuya Higashiyama
Division of Biological Science, Graduate School of Science/JST-ERATO Higashiyama Live-Holonics Project, Nagoya University, Furo-cho, Chikusa-ku, Nagoya, Aichi, Japan
Chapter 6 *LUREs*

Shuji Hinuma
Department of Food and Nutrition, Faculty of Human Life Sciences, Senri Kinran University, Suita-shi, Osaka, Japan
Chapter 120 *Prolactin-Releasing peptide*

Stefan Hippenstiel
Department of Internal Medicine/Infectious Diseases and Pulmonary Medicine, Charité – Universitätsmedizin Berlin, Berlin, Germany
Chapter 205 *Adrenomedullin*

Yuki Hirakawa
School of Biological Sciences, Monash University, Melbourne, VC, Australia
Chapter 14 *TDIF*

Shuichi Hirose
PharmaDesign, Inc., Chuo-ku, Tokyo, Japan
Chapter 239 *In Silico Search for Biologically Active Peptides*

Jochen R. Hirsch
Pharis Biotec GmbH, Hannover, Germany
Chapter 199 *ANP*

Andreas C. Hocke
Department of Internal Medicine/Infectious Diseases and Pulmonary Medicine, Charité – Universitätsmedizin Berlin, Berlin, Germany
Chapter 205 *Adrenomedullin*

Robert S. Hodges
Department of Biochemistry and Molecular Genetics, University of Colorado, School of Medicine, Aurora, CO, USA
Chapter 77 *Antiadhesin Peptide-Based Vaccines for* Pseudomonas aeruginosa

Werner Hoffmann
Institute of Molecular Biology and Medicinal Chemistry, Otto-von-Guericke-University Magdeburg, Magdeburg, Germany
Chapter 182 *TFF Peptides*

Tomas Hökfelt
Department of Neuroscience, Karolinska Institutet, Stockholm, Sweden
Chapter 251 *Classical Neurotransmitters and Neuropeptides*

Jens Juul Holst
Department of Biomedical Sciences and the NovoNordisk Foundation Center for Basic Metabolic Research, University of Copenhagen, The Panum Institute, Copenhagen N, Denmark
Chapter 168 *GLP 1/2, Enteroglucagon, Glicentin, and Oxyntomodulin*

Peter Holzer
Research Unit of Translational Neurogastroenterology, Institute of Experimental and Clinical Pharmacology, Medical University of Graz, Graz, Austria
Chapter 181 *Tachykinins*

Frank M. Horodyski
Department of Biomedical Sciences, Heritage College of Osteopathic Medicine, Ohio University, Athens, OH, USA
Chapter 30 *Allatotropin*

Hiroshi Hosoda
Department of Biochemistry, National Cerebral and Cardiovascular Center Research Institute, Suita-city, Osaka, Japan
Chapter 191 *Ghrelin*

Xiaowen Hou
Beckman Institute and Center for Biophysics and Computation Biology, University of Illinois at Urbana-Champaign, IL, USA
Chapter 240 *New Mass Spectrometric Approaches for Uncovering Neuropeptides*

Alisa Huffaker
United States Department of Agriculture, Agricultural Research Service Center for Medical, Agricultural, and Veterinary Entomology, Chemistry Research Unit, Gainesville, FL, USA
Chapter 2 *Defense Signal Peptides*

Norio Iijima
Department of Anatomy and Neurobiology, Graduate School of Medicine, Nippon Medical School, Bunkyo-ku, Tokyo, Japan
Chapter 120 *Prolactin-Releasing peptide*

Momoko Ikeuchi
National Institute for Basic Biology, Okazaki, Japan
Department of Biological Sciences, Graduate School of Science, University of Tokyo, Japan
Chapter 11 *ROTUNDIFOLIA4*

Julita S. Imperial
University of Utah, Salt Lake City, UT, USA
Chapter 61 *Snail Peptides*

Giovanna Improta
Department of Physiology and Pharmacology "Vittorio Erspamer," University Sapienza, Rome, Italy
Chapter 55 *Tachykinins*

Akio Inui
Department of Psychosomatic Internal Medicine, Kagoshima University Graduate School of Medical & Dental Sciences, Kagoshima, Japan
Chapter 154 *NPY*

Nigel Irwin
School of Biomedical Sciences, SAAD Centre for Diabetes and Pharmacy, University of Ulster, Coleraine, Northern Ireland, UK

Edward P. Masler
Nematology Laboratory, Agricultural Research Service, United States Department of Agriculture, Baltimore Avenue, Beltsville, MD, USA
Chapter 36 *Free-Living Nematodes*

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY
Copyright Elsevier 2024

Yoshikatsu Matsubayashi
National Institute for Basic Biology, Nishigonaka, Myodaiji, Okazaki Aichi, Japan
Chapter 7 *Phytosulfokine*
Chapter 10 *Root Meristem Growth Factor*

Harman S. Mattu
Warwickshire Institute for the Study of Diabetes, Endocrinology and Metabolism (WISDEM), UHCW NHS Trust, Coventry, UK
Chapter 137 *Orexins*

Aaron G. Maule
Parasitology-Molecular Biosciences, Institute of Agri-Food and Land Use, School of Biological Sciences, Queen's University Belfast, Belfast, UK
Chapter 40 *Parasitic Nematode Peptides*

Patricia J. McLaughlin
Department of Neural and Behavioral Sciences, Penn State University College of Medicine, Milton S. Hershey Medical Center, Hershey, PA, USA
Chapter 217 *POMC-Derived Opioid Peptides*
Chapter 219 *Proenkephalin-Derived Peptides*

Ivan F. McMurtry
Center for Lung Biology, Departments of Medicine and Pharmacology, University of South Alabama, Mobile, AL, USA
Chapter 206 *Endothelin-1*

Ellen Meelkop
Queensland Brain Institute, University of Queensland, Brisbane, QLD, Australia
Chapter 41 *Pigment-Dispersing Factor*

Saher Mehdi
Department of Plant Sciences, University of Oxford, Oxford, UK
Chapter 8 *POLARIS*

Pietro Melchiorri
Institute of Medical Pharmacology, University La Sapienza, Rome, Italy
Chapter 53 *Opioid and Bv8 Peptides*

R.P. Millar
Mammal Research Institute, University of Pretoria, Pretoria, South Africa; UCT/MRC Receptor Biology Research Unit, University of Cape Town, Cape Town, South Africa; Center for Integrative Physiology, University of Edinburgh, Edinburgh, Scotland, UK
Chapter 106 *GnRH (LHRH)*

Laurence J. Miller
Departments of Medicine and Molecular Pharmacology and Experimental Therapeutics, Mayo Clinic, Scottsdale, AZ, USA
Chapter 179 *Secretin*

Miles Miller
Alpert Medical School at Brown University, Providence, RI, USA
Chapter 226 *Augurin and* Ecrg4*-derived Neuropeptides*

Mulugeta Million
CURE/Digestive Diseases Research Center, Division of Digestive Diseases, Department of Medicine, University of California Los Angeles, CA, USA; Center for Neurobiology of Stress, Division of Digestive Diseases, Department of Medicine, University of California Los Angeles, CA, USA; VA Greater Los Angeles Healthcare System, Los Angeles, CA, USA
Chapter 183 *Urocortins*

Naoto Minamino
Department of Molecular Pharmacology, National Cerebral and Cardiovascular Center, Suita, Osaka, Japan
Chapter 192 *Natriuretic Peptides*
Chapter 243 *Peptidomics Strategy for Discovering Endogenous Biologically Active Peptides*

M. Mittelman
Department of Medicine, Sourasky Medical Center, Tel-Aviv University, Tel-Aviv, Israel
Chapter 221 *Erythropoietin*

Takashi Miyauchi
Department of Medicine (Cardiology), Division of Clinical Medicine, University of Tsukuba, Tsukuba, Ibaraki, Japan; Life Science Center for Tsukuba Advanced Research Alliance (TARA), University of Tsukuba, Tsukuba, Ibaraki, Japan
Chapter 190 *Endothelins*

Mikiya Miyazato
Department of Biochemistry, National Cerebral and Cardiovascular Center Research Institute, Suita-city, Osaka, Japan
Chapter 191 *Ghrelin*

Hirokazu Mizoguchi
Department of Physiology and Anatomy, Tohoku Pharmaceutical University, Sendai, Japan
Chapter 212 *Endomorphins*

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY
Copyright Elsevier 2024

Malte Mohme
Institute for Neuroimmunology and Clinical Multiple Sclerosis Research, Hamburg University, Hamburg, Germany
Chapter 94 *Peptide Recognition by T Cells*

Maité Montero-Hadjadje
INSERM, U982, Laboratory of Neuronal and Neuroendocrine Communication and Differentiation, Institute for Biomedical Research and Inovation (IRIB), University of Rouen, Mont-Saint-Aignan, France
Chapter 49 *Chromogranins/Secretogranins*

Terry W. Moody
Department of Health and Human Services, National Cancer Institute and National Institute of Diabetes and Digestive and Kidney Diseases, Bethesda, MD, USA.
Chapter 69 *Bombesin-Related Peptides*
Chapter 76 *VIP/PACAP Receptors*
Chapter 161 *Bombesin-related Peptides*

Neeloffer Mookherjee
Manitoba Centre for Proteomics and Systems Biology, Department of Internal Medicine, University of Manitoba, Winnipeg, MB, Canada
Chapter 15 *Cathelicidins*

Timothy H. Moran
Department of Psychiatry and Behavioral Sciences, Johns Hopkins University School of Medicine, Baltimore, MD, USA
Chapter 144 *CCK*

Irene Morganstern
The Rockefeller University, New York, NY, USA
Chapter 147 *Galanin*

Masatomo Mori
Department of Medicine and Molecular Science, Gunma University Graduate School of Medicine, Maebashi, Japan
Chapter 172 *Nesfatin-1*

Fabrice Morin
INSERM U982, Laboratory of Neuronal and Neuroendocrine Cell Differentiation and Communication, European Institute for Peptide Research (IFRMP 23), Regional Platform for Cell Imaging (PRIMACEN), University of Rouen, Mont-Saint-Aignan, France
Chapter 102 *Endozepines*

John F. Morris
Department of Physiology, Anatomy and Genetics, University of Oxford, Oxford, UK
Chapter 129 *Vasopressin and Oxytocin*

Daniel S. Moura
Laboratório de Bioquímica de Proteínas, Departamento de Ciências Biológicas, Escola Superior de Agricultura "Luiz de Queiroz", Universidade de São Paulo, Piracicaba, São Paulo, Brazil
Chapter 9 *RALF Peptides*

Anna J. Mudge
The Integrative Cell Biology Laboratory, School of Biological and Biomedical Sciences, Durham University, Durham, UK
Chapter 8 *POLARIS*

Joram D. Mul
Department of Medicine, Metabolic Diseases Institute, University of Cincinnati, Cincinnati, OH, USA
Chapter 153 *Melanocortins*

Karnam S. Murthy
Department of Physiology and Biophysics, Virginia Commonwealth University, Richmond, VA, USA
Chapter 184 *Vasoactive Intestinal Peptide*

Martin G. Myers Jr.
Division of Metabolism, Endocrinology, and Diabetes, Department of Internal Medicine. Department of Physiology and Neuroscience Graduate Program University of Michigan Medical School, Ann Arbor, MI, USA
Chapter 152 *Leptin*

Ronald J. Nachman
Areawide Pest Management Research, Southern Plains Agricultural Research Center, U.S. Department of Agriculture, College Station, TX, USA
Chapter 31 *B-Type Allatostatins and Sex Peptides*
Chapter 37 *The FXPRLamide (Pyrokinin/PBAN) Family*
Chapter 43 *Sulfakinins*

Jean-Louis Nahon
CNRS-UMR 7275, Institut de Pharmacologie Moléculaire et Cellulaire, Sophia-Antipolis, Valbonne, France. University of Nice-Sophia Antipolis, Nice, France
Chapter 110 *MCH*

Sushma Naithani
228 Plant Science Building, Department of Plant Biology, Cornell University, Ithaca, New York, NY, USA
Chapter 12 *SCR*

Tomoaki Nakada
Department of Veterinary Medicine, Nihon Veterinary Life Science University, Musashino, Tokyo, Japan
Chapter 54 *Sodefrin and Related Pheromones*

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Tomoya Nakamachi
Department of Anatomy, Showa University School of Medicine, Shinagawa-Ku, Tokyo, Japan; Center for Biotechnology, Showa University, Hatanodai, Shinagawa-ku, Tokyo, Japan
Chapter 119 *PACAP*

Yuki Nakamura
Molecular Genetics, Institute of Life Science, Kurume University, Kurume, Fukuoka, Japan
Chapter 104 *Ghrelin*

Natalia N. Nalivaeva
I.M. Sechenov Institute of Evolutionary Physiology and Biochemistry, St Petersburg, Russia
Chapter 241 *Peptide Degradation (Neprilysin and Other Regulatory Peptidases)*

June B. Nasrallah
Department of Plant Biology, Cornell University, Ithaca, NY, USA
Chapter 12 *SCR*

Dick R. Nässel
Department of Zoology, Stockholm University, SE Stockholm, Sweden
Chapter 44 *Tachykinin Peptides*

L. Gabriel Navar
Department of Physiology and the Renal and Hypertension Center of Excellence, Tulane University School of Medicine, New Orleans, LA, USA
Chapter 204 *Renin–Angiotensin System*

Pratap Neelakantan
Hammersmith Hospital, Imperial College, London, UK
Chapter 81 *Peptide Vaccines for Myeloid Leukemias*

Lucia Negri
Department of Physiology and Pharmacology "Vittorio Erspamer", Sapienza University of Rome, Roma, Italy
Chapter 53 *Opioid and Bv8 Peptides*

Ingolf F. Nes
Department of Chemistry, Biotechnology and Food Science Laboratory of Microbial Gene Technology, Norwegian University of Life Sciences, Norway
Chapter 16 *Class II Non-Lantibiotic Bacteriocins*

D. Neumann
Department of Cell and Developmental Biology, Sackler Faculty of Medicine, Tel-Aviv University, Tel-Aviv, Israel
Chapter 221 *Erythropoietin*

Cindy Neveu
INSERM U982, Laboratory of Neuronal and Neuroendocrine Cell Differentiation and Communication, European Institute for Peptide Research (IFRMP 23), Regional Platform for Cell Imaging (PRIMACEN), University of Rouen, Mont-Saint-Aignan, France
Chapter 122 *26RFa*

Tzi Bun Ng
School of Biomedical Sciences, Faculty of Medicine, The Chinese University of Hong Kong, Hong Kong, China
Chapter 23 *Antifungal and Antibacterial Peptides of Fungal Origin*
Chapter 24 *Fungal Peptides with Ribonuclease and Ribosome Inactivating Activities*

Stephanie Y.L. Ng
School of Biological Sciences, The University of Hong Kong, Hong Kong SAR, China
Chapter 123 *Secretin*

Graham M. Nicholson
Neurotoxin Research Group, School of Medical and Molecular Biosciences, University of Technology, Sydney, NSW, Australia
Chapter 63 *Spider Peptides*

Pierre Nicolas
ER3 Biogenèse des Signaux Peptidiques, Université Pierre et Marie Curie, Université Paris, Paris, France
Chapter 50 *Dermaseptins*

Toshio Nishikimi
Department of Medicine and Clinical Science, Kyoto University Graduate School of Medicine, Sakyo, Kyoto, Japan
Chapter 192 *Natriuretic Peptides*

Mariko Nishiyama
Department of Biochemistry and Molecular Pharmacology, Chiba University Graduate School of Medicine, Chuo-ku, Chiba, Japan
Chapter 239 *In Silico Search for Biologically Active Peptides*

Rubén Nogueiras
Department of Physiology, School of Medicine, University of Santiago de Compostela-Instituto de Investigación Sanitaria, Santiago de Compostela, Spain
Chapter 148 *Ghrelin*

Raymond S. Norton
Medicinal Chemistry, Monash Institute of Pharmaceutical Sciences, Monash University, Parkville, VIC, Australia
Chapter 60 *Sea Anemone Peptides*

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY

Laura A. Novotny
Center for Microbial Pathogenesis, The Research Institute at Nationwide Children's Hospital, Department of Pediatrics and The Ohio State University College of Medicine, Columbus, OH, USA
Chapter 82 *Peptide Vaccines for Otitis Media*

Krzysztof W. Nowak
Department of Animal Physiology and Biochemistry, Poznan University of Life Sciences, Poznan, Poland; Department of Hepatology and Gastroenterology and Interdisciplinary Centre of Metabolism: Endocrinology, Diabetes and Metabolism. Charité-University Medicine Berlin. Augustenburger Platz, Berlin
Chapter 133 *Leptin*

Fred Nyberg
Department of Pharmaceutical Biosciences, Division of Biological Research on Drug Dependence, Uppsala University, Uppsala, Sweden
Chapter 211 *Casomorphins/Hemorphins*

Laura Ochoa-Callejero
Oncology Area, Center for Biomedical Research of La Rioja (CIBIR), Logroño, Spain
Chapter 131 *Adrenomedullin Peptides*

Sven Ove Ögren
Department of Neuroscience, Karolinska Institutet, Stockholm, Sweden
Chapter 251 *Classical Neurotransmitters and Neuropeptides*

Hideko Ohgusu
Molecular Genetics, Institute of Life Science, Kurume University, Kurume, Fukuoka, Japan
Chapter 237 *Ghrelin* O-*Acyltransferase (GOAT)*

Shinsuke Oh-I
Department of Medicine and Molecular Science, Gunma University Graduate School of Medicine, Maebashi, Japan
Chapter 172 *Nesfatin-1*

Opeolu O. Ojo
Diabetes Research Group, University of Ulster Coleraine, UK
Chapter 51 *Insulin-Releasing Peptides*

Baldomero M. Olivera
University of Utah, Salt Lake City, UT, USA
Chapter 61 *Snail Peptides*

Francisco E. Olucha-Bordonau
Department of Anatomy and Human Embryology, Faculty of Medicine, University of Valencia, Valencia, Spain
Chapter 121 *Relaxin*

Joost J. Oppenheim
Laboratory of Molecular Immunoregulation, Center for Cancer Research, National Cancer Institute at Frederick, Frederick, MD, USA
Chapter 92 *Neuroimmune Peptides*

Ian Orchard
Department of Biology, University of Toronto Mississauga, Mississauga Road, Mississauga, ON, Canada
Chapter 35 *FMRFamide-like peptides (FLPs)*
Chapter 42 *Proctolin*

André J. Ouellette
Department of Pathology & Laboratory Medicine, USC Norris Comprehensive Cancer Center, Keck School of Medicine, University of Southern California, Los Angeles, CA, USA
Chapter 177 *Paneth Cell* α-*Defensins*

Gustavo Pacheco-López
Physiology and Behavior Laboratory, Institute of Food, Nutrition and Health, ETH–Zurich, Schwerzenbach, Switzerland
Chapter 149 *GLP-1*

Nigel M. Page
School of Life Sciences, Kingston University London, Kingston-upon-Thames, UK
Chapter 125 *Tachykinins*

Mario Sergio Palma
Center of Study of Social Insects/Department of Biology Institute of Biosciences of Rio Claro, São Paulo State University, Rio Claro, SP, Brazil
Chapter 58 *Hymenoptera Insect Peptides*

Weihong Pan
Blood–Brain Barrier Group, Pennington Biomedical Research Center, Baton Rouge, LA, USA
Chapter 112 *MIF-1/Tyr-MIF-1*
Chapter 230 *Neurotrophic Peptides*
Chapter 253 *Peptide Chronomics*

Yoonseong Park
Department of Entomology, Kansas State University, Manhattan, KS, USA
Chapter 33 *Developmental Peptides: ETH, Corazonin, and PTTH*

Marc Parmentier
Institut de Recherche Interdisciplinaire en Biologie Humaine et Moléculaire (I.R.I.B.H.M.), Faculté de Médecine, Université Libre de Bruxelles, Brussels, Belgium

Preface to the 1st Edition

When Bernard Westerop, the skilled publishing editor of the journal *Peptides*, suggested that I edit a book on peptides, my initial reaction was the same as it had been when I was asked many years ago to be editor of the first peptide journal: I would better wait until I stop doing basic research.[1] However, it did not take me long to realize that if the book was properly organized, I could greatly accelerate my main goal as a journal editor: bringing together all aspects of biologically active peptides.

Investigators in selected areas of research, frequently, are oblivious to work in related areas. In the peptide field, for example, many investigators working with mammalian peptides are unaware of the large number of peptides from other forms of life, such as the hundreds of venom peptides from scorpions, snakes, sea anemones, spiders, insects, and worms. They also usually overlook the applicability of many pertinent observations made with different types of peptides, such as those in bacteria. This point is emphasized by a statement in the chapter by Nicolas and Amiche: "The discovery of the considerable extent of sequence identity between the neuropeptide and antimicrobial peptide precursors is unprecedented"; I suspect that it is also little known. and who would have thought that plants make peptides (the first being identified in 1991 by Clarence A. (Bud) Ryan, editor of the Plant Peptides Section) and that they can function as hormones.

Senior Publishing Editor, Tari Paschall, and Director of Development, Jasna Markovac, were very helpful and encouraged the publication of this amalgamation in a book large in length, width, and depth. One of the first decisions I had to make was whether the book should contain a few large chapters or many small ones. Since my goal was to assemble the disparate aspects of the field in one place for the first time, I chose to try to include as many types of peptides as possible, discussed by experts for each category. After careful consideration, I decided to organize this vast field into 20 sections, with some peptides intentionally discussed in more than one section. I then carefully chose the editors for these 20 sections. Thereafter, I was largely guided by their choices of chapters and authors. Although we tried to include articles for as many important peptides as possible, there were obviously some omissions, including at least one of my own favorite peptides, but we were more interested in showing the breadth of the peptide field.

The next big problem arose in enforcing the page restriction for each chapter. Understandably, there was the tendency for the authors to include everything. Although we tried to impose uniformity in design of the chapters, we were flexible in allowing authors to choose a balance between the amount of text and number of references within the space limitation. Reviews were cited wherever possible to save space. Even so, most chapters were initially too long to allow publication of all the material in a single volume.

There was one figure, however, suggested by Hubert Vaudry, that was incorporated into all chapters of his Brain Peptides section. This was a template of a sagittal section of the brain depicting the distribution of the peptide (cell bodies and fibers) or the peptide precursor mRNA. It serves to unify his large section of the Handbook, and his outline provided homogeneity to several other sections, including those involving Plant, Bacteria, Invertebrate, and Amphibian peptides:

1. Discovery
2. Structure of the Precursor mRNA/Gene
3. Distribution of the mRNA
4. Processing of the Precursor
5. Receptors and Signaling Cascades
6. Information on Active and/or Solution Conformations (if available)
7. Biological Actions Specific to the Organ or System
8. Pathophysiological Implications

Since the first few of these items could be discussed in several sections of the book, it was decided that the general background sections common to several chapters dealing with mammalian peptides would be discussed primarily in the Brain Peptides Section. For other sections, such as GI Peptides, this same outline is followed except that the focus is specific for the GI tract.

Variations of this outline are used in other sections. For example, for the Ingestive Peptides Section, David York recommended this outline:

1. Description of the effects on feeding behavior,
2. Studies from genetic manipulations or mutations, for example, knockouts, transgenics, siRNA experiments,
3. Functional response of the peptide/gene to differing metabolic and feeding states,
4. Sites of action and neural networks affected,

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY

Copyright Elsevier 2024

5. Interactions with other peptidergic/aminergic systems,
6. Physiological and pathophysiological implications.

Other section editors recommended further variations. The Vaccine Peptides Section included the disease target as one of the categories. Naoto Minamino, discoverer of several peptides, recommended use of the Brain Peptides Section format but also noted that cardiovascular peptides are known to participate in the pathogenesis of cardiovascular diseases, and their plasma concentrations are often used as markers for their diagnosis, prognosis, and therapy. Therefore, he instructed authors in his Cardiovascular Peptides Section to focus on the peptides' endogenous form and concentration in plasma as well as their alteration under normal (physiological) and diseased (pathological) conditions.

The book tries to keep the abbreviations consistent. However, for some—for example, LHRH/GnRH and orexin/hypocretin—we allowed differences to reflect the authors' previous work already in the literature, even though I was an author of the paper showing that LHRH released both gonadotropins[4] and even though my one paper[2] on orexin/hypocretin used only the term *orexin*. Therefore, while there are a large number of chapters written by different authors, there is more uniformity in organization than would be expected from so many contributors. Discussion of some of the same peptides in different sections emphasizes the system involved. Conversely, some peptides discussed in only one section have actions that could fit into several sections (e.g. IGF-l). Many of the chapters are written by the investigator who made the initial discovery of the peptide being discussed.

For those mammalian peptides included in more than one section of the book, the emphasis is different in each section. Some degree of overlap was necessary, but it was kept to a minimum by the early transmission of the chapters in the Brain Peptides Section to the authors of chapters dealing with the same peptides in other sections. This was accomplished by the imposition of a deadline for the Brain Peptides chapters that was 2 months sooner than that for the other chapters. Moreover, each author was provided with the e-mail addresses of all authors and encouraged to communicate directly, especially after receiving drafts of related chapters from me.

It is very satisfying for me to see the tremendous body of knowledge in the field of biologically active peptides brought together in a single volume. I am especially gratified that so many chapters inherently reflect some of the concepts with which I have been personally involved: Peripheral peptides can affect the brain, endogenous antiopiate peptides exist, peptides can exert multiple effects, peptides can cross the blood–brain barrier directly, and others.[3] It is now almost inconceivable that they were once so controversial.

Despite the restrictions inherent in this large undertaking, the section editors and contributors were extremely cooperative, and I thank all of them. Their enthusiastic encouragement should ensure that this book will not only serve as an important reference source but will also widen the scope of the important field of biologically active peptides.

Abba J. Kastin
Pennington Biomedical Research Center,
Baton Rouge, LA 70808-4124,
peptides@pbrc.edu

After the publisher received all manuscripts, including this Preface, they decided that the formidable task of restricting the length of each chapter had been so successful that all materials designated for the supplemental disk could now be incorporated into this book.

Preface to the 2nd Edition

The preface for the first edition of the *Handbook of Biologically Active Peptides* includes discussion of the conception, purpose, and organization of the book. These remarks remain applicable to this second edition. Obviously, the publication of a second edition indicates that the first must have fulfilled the need we perceived of bringing together in one place information about biologically active peptides originating in disparate communities of investigators. This is extremely gratifying to all of us.

Janice Audet, the Senior Acquisitions Editor, and Mary Preap, Editorial Project Manager, have been very receptive to improvements for this edition. We have added chapters to accommodate newly discovered biologically active peptides, shortened the chapter titles, broadened the section of general topics, and most importantly, added a section on peptide biosynthesis and processing. This section adds details for many of the peptides discussed elsewhere in the book. This intentional overlap, like that among many sections, reflects the differing focus of each section, even when discussing the same peptide.

With a large number of authors, every effort has been made to ensure some degree of uniformity. Where appropriate, chapters follow this basic format:

- Discovery
- Structure of the mRNA/gene
- Processing of the precursor
- Distribution of the mRNA/peptide
- Receptors and signaling cascades
- Biological actions
- Pathophysiological implications

More uniformity was attempted by my own editing of each chapter, even after that by the Section Editors, with enforcement of a short abstract, maximal total length, and (most difficult for the authors) limitation of references to no more than 35. This means that the work of many investigators could not be cited in their original form but rather in reviews or only by name or finding. As promised the authors, I accept full blame for this. The authors, section editors, publishers, and I hope you find this second edition of the *Handbook of Biologically Active Peptides* interesting and useful.

Chapter 1

CLAVATA3

Shinichiro Sawa

ABSTRACT

Plant meristem is a unique structure made up of a self-renewing population of undifferentiated pluripotent stem cells. Shoot apical meristem (SAM) produces all aerial parts of postembryonic organs. *clavata3* (*clv3*) mutant produces fascinated SAM and flowers with increased floral organs in *Arabidopsis*. CLV3 restricts the size of the central zone in SAM and floral meristem (FM), controlling plant architecture. The *CLV3* gene encodes a precursor peptide with 96 amino acids. The mature CLV3 peptide is secreted from the apical tip of the SAM and FM as a glycopeptide of 13 amino acids with two hydroxyproline residues. The CLV3 peptide moves to the central part of the meristematic tissue and is recognized by at least three receptor complexes, CLV1, CLV2-Suppressor of LLP1 2 (SOL2)/CORYNE (CRN), and RECEPTOR LIKE PROTEIN KINASE 2 (RPK2). Phosphatases and kinases transmit the CLV3 signal. Here, we review the CLV3 peptide signaling network regulating meristem maintenance in *Arabidopsis*.

DISCOVERY

Shoot apical meristem (SAM) is known to be a meristem that provides cells for postembryonic growth and development (Fig. 1). The SAM is a collection of cells that continuously renew themselves by cell division and provide cells to new organs. Although continuous cell division and differentiation of their daughters are observed in meristematic regions, meristem size and the number of stem cells are kept constant. These observations suggest that stem cell maintenance and new organ formation are well balanced.[10,14] Recently, it has been shown that intercellular communication controls the organization and maintenance of SAM, as well as cell fate specification. Thus, stem cell maintenance requires well-coordinated regulation of different signals for meristem homeostasis.

The term meristem was first defined by Carl Wilhelm von Nageli in his book.[12] Meristem is a formative plant tissue made up of cells capable of dividing and giving rise to new cells.[16] Because of its essential role in higher plants, meristems have received much attention from plant scientists for >150 years.

The organization of the SAM can be divided into two areas (Fig. 1): the central zone (CZ), and the peripheral zone (PZ). In the SAM of plants, a balance between the division of stem cells in CZ and differentiating cells in PZ must be maintained. Genetic analyses of *Arabidopsis thaliana* show that *clv1*, *clv2*, and *clv3* are the loss-of-function mutants that exhibit remarkable phenotypes of shoot fascination, enlarged floral meristems, and increased numbers of floral organs (Fig. 2).[2] *CLV1* encodes a membrane-associated receptor-like kinase (RLK) that has leucine rich repeat (LRR) and kinase domains in its predicted extracellular and intracellular domain, respectively. *CLV2* encodes an LRR-receptor-like protein lacking a kinase domain.[3,5] *CLV3* encodes a 96-amino-acid peptide with a secretory signal sequence and a 14-amino-acid CLV3-ESR related (CLE) domain in its N-terminal and C-terminal region, respectively.[4] Together with genetic and biochemical analysis, CLV3 has been suggested as an extracellular signaling peptide that is responsible for the regulation of meristematic activity in *Arabidopsis*.

STRUCTURE OF THE PEPTIDE

The structure of the CLV3 peptide was examined by LC-MS/MS analysis by the use of peptides purified from a medium of cultured *Arabidopsis* plants overexpressing the *CLV3* gene.[13] The CLV3 peptide consists of 13 amino acids with two hydroxyproline residues (Fig. 3). The second hydroxyproline residue is modified with a linear b-1,2-linked triarabinoside. Dissociation constants (K_d) for the binding of CLV3 peptide with or without arabinose modification to the CLV1 ectodomain are 1.0 and 280 nM, respectively. Accordingly, arabinose modifies CLV3 peptide function in *Arabidopsis* compared with a CLV3 peptide without glycosylation.

However, a 12-amino-acid CLV3 peptide with two hydroxyproline was also isolated from callus cells,[8] and the corresponding synthetic peptide was also functional *in vivo*. However, its efficiency is lower than that of 13-amino-acid CLV3 peptides with a sugar modification. These results indicate that the arabinose chain is important for the function of the CLV3 peptide.

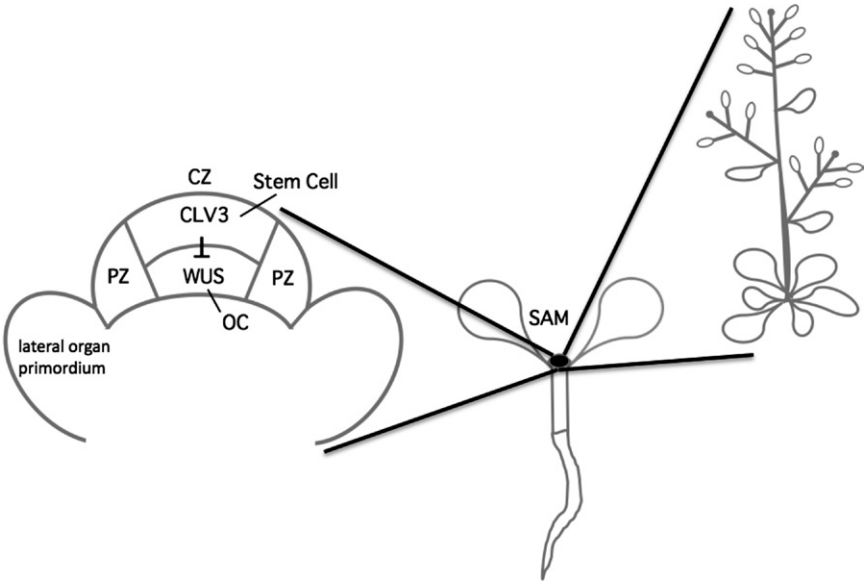

FIGURE 1 A model of the structures of SAM. SAM can be divided into two zones, the peripheral zone, PZ, and the central zone, CZ. CZ can be also divided into two regions, the stem cell region and the organizing center (OC). *CLV3* is expressed in the stem cell region, and *WUS* is expressed in the OC. All the upper ground tissues of the plant are produced by the activity of SAM.

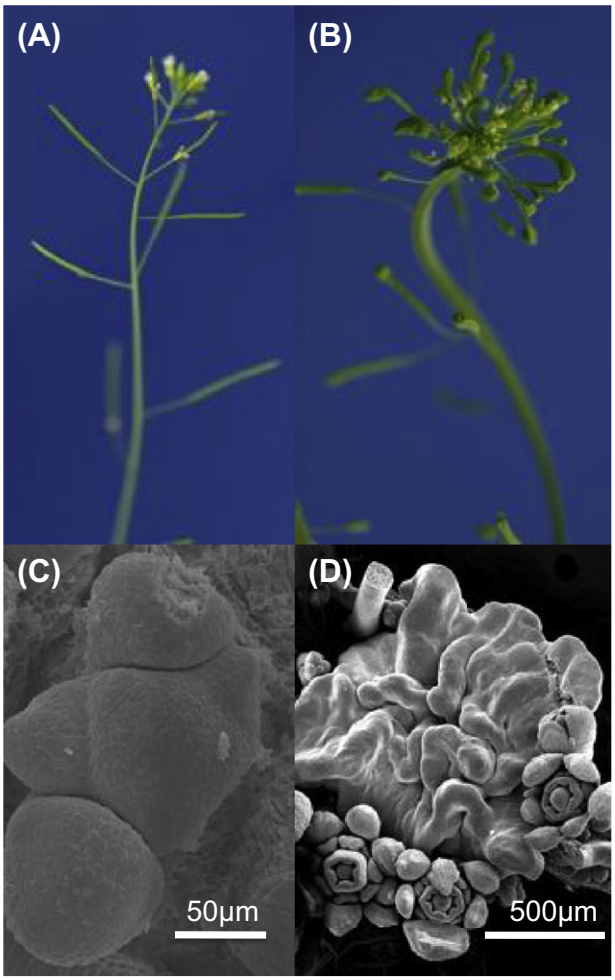

FIGURE 2 *clv3* mutant phenotypes. Compared with WT (A, C), *clv3* produces fasciated stem, increased number of floral organs, and larger shoot apical meristem (B, D).

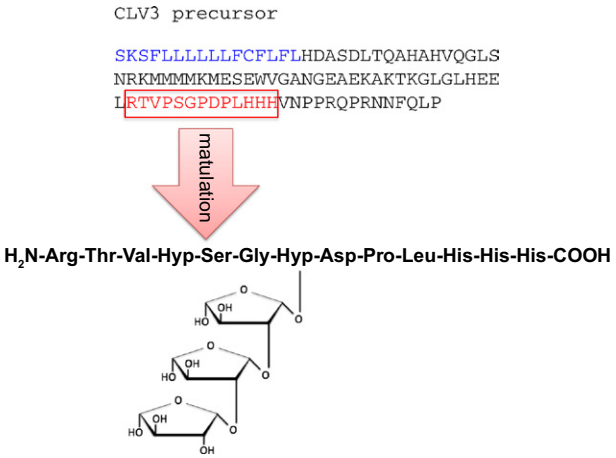

FIGURE 3 Structure of CLV3 preprotein and matured peptide. See color plate 1.

CLV3 is a member of the CLE family, and 26 kinds of CLE peptides are encoded in the *Arabidopsis* genome. The structure of CLE2 is similar to that of CLV3. However, CLE2 is a 12-amino-acid peptide.[13] So, CLE peptides seem to have various structural types, including different length and/or modifications.

DISTRIBUTION OF THE mRNA AND PEPTIDE

CLV3 gene expression is observed in the stem cell region at the apical tip of SAM (Fig. 1).[4] However, nobody knows the spatial distribution of mature CLV3 peptides.

Expression of *WUSCHEL* (*WUS*), a CLV3 downstream gene, is observed in the organizing center at the central part

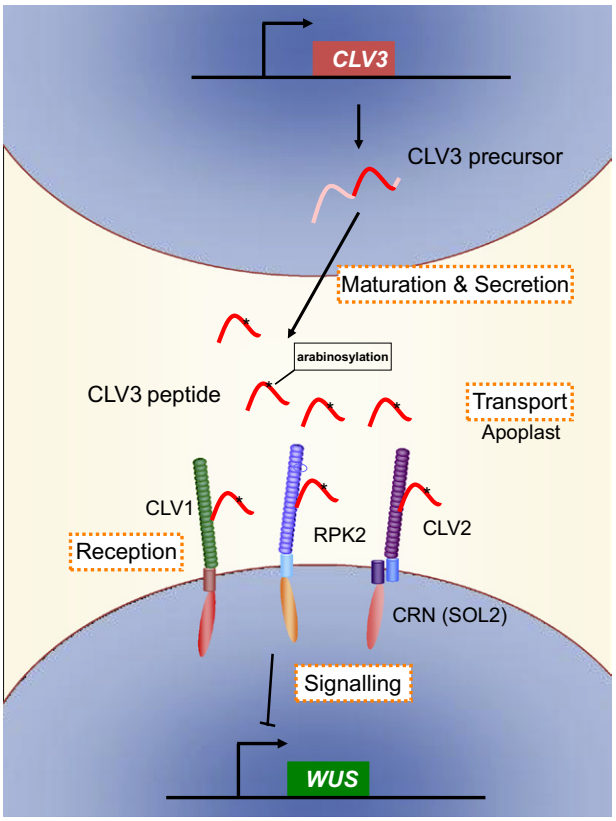

FIGURE 4 A schematic model of the CLV3 signaling pathway.

of SAM (Fig. 1), and the CLV3 peptide seems to move a short distance from the apical tip to the region around the central part of meristematic tissue.

BIOLOGICAL FUNCTIONS

clv mutants produce enlarged SAM and FM. Overexpression of the *CLV3* gene and application of the CLV3 peptide induce SAM and RAM consumption phenotypes.[8,6] In particular, *clv* mutants show enlarged CZ.[2] The CLV3 peptide seems to function to restrict the size of CZ, regulating meristematic tissue architecture.

RECEPTORS AND SIGNALING CASCADES

The CLV3 peptide is secreted from the apical tip of SAM to suppress a homeodomain transcription factor *WUS* gene expression noncell autonomously (Figs 1 and 4). However, *WUS* induces *CLV3* expression, giving rise to a negative feedback loop.[15]

CLV1, CLV2, SOL2/CRN, and RPK2 function as CLV3 receptors (Fig. 4). *RPK2* encodes an LRR-RLK, and *SOL2/CRN* encodes membrane bound kinase without an extracellular domain.[11,9,7] Genetic and biochemical analyses mainly agree that three major complexes perceive the CLV3 signal: CLV1, CLV2–SOL2/CRN hetero-oligomer, and RPK2 homooligomer.[7]

CLV3 ligand however induces CLV1 phosphorylation.[1] Type-2C kinase-associated protein phosphatase (KAPP) directly interacts with the CLV1 kinase domain, and functions as a negative regulator of CLV signaling transduction.[17] The *poltergeist* (*pol*) mutation suppresses the *clv1*, *clv2*, and *clv3* abnormalities.[18] *POL* and its homolog, *POLTERGEIST LIKE 1* (*PLL1*) encodes phosphatase type 2C (PP2C) protein, acting downstream of the CLV1 to maintain *WUS* expression. In addition to phosphatases, Rho GTPase-related protein (Rop), *MAP kinase kinase 4* (*MKK4*) and MAP kinase 6 (MPK6), components of the mitogen-activated protein (MAP) kinase cascade have been implicated in the mediation of phosphosignaling that regulates *WUS* expression downstream of the CLV3 peptide.[1,17]

Chapter 2

Defense Signal Peptides

Yube Yamaguchi, Gregory Pearce and Alisa Huffaker

ABSTRACT

Six genetically distinct families of plant defense signal peptides have been discovered. These include systemin, Plant elicitor peptides (Peps), and *Glycine max* (Pep914/890), all derived from larger precursors without traditional N-terminal secretion signals; hydroxyproline-rich systemins (HypSys), glycopeptides derived from precursors containing signal sequences for secretion through the ER and Golgi; and *Glycine max* Subtilisin Peptide (*Gm*SubPep) and inceptin, both embedded in proteins with nondefensive roles. These peptide signals may also be classified according to their regulatory functions: systemin, HypSys, and inceptin regulate antiherbivory responses, whereas Pep, *Gm*SubPep, and *Gm*Pep914/890 induce defenses against pathogens. With the exception of Peps, which are conserved across both monocots and dicots, each group of defense-signaling peptides is specific to particular plant families. This indicates that peptides evolved as signals through many distinct events during the arms race between plants and their biotic attackers, implying that more unique plant defense peptides are yet to be discovered.

DISCOVERY

Tomato and potato plants accumulate protease inhibitor proteins in leaves in response to herbivore attack or severe mechanical wounding. This accumulation occurs not only in wounded leaves but also systemically in undamaged leaves. After nearly two decades of intense efforts to identify the "protease inhibitor inducing factor," a microgram of the active factor was isolated from approximately 60 pounds of tomato leaves and identified as an 18 amino acid peptide called systemin (Sys).[19] When the peptide was chemically synthesized and supplied to young tomato plants, it induced protease inhibitor accumulation with a half-maximal activity of 40 fmol peptide per plant. Sys was the first peptide signal to be isolated and identified from a plant tissue.

Although a gene encoding systemin-like peptide is not found in the leaves of tobacco plants, leaves of young tobacco plants do exhibit systemic wound-inducible synthesis of trypsin inhibitor. Thus, a signaling pathway to activate protease inhibitor activity upon wounding as in tomato and potato must also exist in tobacco. These observations led to a search for defense peptide signals in the leaves of tobacco plants. This search was facilitated by the development of a biological assay using suspension-cultured cells that was much more rapid and simple than the whole-plant assay used for the isolation of Sys.[12,18] The new assay was based on the observation that addition of Sys to suspension-cultured tomato cells causes a rapid increase in the pH of the extracellular medium (up to 1 pH unit in 10min), heretofore referred to as the "alkalinization response." This pH change is among the earliest events induced by Sys and results from a calcium- and phosphorylation-dependent transient deactivation of a proton-pumping ATPase in the plasma membrane. The addition of microliter amounts of fractionated tobacco leaf extracts caused a strong alkalinization response in tobacco cells, suggesting that tobacco leaves may contain a signal analogous to Sys in tomato. With this assay, two 18 amino-acid glycopeptides that contain multiple hydroxyproline residues were identified and characterized.[16] Both peptides induce the synthesis of trypsin inhibitors when supplied through cut stems at nanomolar concentrations. Because of their similarities to tomato systemin in size, hydroxyproline content (derived from prolines), and their signaling characteristics, they were called Tobacco Systemin I and Tobacco Systemin II, designated here as *Nicotiana tabacum* Hydroxyproline-rich Systemins, or *Nt*HypSys I and *Nt*HypSys II.

Application of the alkalinization assay to nonsolanaceous plants has resulted in the isolation of several novel defense-related peptides, none of which bears homology to systemins or HypSys. Arabidopsis Plant Elicitor Peptide 1 (*At*Pep1, a 23 amino acid peptide) was isolated from *Arabidopsis thaliana* (mouse-ear cress),[6] and *Gm*Pep914 (an 8-amino acid peptide) and *Gm*SubPep (a 12-amino acid peptide) were isolated from soybean.[20,31] All these peptides seem to be primarily signals to activate pathogen defense responses.

Aside from systemin, inceptins are the only plant defense peptides identified without the use of the alkalinization assay.[28] Interestingly, inceptins, cyclic 11-amino acid peptides present in the Vigna and Phaseoulus species of the Fabaceae, were isolated from oral secretions of lepidopteran insect larvae as elicitors of plant ethylene production. Although inceptins are found in insect oral secretions, they are fragments

of the regulatory domain of plant chloroplastic ATPase subunit 3. As caterpillars feed on leaves, digestive enzymes in the larval midgut specifically process the cATPase protein to produce inceptins, which are then regurgitated back onto the leaf tissue during the course of feeding to induce plant defense. It is not yet known whether inceptins are ever produced in the absence of herbivory through endogenous proteolytic activities.

The structures of precursor proteins and mature peptide sequences characterized thus far are listed in Fig. 1.

SYSTEMIN

Structure of the Peptide

Tomato systemin consists of the amino acid sequence: +AVQSKPPSKRDPPKMQTD– without any posttranslational modifications and is derived from the C-terminus of the 200 amino acid precursor protein called *Sl*proSys.[11,19] Systemin-like peptides are found in potato, nightshade, and pepper, all members of the Solanoideae subfamily of the Solanaceae family.[12] The gene has not been detected in tobacco or petunia, members of the Nicotianoideae and Petunioideae subfamilies, respectively, nor in species of any other plant families. The amino acid sequences of Sys peptides from tomato, potato, nightshade, and pepper differ by only a few residues.

Structural features of all systemin family members include charged amino acids flanking tandem proline motifs.[12,18] The tandem prolines are thought to cause the weak poly(L-proline) II, 3_1 helical conformation (PPII) found in *Sl*Sys. PPII conformations tend to form left-handed helices and are known to be involved in recognition events in animals. In each peptide, the tandem prolines are flanked by charged residues, and this charged PPII conformation may play an important role in receptor recognition. Substitution of the penultimate threonine residue at position #17 of *Sl*Sys with an alanine totally abolishes activity while generating a powerful competitive inhibitor.[26]

Structure of the Precursor Protein

The 200 amino acids composing *Sl*proSys are rich in charged residues, with 10% being Asp, 17% Glu, and 15% Lys. Regions rich in Lys and Glu residues resemble KEKE motifs that are hypothesized to mediate protein–protein interactions.[23] The processing enzymes that produce *Sl*Sys from *Sl*proSys have not been identified, nor is it known whether *Sl*Sys or *Sl*proSys is transported to the apoplast from the cytoplasm or by what mechanism this is accomplished. Wound-inducible proteases have been identified in leaves[18] and may play a role in processing *Sl*proSys to *Sl*Sys.

Prosystemin Gene Expression Patterns

The systemin precursor is located in the cytosol and nucleus of phloem parenchyma cells of minor veins and midribs of leaves and in the bicollateral phloem bundles of petioles and stems of tomato plants.[15] The gene encoding prosystemin is wound inducible in leaves; the transcript is detected within 30 min of wounding, and maximal accumulation occurs within 3h[26] When wound-responsive genes are temporally classified, *SlproSys* is among the "early genes" expressed along with several signaling genes. This is in contrast to genes encoding directly defensive proteins such as protease inhibitors that are "late genes," for which transcription begins 1–2h after wounding and maximizes after about 8 h.[26]

Biological Functions

*Sl*Sys was established as a primary wound signal for the systemic induction of defense genes in tomato plants through antisense technology, showing that the inhibition of the synthesis of *Sl*proSys also blocked systemic wound signaling and defense against herbivore attack.[12,18] Analyses using the systemin-signaling mutant, *spr2*, revealed that systemin induces JA synthesis in the companion cell-sieve element complex of the vascular bundles, leading to systemic protease inhibitor induction.[9,27] Systemin also increases the release of plant volatiles that attract natural enemies of insect herbivores.[12,18] Protease inhibitors induced by systemin are required for resistance against a fungal pathogen, *Botrytis cinerea*.[2]

Receptors and Signaling Cascades

By photoaffinity-labeling techniques, specific binding of systemin was detected in tomato suspension cells to SR-160, a 160kDa leucine-rich repeat receptor kinase (LRR-RK) identical to the tomato brassinosteroid receptor BRI1.[12,18] However, although SR160/BRI-1 binds systemin, it is probably not the physiological receptor that transduces the systemin signal.[10] The systemin receptor is hypothesized to be a BRI1-like receptor (BRL), and because systemin perception does not occur in leaf mesophyll cells, the receptor is thought to be localized to vascular tissues.[4] BRI1 interacts with BRI1-associated kinase 1 (BAK1), as do many other receptors, including PEPR1, FLS2, and EFR, all of which bind peptide signals that activate defense.[28] In addition to probably being highly homologous to BRI1, it is possible that the systemin receptor associates with BAK1, which could lead to colocalization with BRI1 on the plasma membrane.

Perception of systemin at the cell surface rapidly activates plasma membrane depolarization and causes ion channels to open resulting in an efflux of K^+ and influx of Ca^{2+} into the cell.[26] These changes are accompanied by the activation of both a MAP kinase and calmodulin and subsequent inactivation of a plasma membrane proton ATPase.[26] The main target of these events is stimulation of phospholipase activity, which results in the release of linolenic acid from thylakoid membranes in the chloroplast. Linolenic acid is the precursor to the production of the phytohormone jasmonic acid and other oxylipin signals through the octadecanoid pathway. The phytohormone ethylene is also produced in response to systemin and acts together with jasmonic acid to regulate the expression of defense genes and synthesis of defense metabolites.[26] In addition to ethylene and jasmonic acid, a number of other molecules have been identified as second messengers downstream of systemin signaling, including hydrogen peroxide, nitric oxide,

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

and oligogalacturonic acid. Systemin amplifies wound signaling by rapidly inducing expression of its own gene and other signaling genes such as lipoxygenase and calmodulin in the vasculature.[26] This is hypothesized to allow signals to traverse the plant quickly through the phloem. Genes that encode defensive proteins such as protease inhibitors and polyphenol oxidase require additional response time and are expressed in the mesophyll cells rather than the vasculature.[26]

HypSys

Structure of the HypSys Peptides

Tobacco hydroxyproline-rich systemins, *Nt*HypSys I and II, originate from a single secreted prepropolypeptide of 165 amino acids that contains the *Nt*HypSys I sequence near the N-terminus and the *Nt*HypSys II sequence near the C-terminus.[16] Neither peptide exhibits homology with *Sl*Sys, but the –OOS– motifs are similar to the *Sl*Sys –PPS– motif and would result from posttranslational hydroxylation of proline during secretion. The two HypSys peptides have multiple regions that are contiguous hydroxyproline, serine, and threonine residues. These residues, flanked by charged amino acids, comprise >50% of each peptide. Mass spectroscopy of the two peptides revealed that the attached carbohydrate moieties consist of pentose residues: nine in *Nt*HypSys I and six in *Nt*HypSys II.[16] Multiple HypSys peptides have been isolated from petunia, nightshade, potato, and sweet potato and in each case are derived from single precursor proteins homologous to the tobacco precursor.[12,18] The native peptides are active at low nanomolar concentrations in the alkalinization assay, but the synthetic peptides without carbohydrate moieties have greatly reduced activity, indicating the importance of glycosylation for their biological activity. Because of the low binding affinity of synthetic HypSys peptides, receptors for HypSys peptides have not been isolated.

Structure of the Precursor Protein

The presence of multiple signaling peptides contained within a single precursor is a characteristic of many animal peptide hormones, but the tobacco HypSys precursor provides the first example in plants. Although the tobacco HypSys precursor protein contains two HypSys sequences, tomato, petunia, nightshade, and potato HypSys precursors, all contain three HypSys sequences, and the sweet potato precursor contains six HypSys peptides.[12,18]

All precursor proteins contain N-terminal secretion signals, and localization of *Sl*proHypSys in the cell wall matrix was confirmed by immunocytochemical staining.[14] *Sl*proHypSys processing must occur in the apoplast upon wounding, suggesting either that nonspecific cytoplasmic proteases are mixed with cell walls upon damage or that specific proteases are synthesized or activated in response to wounding.

Expression Patterns of *preproHypSys*

The transcripts of *preproHypSys* from tobacco, tomato, petunia, nightshade, and sweet potato accumulate upon treatment by wounding and MeJA,[12,18] while no changes in *N. attenuata* were observed.[1] Furthermore, the expression of *N. tabacum preproHypSys* was strongly induced by chewing and phloem-feeding insects, *Manduca sexta* larvae and *Bemisia tabaci* adult flies.[25] Observed transcript accumulation of these precursors in response to herbivores or wound-related stimuli supports the role of HypSys peptides in defense against herbivores.

Biological Functions

Supplying HypSys through the cut stem induced defense genes that are also induced by MeJA and by insects and/or pathogens: protease inhibitor genes in tomato, tobacco, nightshade, and sweet potato and a defensin gene in petunia.[12,18] In nightshade, genes encoding a lipoxygenase D and phospholipase A2, both involved in JA biosynthesis, are also rapidly induced by *Sn*HypSys. More direct evidence for the defensive role of HypSys peptides was obtained from experiments with *N. tabacum* and *N. attenuata*. Transgenic tobacco plants overexpressing *Nt*preproHypSys have increased levels of protease inhibitors and polyphenol oxidase and display enhanced resistance against *Helicoverpa armigera* larvae.[24] Experiments with transgenic *N. attenuata* silenced in the production of *Na*preproHypSys reveal that *Na*HypSys regulates a malonylation step in the synthesis of 17-hydroxygeranyllinallol diterpene glycoside, an antiherbivore compound.[3]

Tomato and nightshade have Sys in addition to HypSys. How the combined roles of Sys and HypSys are coordinated during wounding is not fully understood, but the production of multiple defense signaling peptides at wound sites may play an important role in stimulating rapid, robust synthesis of JA. If enzymes that process the peptide precursors were among the wound and jasmonate-induced proteases, then JA would promote production of both precursors and peptide signals as it traverses the vascular bundles. This would in turn serve to further amplify levels of JA. Both *Sl*proSys and *Sl*preproHypSys are localized in phloem parenchyma cells adjacent to companion cells[14,15] where JA biosynthesis occurs and a cooperative interaction between these cells may be important in tomato plants to achieve a vigorous defense response.[13] Tobacco, which has a much weaker systemic response than tomato, does not synthesize systemin but may amplify JA synthesis through release of HypSys

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

peptides. Understanding the complex interactions among Sys, HypSys, and JA, as well as with other wound-induced signals, such as ET and H_2O_2, will be a key challenge for future research.

PLANT ELICITOR PEPTIDES (PEPS)

Structure of the Peptides

*At*Pep1 is derived from the 23 carboxyl-terminal residues of a 92 amino acid precursor polypeptide, *At*PROPEP1 (At5g64900).[6] Seven *At*PROPEP paralogs encoded in the Arabidopsis genome share a 10-amino acid motif, SSG(K/R)xGxxN, at the carboxyl-terminus of each deduced protein within the putative *At*Pep peptide region. Analyses of the biological activities of alanine-substituted analogs, or of *At*Pep1 with deletions at the N-terminus, reveal that the 10 C-terminal residues are necessary for activity, and modifications within the core motif, presented above, reduce the activity of the peptide several fold.[21] Substitution of Gly-17 in the conserved SSG sequence of the motif with Ala totally abolishes activity, but the analog is not a competitor of native *At*Pep1 in the alkalinization assay.[21] The amino-terminal regions of the *At*Pep peptides deduced from all the paralogs are cationic in nature. *At*Pep1 has a predicted p*I* of 11.2 with five lysines and two arginines concentrated at the amino-terminal half of the peptide.[21]

Structure of the Precursor Proteins

All the *At*PROPEP precursor proteins have negatively charged Glu/Asp repeats, interrupted by single Lys/Arg residues (KEKE motifs[23]). The precursors of all *At*Pep family members lack signal sequences that would target them through the classical secretory pathway. However, the *At*Peps interact with two cell surface receptors[32] to initiate defense signaling, indicating that AtPeps or their precursors are exported from the cell. The mechanisms of how *At*Peps arrive at the cell surface are not known, but the KEKE motifs along with an amphipathic helix motif conserved in all PROPEP precursor proteins have both been previously described as protein–protein interaction motifs.[23] Thus, these regions may interact with some yet unknown protein(s) such as chaperones or processing enzymes to facilitate processing and/or export.

*At*PROPEP orthologs have been predicted from the database of many plant species, including important crop plants such as canola, potato, rice, soybean, and maize.[6] All of these genes encode putative precursor proteins of 93–154 amino acids, and all lack signal sequences, contain KEKE motif regions, and have predicted amphipathic regions. The putative *At*Pep regions of these orthologs are Lys/Arg rich. The only absolutely conserved residue in the AtPep region is Gly that, when substituted with Ala in *At*Pep1, abolishes activity. The synthetic maize ortholog, ZmPep1, has biological activity.[5]

Expression Pattern of *At*PROPEPs

The genes encoding *At*PROPEPs are expressed at low basal levels in all Arabidopsis tissues from newly germinated seedlings to mature, seed-setting plants with basal levels in flowers and roots being somewhat higher than in other tissues.[6] The Arabidopsis *AtPROPEP* genes in leaves are differentially inducible by wounding, MeJA, ET, SA, microbe-associated molecular patterns (MAMPs), and pathogen infection.[6,7] Additionally, *AtPROPEP* genes are differentially inducible by supplying *At*Peps to young plants, indicating that feed-forward positive regulation exists within the signaling pathway of *At*Peps.[7] The gene encoding the maize ortholog, *Zm*PROPEP1 is transcribed in leaves in response to treatment with *Zm*Pep1 peptide or JA, further supporting a feed-forward amplification mechanism. Transcript corresponding to the *Zm*PROPEP1 gene also accumulates in leaves infected with the fungal pathogen *Cochliobolus heterostrophus*.[5]

Biological Functions

*At*Pep1 was the first peptide defense signal identified in the model plant *Arabidopsis thaliana* and has rapidly provided new insights into mechanisms regulating pathogen defense in this plant. Peps activate the accumulation of both transcripts encoding defense genes and defense-related metabolites. In Arabidopsis, the *PR-1* (pathogenesis-related protein) and *PDF1.2* (defensin) genes associated with the activation of SA- and JA-dependent defenses are transcribed in leaves supplied with *At*Pep peptides.[6,7] This transcriptional activation is compromised in mutants defective in biosynthesis or perception of the defensive hormones, JA, ET, and SA. Transgenic Arabidopsis plants with increased expression of *At*PROPEP1 also constitutively expressed defense genes including PDF1.2 and PR1. In maize, *Zm*Pep treatment stimulates the expression of genes encoding a number of defense proteins, including chitinases, a protease inhibitor and biosynthetic enzymes for the production of benzoxazinoid phytoalexins.[5] This activation of gene expression in maize is accompanied by *de novo* benzoxazinoid synthesis and accumulation of a particularly reactive phytoalexin precursor, HDMBOA-Glc.

Peps enhance disease resistance in both Arabidopsis and maize. Pretreatment of Arabidopsis leaves with *At*Peps before inoculation with the bacterial pathogen *Pseudomonas syringae* pv. tomato DC3000 results in a dramatically reduced bacterial propagation.[32] Arabidopsis plants constitutively expressing the *AtPROPEP1* gene are more resistant to root rot caused by the oomycyte root pathogen *Pythium irregulare*

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

than are wild-type plants.[6] Pretreatment of maize leaves with *Zm*Pep1 reduces Southern leaf blight lesions and cell death caused by *Cochliobolus heterostrophus*.[5] Similarly, *Zm*Pep1 application to maize stems before inoculation with *Colletotrichum graminicola* reduces symptoms of anthracnose stalk rot as compared with water-treated stems. All these findings support the role of Peps as activators of pathogen defense responses.

Receptors and Signaling Cascades

Two *At*Pep receptors, *At*PEPR1 and *At*PEPR2, were identified by photoaffinity labeling and mutant analyses.[8,32] Both *At*PEPR1 and *At*PEPR2 are structurally similar to FLS2, EFR, and Xa21 receptors for peptide MAMPs and belong to the subfamily LRR XI. Kinetic analyses of *At*Pep1 binding to tobacco suspension-cultured cells expressing either *At*PEPR1 or *At*PEPR2 indicate that *At*Pep1 binds to the cell surface within a minute, with a K_d of 0.56 and 1.25nM, respectively.[32] In a double T-DNA insertional mutant of both *At*PEPR1 and *At*PEPR2, all effects caused by *At*Pep treatment are abolished, including reduced propagation of *P. syringae*.[32] In addition to an active kinase domain, the cytosolic portions of both *At*PEPR1 and *At*PEPR2 contain a guanylyl cyclase (GC) domain. This GC domain generates cGMP, and it is hypothesized that cGMP generated by this domain activates a cyclic nucleotide-gated Ca^{2+} conducting channel (CNGC2) that is required for the defense response.[22] In addition to Ca^{2+}, Peps induce the production of a number of downstream defense signals, including JA, ET, H_2O_2, and NO.[5–8] Perturbation of these downstream signals through mutation or application of inhibitors compromises AtPep-induced responses.[6,7]

Little is known about other downstream components of Pep signaling. Expression of genes encoding a number of defense-related kinases and WRKY transcription factors is activated by AtPep treatment.[32] This indicates that they may have a role in Pep signal transduction, but experimental evidence is required to confirm this hypothesis. *At*PEPR1, *At*PEPR2, EFR, and FLS2 all interact with the same coreceptor, BRI-associated kinase 1 (BAK1), which is required for both MAMPs and *At*Pep signaling.[30] These observations indicate that downstream pathways of Pep/PEPR overlap with MAMP signaling pathways and support the idea that *At*Peps amplify the defense responses initiated by MAMPs.[32]

*Gm*SubPep

Structure of the Peptide

The first identified peptide from soybean, *Gm*SubPep, is 12 amino acids in length with a highly basic net charge: NTPPRRAKSRPH.[20] *Gm*SubPep is active at low concentrations (<0.25nM) and produces a pH change of the suspension cell media within 10min. Alanine substitution at each amino acid position within the peptide results in almost a complete loss of alkalinization-inducing activity for [A^{10}]*Gm*SubPep (Arg-substituted) and [A^{12}]*Gm*SubPep (His-substituted), and both of these analogs successfully compete with *Gm*SubPep in the alkalinization assay.[17] Thus, *Gm*SubPep activity and possible association and transduction of signaling via its putative receptor are mediated through the carboxyl-terminal portion of the peptide. Truncated peptides produced by sequential removal of single amino acids from the amino terminus of *Gm*SubPep cause a 1000-fold decrease in activity after the removal of one amino acid [*Gm*SubPep(2–12)] and a complete loss of activity upon removal of three amino acids. However, these truncated analogs do not compete with *Gm*SubPep in the alkalinization assay.[17] The amino-terminal portion of the peptide may facilitate receptor binding but is not required for transduction of the signal, similar to systemin.[17] In agreement with these results, both [A^{10}]*Gm*SubPep and *Gm*SubPep(2–12) are incapable of activating expression of defense genes relative to *Gm*SubPep.

Structure of the Precursor Protein

The peptide sequence was derived from a gene designated Glyma18g48580 encoding a subtilisin-like protease (subtilase); thus, the peptide was named "*Glycine max* Subtilase Peptide" (*Gm*SubPep).[20] The full length coding region of Glyma18g48580 was sequenced, and reveals all the characteristics of a plant subtilase, including a signal sequence for secretion out of the cell. The *Gm*SubPep sequence is located just after the protease-associated domain within the peptidase S8 region, in a region unique to a small group of leguminous plants. In agreement with this, only soybean suspension cells are responsive to *Gm*SubPep in the alkalinization assay. Although more research is required, it would seem that *Gm*SubPep enters the apoplast embedded in the subtilase and a processing event releases *Gm*SubPep for association with its putative receptor. The processing events for release of *Gm*SubPep will be an exciting area of research along with the identification of a cell-surface receptor.

Biological Functions

*Gm*SubPep, in addition to its activity in the alkalinization assay, is also capable of inducing the expression of genes encoding defense proteins including a chitinase and a chalcone synthase involved in the biosynthesis of the phytoalexin glyceollin.[20] Interestingly, the expression of the gene encoding the subtilase (Glyma18g48680) is unresponsive to the application of hormones known to induce defense responses, such as JA, SA, and ET. This, coupled with high constitutive

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

expression levels in all tissues of the plant, suggests a nondefensive role for the protease. The specific role of *Gm*SubPep will be revealed with insect/pathogen studies to elucidate mechanisms and temporal dynamics of *Gm*SubPep release from the subtilase.

*Gm*Pep914/890

Structure of the Peptides

A second peptide was isolated by the alkalinization assay from the crude soybean leaf extracts.[31] This eight amino acid peptide was named *Gm*Pep914 (DHPRGGNY), based on its monoisotopic mass. Synthetic *Gm*Pep914 peptide is capable of alkalinizing the cellular media at 0.25nM and requires only 5–10 min to achieve a maximal response. An alanine-substitution scan of *Gm*Pep914 reveals that substitution at positions 7 and 8 within the peptide ([A^7]*Gm*Pep914 and [A^8]*Gm*Pep914) causes a complete loss of alkalinizing activity. Neither analog is capable of competing with *Gm*Pep914 in the assay, suggesting that they are incapable of binding a putative membrane-bound receptor.[31] Additionally, the removal of either the amino-terminal or carboxyl-terminal amino acid abolishes peptide activity. This is in agreement with the strict conservation of the *Gm*Pep914 regions of the putative precursors found in the GenBank described below.

Structure of Precursor Proteins

A predicted coding sequence found in the soybean genome database (Glyma12g00990) reveals a 52-amino acid precursor (*Gm*proPep914) with *Gm*Pep914 located at the carboxyl-terminus of the putative protein. In addition to *Gm*proPep914, a second cDNA encoding a 52 amino acid precursor peptide was isolated with a very similar sequence, including an eight amino acid carboxy-terminal region that differs from *Gm*Pep914 by only one amino acid. This putative peptide was named *Gm*Pep890 and the precursor, Glyma09g36370, was named *Gm*proPep890. *Gm*Pep890 (DLPRGGNY) was synthesized and found to be as active as *Gm*Pep914 in the alkalinization assay. *Gm*proPep914 and *Gm*proPep890 share 84.6% sequence homology and, like the *At*proPeps and prosystemin (see above), have no discernible signal sequence for secretion.[31]

A search of homologs of *Gm*proPep914/890 reveals similar EST sequences in three other members of the Fabales: *Glycyrrhiza uralensis* (licorice), *Medicago truncatula*, and *Cajanus cajan*, a major legume crop of the tropics.[31] A search using only the *Gm*Pep914/890 peptide region reveals two additional homologs from the Cucurbitales family, a close relative to the Fabales. Thus, like systemin, it would seem that *Gm*Pep914/890 has evolved within a tight ecological niche.

Expression Pattern of *Gm*PROPEP914/890

*Gm*Pep914/890 induces the expression of the genes encoding their respective precursors *Gm*PROPEP914/890, when supplied to soybean suspension-cultured cells.[31] In experiments with soybean plants, *Gm*PROPEP914/890 exhibits high constitutive expression levels in roots with low basal levels in other tissues. However, upon treatment with jasmonate, salicylate, and ethylene, expression levels of both precursor genes increase in leaves. *Gm*proPep914 orthologs found in the EST database from other plant species are mainly contained in cDNA libraries prepared from underground tissues, which are surrounded by a plethora of potential microorganism invaders.[31]

Biological Functions

*Gm*Pep914/890 have no sequence homology to *Gm*SubPep; however, GmPep914/890 and GmSubPep induce the same defense genes in soybean suspension cells, including *CYP93A1*, *Chib1-1*, and *achs-1*.[31] Analysis of the biological functions of *Gm*Pep914/890 has just begun. However, similarities in activities of *Gm*Pep914/890 and the Plant Elicitor Peptides, such as transcriptional activation of genes encoding both peptide precursors and defense proteins, suggest that *Gm*Pep914/890 might act as amplifiers of defense responses initiated by biotic stresses, similar to AtPep peptides.

INCEPTINS

Peptide Structure

Inceptins are regulators of herbivore defense in *Vigna* and *Phaseoulus* species of legumes.[28] These disulfide-bridged peptides are released from a highly conserved regulatory domain in the γ-subunit of chloroplastic ATP synthase. Regulatory activity of the γ-subunit relies upon sequence fidelity at this position, with cATPase activation occurring through the reduction of a disulfide bridge between the regulatory domain and the inhibitory ε-subunit. Inceptin peptides contain two cysteines, including one that forms a bridge to the ε subunit and are classified as cryptides, peptide signals derived from proteins of unrelated function rather than from a standard propeptide precursor. The first cryptides discovered in plants, inceptins are proteolyzed from the cATPase by digestive enzymes in the midgut of the Fall armyworm (*Spodoptera frugiperda*) during herbivory.[28] While feeding, the insects regurgitate inceptins back onto the plant where it is recognized as an elicitor to activate antiherbivore defenses. Supplementation of insect diet with recombinant cATPase γ-subunit protein confirm that cATPase is the source of inceptins; insects supplied with cATPase-supplemented

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

diet produce inceptin peptides, whereas those on nonsupplemented diet do not.[8] Furthermore, larvae feeding on roots, which do not contain chloroplastic ATPase, do not produce inceptins.

Inceptins are released by insect digestive enzymes through what is probably nonspecific proteolysis, and several forms can be detected in larval oral secretions.[29] Each inceptin is a short, acidic peptide with a core motif consisting of the disulfide-bridged cyclic domain. The bioactive peptides range in size from 11 to 13 amino acids because of amino-terminal extensions to the core domain of varying lengths. Eleven- and 12mer inceptins are slightly more active than the 13mer, with half-maximal active concentrations of 68 and 45fmol per leaf (as compared with 87fmol per leaf for the 13mer). Freshly collected insect oral secretions contain a blend of the three inceptins but with time the longer peptides break down to yield the very stable 11mer.[29]

Alanine substitution studies of the 11mer inceptin sequence, +ICDINGKCVDA–, reveals that Asp10 is absolutely required for elicitor activity and that substitutions at Asp3 and Cys8 substantially reduce bioactivity.[29] Interestingly, substitution at Cys2, which forms a disulfide bridge to Cys8, has little effect on elicitor activity. This indicates that although cyclization resulting from disulfide bonding confers stability to inceptins, it is not required for signaling function. As for many other plant peptide signals, inceptin activity requires conservation of the carboxyl-terminus but is tolerant of amino-terminal substitutions.

Distribution of the mRNA/peptide

The chloroplastic ATP synthase from which inceptin is derived is ubiquitous and constitutively present in foliar and other chloroplast-rich tissues. Because inceptins are the products of a domain particular to chloroplastic ATP synthases, they are not generated from other ATPase proteins. Because of the cleavage of inceptin from the γ-subunit by insect digestive enzymes, it seems probable that the production of bioactive peptide is limited to occasions of biotic interaction. It is not known whether endogenous plant proteolysis activities ever result in inceptin production in the absence of herbivory. Although inceptins act as defense elicitors only in *Vigna* and *Phaseoulus* species, the corresponding domain of the cATPase γ-subunit is widely conserved across plant species, and inceptin peptides are detected in oral secretions of armyworms that have fed on maize and tobacco as well as legumes.[28]

Biological Functions

Activation of plant defense against herbivores is associated with an ethylene burst, and *S. frugiperda* herbivory promotes ethylene synthesis in numerous plant species including *Vigna*. However, the fatty acid–amide conjugates from *S. frugiperda* oral secretions that elicit antiherbivore defense in some plant species are not active in *Vigna*. Inceptins were discovered through a search for the molecule responsible for elicitor activity in *Vigna* by the use of an induced-ethylene assay. In addition to promoting ethylene production, inceptins activate both direct and indirect herbivore defenses.[28]

Inceptin treatment results in the production of volatile organic compounds including a variety of terpenes as well as indole and methyl salicylate.[28] These volatiles mediate indirect plant defense by attracting natural enemies of *S. frugiperda*. In addition to promoting volatile emission, inceptins stimulate responses associated with direct defenses against herbivores. These include induced expression of a gene encoding a cystatin protease inhibitor and production of cinnamic acid, which is a precursor to phenylpropanoid defense metabolites.[28] The importance of inceptin-regulated defenses against *S. frugiperda* was confirmed in plants pretreated with the 11mer peptide. Larvae feeding on inceptin-pretreated leaves grow at a slower rate and have reduced endpoint larval biomass as compared with those allowed to feed upon leaves pretreated with a water control.[28]

Receptors and Signaling Cascades

The mechanism of inceptin perception is not yet known. The inceptin motif is present in cATP synthase proteins of most plants and *S. frugiperda* feeding on plants such as tobacco and maize produce inceptin peptides. However, the peptide activates downstream defenses only in *Vigna* and *Phaseolus* species. Because the proteolytic cleavage of inceptin seems to be fairly universal, it is not signal biogenesis that has specially evolved in these species but a mechanism for perception. As such, two potential mechanisms have been postulated for inceptin perception, R-gene guard protein mediated and receptor mediated.[28] According to the guard hypothesis, invading organisms are indirectly recognized through their effects on plant proteins: Proteases from these attackers cleave plant proteins (targets) into inappropriate nonnative fragments that are perceived by R protein guards. Inceptin functions as a classical guard hypothesis target in that proteolytic activity from caterpillars cleaves the cATPase γ-subunit into an inappropriate peptide fragment that is recognized by the plant. This peptide fragment might be recognized through the interaction with a guard R protein evolved in legume species. Alternatively, a pattern recognition receptor may have evolved in these species that interacts specifically with inceptin to activate signaling.

Although the initial perception of inceptin is not yet understood, downstream signal transduction is known to involve

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

phytohormones. Inceptin activates concurrent synthesis of salicylic acid, jasmonic acid, and ethylene, indicating a cooperative role for the three phytohormones in coordinating defense against herbivores in *Vigna* and *Phaseolus*.[28]

CONCLUSIONS

Although systemin and HypSys were initially identified as elicitor peptides targeting herbivores, and Peps targeting pathogens, recent analyses suggest the involvement of these peptides in both herbivore and pathogen resistance. *Sl*Sys is required for resistance against the fungal pathogen, *Botrytis cinerea*,[2] *Ph*HypSys induces an antimicrobial protein, defensin,[12,18] and *Zm*Pep1 upregulates the production of benzoxazinoids, secondary metabolites associated with herbivore and pathogen resistance.[12,18] Because both herbivore and pathogen (especially fungal) resistances are mediated through the JA/ET signaling pathways, and most of the known elicitor peptides function through JA/ET signaling pathways, these results are logical. It would be interesting to investigate the possible involvement of the isolated pathogen defense peptides, *Gm*SubPep and *Gm*Pep914/890, for responses against herbivores.

Six families of endogenous elicitors have been identified thus far. Among these, Peps seem to be conserved throughout the angiosperms,[6] whereas the other elicitor peptides are specific to certain plant orders or families. Systemin has been found only in plants belonging to the Solanoidae subfamily of the Solanaceae family,[12,18] whereas HypSys is conserved within the Solanale order, which includes the sweet potato.[12,18] *Gm*Pep914 homologs are predicted from some legumes and from cucumber, both belonging to the nitrogen fixing clade of eurosids I.[31] *Gm*SubPep has been found only in soybean thus far.[20] These observations suggest that plant defense signaling peptides emerged multiple times during evolution, and Pep peptides probably emerged before the separation of dicots and monocots. For inceptin, only Vigna and Phaseoulus legume species respond to inceptin, although the peptide sequence is conserved in chloroplastic ATP synthase γ-subunits from various plants.[28] This suggests the recent emergence of receptors for inceptin in legumes.

It is evident that a diversity of peptide elicitors can exist even in a single plant species. Both systemin and HypSys are found in tomato, and systemin and HypSys regulate systemic wound signaling cooperatively through the octadecanoid pathway.[13] Soybean contains putative *At*Pep homologs, *Gm*SubPep and *Gm*Pep914/890, although their distinct roles in defense responses are yet to be investigated. The presence of multiple peptide elicitors and general elicitors such as oligogalacturonides in plants suggests that plants evolved multilayered systems to ensure a potent defense response against a wide array of invading organisms.

Studies of plant defense signaling peptides are still in their infancy, and the peptides identified thus far probably represent only a small fraction of elicitor peptides in the plant kingdom. A better understanding of the diversity and conservation of defense signaling peptides in higher plants will be facilitated by the isolation of peptides from as yet unstudied plant species. Continued study of signaling mechanisms and protective responses regulated by these peptides will facilitate their application to enhance plant resistance to both herbivores and disease.

Chapter 3

DVL/RTFL

Elene R. Valdivia, Kate L. Hertweck, Sung Ki Cho and John C Walker

ABSTRACT

The DEVIL (DVL) or ROT-FOUR-LIKE (RTFL) family of small proteins was discovered during activation-tagging screens in *Arabidopsis*. Overexpression of several of these genes results in similar pleiotropic phenotypes: shortened rosette leaves and floral organs, altered silique development, and stalks at the base of pedicels and trichomes. Silenced lines or insertional mutants have no noticeable phenotype. More than 20 *DVL/RTFL* genes have been identified in Arabidopsis. The corresponding proteins (40–144 amino acids) share a highly conserved region of 30 amino acids located close to the C terminus, which is sufficient for their function. The overexpression of phenotypes might be explained by the alterations in polarized cellular proliferation. The mechanism of action of these small proteins is currently unknown. They seem to be localized to the plasma membrane where they might interact with a receptor. DVL/RTFL overexpression alters a large number of genes involved in signaling pathways, particularly in hormonal responses.

DISCOVERY

The first work identifying the DVL/RTFL gene family was published in 2004.[10] Because of their short open reading frames (~150 nt), these genes had not been detected during the initial annotation of the *Arabidopsis thaliana* genome. They were discovered when an activation-tag insertion that results in siliques with horned tips was mapped between genes At5g16020 and At5g16030. The insertion causes the overexpression of a 153-bp ORF, which was identified as an unannotated gene and named *DEVIL1* (*DVL1*). A search for homologous sequences in the Arabidopsis genome identified at least 20 additional members of the *DVL* family (Figure 1A). When overexpressed, several of them (*DVL2* to *DVL5*) showed phenotypes similar to those in the *DVL1* activation-tagged line (*dvl-1D*). In addition to altered siliques, other common phenotypes were rounder leaves and shorter petal and sepals.

Shortly after this first report, a second group published the characterization of an activation-tagged Arabidopsis line overexpressing another gene from this family.[8] The line was identified by its rounder leaves in a screen for mutations affecting leaf morphology. The altered gene was thus named *ROTUNDIFOLIA4* (*ROT4*), which corresponds to *DVL16*. The genes homologous to ROT4 were named ROT-FOUR-LIKE (RTFL).

STRUCTURE OF THE PEPTIDE

The Arabidopsis DVL/RTFL peptides/polypeptides range in size from 40 to 144 amino acids, but they all share a highly conserved region of about 30 amino acids located at or very close to the C-terminus[8,10] (Figure 1B). This region has been dubbed the RTF domain and is also conserved in DVL/RTFL proteins from other species. Overexpression of truncated or mutated versions of ROT4 has shown that this region, which is enriched in basic amino acids, is strictly required and sufficient for the peptides to induce phenotypic changes.[4,8,10] This observation could explain the similarity in the overexpression of phenotypes of different *DVL* genes. The remaining sequence of these short proteins is poorly conserved and frequently repetitive, with an abundance of polar residues. There is currently no information regarding possible function for the nonconserved regions.

It has been suggested that the one or two basic amino acid at the start of the conserved region could serve as a signal for proteolysis processing.[11] The DVL1 protein maintains its activity when fused to GFP at the N-terminus, but not if fused at the C-terminus, where the putative proteolytic processing would not remove this large addition. However, lines overexpressing ROT4 fused to GFP at both the N- and C-terminus showed phenotypic alterations, although these were milder in the second case.[9,11] That free GFP was not detected in these lines suggests that posttranslational proteolytic processing is not strictly required for DVL/RTFL activity, at least in this case.

DISTRIBUTION OF THE mRNA/PEPTIDE

More than 20 members of the DVL/RTFL family have been identified in Arabidopsis. Constitutive expression of 10 out of 11 *DVL* genes tested, including *DVL1* and *ROT4*/*DVL16*, results in similar phenotypes in rosettes, inflorescences, and siliques.[8,11] This could be interpreted as evidence of extensive

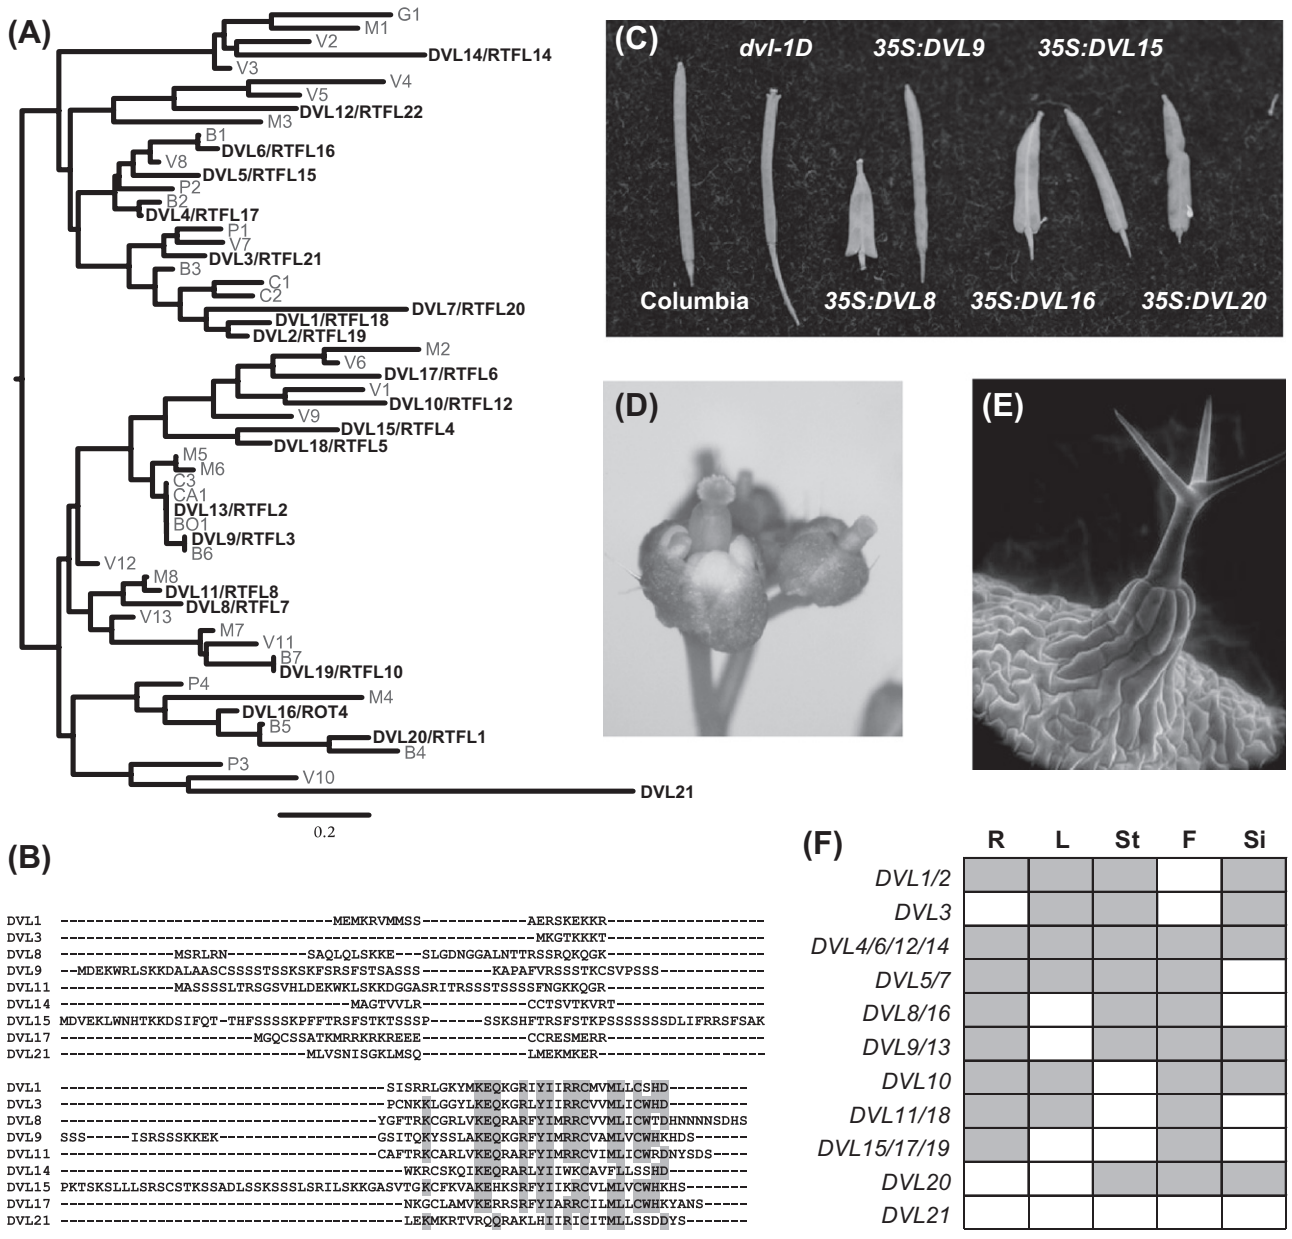

FIGURE 1 Diversification of the DVL/RTFL family. (A) Phenogram of DVL/RTFL proteins. *Arabidopsis* proteins are identified by their annotation. Proteins from other species were obtained from BAC sequences available on GenBank and are labeled as follows: *Boechera* (BO), *Brassica* (B), *Capsella* (CA), *Gossypium* (G), *Cleome* (C), *Medicago* (M), *Populus* (P), and *Vitis* (V). Sequences were aligned with ClustalW by a JTT subsitution matrix.[6] A neighbor-joining phenogram was constructed in MEGA.[5] The aligned sequences and tree are available on TreeBase (accession number 11894). The short length of the aligned matrix resulted in weak bootstrap support, but the general topological relationships appeared regardless of analysis parameters. (B) Alignment of selected DVL proteins. (C) Siliques from different *DVL* overexpressing lines. (D) Inflorescences from *dvl1-1D*. (E) Protrussion at the vase of tricomes in a *DVL9* overexpressing line. (F) Expression pattern of individual *DVL* genes determined by RT-PCR. Tested issues were root (R), leaf (L), stem (St), flower (F), and silique (Si). *DVL* genes with the same expression pattern are grouped together.

functional overlap. An alternative explanation is that these genes have specialized functions in different organs or cell types, but they work through a common mechanism and can substitute for each other.

To examine the expression profiles of the individual DVL genes, RT-PCR was performed on tissues from wildtype Col-0 (Figure 1F). All the DVL genes, with the exception of *DVL21* which was never amplified despite repeated attempts, are expressed in at least two of the tissues tested (root, seedling, stem, flower bud, and silique), although with different levels of expression. The lack of detectable expression of DVL21 was confirmed by the Arabidopsis Tiling Array Transcriptome Express Tool.[12] The highly divergent nature of this sequence suggests that it could be a pseudogene (Figure 1A).

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

The phylogenetic analysis of the family suggests that diversification was already advanced by the time of divergence of the *Vitis* and Arabidopsis lineages (Figure 1A). The two most recently duplicated pairs of Arabidopsis genes are *DVL1*/*DVL2* and *DVL9*/*DVL13*. They also share the same expression profiles, and it would not be surprising if they have overlapping functions (Figure 1F). In older gene duplications, such as *DVL8*/*DVL11* or *DVL16*/*DVL20*, differences in the expression pattern can be detected, suggesting a higher degree of functional specialization. The widespread expression of the *DVL*/*RTFL* genes at the organ level suggests that the functional specialization in this family could be at the level of cell type or in the responses to internal or external stimuli.

BIOLOGICAL FUNCTION

Our understanding of the biological function of the *DVL*/*RTFL* peptides has been hampered by the lack of noticeable loss-of-function phenotypes in either mutants or silencing lines. Because of the small size of the *DVL/RTFL* genes insertional mutants are not very abundant. An Arabidopsis line with an insertion in *RTFL4*/*DVL15* and two rice lines with insertions in other *DVL/RTFL* genes have been described as lacking a morphological phenotype.[8] Similarly, RNAi constructs targeting *DVL1*, *DVL3* or both genes simultaneously failed to produce any visible alterations despite strong reductions in gene expression.[10] Our laboratory has analyzed many insertional mutants individually and in crosses, as well as additional silencing lines without observing any noticeable phenotypes. These results could be caused by genetic redundancy or by the involvement of these genes in responses to very specific conditions.

Currently, the only evidence for the biological function of the DVL/RTFL family is the phenotypes observed in overexpression lines, which involve severe alteration in plant development. It is difficult to draw firm conclusions about the function of these genes from the results of their expression at nonphysiological levels, but they seem to be able to alter the developmental program of many different organs. Because a 32-amino-acid fragment is sufficient for this effect, the most probable explanation is that the DVL/RTFL peptides play some sort of signaling role.

One of the characteristic phenotypes of DVL/RTFL overexpression is the alteration in silique development, giving rise to valves that are shorter and wider. Their precise shape is somewhat variable as overexpression of different DVL genes result in remarkably different shapes, with wider regions at the tip or the base (Figure 1C). Sepals and petals also tend to be shorter resulting in protruding pistils in young flowers (Figure 1D). It has been determined that the rounder leaves caused by overexpression of *ROT4*/*DVL16* have a reduced number of cells specifically in the longitudinal axis.[8] The cell size on the other hand does not appear to be altered. This phenotype suggests that *ROT4* supresses polarized cell proliferation. Because sepals, petals, and silique valves are leaf-derived organs, it is possible that a similar mechanism explains their shortening in *DVL*/*RTFL* overexpression lines. A more recent analysis revealed that ROT4 overexpression slows down the rate of cell production instead of prematurely ending the phase of cell division.[4] More precisely, it appears that, in this line, the size of the meristematic zone is somewhat reduced in the proximodistal axis. Additionally, overexpression of *ROT4* results in shorter petioles.

Another distinct phenotype caused by *ROT4* overexpression is a protrusion of the main inflorescence stem at the base of pedicels.[4] This protrusion does not look much different from the pedicel, from which it is separated by a sharp bend and a vestigial abscission zone. This same phenotype was observed in plants overexpressing DVL9,[11] and plants with inducible overexpression of DVL4. Another phenotype that is possibly related is a stalk-like protrusion at the base of the trichomes, which is filled with small mesophyll cells (Figure 1E). This phenotype is present in leaves, stems, and sepals and has been observed in lines overexpressing different *DVL* genes.[4,11] The pedicel and trichome phenotypes might involve a localized increase in polarized cell proliferation, opposite to what happens in leaves.

In *Medicago truncatula MtDVL1* is induced during nodule formation, and its overexpression results in reduced nodulation.[1] It is possible that this phenotype is also linked to the regulation of cell proliferation because cell-cycle reactivation in response to infection is a key step in the nodulation process.

To understand the pathways affected by *DVL* overexpression, a genomewide expression analysis was performed on a line where DVL4 expression is activated by dexamethasone application.[8] In this experiment, 310 genes were upregulated two-fold or more 9–10 h after induction. These genes were grouped by their biological functions using the functional categorization of the Munich Information Center for Protein Sequences (MIPS, http://www.mips.biochem.mpg.de).[2] The percentage of upregulated genes in each category was compared with the percentage of Arabidopsis genes classified in the same category (Figure 2A).

Among the genes upregulated in response to *DVL4* overexpression, there is a large percentage associated with metabolism (28.9%). Other functional categories that are overrepresented among the upregulated genes are 34 (interaction with environment), 36 (systemic interaction with the environment), and 40 (cell fate). Within category 34, the upregulated set of genes is enriched in the subcategory involved in sensing and reacting to environmental stimuli, such as chemoperception, gravitropism, and circadian rhythm (Figure 2B). Among the genes grouped in category 36, many of the upregulated genes are involved in response

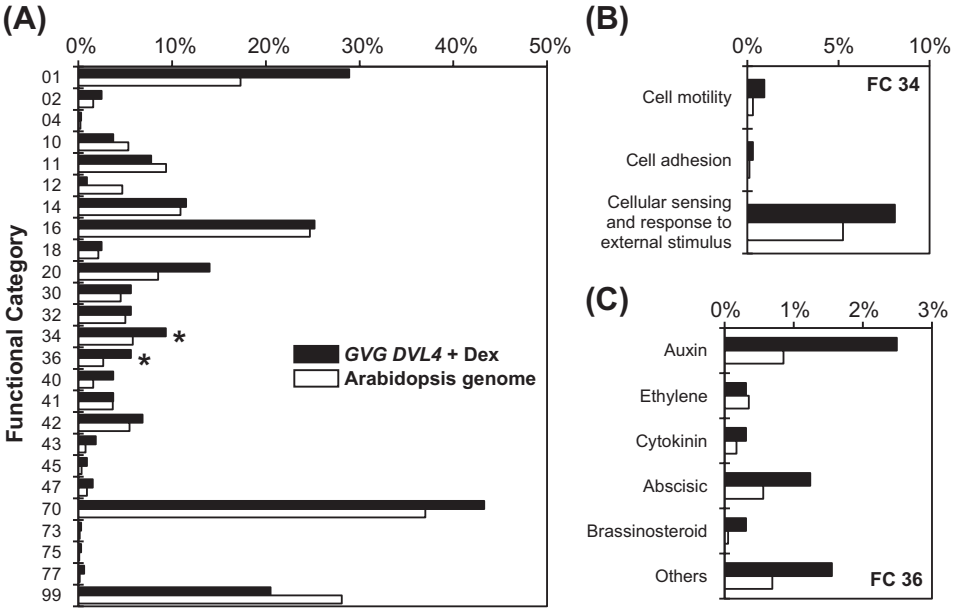

FIGURE 2 Comparative functional analysis of genes upregulated by inducible *DVL4* overexpression. (A) Distribution of genes upregulated by *DVL4* overexpression (black) and Arabidopsis genes (white) in the functional categories defined by the Munich Information Center for Protein Sequences. Asterisks indicate categories analyzed in B and C. Categories are labeled as follows: 01 metabolism, 02 energy, 04 storage protein, 10 cell cycle and DNA processing, 11 transcription, 12 protein synthesis, 14 protein fate (folding, modification, destination), 16 protein with binding function or cofactor requirement (structural or catalytic), 18 regulation of metabolism and protein function, 20 cellular transport, transport facility and transport routes, 30 cellular communication/signal transduction mechanism, 32 cell rescue, defense and virulence, 34 interaction with the environment, 36 systemic interaction with the environment, 40 cell fate, 41 development (systemic), 42 biogenesis of cellular components, 43 cell type differentiation, 45 tissue differentiation, 47 organ differentiation, 70 subcellular localization, 73 cell type localization, 75 tissue localization, 77 organ localization, 99 unclassified proteins. (B) Percentage of genes upregulated by DVL4 overexpression in subcategories within functional category 34 (Interaction with environment) compared to total Arabidopsis genes. (C) Percentage of genes upregulated by DVL4 overexpression in subcategories within functional category 36 (Systemic interaction with the environment) compared with total Arabidopsis genes.

to different hormones (Figure 2C). One of the genes involved in auxin responses (NAC1) is actually the gene showing the highest upregulation in response to *DVL4*. It is therefore possible that the alterations in cell proliferation observed in overexpression lines are the results of changes in hormonal responses. What seems clear is that *DVL/RTFL* overexpression is capable of causing profound changes in the developmental program.

RECEPTORS AND SIGNALING CASCADES

The similarity in the overexpression phenotypes of different *DVL* genes points to the possibility of a common receptor or several receptors with similar specificity. In addition, the fact that the conserved domain is required and sufficient for the activity of the peptides indicates that this is the region that interacts with the putative receptor. Even if the receptor is common or very similar for different members of the family, it is probable that different signaling cascades are triggered in different organs or cell types leading to the diversity of observed phenotypes.

One of the open questions about the DVL/RTFL family is whether these small proteins are secreted to the apoplastic space and interact with extracellular receptors or they exercise their effect in the cytoplasm interacting with intracellular partners. That these proteins lack a signal peptide points toward the second possibility, but there is significant evidence for the existence of non-classical or leaderless secretion pathways in plants.[9] Interestingly, most DVL/RTFL proteins are predicted as extracellular by SecretomeP, a program designed to identify nonclassically secreted proteins, although the prediction program was trained with mammalian sequences.[3] Weighting against an extracellular receptor is the observation that overexpression of GFP-DVL1 fusions with an added signal peptide did not produce phenotypic effects, whereas GFP-DVL1 overexpression in the cytoplasm resulted in a similar phenotype to overexpression of unmodified DVL1.[11] However, this result can also be interpreted as suggesting the need of some form of activation though posttranslational processing in the cytoplasm before secretion to the apoplast.

Both ROT4-GFP and GFP-ROT4 fusions are localized to the plasma membrane.[4,8] The overexpression of these constructs results in a similar phenotype to ROT4 overexpression, suggesting that the plasma membrane could be the native localization of DVL/RTFL proteins. Because ROT4 does not include a transmembrane domain, this could reflect the localization of a putative receptor or interacting

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

partner. The question that remains to be solved is whether the interaction happens on the extracellular or intracellular side of the plasma membrane.

The localization of the receptor is related to the issue of transport. An intracellular receptor would suggest a local effect for the DVL/RTFL proteins limited to the same cell where they are produced or to the neighboring cells that they could reach through transport via plasmodesmata. Local overexpression of a GFP-ROT4 fusion in developing leaves was achieved through a construct in which Cre/Lox recombination was activated randomly by heat treatment.[4] Activation in young leaf primordia leads to large sectors of overexpressing cells. When these sectors are located in one of the leaf margins, the petiole on that side is shortened while the other side of the petiole is unaffected. This result points to a localized action of the DVL proteins and excludes a fast transport of GFP-ROT4 capable of establishing a uniform level of protein throughout the leaf. However, it is compatible with local cell-to-cell transport or even long distance transport at a slow rate.

Overexpression of DVL/RTFL genes results in the upregulation and downregulation of large numbers of genes, some of which are probably involved in signaling cascades. When DVL1, DVL2, DVL3, DVL4, or DVL5 are overexpressed, the mRNA level of *AGL/FUL8* decreases two- to five-fold.[10] This MADS-box gene participates in fruit–valve differentiation and could be involved in the alteration of silique development observed in these lines. A microarray analysis of Arabidopsis plants with constitutively activated ROT4 expression detected 17 genes that were upregulated three times or more, but none of these genes has a clear connection to signaling cascades or the regulation of cell division.[8] However, the list includes several genes that could be involved in pathogen responses.

An Arabidopsis line with expression of DVL4 controlled by dexamethasone application has permitted the identification of 422 genes whose expression is strongly upregulated or downregulated after 9–10 h of treatment.[7] Among these early responding genes transcription factors are overrepresented. The gene showing the strongest response in this experiment is *NAC1* (At1g56010), a transcription factor involved in auxin responses. When two Arabidopsis lines with independent insertions in NAC1 are crossed to the constitutively activated line *dvl1-1D*, the presence of either insertion in hemizygosis is sufficient to block the phenotype caused by *DVL1* overexpression. This blockage persists in the descendants of these crosses even when they did not receive the actual insertions in *NAC1*, suggesting some kind of epigenetic effect. The insertions in *NAC1* do not seem to affect the expression levels of *DVL1*. It is possible that the blockage of *DVL1* activity in these plants takes place at the translational or posttranslational level. An alternative explanation is that insertions in *NAC1* cause epigenetic modifications in genes involved in the signaling cascades activated by DVL1 of which NAC1 itself could be a member.

Chapter 4

EPF

Tatsuo Kakimoto

ABSTRACT

The *EPIDERMAL PATTERNING FACTOR* (EPF) family of *Arabidopsis thaliana* comprises nine genes that encode small cysteine-rich secretory peptides. *EPF2* is expressed in early-stage stomatal lineage cells, which contribute to the production of both stomatal and non-stomatal cells, and functions as a negative-feedback regulator that limits the number of epidermal cells. *EPF1* is also expressed in stomatal lineage cells and prevents contact formation of stomata by regulating the formative asymmetric cell division plane. Another family member, *EPF-LIKE9(EPFL9)/STOMAGEN*, is expressed in the inner cells of developing leaves and positively regulates stomatal density. Although the functions of these peptides are different, their genes require the same putative receptor components, ERECTA-family (ERf) transmembrane kinases and the TOO MANY MOUTHS (TMM) receptor-like protein. Their peptide signals are transmitted through an MAP kinase cascade, which destabilizes SPEECHLESS (SPCH) protein, a master regulator of stomatal lineage identity.

DISCOVERY

To identify new peptide mediators, we performed a screen involving the overexpression of many *Arabidopsis* genes that encode peptides/polypeptides (<150 amino acids) with a secretory signal sequence.[9] We identified genes that affect epidermal cell patterning, including those later designated *STOMAGEN/EPFL9*, *EPF1* (EPIDERMAL PATTERNING FACTOR 1), and *EPF2*, among which *EPF1* was the first to be reported.[9] Overexpression of the *STOMAGEN* gene increases the number of stomata, whereas overexpression of *EPF1* and *EPF2* genes decreases the number of stomata. Because overexpression possibly causes phenotypes unrelated to the gene's true role, we examined the expression patterns and phenotypes of loss-of-function mutants, the results of which let us focus on EPF1, EPF2,[10] and Stomagen.[14] EPF2[12] and Stomagen[11,22] were also identified as genes co-expressed with EPF1 and other genes that are expressed in the stomatal lineage cells. *CHALLAH (CHL)/EPFL6* was identified as the gene responsible for the *challah* mutant, which suppressed the lack-of-stomata phenotype of *too many mouths* mutants in hypocotyls and stems.[1] *CHAL* and two other genes with redundant functions, *CHL-LIKE* (*CHL)1* and *CHL2*, form the *CHAL* subfamily of the *EPF* family.[2]

STRUCTURE OF THE PEPTIDE

EPF-family genes (*EPF1*, *EPF2*, and [*EPF-LIKE EPFL*]*1–9*) encode 102–172 amino acid polypeptides with a secretory signal sequence at their N-terminus. Of these small proteins, the structure of the mature form has been experimentally determined for only Stomagen/EPFL9.[14,22] The mature Stomagen peptide is derived from the carboxy-terminal 41 amino acid residues of the gene-coded product, which share sequence similarity with all the other EPF-family members (see also the Stomagen section of this book). Stomagen has six cysteine residues that form three disulfide bonds.[14] These six cysteines are perfectly conserved in all EPF-family members. EPF1, EPF2, and EPFL7 have two additional cysteines (Fig. 1). This protein family is present in diverse plant species.

DISTRIBUTION OF THE mRNA/PEPTIDE

In *Arabidopsis*, a fraction of the leaf protodermal cells (undifferentiated epidermal cells) take the stomatal lineage and become meristemoid mother cells (MMCs), which each asymmetrically divide to form a small triangular cell (meristemoid) and its sister cell (termed a stomatal lineage ground cell, SLGC).[21] Cells that do not take the stomatal lineage differentiate into general epidermal cells called pavement cells. The meristemoid and the SLGC may also undergo asymmetric cell division forming a meristemoid and an SLGC. The meristemoid finally becomes a guard mother cell (GMC), which symmetrically divides to form a pair of guard cells that constitute a stoma. SLGCs finally differentiate into pavement cells. Thus, the number of MMCs and the number of asymmetric cell divisions determine the number of stomatal and non-stomatal epidermal cells (Fig. 2). These developmental steps have been anatomically examined in detail,[7] as have the underlying molecular mechanisms.[4,6,19,20]

FIGURE 1 Alignment of the C-terminal halves of the EPF-family proteins of *Arabidopsis*. EPFL6 = CHAL, EPFL5 = CLL1, EPFL4 = CLL2, Stomagen = EPFL9. This region represents the mature Stomagen/EPFL9.

The *EPF2* promoter–*GFP* (*GREEN FLUORESCENT PROTEIN*) signal is detected in MMCs, meristemoids, and SLGCs. The *EPF1* promoter–*GFP* signal is detected in meristemoids, GMCs, and young guard cells. *STOMAGEN* is expressed in the inner cells of developing leaves, carpels, stamens, and sepals, which have stomata. *CHAL/EPFL6* is preferentially expressed in the inner cells of hypocotyls and inflorescence stems, in midveins of leaves, and in the ovule chalazal region; however, it is not expressed in stomatal lineage cells.[1]

Biological Functions

Stomata consist of a pair of guard cells with a pore in-between. They change pore size, depending on the environmental status, through quick modulation of the turgor pressure of guard cells. Stomatal density and placing patterns are species-specific, but also change depending on the environment.[5]

In *Arabidopsis*, stomata are more evenly distributed than would occur randomly. In most plant species, stomata are not formed adjacent to one another, but are always separated by at least one pavement cell (one-cell-spacing rule[8]). This pattern is ensured by correct placement during the asymmetric cell division that forms the meristemoid; meristemoids are not formed in contact with previously formed meristemoids, GMCs, or young guard cells. It had been hypothesized that these cells produce an intercellular signaling molecule that inhibits the contact formation of new meristemoids.[4,7] This hypothetical molecule has been proven to be EPF1 based on three findings: first, *EPF1* is expressed in these cells; second, in the loss-of-function *epf1* mutant, the asymmetric cell division plane forming the meristemoid is placed in the wrong position, causing contact formation of stomata; and third, overexpression of *EPF1* decreases the number of stomata without decreasing the total epidermal cell number. These results indicate that EPF1 regulates the position of the asymmetric cell division plane, so that new meristemoids are not formed in contact with previously formed meristemoids, GMCs, or guard cells. The overexpression phenotype suggests that EPF1 may also regulate cell fate independently of its regulation of the cell division plane[9] (Fig. 2).

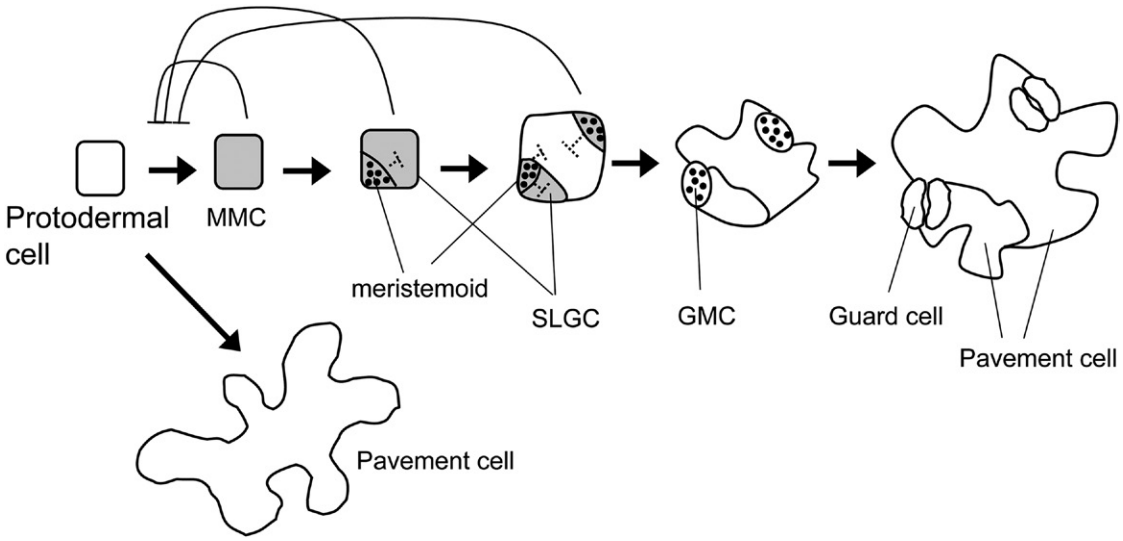

FIGURE 2 Epidermal lineages and regulatory mechanisms mediated by peptide signaling molecules. A fraction of the protodermal cells of the leaf primordium are selected to be meristemoid mother cells (MMCs), which asymmetrically divide to form small triangular cells (meristemoid) and sister cells (stomatal lineage ground cells, SLGCs). Meristemoids eventually give rise to pairs of guard cells that form the stoma, and the SLGCs eventually give rise to pavement cells. *EPF2*-expressing cells are shaded, and *EPF1*-expressing cells are dotted. EPF2 inhibits the formation of MMCs (solid line), limiting the number of epidermal cells. EPF1 regulates the positioning of the meristemoid (broken line). GMC, guard mother cell.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Cell proliferation stops when the correct number of cells is formed. *EPF2* overexpression inhibits the formation of MMCs, thereby decreasing the total number of both stomatal and non-stomatal cells. By contrast, mutation in the *EPF2* gene results in increased number of both stomatal and non-stomatal cells, but the one-cell-spacing rule is maintained. Because *EPF2* is expressed in MMCs, meristemoids, and SLGCs, which are proliferative, extracellular EPF2 concentration should increase when the number of these proliferative cells increases. Thus, EPF2 acts as a negative-feedback molecule that limits the total number of epidermal cells.[10]

The *tmm* mutant has an increased number of stomata in its leaves and cotyledons, but lacks stomata in its hypocotyls and inflorescent stems. The *chal* mutation suppresses the stomata-less phenotype in the *tmm* hypocotyls and stems.[1] The *cll1* or *cll2* mutation enhances the *chal* phenotype in the *tmm* background. These results indicate that CHAL, CLL1, and CLL2 repress stomatal formation in the hypocotyls and in the stem, and that TMM represses the effects of CHAL family peptides. Because CHAL family genes are not highly expressed in stomatal precursor cells but are mainly expressed in the inner cells of the hypocotyl and of the stem, these peptides may act in a non-tissue autonomous manner. CHAL family peptides also control plant height, because *chal;cll1* and *chal;cll2* double mutants are short.[2] EPFL4/CLL2 and FPFL6/CHAL regulate stem elongation through the action of ER. EPF1 and EPF2 directly bind ERf receptor proteins.[23]

STOMAGEN/EPFL9 is expressed in the inner cells of developing leaves and is a positive regulator of stomatal formation. For the function of Stomagen, please refer to the chapter on Stomagen in this section of the book.

Receptors and Signaling Cascades

The candidate receptor components for EPF-family ligands are: ERECTA (ER), ERECTA-LIKE 1(ERL1), ERL2, and TMM. The ER-family proteins comprise an N-terminal leucine-rich repeat (LRR) followed by a transmembrane segment, and a C-terminal Ser/Thr kinase domain. TMM possesses only the LRR and the transmembrane segment. In the triple *er;erl1;erl2* mutant and the *tmm* mutant, the number of stomatal lineage cells is increased, which results in the production of more stomata and the one-cell-spacing rule is disrupted. This indicates that these putative receptor components control entry into the stomatal lineage and the asymmetric cell division that forms the meristemoid.[21]

Overexpression of *EPF1* or *EPF2* decreases the number of stomata in wildtype plants,[9,10,12] but not in the triple *er;erl1;erl2* mutant or in the *tmm* mutant.[9,10] This indicates that EPF1 and EPF2 require TMM and either ER, ERL1, or ERL2. Stomagen, on the other hand, decreases the stomatal number, when its gene is overexpressed or mature peptide is applied. Interestingly, Stomagen also requires TMM[14,22] (the requirement for the ER family has not been examined). EPF1 and EPF2 directly bind ERf receptor proteins.[16] Taken together, a plausible model would be that EPF2 and EPF1 compete with Stomagen for the same receptor complex that contains the ER family proteins and TMM. Supporting this model, Stomagen does not increase the stomatal number in the absence of *EPF1* and *EPF2*.[14]

An MAP kinase cascade is believed to be downstream of this receptor complex. In this MAP kinase cascade, MAP kinase kinase kinase, YODA (YDA)[3]; two MAP kinase kinases, MKK4 and MKK5; and two MAP kinases, MPK3 and MPK6 play important roles.[24] The MAP kinase system phosphorylates the beta helix-loop-helix transcription factor SPEECHLESS (SPCH) to destabilize it.[15] Because SPCH, which functions together with two other beta helix-loop-helix proteins (SCREAM and SCREAM2[13]), is required for the identity of early stomatal lineage cells,[17,18] destabilization of SPCH causes cells to become pavement cells.

To summarize the model, EPF1 and EPF2 are perceived by receptor complexes containing TMM and ER family receptor kinases, which in turn activate the MAP kinase cascade and the degradation of SPCH, inhibiting the acquisition or the maintenance of stomatal lineage identity. However, although the same set of receptor components is required for the functions of EPF1 and EPF2, these ligands are differentially recognized by the receptor(s). Overexpression of *EPF1* and *EPF2* leads to the loss of stomata, but through different pathways. The use of cell-type specific GFP marker lines showed that *EPF2*, but not *EPF1*, inhibits the formation of MMC. *EPF1*, however, inhibits the identity of the meristemoid.[10] The mechanism behind this recognition specificity is not yet known. EPF1 thus regulates both the asymmetric cell division plane and, independently, it may regulate cell identity. EPF1 most likely regulates cell identity through SPCH. EPF1 also controls the position of asymmetric cell division plane, perhaps independently of SPCH. The extracellular EPF1 gradient may cause subcellular local activation of the MAP kinase cascade, regulating the asymmetric cell division plane, via an as yet unknown mechanism.

The receptor complexes can also execute more complex tasks. *CHAL*, *CLL1*, and *CLL2* decreases leaf stomatal density when any one of them is overexpressed. These genes require ER family genes to function. Surprisingly, these three genes do not require TMM and also function more effectively in *tmm* mutants.[2] This suggests that TMM represses the signal transduction events initiated by these three peptides. CHAL, CLL1, and CLL2 may also regulate inflorescence elongation, since *chal;cll1;cll2* is a semidwarf mutant like *er*.[2]

The biological functions of the EPF-family peptides have been well characterized by genetic methods. However, information regarding the biochemical basis for the actions of these proteins is limited. How these peptide family members, together with the same set of receptor components, exert different functions is a challenging problem to solve.

Chapter 5

IDA/IDL

Melinka A. Butenko, Robert Kumpf and Reidunn B. Aalen

ABSTRACT

Floral organ abscission, the shedding of petals, sepals, and filaments, from *Arabidopsis thaliana* is a developmentally controlled process that requires the INFLORESCENCE DEFICIENT IN ABSCISSION (IDA) peptide ligand and the two leucine-rich repeat (LRR) receptor-like kinases, (RLK), HAESA (HAE) and HAESA-LIKE 2 (HSL2). IDA belongs to a larger protein family that together comprises the IDA-LIKE (IDL) proteins. These proteins are all extracellular localized proteins that share a common C-terminal domain—the EPIP domain—which contains the functional peptides. Although the exact functions of the IDL peptides are not known, the expression pattern of the *IDL* genes indicates that they may be involved in regulating cell separation processes important during plant development. Here we give an overview of the discovery of the *IDA* and *IDL* genes, their expression pattern, biological function, and genetic and biochemical studies that have been performed to reveal the IDA signaling pathway.

DISCOVERY

Since the first discovery of a plant peptide capable of having signaling activity, small molecules identified as plant peptide ligands have been identified by biochemical or genetic approaches. The INFLORESCENCE DEFICIENT IN ABCSISSION (IDA) peptide ligand was identified by traditional genetic screening based on random mutagenesis followed by cloning of the mutated gene. With the aim of identifying genetic components regulating floral organ abscission in *Arabidopsis thaliana*, a population of mutants with random T-DNA insertions was screened for deficiency in floral organ abscission.

In wildtype (WT) *Arabidopsis* flowers, the shedding of flower petals, sepals, and filaments supervenes shortly after pollination or anthesis (Figure 1A). By contrast, one of the mutant lines identified retain its perianth and stamens indeterminately (Figure 1B). This mutant, caused by a homozygous recessive monogenic mutation, was named *ida*.[5] PCR-based cloning techniques determined the T-DNA location of the *ida* mutation to be upstream of a small open reading frame, which later was annotated as *At1g68765*, and corresponds to the *IDA* gene.

IDA encodes a small protein of 77 amino acids (aa) with an N-terminal hydrophobic region, which was predicted by SignalP software to act as a signal peptide (SP), and this was proved by genetic and subcellular localization studies.[2,5,27] An *in silico* approach was undertaken to determine whether the *Arabidopsis* and other plant genomes encode proteins with similarities to *IDA*. Several *IDA-LIKE* (*IDL*) transcripts from both dicots and monocots were identified, including one cDNA (*IDL1*) and four unannotated putative *IDL* genes (*IDL2*, *IDL3*, *IDL4*, and *IDL5*) from *Arabidopsis*. RT-PCR was performed to verify that the unannotated *IDL* genes were expressed. The *IDL* transcripts encode proteins with predicted N-terminal SPs and a conserved C-terminal motif common to IDA, which we have named EPIP[5,27] (Figure 2A). The EPIP domain of IDA and the IDL proteins share similarities to that of the CLE domain[27] (Figure 2B) (see the chapter on CLV3 and CLE peptides elsewhere in

FIGURE 1 Phenotypes of the ida mutant. (A) In wildtype Arabidopsis plants, the floral organs (petals, sepals, and filaments) abscise shortly after the flower is pollinated (arrow head). (B) In the inflorescence deficient in abscission (ida) mutant, the floral organs remain attached indefinitely to the receptacle of the growing fertilized silique (arrow). See color plate 2.

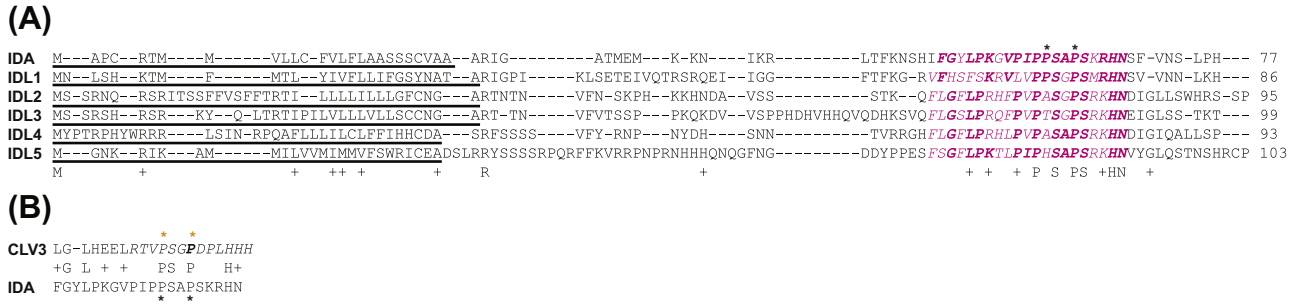

FIGURE 2 Alignment of IDA and IDL proteins and similarities to the mature CLV3 Peptide. (A) The IDA and IDL proteins have predicted N-terminal signal peptides (underlined) and a conserved C-terminal EPIP domain (italics in magenta). Amino acids (aa) in the EPIP domains of the IDL proteins identical to the IDA-EPIP domain are in bold italics, asterisks indicate prolines, which are probably hydroxyprolinated in IDA. Identical aa are indicated by letters and conserved aa by (+). (B) The mature CLV3 (MCLV3) peptide, indicated in italics, and some of the upstream aa have similarities to the EPIP domain of IDA. Identical aa are indicated by letters and conserved aa by (+). The MCLV3 peptide has two hydroxyprolines, indicated by orange asterisks, where one is posttranslationally modified with triarabinoside (bold italics). The predicted hydroxyprolines of the IDA-EPIP domain are indicated with black asterisks. See color plate 3.

this Plant Peptides Section of the book), and as no other hydrophobic regions, apart from the predicted SP, are found in these proteins, we infer that they were soluble and probably act as a new family of peptide ligands.[5] Further indication of their function as a new family of peptide ligands in *Arabidopsis* comes from *in planta* domain swap studies.[27]

STRUCTURE OF THE IDA AND IDL PEPTIDES

The IDA and IDL proteins can be divided into three regions: the N-terminal SP, a variable region with very little aa similarity between the proteins, and a conserved 20 aa EPIP domain (Figure 2A). A set of *in vivo* experiments elucidated the mature structure of the active peptide ligands.

When *Arabidopsis* plants overexpress (OX) IDA under the control of the cauliflower mosaic virus 35S promoter (35S), a series of phenotypes related to organ abscission are observed.[26] The plants portray precocious floral organ abscission, where all floral organs abscise at an earlier floral developmental stage than in WT plants; abscission of organs, such as cauline leaves and pedicels, not normally shed in *Arabidopsis*; and lastly an enlargement of the specialized abscission zone (AZ) cells at the point where the organs detach from the plant.[26] A certain amount of genetic redundancy exists between *IDA* and the *IDL* genes because plants which OX the *IDL* genes have phenotypes mimicking those of IDA OX lines to varying extents.[27] Interestingly, based on the full-length protein sequence, IDL1 is most closely related to IDA (Figure 2A), and OX of IDL1 gives the most similar phenotypes to plants OX IDA. *IDL1* has the ability to fully rescue *ida* when expressed under the regulatory elements of *IDA*, while plants expressing the other *IDL* genes show partial recovery of the abscission defect. Because the only conserved part between IDA and the IDL proteins is the EPIP domain (Figure 2A), domain swap experiments, in which the EPIP and C-terminal end (EPIP-C) of the IDL proteins are exchanged for that of IDA, were performed to test for possible rescue of the *ida* phenotype. The EPIP-C of IDL1 has the highest rescue ability; however, the EPIP-C of IDL2, IDL3, and IDL4 has a greater tendency to revert the abscission phenotype of *ida* than the IDL2, IDL3 and IDL4 gene swap constructs, indicating that the variable region of the IDA protein gives functional support to the EPIP domain.[27] For CLV3, the processing of the mature CLE peptide requires a few residues upstream from the CLE domain,[19] and it is therefore possible that residues in the variable region of the IDA protein are required to facilitate correct processing of the EPIP, or part of the EPIP, domain in floral AZ cells.

Both the gene swap and domain swap experiments between *IDA* and the *IDL* genes indicate that as for the CLE proteins,[18] the C-terminally located EPIP domain is sufficient for function. In accordance with this, *in vivo* results where deletion constructs of the IDA protein were used to complement the *ida* mutant phenotype, show that the EPIP domain is essential and sufficient for the function of the IDA protein.[27] Additionally, synthetic IDA-EPIP and IDL1-EPIP-C peptides have been used in a bioassay in which the percentage of flowers undergoing abscission at a given time point is recorded. There were a significant number of flowers undergoing abscission at earlier time points when treated with IDA-EPIP or IDL1-EPIP-C peptides than the untreated ones. Furthermore, the IDA-EPIP synthetic peptide could partially rescue the floral abscission defect of *ida* flowers.[27] However, relative high amounts (10 μM) of peptide needed to be used in the bioassay before a response was detected, and a full rescue of the abscission defect of *ida* flowers was not observed, indicating that the mature active peptide *in vivo* could be shorter than the EPIP domain, modified, or both. In higher plants, many of the peptide ligands identified are posttranslationally modified,[16] and the mature CLV3 peptide has hydroxyproline arabinosylation, which is important for its biological activity and high-affinity binding to CLV1.[20]

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Preliminary bioassay experiments with different synthetic IDA peptides indicate that the mature active peptide of IDA is shorter than the EPIP domain and also requires hydroxyprolination of key prolines (Figure 2A), which possibly may be further modified *in vivo*.

DISTRIBUTION OF THE mRNA AND BIOLOGICAL FUNCTION OF THE IDA AND IDL PEPTIDES

Floral organ abscission in *Arabidopsis* is divided into four distinct developmental stages.[21] The first stage, which normally occurs early during floral development, is the differentiation of specialized AZ cells where the organ will later separate from the plant. If the AZ cells are not differentiated, abscission will not take place, as with the double mutant of *BLADE-ON-PETIOLE 1* and *2* (*BOP1 BOP2*), which does not portray anatomically distinct AZ cells.[17] The second phase starts as the organs prepare to separate from the plant, often preceded by environmental or hormonal stimulus, and the AZ cells become competent to respond to abscission signals. Subsequently, the pectin in the cell walls between AZs start to degrade followed by an expansion in the size of the AZ cells.[24] Ultimately, the actual separation of the organ supervenes and a lignified protective layer develops on the distal side of the AZ to protect the plant from pathogen attack.

Mutations in *IDA* block floral abscission at a late stage in the floral abscission process which is consistent with the expression of *IDA* in the floral organ AZs during the course of the abscission process.[5,26] Both a *promoter:GUS* reporter of *IDA* and *in situ* experiments have shown that *IDA* is expressed shortly after the AZ cells become competent to respond to abscission signals and the initial loosening of the cell walls takes place.[5,6] The expression level is highest before organ separation and the specific AZ signal is maintained throughout the floral abscission process. The GUS expression is restricted to the AZ at the bases of all floral organs (filaments, petals, and sepals) in addition to the nectaries (Figure 3A). *GUS* expression is also observed after the floral organs are abscised but is then restricted to the nectaries.[5]

Evidence from many different abscission model systems supports the promoting effect of ethylene in the regulation of abscission in dicotyledonous plants. In *Arabidopsis*, exposure to exogenous ethylene accelerates the abscission process,[3,5] although the developmentally regulated pathway of floral abscission acts independent of ethylene.[3,5,12] Consistent with this, the *ida* mutant is sensitive to ethylene and exposure of exogenous ethylene does not rescue the abscission defect of *ida*. However, *GUS* expression driven by the *IDA* promoter in the ethylene insensitive *etr-1* mutant background[4] has a different spatial distribution compared with that of WT. The GUS signal is detected in the nectaries but is absent from the AZ region.[6] This makes it possible that the delay in floral abscission observed in the *etr-1* mutant[3] may in part result from the restricted expression pattern of *IDA*.

35S:IDA plants display ectopic abscission of pedicels and leaves, but OX of IDA does not induce middle lamella breakdown between all cells even if *IDA* is abundantly expressed in all organs.[26] This indicates that for cells to respond to IDA signaling some indispensable components must be present for IDA-induced abscission to occur. Although, WT *Arabidopsis* does not have fruit or leaf abscission, detailed morphological analysis shows the presence of vestigial AZs at the proximal end of the pedicels and cauline leaves, suggesting that the components necessary to respond to IDA signaling are present in these cells and that it is the restricted expression pattern of *IDA* that hinders cell separation from normally taking place in these tissues.[26] Consistent with this idea, if *IDA* is OX in the double mutant *bop1 bop2* background that does not differentiate floral or vestigial AZs, none of the *IDA* OX phenotypes are observed.[17]

The exact function of the *IDL* genes is not known. Because of the small size of the coding region of the genes (all under 350 bp), it is difficult to obtain insertion or point mutants, and where these exist, single mutants do not show distinct phenotypes, probably resulting from redundancy between genes with overlapping expression masking the effect of the mutation. We can therefore only speculate on the biological function of these genes based on their expression profiles which suggests that the encoded proteins may share a common role in regulating other cell to cell separation events during plant development.[27] The expression pattern of the different *IDL* genes was investigated with *promoter:GUS* reporter constructs. *IDL5* is expressed in the vascular tissue early during development, shortly after the seedling has opened the seed coat, and this expression persists until the seedling has opened its cotyledons (Figure 3B). After germination *IDL1*, *IDL2*, *IDL3*, and *IDL4* are all expressed in the vascular tissue of the expanding cotyledons and primary leaves (Figure 3C), and except for *IDL1* and *IDL5*, expression is also observed in the guard cells. In the leaf, during the maturation of continuous tubes of tracheary elements, the middle lamella between two neighboring tracheary elements is digested completely by cell-wall-degrading enzymes.[11] It is possible that the *IDL* genes may play a role in regulating this process.[27]

Consistent with the expression in the leaves, *IDL2*, *IDL3*, and *IDL4* are also expressed in the vascular tissue of the root where the expression accumulates around the emerging lateral roots (Figure 3D) and they may possibly be involved in connecting the xylem and phloem of the new meristem to the main root. Interestingly, in the mature plant these three genes are also expressed in the floral AZ; however, their expression is apparently not sufficient to induce cell separation of floral organs when *ida* is mutated, indicating that the active part of these IDL proteins, probably

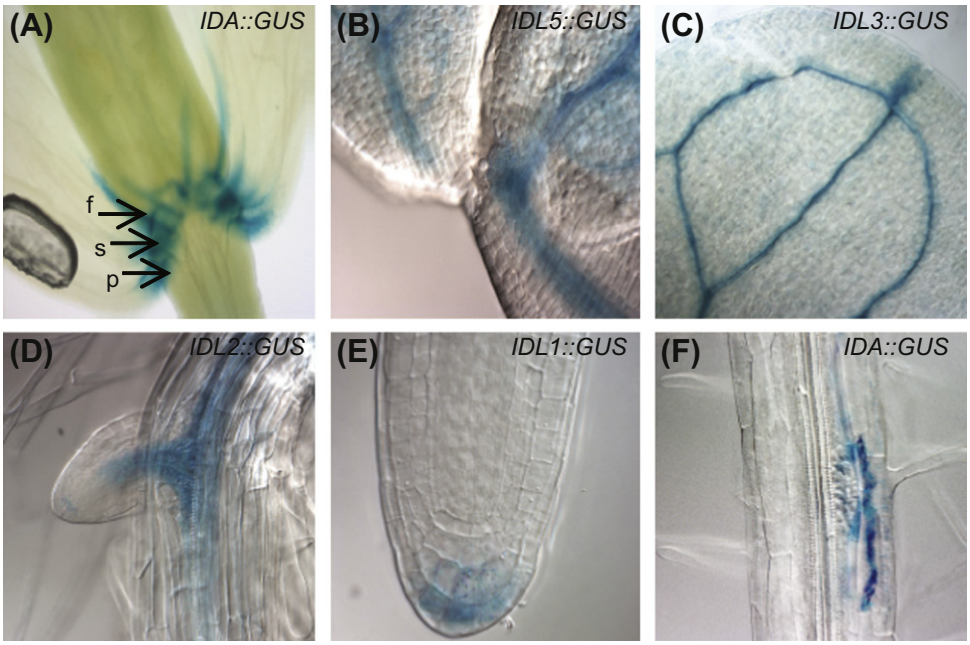

FIGURE 3 *Promoter:GUS* expression of IDA and IDL genes. (A) IDA is expressed in the filament (f), sepal (s), and petal (p) abscission zones during the abscission process. (B) IDL5 expression in the vascular tissue shortly after germination. (C) IDL1, IDL2, IDL3, and IDL4 are all expressed in the vascular tissue of the expanding cotyledon, here IDL3 is shown as a representative example. (D) IDL2, IDL3, and IDL4 are all expressed in the vascular tissue of the main root, and the expression accumulates around the lateral root; here, IDL2 is shown as a representative example. (E) IDL1 expression in the columella cells at tip of the main root. (F) IDA is also expressed in the cortex and epidermal cells of the main root during lateral root emergence. See color plate 4.

has a low affinity for the native receptors recognizing the IDA peptide ligand.

IDL1 has a specific pattern of expression in the columella cells of the tip of the primary root (Figure 3E). Interestingly, these cells undergo a cell separation event during root cap sloughing to allow the primary root to penetrate the soil.[8] Initial experiments with RNA interference lines indicates that this peptide ligand is involved in cell separation during columella cell loosening, which is important for the growth of the primary root. This, together with the genetic complementarity between IDL1 and IDA, opens the possibility that IDL1 and IDA may have similar signaling abilities.[7] Detailed studies of *IDA* expression during root development using a *promoter:GUS* construct show specific GUS expression in the cortex and epidermal cells overlaying the lateral root primordia (Figure 3F). As these cells need to undergo cell separation to facilitate the emergence of the outcoming primordia it appears that IDA plays a more general function in regulating cell separation outside the AZ cells. Initial experiments indicate that key hydrolytic enzymes necessary to degrade the cell wall during lateral root emergence are affected in the *ida* mutant. It is therefore possible that IDA induces similar signaling pathways as well as similar cell wall remodeling enzymes during different cell separation processes in *Arabidopsis*. Concurrent with this idea, *in situ* results have shown that *IDA* is also expressed in the dehiscence zone of the silique, where cell separation takes place when the valves open to allow for seed dispersal.[6]

RECEPTORS AND SIGNALING CASCADE OF IDA

Many mutants have been identified with changes in floral organ abscission.[1,14] Although some mutations lead to mutants with a delay in the abscission process, such as the *delayed in abscission* (*dab*) mutants,[22] others, such as *ida*, have a complete lack of abscission. These include the *bop1 bop2* double mutant,[17] the recently described mutant *never-shed* (*nev*) with a mutation in a gene encoding an ADP-ribosylation factor-GTPase-activating protein,[15] and a reported antisense line of the leucine-rich repeat (LRR) receptor-like kinase (RLK) encoding gene *HAESA* (*HAE*).[12] Because of the similarity in phenotypes between the *HAE* antisense line and the *ida* mutant it was early speculated whether HAE could function as a receptor for the IDA peptide ligand.[5]

Single knockout mutants of *HAE* are indistinguishable from WT plants and have normal floral organ abscission.[9,27] However, *HAE* belongs to a gene family that includes two paralogs,[25] *HAESA-LIKE 1* (*HSL1*) and *HAESA-LIKE 2* (*HSL2*) and a promoter driven *HSL2* GUS expression is restricted to floral organ AZ cells identical to that of *HAE*.[9] The overlapping expression pattern of *HAE* and *HSL2* suggests that these two genes are functionally redundant. Consistent with this,

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

a knockout T-DNA line of *HSL2* shows normal abscission while a double mutant of *HAE* and *HSL2* is completely deficient in floral organ abscission.[9,27] As for *ida*, the morphology of the AZ in the *hae hsl2* plants appears normal, and the mutations affect the abscission process during the separation stage.[9,27] None of the OX phenotypes of *IDA* are present in *hae hsl2,* showing that *hae hsl2* is epistatic to *35S:IDA*.[9,27] This, in addition to IDA-EPIP peptides having no effect on the floral deficiency of *hae hsl2*,[27] substantiates the idea that HAE, HSL2, or both, function as receptors for IDA. It is still however, not clear which of the receptors, or if both receptors, have the predominant role in relaying the IDA signal. However, preliminary binding studies indicate that HSL2 may have a higher affinity for IDA than HAE.

Interestingly, both *HAE* and *HSL2* are expressed in the vestigial AZs where OX of *IDA* causes ectopic abscission. The similarity between the OX phenotypes of the *IDL* genes to those of *IDA* indicates that when these proteins are abundantly present they too can relay a signal via HAE, HSL2 or both. This opens the possibility that the native receptors to the IDL peptides may be other closely related HSL receptors.[7]

Genetic and biochemical studies have shown that the *MAP KINASE KINASE 4* (*MKK4*) and *MKK5* and the *MAP KINASE* 3 (*MPK3*) and *MPK6* act downstream of *IDA* and *HAE HSL2*.[9] Consequently, there seems to be a core signaling pathway regulating cell separation in floral abscission where IDA activates either one or both of the RLKs HAE and/or HSL2 causing autophosphorylation of the kinase receptor domains and the transduction of a phosphorelay signal through a MAPK cascade including MKK4, MKK5, MPK3, and MPK6 (Figure 4).

To identify additional components of the IDA signaling pathway we screened progeny of mutagenized *ida* seeds for suppressor mutants that showed normal floral organ abscission. Of the 13 revertant lines identified, two of them had, in addition to normal organ shedding, the characteristic downward pointing silique phenotype conferred by mutations in the *KNOTTED-LIKE HOMEOBOX* (*KNOX*) gene *BREVIPEDICELLUS* (*BP*)/*KNOTTED-LIKE FROM ARABIDOPSIS THALIANA1* (*KNAT1*).[10,28] Sequencing of the *BP*/*KNAT1* gene identified point mutations in each of the two revertant lines.[24] In addition, a null-allele deletion mutant of *BP*/*KNAT1*, *bp-3*, is capable of reverting the floral organ abscission defect of both *ida* and *hae hsl2*.[24]

Physiological and morphological analyses show that *bp-3* had a precocious dissolution of the middle lamella, indicating that *BP*/*KNAT1* functions as an inhibitor of abscission and is important for regulating the proper timing of cell separation.[24] This has also been proposed for *NEV*, and interestingly a suppressor of *nev*, the LRR-RLK *EVERSHED* (*EVR*)[13] is downregulated in the *bp* mutant.[29] However, unlike *bp-3*, *evr* is not capable of rescuing the abscission defect of *ida* or *hae hsl2* so EVR inhibits abscission independently of IDA, but BP/KNAT1 may mediate crosstalk between the IDA-HAE/HSL2 and the EVR pathways (Figure 4).

During inflorescence development, *BP*/*KNAT1* restricts the expression of the two KNOX domain genes *KNAT2* and *KNAT6* to promote correct inflorescence growth.[23] Expression studies from AZ cells with *promoter:GUS* constructs of *KNAT2* and *KNAT6* show that this is also the case in AZ cells. Moreover, a double mutant of *knat2 knat6* rescues the premature abscission observed in *bp-3* mutants.[24] This

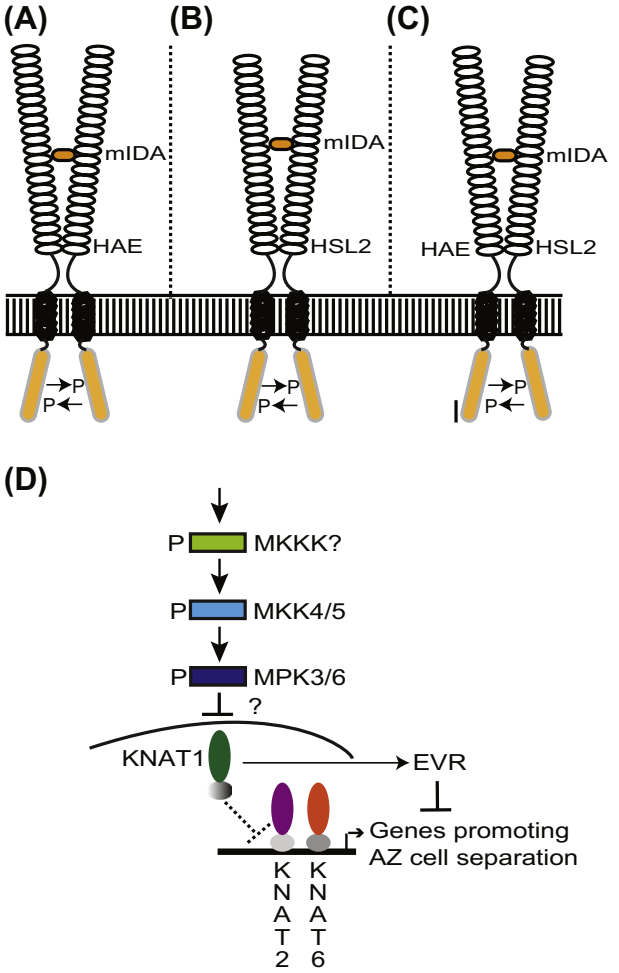

FIGURE 4 (A)–(C) A mature posttranslational modified IDA peptide consisting of the EPIP, or part of the EPIP, domain may bind the extracellular LRRs of an HAE homodimer (A), an HSL2 homodimer (B), or an HAE HSL2 heterodimer (C) and cause autophosphorylation (P) of the kinase receptor domains. (D) The signal from IDA-HAE/HSL2 is suggested to be transduced via a phosphorelay involving MKK4, MKK5, MPK3, and MPK6. Genetic evidence suggests that BP/KNAT1 acts as a negative downstream component of this signaling pathway by inhibiting cell separation and the expression of KNAT2 and KNAT6. On activation of the IDA signaling pathway, the BP/KNAT1 restriction of KNAT2 and KNAT6 is elevated, and these transcription factors can act as positive regulators of floral organ separation by positively regulating genes promoting AZ cell separation. In addition, BP/KNAT1 is a positive regulator of EVR, which influences cell separation by a separate parallel pathway.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

indicates that *KNAT2* and *KNAT6* act as positive regulators of cell separation during floral abscission downstream of *BP/KNAT1*. When *IDA* is OX in the *knat2 knat6* mutant background, the early abscission phenotype is lost. Conversely, when *KNAT2* or *KNAT6* are OX in the *ida* mutant background, rescue of the *ida* abscission defect is observed. This is consistent with the hypothesis that IDA signaling positively regulates *KNAT2* and *KNAT6*, and indeed promoter driven *GUS* expresssion of *KNAT2* and *KNAT6* is absent from the AZ of both the *ida* and *hae hsl2* mutants.[24]

The collected experiments performed by several scientists in the recent years have allowed us to propose the following signaling cascade for the IDA peptide ligand (Figure 4): A posttranslationally modified IDA peptide binds the LRR of either a homo- or heterodimer including HAE and/or HSL2 and induces a MAPK signaling cascade that acts to regulate *BP/KNAT1*. Because the transcriptional level of *BP/KNAT1* is unaltered in *ida* and *hae hsl2*, the regulation is probably at the protein level and may include dimerization with another homeodomain protein or posttranscriptional modifications of BP/KNAT1. The activation of the IDA pathway elevates the *BP/KNAT1* restriction of *KNAT2* and *KNAT6,* and these transcription factors may in turn positively regulate the transcription of genes involved in cell separation, such as cell wall remodeling (CWR) enzyme.

Future experiments investigating the cellular and subcellular localization of BP/KNAT1 during WT abscission compared with *ida* will hopefully provide an insight into how the IDA signaling pathway regulates the action of BP/KNAT1. Genetic identification of the remaining revertant lines will surely provide more detailed information on the IDA signaling system and certainly aid us in drawing parallels between the regulation of cell separation in the floral AZ and in lateral root emergence.

Chapter 6

LUREs

Tetsuya Higashiyama

ABSTRACT

The pollen tube is a tip-growing cell that emerges from pollen grains. It contains two immotile sperm cells and transports them to the ovule, which contains the egg cell. Pollen-tube guidance to the ovule is critical for the successful fertilization of flowering plants. The existence of chemotropic factors derived from the ovule was postulated >140 years ago in the late 1860s. Ovular attractants, called LURE peptides, were first identified in 2009 in the model plant *Torenia fournieri*. LUREs are defensin-like peptides that are specifically and abundantly expressed in two synergid cells adjacent to the egg cell. LUREs show severe species preference and attraction specificity and might be involved in reproductive isolation. Unlike SCR/SP11, another defensin-like peptide for self-incompatibility in flowering plants, many LUREs are probably involved in generating the attraction signal for the pollen tube.

DISCOVERY

The study of pollen-tube guidance and associated attractants has a long history.[4,7] Chemotropic attractant factors derived from the ovule of flowering plants were first postulated as early as the 1860s[22] when researchers observed that pollen tubes grow toward the ovule *in vitro*. Since then, many plant biologists have attempted but failed to identify attractants derived from the ovule. These classical biochemical experiments were based on various bioassay systems and led to the identification of external calcium ions as a possible attractant in snapdragons.[18] However, external calcium ions are necessary for the growth of the tip of the pollen tube.[8] Attraction and growth stimulation were not clearly distinguished in these systems.[7,8]

One difficulty associated with bioassays of pollen-tube attraction is that pollen tubes still grow, but in random directions, without specific attractants if the medium contains the requisite compounds to sustain tube growth, such as water, calcium, borate, and sucrose.[8] In animals, the chemoattractant protein for the neuronal growth cone, netrin, was identified in 1994 using an *in vitro* assay.[14] This study showed that neural cells emerge from tissues only when netrin proteins are present in the medium.

In 1998, an *in vitro* system was developed in *Torenia fournieri*, a unique plant with a protruding female gametophyte.[10] The haploid female gametophyte, known as the embryo sac, usually has one egg cell and two synergid cells at the micropylar end, three antipodal cells at the opposite chalazal end, and one huge central cell in the middle.[5] Pollen tubes were directly attracted to the protruding micropylar end of this female gametophyte (Figure 1; for movies[7]). This was consistent with genetic analyses in *Arabidopsis thaliana* showing that the female gametophyte governed pollen-tube guidance to the ovule.[11] Laser ablation experiments showed that the attraction signal in *T. fournieri* was derived from the two synergid cells on the side of the egg.[12] This attraction activity has severe species preference and specificity even in closely related species,[9] suggesting that it is probably a rapidly evolving molecule(s). Thus, genes expressed in synergid cells of *Torenia* were examined using manually collected synergid cells to identify attractant candidates among the peptides and proteins.[20] The synergid cell showed a unique gene expression profile: various cysteine-rich peptides (CRPs) are abundantly expressed. Three major CRPs, TfCRP1, TfCRP2, and TfCRP3, were analyzed, and recombinant peptides of TfCRP1 and TfCRP3 showed strong activity to attract pollen tubes. These peptides were named LUREs (TfCRP1 as LURE1 and TfCRP3 as LURE2). Knockdown of *LURE1* or *LURE2* genes by injecting morpholino antisense oligomers impaired pollen-tube attraction. These results indicate that LURE1 and LURE2 are diffusible attractant molecules derived from the synergid cell of the ovule (Figure 2).[20] Genomic PCR analysis of TcCRP1 from a closely related species, *Torenia concolor*, identified a LURE1 homolog that also showed species-preferential attraction activity (Figure 2).[13]

STRUCTURE OF THE PEPTIDE

The apparent molecular masses of mature LURE1 and LURE2 are 8.6 and 9.8 kD, respectively, based on Western blotting of endogenous LUREs from the pistil.[20] Cleavage sites of the signal peptide of LURE1 and LURE2 have been precisely predicted using the SignalP program.

The molecular weights of these endogenous LUREs are similar to those of recombinant LURE peptides expressed in *Escherichia coli* (predicted mature peptides lacking N-terminal signal sequences). These recombinant peptides of LURE1 and LURE2 show pollen-tube attraction activity at very low concentrations, as described below. Thus, it has been proposed that LURE1 and LURE2 are cleaved as predicted but are not substantially processed further. Secretion of endogenous LURE1 and LURE2 was confirmed by immunostaining, as described below.[20] The predicted mature peptides of LURE1 and LURE2 contain six cysteines. The molecular structures of the LUREs have not been resolved, but correct intramolecular disulfide bonds between the six cysteines have been suggested to be critical for their activity. Refolding is critical for pollen-tube attraction by recombinant LURE peptides, and refolded LUREs are mainly monomers.[20]

DISTRIBUTION OF THE mRNA/PEPTIDE

LURE1 and *LURE2* genes are specifically expressed in the two synergid cells on the side of the egg cell, independent of pollination, as shown by reverse transcription polymerase chain reaction (RT-PCR) of isolated female cells and immunostaining of ovules.[20] LURE1 and LURE2 peptides are secreted directionally toward the micropylar end of the egg and accumulate in the filiform apparatus. The filiform apparatus is a structure formed by the ingrown and/or thickened cell walls of the two synergid cells, and might be involved in active secretion and/or protection of the female gametophyte from pollen-tube thrust.[5] Accumulation of LURE peptides in the filiform apparatus is consistent with the behavior of pollen tubes; pollen tubes enter the female gametophyte through the region of the filiform apparatus.

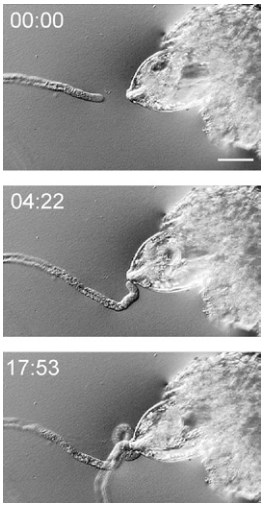

FIGURE 1 Pollen-tube attraction in the *in vitro Torenia* system. Two pollen tubes are attracted to the protruding embryo sac of Torenia fournieri. Pollen tubes are touching the filiform apparatus of two synergid cells in the embryo sac. Sequential images are shown and time after the start of observation is indicated as mm:ss. Modified after Ref. 7. Scale bar = 30 μm.

BIOLOGICAL FUNCTIONS

Pollen-tube guidance involves multistep controls exerted by various female tissues along the path of the pollen tubes.[7] LURE peptides govern the last guidance step over short distances, possibly at 100–200 μm from the female gametophyte.[21] The last guidance step is precise and is known as micropylar guidance.[21] The existence of attractants in other guidance steps remains unclear. Chemocyanin, a basic cell wall protein expressed in the lily stigma, is a good guidance molecule candidate.[15] Chemocyanin has ability to attract (reorient) pollen tubes *in vitro*; however, knockdown analyses have not been successful. It remains unknown whether LURE peptides are common in other flowering plants. Because CRPs generally show rapid molecular evolution, conventional homology searches are difficult for identifying LURE homologs in other plants. However, in *Arabidopsis thaliana*, CRPs are likely to be involved in synergid cell functions, including micropylar pollen-tube guidance.[21] ZmEA1, a nondefensin-like peptide, has been suggested as a possible pollen-tube attractant candidate for micropylar guidance in *Zea mays*.[2,17]

An *in vitro* attraction assay using recombinant LURE peptides has been used for characterization (Figure 3).[20] For quantitative analysis, recombinant peptides are embedded in gelatin beads approximately 40 μm in diameter and placed in front of each pollen tube using a micromanipulator to examine whether they attract pollen tubes. Pollen-tube attraction is a concentration-dependent process. At optimum concentrations, >60% of pollen tubes are attracted, which is similar to the frequency of attraction in manipulated ovules.[20] Surprisingly, the minimum concentration is 40 pM for both LURE1 and LURE2,[3,20] which means that only 1000 LURE molecules in the bead are sufficient to attract pollen tubes. Attraction of the pollen tube by LUREs might not simply

result from a LURE concentration gradient, as implied by visualization of LURE2 with Alexa labeling.[3]

The attraction activity of LUREs is similar to that of the synergid cell.[20] *T. fournieri* pollen tubes are preferentially and specifically attracted to ovules of their own species in the presence of ovules of *Torenia concolor* or *Lindernia micrantha*.[9] Consistently, pollen tubes of *T. concolor* and *L. micrantha* are less attracted and scarcely attracted, respectively, by LURE peptides from *T. fournieri*.[13,20] In the *in vitro Torenia* system, pollen tubes are grown through a cut style, as tubes become competent by growing through the pistil. The pollen tubes cultivated in semi-*in vitro* conditions, but not tubes germinated *in vitro*, are attracted to the synergid cell. Consistently, only competent pollen tubes growing through a cut style are attracted by LURE peptides.[20]

When LUREs were initially identified, only three major CRPs expressed in the synergid cell were examined. However, there are even more CRPs expressed in synergid cells, and some of them are likely to be candidate LUREs.[6] A mixture of plural or multiple LURE peptides might generate the attraction signal for micropylar guidance. It has also been proposed that LURE1 and LURE2 might have independent functions.[6]

RECEPTORS AND SIGNALING CASCADES

Receptors for LUREs have not been identified. The severe species preferentiality and specificity of LURE activity imply that some partner molecules on the plasma membrane of the pollen tube, possibly with highly variable domains, bind to the LUREs. Because the direction of tip growth is controlled at the tip by changing the exit site of secretory vesicles, it is plausible that the receptor is localized at the tip of the pollen tube.[21] Endocytosis actively occurs in the subapical region of the pollen tube for recycling of molecules at the tip.[1] Thus, the receptor might also be recycled at the tip. Pollen-tube competence, as described above, might involve some modifications of the receptor and/or signaling cascades.

Amino acid sequences are significantly divergent between LURE1 and LURE2, except for the conserved cysteines (Fig. 2).[20] The difference in amino acid sequence between LURE1 of *T. fournieri* and its homolog, *T. concolor* (TcCRP1), is only eight amino acids; however, this difference leads to significant species specificity.[13] Thus, because LURE1 and LURE2 are more highly diverged, they may bind to different receptors. Receptors for many plant peptide ligands, including defensin-like SCR/SP11, are serine–threonine receptor kinases with one transmembrane domain. However, the response of the pollen tube to LURE peptides is rapid and spatially precise. Involvement of other types of receptors has also been discussed.[21]

LURE-specific signaling cascades are unknown, but the directional signals from expected receptors are likely to modify signaling cascades related to tip growth of the pollen tube.[21] Alterations in the distribution of tip-focused concentration gradients of internal calcium ions and cAMP change the direction of growth, as shown using caged compounds and inhibitors.[16,19]

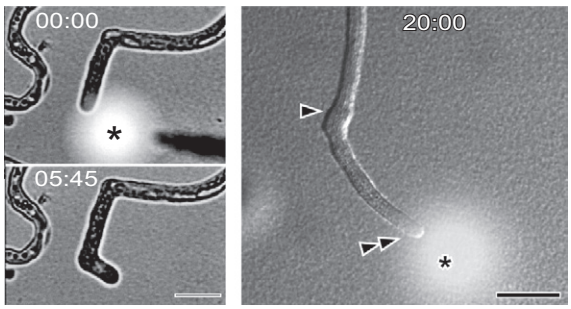

FIGURE 3 Pollen-tube attraction by recombinant LUREs. Pollen tubes were attracted using a micropipette (left) or a gelatin bead (right). Recombinant LURE2 (left) and LURE1 (right) were used. Note that the pollen tubes changed their direction to orient toward the injected LURE2 (left top, an asterisk) and a gelatin bead containing LURE1 (right, an asterisk). In the right panel, an arrowhead marks the position of the tip of the pollen tube when a gelatin bead was placed, and double arrowheads indicate the tip of the pollen tube growing toward the bead. Sequential images are shown in the left panels, and time after applying peptides is indicated as mm:ss. Modified after Ref. 20. Scale bar = 20 μm.

Chapter 7

Phytosulfokine

Yoshikatsu Matsubayashi

ABSTRACT

Phytosulfokine (PSK) is a 5-amino-acid secreted peptide that contains two sulfated tyrosines. PSK was initially identified as a growth-promoting signal involved in the "density effect" in plant cell cultures. Addition of PSK to culture medium significantly improves the efficiency of cellular proliferation, even when the initial cell population is below the critical density. It was later shown that PSK also promotes *in vitro* tracheary element differentiation, somatic embryogenesis, and pollen germination. PSK is produced from approximately 80-amino-acid precursor peptides via post-translational sulfation and proteolytic processing. Genes encoding PSK precursors are widely expressed in a variety of tissues and upregulated by wounding. PSK is recognized by a membrane-localized leucine-rich repeat receptor kinase, PSKR1. Disruption of PSKR1 and its homologs in *Arabidopsis* causes growth defects such as short roots, smaller leaves, and early senescence. PSK signaling affects potential for growth and cellular longevity, thereby exerting a pleiotropic effect on individual cells in response to environmental conditions.

DISCOVERY AND STRUCTURE OF PSK

Almost all plant cells, even when fully differentiated, can dedifferentiate and proliferate *in vitro* to form a callus. Lines of evidence suggest that population of living cells are required to support callus formation and successive proliferation *in vitro*. This requirement is greater for more mature cells. Dilution of dispersed mature mesophyll cells in excess culture medium significantly prevents callus formation, even if auxins, cytokinins and nutrients are supplied.[15] A similar phenomenon has also been observed for transdifferentiation of mesophyll cells into tracheary elements (TEs).[16] If dispersed *Zinnia* mesophyll cells are cultured below a critical cell density, TE formation is greatly suppressed, indicating that cell-to-cell communication is also involved in transdifferentiation. Similarly, somatic embryo formation from a suspension of carrot cells is dependent on cell density.[7] Interestingly, this population dependence is lessened by the addition of conditioned medium in which cells have previously been grown, indicating that such cell-to-cell communication is mediated by secreted signal(s).[7,15,16]

Phytosulfokine (PSK), a 5-amino-acid-sulfated peptide is the primary signal molecule responsible for the above examples of cell-to-cell communication (Figure 1A).[4,7,15,16] PSK was first purified from conditioned medium derived from an asparagus (*Asparagus officinalis* L.) suspension culture, based on its ability to promote cell division of asparagus mesophyll cells cultured at low cell density.[15] PSK has been detected at nanomolar levels in culture media of various plant cell lines including asparagus,[15] rice,[17] maize,[17] *Zinnia*,[12] carrots,[4] and *Arabidopsis*.[25] This suggests that among higher plants, PSK is widely distributed with strict sequence conservation. Structure–activity analysis indicates that the N-terminal tripeptide fragment Tyr(SO_3H)–Ile–Tyr(SO_3H) is the active core of PSK.[10]

PSK is generated by tyrosine sulfation followed by enzymatic processing of approximately 80-amino-acid precursor peptides that have a secretion signal at its N-terminal (Figure 2).[11,24–26] In *Arabidopsis*, five paralogous genes encoding PSK precursors have been identified. Each predicted precursor peptides has a secretion signal at the N-terminus and a PSK sequence close to the C-terminus. However, these precursors exhibit extreme diversity, for example, only a small number of residues close to the C-terminus including PSK domain are conserved. Many amino acid substitutions are likely to be evolutionally allowed to accumulate in the outside region of the mature peptide domains because these regions are digested by proteolytic processing.

In vitro studies have suggested that proteolytic processing of PSK is mediated, at least in part, by a subtilisin-like serine protease, AtSBT1.1.[21] Its recognition site is, however, between Leu and His located several residues upstream of the mature PSK domain. This observation indicates that substrate specificity of plant subtilases is distinct from those of animal subtilisin/kexin-like prohormone convertases that exactly recognize the C-terminal side of paired basic amino acids. Plant subtilases have greater structural similarity with prokaryotic degrading-type subtilases than with animal processing-type subtilases, resulting from a lack of the P-domain characteristic of animal enzymes.[2] Proteolytic processing of plant peptide signals may involve several complex steps, such as initial cutting and further trimming of the peptides.

BIOLOGICAL FUNCTION OF PSK *IN VITRO*

Biological function of PSK *in vitro* is pleiotropic. Addition of chemically synthesized PSK to culture medium significantly improves the efficiency of cellular proliferation (Figure 1B),[15,17] even when the initial cell population is below the critical density. PSK also stimulates *in vitro* tracheary element differentiation of *Zinnia* mesophyll cells (Figure 1C),[16] somatic embryogenesis (Figure 1D),[4,5,7] adventitious root formation[23] and pollen germination.[3] PSK also promotes production of taxol, a potent antitumor drug.[6] Microarray analysis of gene expression in mechanically dispersed *Zinnia* mesophyll cells under PSK treatment have shown that PSK downregulates stress-related genes such as chitinases, phenylpropanoid biosynthesis enzymes and 1-aminocyclopropane-1-carboxylic acid.[19] Supporting this, when PSK is applied to plant seedlings at high concentrations, it retards senescence under stress conditions.[22]

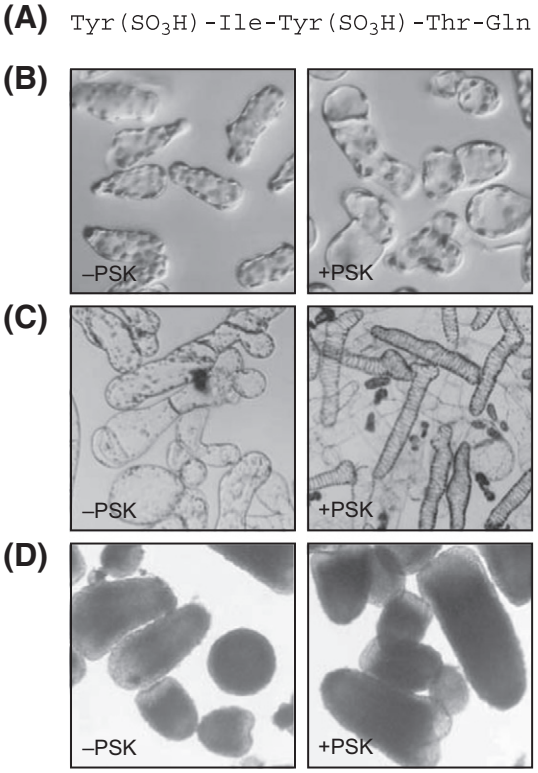

FIGURE 1 Structure and biological activities of PSK *in vitro*. (A) PSK is a 5-amino-acid peptide containing two sulfated tyrosines. (B–D) PSK promotes cell division of asparagus mesophyll cells (B), tracheary element differentiation of *Zinnia* mesophyll cells (C), and somatic embryogenesis of carrot suspension cells (D). PSK was added to each culture at final concentration of 10 nM.

EXPRESSION PATTERN AND *IN VIVO* FUNCTION OF PSK

PSK precursor genes are redundantly distributed in the genome (5 genes in *Arabidopsis*), and are found in a variety of angiosperm[9] and gymnosperm[5] plant species. In *Arabidopsis*, *AtPSKs* are expressed in a variety of tissues including roots, leaves, stems, flowers, siliques, and calluses.[11] Among the plant parts that are above the ground, *AtPSK2*, *AtPSK3*, *AtPSK4*, and *AtPSK5* were expressed in cotyledons and leaves and were most abundantly expressed in vascular bundles. In roots, *AtPSK3* was primarily expressed in root tips, whereas expression of *AtPSK2*, *AtPSK4*, and *AtPSK5* was mainly detected in the more mature regions of the root. Expression of *AtPSK4* and *AtPSK5* is highly upregulated on mechanical wounding.

PSK precursor genes are so small and redundant that the loss-of-function analysis is not easily applicable. Instead, knockout mutants of the genes for PSK receptors provide informative phenotypes (described below). Identification of tyrosylprotein sulfotransferase (TPST), an enzyme that catalyzes the tyrosine sulfation of the peptides, also provides a hint about *in planta* function of PSK.[8]

Arabidopsis TPST (AtTPST) is a Golgi-localized 62-kDa transmembrane protein.[8] AtTPST is expressed throughout the plant body, and the highest levels of expression are observed in the root apical meristem. A loss-of-function mutant of *AtTPST* (*tpst-1*) displays a semidwarf phenotype accompanied by stunted roots, loss of root stem cells, pale green leaves and early senescence.[8] Severe short root phenotype is characterized by considerable reduction in root meristem size and loss of coordination between cell elongation and expansion in the elongation-differentiation zone. Because TPST is an enzyme indispensable for biosynthesis of sulfated peptides, these phenotypes should reflect deficiencies in all the functional tyrosine-sulfated peptides. Interestingly, a novel sulfated peptide, root meristem growth factor (RGF), plays a central role in root meristem development, but RGF alone is not sufficient for full restoration of *tpst-1* root phenotype.[18] PSK is required

for cell elongation in the elongation zone and enhances cell division in the meristematic zone.[18]

RECEPTOR FOR PSK AND *IN PLANTA* FUNCTION OF PSK

Specific binding sites for PSK were detected on the surface of suspension-cultured cells and in plasma-membrane-enriched fractions of various plants.[14,17] Scatchard analysis using [^{3}H]PSK has revealed the existence of a high-affinity PSK-binding site in microsomal fractions derived from carrot cells with a dissociation constant (K_d) of 4.2 nM.[12] This PSK receptor protein has also been visualized by photoaffinity labeling of carrot-plasma-membrane fractions using the photoactivatable ^{125}I-labeled PSK analog.[12,13]

The PSK-binding protein was purified from microsomal fractions of carrot (*Daucus carota* L.) cells by detergent solubilization and specific ligand-based affinity chromatography using a PSK-Sepharose column.[12] Molecular cloning of this protein revealed that PSK receptor (DcPSKR1) is a 1021 amino acid protein containing an N-terminal hydrophobic signal sequence, extracellular leucine-rich repeats (LRRs), a 36-amino-acid island domain, a transmembrane domain, and a cytoplasmic kinase domain. Photoaffinity labeling followed by fragmentation analysis revealed that the 15 amino acid region Glu^{503}–Lys^{517} located on the N-terminal side of the 36 amino acid island domain is the ligand binding domain of DcPSKR1.[20]

Arabidopsis PSK receptor (AtPSKR1) was further identified based on overall amino acid similarity to DcPSKR1.[11] AtPSKR1 was a 1008 amino acid LRR-RK that has 60% amino acid sequence identity to DcPSKR1 and contains 21 tandem copies of LRR, a 36-amino-acid island domain between the 17th and 18th LRRs, a single transmembrane domain, and a cytoplasmic kinase domain. In addition, amino acid sequences in the island domain are highly conserved between DcPSKR1 and AtPSKR1. PSK binds AtPSKR1 with a dissociation constant (K_d) of 7.7 nM, which is similar to the K_d of DcPSKR1.

Disruption of AtPSKR1 and its two homologs in *Arabidopsis* causes pleiotropic growth defects such as reduced root length, smaller leaves, and early senescence (Figure 3).[1,11] The short root phenotype is characterized by a significant decrease in cell size and a reduced meristem size, indicating that PSK regulates both meristem activity and cellular expansion (elongation). Adult plants of this triple mutant show a semidwarf phenotype with smaller leaves than that of wildtype plants, because of the decreases in cell number and cell size. At the bolting stage, mutant leaves exhibit premature senescence phenotypes. By contrast, seedlings overexpressing *AtPSKR1* develope larger leaves than the wildtype and exhibit delayed senescence. These results strongly suggest that PSK represents a novel class of hormones that affect the potential for cellular growth and longevity, thereby exerting a pleiotropic effect on individual cells in response to environmental conditions.

PSY1, A SULFATED GLYCOPEPTIDE FUNCTIONALLY SIMILAR TO PSK

PSY1 is an 18-amino-acid secreted glycopeptide containing one sulfated tyrosine residue and an L-arabinose sugar chain (Figure 4A). This glycopeptide was identified by exhaustive analysis of tyrosine-sulfated peptides in *Arabidopsis* cell culture media.[1] This peptide is derived from near the C-terminal region of the 75-amino-acid precursor peptide (Figure 4B). The *Arabidopsis* genome also contains two genes encoding PSY1 homologs with significant similarity within the mature peptide domain (Figure 4B). Interestingly, the physiological activity of PSY1 is closely similar to that of PSK. When PSY1 is directly added to the culture

medium of *Arabidopsis* suspension cells, it significantly promotes cellular proliferation in a dose-dependent manner. PSY1 also promotes proliferation of dispersed asparagus mesophyll cells at nanomolar concentrations. *PSY1* is widely expressed in various *Arabidopsis* tissues and is highly upregulated by wounding. Transgenic seedlings overexpressing PSY1 develop longer roots and larger cotyledons than wildtype do mainly because of an increase in cell size. These results indicate that PSY1 is involved in both cellular proliferation and expansion. Two structurally distinct sulfated peptides, PSY1 and PSK, act as physiologically similar growth-promoting signals.

POLARIS

Keith Lindsey, Saher Mehdi, Stuart A. Casson, Anna J. Mudge, Jennifer F. Topping and Junli Liu

ABSTRACT

The POLARIS (PLS) peptide was identified in the plant species *Arabidopsis thaliana* by promoter trapping. The gene encodes an mRNA of ca. 600 bases, at the 3′-end of which is a 36 amino acid open reading frame (ORF). Translation of the ORF is required for biological activity. The transcriptional start of the gene overlaps with the 3′-UTR of an upstream gene. Expression of the *POLARIS* gene is strongest in root tips, but is also detectable in young leaves, and is induced by auxin. Mutation of *POLARIS* leads to several developmental defects, including a short root phenotype and reduced vascular complexity in leaves. Recent results show a role for PLS in repressing ethylene responses, and in promoting ethylene-mediated auxin biosynthesis.

DISCOVERY

Arabidopsis thaliana has proved to be an enormously valuable model organism for the study of plant growth and development, not least because of its ease of transformation and small diploid genome, which has allowed the use of insertional mutagenesis for gene tagging and functional analysis. Several years ago we adopted a promoter trapping strategy to allow gene identification, based on the transcriptional activation of a promoterless *gusA* gene after random insertion into the genomes of plants, including *Arabidopsis*.

A major advantage of this approach over conventional mutagenic strategies is that it not only allows gene detection by the identification of mutant phenotypes, but also simultaneously can provide information on the expression pattern of the tagged gene. It also facilitates gene isolation because the insertion element provides a molecular tag on the genomic sequence in which the gene of interest is located. This can subsequently be cloned by one of a number of polymerase chain reaction (PCR)-based techniques.[9]

The promoter trap strategy we developed involved transforming populations of plants with a promoterless *gusA* gene engineered into a T-DNA vector, allowing agrobacterium-mediated gene transfer. This vector, designated as pΔGUSBin19,[24] is illustrated in Fig. 1. It is activated at high frequency in transgenic populations of several species, and GUS activity can be localized histochemically to allow the screening for insertion into genes that are expressed in tissue-specific patterns.[10]

An area of interest to us has been the identification and functional analysis of genes expressed in embryos and roots. The basal region of the embryo represents the cellular origin of the primary root.[4] We exploited the promoter trapping approach to screen transgenic *Arabidopsis* containing the vector pΔGUSBin19 for lines exhibiting GUS activity in embryos.[22] One line of interest, designated as AtEM101, showed a pattern of GUS activity that was polar in the developing embryo, and hence the tagged gene was named *POLARIS* (*PLS*). GUS activity is detectable from the early heart stage of embryogenesis, a stage at which apical–basal polarity is clearly visible in morphological terms, with cotyledonary primordia flanking the incipient shoot apical meristem at one end, and the developing root apical meristem adjacent to the suspensor at the other end, which is the region of attachment to the maternal tissue (Fig. 2). AtEM101 plants homozygous for the *PLS* promoter trap insertion event exhibited a short root phenotype.[2]

Using the promoter trap T-DNA as a molecular anchor point, we used RACE PCR to clone the *PLS* cDNA. Northern blot analysis using the *PLS* cDNA as a probe showed that wildtype (WT) seedlings accumulate a single low abundance transcript of ca. 500 nucleotides (Fig. 3A), and Southern analysis indicated a single gene copy per haploid genome.[2] Subsequent analysis of the *Arabidopsis* genome sequence has supported the view that *PLS* is a single copy gene.

STRUCTURE OF THE PRECURSOR mRNA/GENE

The genomic sequence at the *PLS* locus, which is on chromosome 4, reveals that the promoter trap T-DNA had inserted into a small ORF of 108bp, located in a 755bp region between two larger genes. One gene, which is not annotated and which we designated as *Gene X*, is 450bp upstream of the promoter trap T-DNA, encodes a predicted

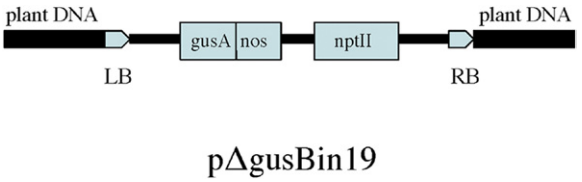

FIGURE 1 Diagrammatic representation of the promoter trap binary vector pΔGUSBin19, used to identify the *POLARIS* gene. At the T-DNA left border (LB) is a promoterless *gusA* gene, which can be activated after insertion into a transcription unit. At the T-DNA right border (RB) is a selectable marker, *npt-II*, conferring kanamycin resistance to transgenic plants. N = *nos* terminator.

92 amino acid peptide of unknown function. The second gene encodes the brassinosteroid receptor BRI1.[8] The identification of the ca. 500 nucleotide *PLS* transcript suggested that *PLS* encodes a distinct gene, and the ORF is not an exon of either of the flanking genes.

This was confirmed by both 5′-RACE PCR and RNAse protection assays, which showed that the transcription of the PLS ORF initiates within the 3′-untranslated region of *Gene X*. Specifically, we identified two transcript initiation sites, 95bp apart and one of which is used more frequently than the other (Fig. 3). The more distal start site (Start Site 1) occurs ca. 117bp upstream of the *Gene X* polyadenylation sequence, and has the sequence ATCCGTAT, with the underlined G representing the initiation site. The more proximal start site (Start Site 2), which is the more frequently used, is ca. 23bp upstream of the polyadenylation site of *Gene X*, with the sequence CCACTTAATA; it was not possible to resolve which of the three underlined bases is the start point for transcription.

Start Site 2 has a predicted TATA sequence (TATATAA) at positions −32 to −26, and Start Site 1 has a poorer TATA-like sequence at −35 to −29 (AATAATA). Sequence analysis of *PLS* 3′-RACE products revealed a variable length of polyadenylation, such that the length of the *PLS* transcript is between 427 and 606 nucleotides, depending upon which transcriptional start site is used and the length of the poly(A) tail.

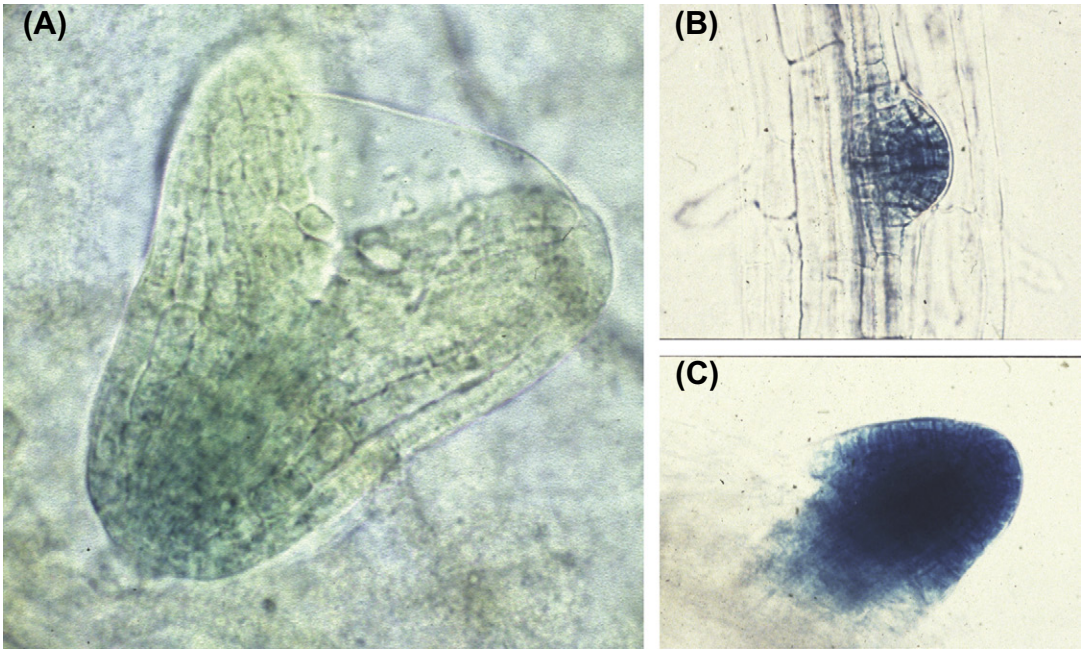

FIGURE 2 *POLARIS-GUS* expression in the basal region of a heart-stage embryo (A) and in the tips of emerging lateral roots of seedlings (B, C).

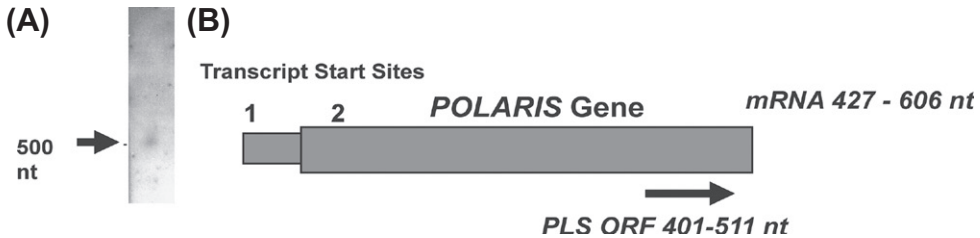

FIGURE 3 The *PLS* gene encodes a low abundance ca. 500 nt mRNA revealed in northern blots (A). Transcription initiated has been mapped by RNAse protection assays and 5′-RACE PCR to either of two start sites (1, 2), with the proximal site (2) used more frequently. The PLS ORF is located toward the 3′-end of the gene, at positions 401–511bp (including the translational stop codon) downstream of transcription Start Site 1.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Sequences 5′ to the Start 2 transcription initiation site were cloned upstream of the *gusA* reporter gene, and transformed *Arabidopsis* plants were generated for functional analysis. A relatively short (−370bp) sequence was sufficient to drive GUS activity in the root tip of transgenics. A longer 5′-flanking sequence (−1190bp upstream of Start Site 2) promoted stronger GUS expression than the shorter sequence.[2] These results provided further support for transcription of the *PLS* gene initiating within the upstream *Gene X* sequence. While apparently unusual in eukaryotes, an overlapping organization has similarly been described for the *EhMCM3* and *EhPAK* genes of *Entamoeba histolytica*,[5] and for the *OTC* and *AUL1* genes of *Arabidopsis*.[17] Mouse and human examples have also been reported.[6,20]

The *PLS* gene was sequenced from two ecotypes of *Arabidopsis*, namely C24 (the original promoter trap background) and Columbia (Col-0), and was found to be identical. The PLS ORF, disrupted by the promoter trap T-DNA, encodes a 36 amino acid peptide of predicted 4.6kDa. The PLS ORF is located toward the 3′-end of the *PLS* transcript (Fig. 3B) and is preceded by an in-frame 27bp ORF (encoding a predicted 9 amino acid peptide) with a stop codon immediately preceding the PLS ATG, and an 8 amino acid peptide that overlaps with the PLS ORF. These upstream ORFs may play a role in regulating the *PLS* transcript stability and/or PLS translation, e.g. see Refs. 12 and 26.

Proof for a functional role for the PLS ORF comes from transgenic complementation experiments in which the short root phenotype of the mutant is complemented by transformation with a partial cDNA containing the WT PLS ORF sequence. Mutation of the PLS ORF ATG prevented complementation, showing that translation of the PLS peptide is required for biological activity.[2]

DISTRIBUTION OF THE mRNA

Northern blot, RT-PCR, and cloned promoter analyses have confirmed the distribution of *PLS* expression throughout different organs, as indicated by the histochemical localization of GUS activity in the original promoter trap line. The *PLS* mRNA is a very low abundance transcript, but is detectable most readily in the distal (apical) regions of roots, and also in young leaves as well as embryos. This is reflected also in promoter–GUS activity in transgenics. In the root, short (5min) histochemical staining times reveal GUS activity in the root columella initials and the lateral root cap, similar to the auxin-responsive DR5-GUS reporter.[18]

Indeed, *PLS* transcription is strongly auxin-inducible, as determined by promoter–GUS histochemistry, northern analysis, or competitor RT-PCR.[2] This induction, which occurs within 30min of auxin application, is only seen with functional auxins, and not with nonfunctional structural analogs, such as 2-naphthylacetic acid or 2,3-dichlorophenoxyacetic acid. The *PLS* promoter contains potential TGTCTC-like auxin response elements.[25] Further support for a dependence of *PLS* expression on correct auxin signaling comes from studies in the *gnom/emb30* mutant background. The GNOM protein is an ARF-GEF required for vesicle trafficking and the correct polar localization of PIN proteins, themselves components of the auxin efflux transport system.[21] In a severe *gn* genetic background, *PLS* expression in embryos and seedlings is depolarized, consistent with the depolarized auxin distribution.[23] The expression of *PLS* in young leaves is also consistent with their being a site of auxin biosynthesis and relatively high concentration, as for roots.[13,14] *PLS* expression is, therefore, a good marker of auxin responses and auxin localization.

PROCESSING

The N-terminal 24 amino acids of the PLS peptide are predicted to form two β-sheets, and the C-terminal 12 amino acids are predicted to form an α-helical domain. There is no obvious targeting sequence in the PLS sequence, suggesting that it is not secreted but remains cytosolic. There is a possibility that the N-terminal region may be processed, as the presence of three basic arginine residues at positions 10–12 may form a turn region and represent a cleavage site. The second β-sheet contains a repeated SIS sequence that, because of the proximity to the arginine residues, may represent a cAMP-/cGMP-dependent protein kinase phosphorylation site, although this has not been determined experimentally. The C-terminal α-helical domain contains the motif KLFKLFK, which has potential to act as a leucine zipper for protein–protein interactions.

BIOLOGICAL ACTIONS

Our effort to investigate the function of the PLS peptide has focused on an analysis of the *pls* mutant and transgenic overexpression phenotypes. Although *PLS* expression is detectable in the developing embryo, there is no obvious mutant phenotype at this stage of the life cycle. However, the first evidence of a role in development is seen at the seedling stage, with defects apparent in root architecture and leaf venation.[2]

Seedlings homozygous for the *pls* mutation show a reduced length of the primary root, to about 50% that of WT over the first 14 days post-germination (Fig. 4A). Cells of the root are shorter and wider (more isodiametric) than WT, and divide less frequently to account for the reduced root length. *pls* also produces fewer lateral roots.[3] Seedlings hemizygous for the *pls* mutation show a primary root length that is intermediate between WT and homozygous mutants, indicating that the mutation is semidominant.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

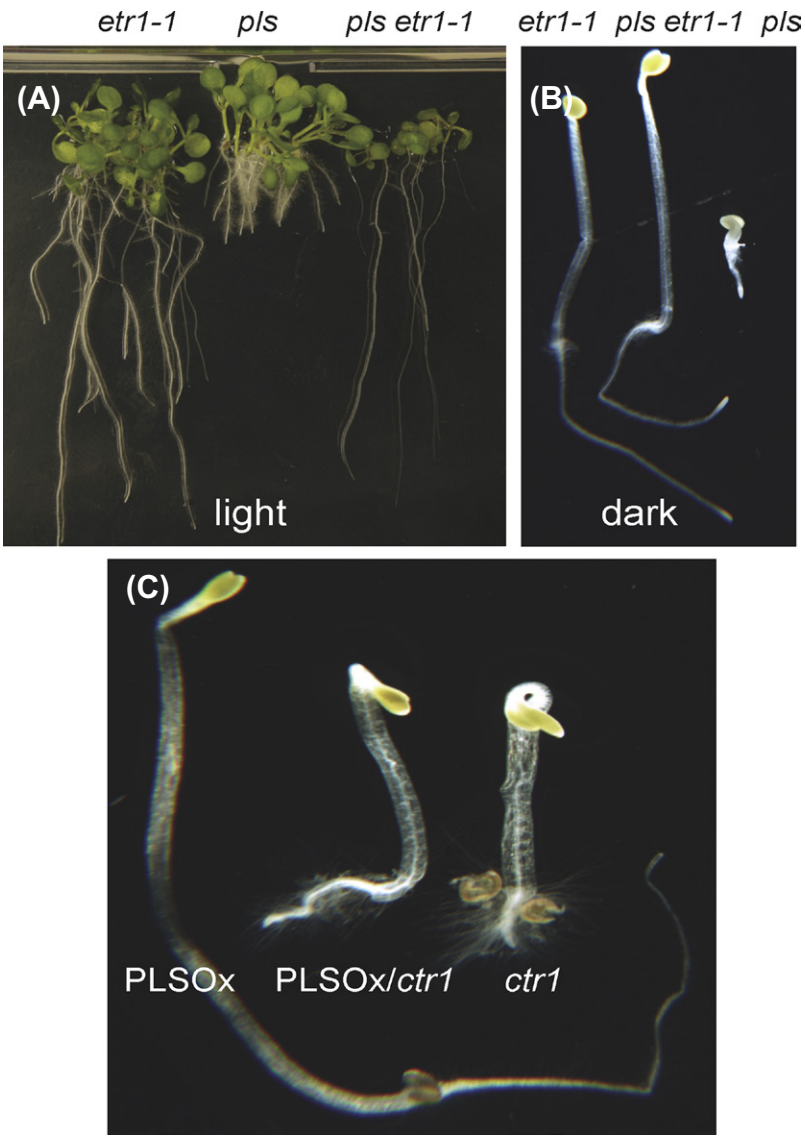

FIGURE 4 Phenotypes of seedlings of the *pls* mutant, the *etr1-1* mutant, and the *pls etr1-1* double mutant grown in the light (A) or in the dark (B). The PLS overexpressor (PLSOx) phenotype is repressed by the *ctr1* mutation (C), indicating that CTR1 functions downstream of PLS.

The overall stature of *pls* flowering plants is reduced compared to WT and more bushy, indicative of a reduced apical dominance. Microscopic analysis of leaves of the rosette at 12 days post-germination revealed a reduced venation compared with WT, and in particular a reduced number of higher order veins branching from the primary strands.[2]

Taken together, these results suggest a requirement for PLS in regulating cell shape and division in the root, vascular patterning in the leaf, and shoot architecture. One hypothesis we can consider is that PLS is required for correct auxin, cytokinin, or ethylene signaling, each of which is known to interact with the other hormone systems, and affect the development of the root and the shoot, including vascular patterning,[15] lateral root development,[1] and the control of apical dominance.[7]

To investigate auxin and cytokinin responses of the *pls* mutant, seedlings were grown *in vitro* in the presence of exogenous auxin or cytokinin over a range of concentrations. *pls* seedlings show reduced responses to auxins, seen as a reduced inhibition of primary root growth in the presence of exogenously supplied 2,4-D or 1-NAA. For example, in the presence of 10nm 1-NAA, WT primary roots are inhibited to 84% the length of untreated roots, whereas *pls* roots are 106% the length of untreated, i.e. showing a slight increase rather than inhibition in growth.[2] This suggests that *pls* seedlings may be defective in auxin transport, responses, or accumulation. Experimental analysis revealed a reduced

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

rate of auxin transport in the *pls* mutant inflorescence stem to the root tip, which contains less free indoleacetic acid (IAA) than WT.[3] The expression of at least some auxin-regulated genes is correspondingly reduced in *pls*, shown as the reduced steady-state level of the *IAA1* gene transcript, supporting the view that *pls* has reduced auxin responses.

In the presence of exogenous cytokinins, *pls* primary roots exhibit an enhanced response compared with the WT. For example, in the presence of 10nm BA, the WT root is not significantly shorter than untreated. However, at the same concentration, the *pls* root growth is significantly inhibited to 71% the length of the untreated root.[2] Transgenic plants overexpressing the PLS transcript show reduced responses to cytokinins, and increased leaf vascularization, an auxin-regulated process, compared with the mutant. This antagonistic relationship between auxin and cytokinin responses in *pls* may reflect the antagonistic interplay of auxin and cytokinin biosynthesis[16] and suggests the requirement for PLS in regulating this interaction, either directly or indirectly.

Auxin and cytokinin also interact with ethylene signaling.[11] Evidence in support of a key role for PLS in modulating ethylene responses come from both mutant and transgenic overexpression analyses. The *pls* loss-of-function mutant exhibits a triple response phenotype (short and wide hypocotyl, exaggerated apical hook) when grown in the dark in air (Fig. 4B), suggestive of a defect in ethylene synthesis or response, but the mutant does not overproduce ethylene gas.[3] This implicates PLS as having a role in ethylene signal transduction. Consistent with this, the short root and triple response phenotypes of the mutant are rescued by the ethylene resistant *etr1* mutation; ETR1 is one of the ethylene receptor proteins.[19] Genetic analysis places PLS action upstream of CTR1, a negative regulator, or ethylene signal transduction (the PLS transgenic overexpression phenotype is blocked by the *ctr1* mutation; Fig. 4C), but downstream of the ethylene biosynthetic pathway. This suggests that PLS may interact directly with the ethylene receptor itself, a model that is supported by our unpublished experimental data but requires further work to confirm.

We have used mathematical modeling in combination with experimentation to analyze the role of PLS in hormone network interactions.[11] This work shows that the level of *PLS* expression influences ethylene, auxin, and cytokinin responses simultaneously. One prediction from the modeling was that the *pls* mutant would accumulate increased levels of biologically active cytokinins and a second prediction was that PLS is required for ethylene-mediated auxin biosynthesis in the root tip. Both predictions have been confirmed.[11]

In summary, the POLARIS peptide represents a new component required for cross-talk between more conventional plant signaling pathways, and modulation of its expression plays a significant role in the modulation of growth. Evidence suggests that the PLS peptide interacts with more than one protein partner—one may be the ethylene receptor complex, while a second appears to be an as yet unknown but distinct protein required for ethylene-mediated auxin biosynthesis.

Chapter 9

RALF Peptides

Juliano R. Guerreiro, Gregory Pearce, Marcio C. Silva-Filho and Daniel S. Moura

ABSTRACT

RALF is a 5kDa peptide signal ubiquitous in the plant kingdom that has been associated with cell elongation. RALF precursors are found as single genes or members of multigene families. When added to the extracellular medium of suspension cells, RALF causes a pH increase followed by the activation of an MAP kinase. Plants overexpressing AtRALF1, one of the 34 isoforms present in *Arabidopsis*, have a semidwarf phenotype. Another RALF from *Arabidopsis*, AtRALF23, is down regulated by brassinolide and when overexpressed produces a shorter and bushier plant. *Nicotiana attenuata*, as opposed to *Arabidopsis*, has only one RALF that, when silenced, produces plants with longer roots. RALF is secreted and two membrane proteins from tomato cell suspensions were reported to bind specifically a ^{125}I-azido-labeled tomato RALF. AtRALF1 has also been found to induce a fast increase in cytoplasm Ca^{2+}, as a result of Ca^{2+} being mobilized from extracellular and intracellular stores.

DISCOVERY

The 49 amino acid peptide called RALF was discovered in leaf extracts of tobacco plants during a search for peptides with activity in the alkalinization assay.[19] The name RALF, short for Rapid Alkalinization Factor, is derived from the fast alkalinization response that the peptide elicits in the assay when compared with other plant bioactive peptides, such as systemin. When added to the media of suspension-cultured cells, RALF causes an alkalinization of the cell medium of approximately one pH unit, a characteristic response of other plant peptide hormones.[14,18,20] Crude protein extracts from tobacco leaves obtained in acidic conditions are rich in bioactive peptides.[19] As peptides from the extracts elute from HPLC columns, small aliquots from each fraction (1–10μL) are added to 1mL of suspension-cultured cells that are growing at a pH near 5. The fractions containing bioactive peptides are identified by the increase in pH of the cell medium that takes place within a few minutes after their addition to the cell cultures.[18,19] A peptide identified in the assay that caused an exceptionally rapid alkalinization response was called RALF and was isolated and characterized.[19] Homologous RALF peptides from tomato and alfalfa leaf extracts have been similarly identified and purified. The peptides have four cysteine residues that form two disulfide bridges, no other posttranslational modification has been found in the peptides and all have equivalent activities when assayed with tomato or tobacco cells. Chemically synthesized tomato RALF is as active as the native tomato RALF in the alkalinization assay.[19] RALF peptides from the model forest tree poplar and from the monocot sugarcane have also been biochemically isolated and proved to elicit similar responses in the alkalinization assay.[9,15]

STRUCTURE OF RALF

The tobacco *RALF* gene encodes a preproRALF precursor protein of 115 amino acids with the RALF sequence of 49 amino acids harbored within the C-terminal region of the protein.[19] This precursor contains six cysteines, with four in the active peptide region as disulfide bonds at Cys84–Cys94 and Cys107–Cys113 essential for its activity (Fig. 1A). The N-terminus contains a hydrophobic signal peptide typical of secreted proteins. A partial *Nicotiana benthamiana* RALF fused to the green fluorescent protein (GFP) confirms the extracellular location illuminating the ERECTA (ER) and the apoplast.[6] The primary structure is well conserved among different RALF isoforms.[19]

RALF precursor has also a dibasic site (Arg–Arg) just upstream of the active peptide, which is characterized by recognition sites for processing. *Arabidopsis* plants overexpressing the *AtRALF1* gene with a mutation at the second Arg of the dibasic site (R69A) do not show the characteristic semidwarf phenotype of AtRALF1 overexpressors.[12] Plants harboring the mutated *AtRALF1* gene show normal root and leaf growth with accumulation of the mutated proprotein and nearly undetectable levels of the processed peptide.[12] Similar results are obtained when the dibasic site of the AtRALF23 isoform is mutated. A subtilisin-like serine protease AtS1P is responsible for the AtRALF23 processing and release of the active peptide.[24]

FIGURE 1 RALF amino acid sequences. (A) Tobacco preproRALF. Signal peptide (underlined) and active peptide (double underlined) are indicated. Asterisks are above the two Arg implicated in processing and connected arrows point the Cys involved in disulfide bonds. (B) Amino acid sequences of tomato RALF-derived peptides used to determine activity in the alkalinization assay. Full alkalinization activity (+++++) was measured after 15min of the addition of 250nM of each peptide.[21]

The molecular weight of RALF is larger than defense-related peptides, such as systemins, and this only compounds the difficulty of identifying critical amino acids for their physiological effects. A structure–activity study revealed that the carboxy-terminal 33 amino acids, RALF(17–49), and the amino-terminal 16 amino acids, RALF(1–16), whether added alone or together exhibit no activity.[21] Sequential additions of four amino acid segments to the RALF(17–49) show that the activity is only recovered when the conserved motif YISY is added to the peptide. Sequential addition of four and eight amino acids, RALF(13–49) and RALF(9–49) respectively, does not restore the alkalinizing activity. Ala substitutions in the YISY motif further show that a substitution of the Ile at position six abolishes the activity. A deletion of the Leu at position 11, ΔL^{11}RALF(5–49), also causes a severe reduction in activity, showing that the amino and the carboxy terminus of RALF must be in the proper spatial arrangement (Fig. 1B).[2,21]

DISTRIBUTION OF THE mRNA/PEPTIDE

RALF, along with other peptide hormones, such as phytosulfokine and CLAVATA3, has highly conserved homologs throughout the plant kingdom.[3,19,26] RALF genes have now been identified and isolated in different tissues and organs from several species including poplar leaves, *Arabidopsis* pollen, *Solanum chacoense* ovule and ovary, *Primula vulgaris* pollen, *Nicotiana attenuata* plant, *Medicago truncatula* roots, soybean pollen, tomato pollen, broccoli flowers, and *Brassica campestris* flower buds.[1,4,5,7–9,11,13,25,27] RALF genes are found as a single copy, as is the case for *N. attenuata*, or as multigene families. *Arabidopsis* has a large family of 34 preproRALF homologs (AtRALFs) with C-terminal coding regions of various degrees of sequence identity with tobacco leaf preproRALF.[17,25] A subgroup of nine RALF homologs within this multigene family shows the highest primary structure identity to the original RALF isolated from tobacco leaves. *In silico* expression data of these nine RALF homologs show tissue specificity for some homologs, AtRALF1 and AtRALF4 for instance, and an almost ubiquitous expression for others, like AtRALF22, AtRALF23, and AtRALF33 (Fig. 2).[19]

In ovarian tissues of *S. chacoense*, five preproRALF cDNAs are present and expressed during fruit maturation.[7] Besides reproductive tissues, the five genes are differentially expressed in other parts of the plants, including roots, stems, and leaves. RALF peptides were purified from hybrid poplar leaves and two unique cDNA clones that code for RALF genes were identified in a poplar cDNA library.[9] Both cDNAs are differentially expressed in tissues of poplar saplings. Several RALF cDNAs have been isolated from pollen. A tomato RALF found in pollen (SlPRALF) has been implicated in the regulation of pollen tube elongation.[5] In *P. vulgaris*, a RALF-like cDNA was identified and its expression suggests an involvement in pollen maturation.[13]

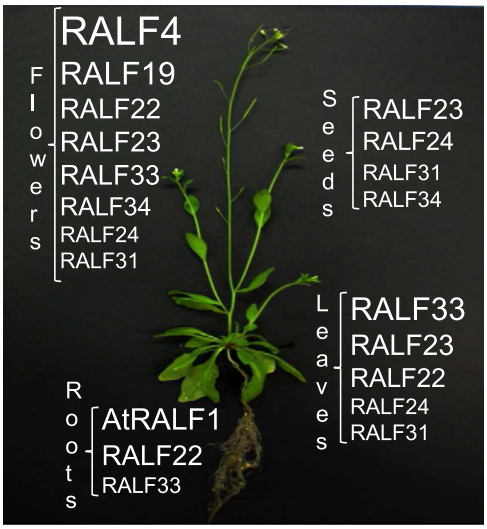

FIGURE 2 Tissue-specific expression of nine RALFs from *Arabidopsis* (AtRALFs) with high sequence identity to tobacco RALF. Font sizes used for AtRALFs indicate the level of expression of each isoform. Expression levels were obtained from eFP Browser at the Bio-Array Resource for Plant Biology.

A soybean pollen transcriptome survey identified a RALF cDNA as one of the top 30 most highly upregulated transcripts.[8]

Two RALF peptides were purified from the monocot sugarcane and gene expression analysis of four RALF genes (*SacRALFs*) showed low or almost undetectable gene expression levels in expanded leaves.[15] In expanding tissues, such as the base of half-emerged leaf blades, SacRALF transcripts are at high levels. The same transcripts are found at low levels at the apical portion, where cell expansion has stopped.[15] RALF gene expression has been associated with nodule formation in legumes and expression analysis of a RALF-like gene from *M. truncatula* shows upregulation upon treatment with nodulation factors.[4,23]

BIOLOGICAL FUNCTIONS

When added to the extracellular medium of suspension cells, RALF peptide causes an increase in the pH followed by the activation of an MAP kinase.[19] RALF also inhibits root growth and development of *Arabidopsis* and tomato seedlings when exogenously applied.[19] RALF inhibition of root growth is not a consequence of injury in the cells or a change in its morphology (Fig. 3). Gene expression profiles of RALF genes from several species also suggest a developmental role.[5,7,9,13,17] RALF peptide regulates the extracellular pH at the root hair tip during root hair development and also mobilizes extracellular and intracellular Ca^{+2}.[10,25] The pollen-specific RALF from tomato does not affect pollen viability but inhibits pollen tube elongation in a specific developmental window.[5,27] RALF peptides isolated from sugarcane (*Saccharum* spp.) leaves when added to culture media inhibit growth of microcalli derived from cell suspension cultures. Microcalli exposed to exogenous SacRALF also show a reduced number of elongated cells. Two RALF isoforms from *Arabidopsis*, AtRALF1 and ATRALF23, when overexpressed, produce semidwarf plants.[12,16] AtRALF23 gene is down regulated in response to treatment with brassinolide (BL) and it appears that AtRALF23 counteracts BL growth-promoting effects, since plants overexpressing AtRALF23 show a diminished response to BL treatments.[24] A clear picture of the function of the RALF peptide in plants is still lacking. However, all evidence points toward a role in plant development, more specifically cell elongation.[5,15,25]

RECEPTORS AND SIGNALING CASCADES

Two membrane proteins of 25 and 120kDa were identified on the external surface of suspension-cultured tomato cells by use of a photoaffinity analog of RALF.[22] Kinetic analyses indicate that the binding of RALF involves high affinity sites that are saturated at 2nM RALF. Unlabeled RALF strongly competes with labeling with the fully active

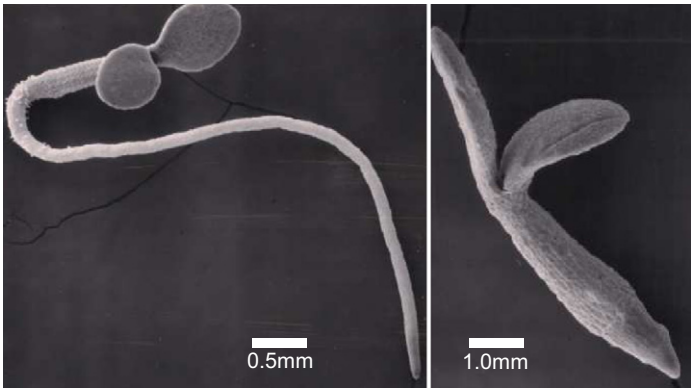

FIGURE 3 Scanning electron microscopy images of *Arabidopsis* seedlings treated with water (left panel) or with 10μM RALF (right panel).

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

photoaffinity analog of RALF at a concentration as low as 2nM, and is completely blocked at 200nM, while two biologically inactive RALF analogs do not compete.[22] Suramin, an inhibitor of peptide ligand receptor interactions in animals and plants, is also a potent competitor of labeling. The properties of the two labeled proteins suggest that both are integral membrane components of the RALF receptor. While RALF–receptor interactions result in the alkalinization response and the activation of an MAP kinase, the mechanism of signal transduction remains obscure. A screening for cell signaling peptides able to induce changes in cytoplasmic Ca^{2+} of *Arabidopsis* seedlings identified AtRALF1 peptide.[10] AtRALF1 induces an increase in Ca^{2+} levels in approximately 40s and is able to reach its maximum at nanomolar concentrations. The increase in cytoplasmic Ca^{2+} was inhibited by pretreating seedlings with EGTA or inhibitors of IP_3-dependent signaling, LiCl and neomycin, indicating that Ca^{2+} is mobilized from the extracellular and intracellular compartments.

Chapter 10

Root Meristem Growth Factor

Yoshikatsu Matsubayashi

ABSTRACT

Root meristem growth factor (RGF) is a 13-amino acid tyrosine-sulfated peptide involved in the maintenance of the root stem cell niche and regulation of meristematic activity in *Arabidopsis*. RGF1 was identified in a search for sulfated peptides that recover root meristem defects of the loss-of-function mutant of tyrosylprotein sulfotransferase. This approach is based on the assumption that phenotypes of loss-of-function mutants of posttranslational modification enzymes reflect deficiencies in the biosynthesis of all the functionally modified peptides. RGFs are produced from ~100-amino acid precursor peptides via posttranslational sulfation and proteolytic processing. Peptides of the RGF family are expressed mainly in the stem cell area and the innermost layer of central columella cells, and diffuse into the meristematic region. RGF peptides regulate root development by regulating expression levels and patterns of PLETHORA transcription factors, which are essential for the maintenance of the root stem cell niche and transit-amplifying cell proliferation.

DISCOVERY OF RGF

Secreted peptide hormones in plants often undergo complex posttranslational modifications that are mediated by specific enzymes, which recognize particular sequences of multiple target peptides. Because such modifications are generally critical for the functions of individual peptide hormones, the presence of novel peptide hormones should be revealed through phenotypic analysis of the mutants of posttranslational modification enzymes.

Tyrosine sulfation is a posttranslational modification that has been found in peptide hormones in both animals and plants.[9] This modification is mediated by tyrosylprotein sulfotransferase (TPST), which catalyzes the transfer of sulfate to the phenolic group of tyrosine. *Arabidopsis* TPST (AtTPST) is a type I transmembrane protein localized in *cis*-Golgi.[5] The loss-of-function mutant of *AtTPST* (*tpst-1*) shows stunted root phenotype accompanied by loss of maintenance of stem cells and a considerable decrease in meristematic activity (Fig. 1). Because *AtTPST* is a single copy gene, phenotypes of *tpst-1* mutant should reflect the deficiency in the biosynthesis of all the functional tyrosine-sulfated peptides found in *Arabidopsis*. Interestingly, two sulfated peptide hormones, PSK[7] and PSY1,[2] promoted cell elongation activity of *tpst-1* roots but did not restore the meristematic activity, indicating that tyrosine-sulfated peptide(s) other than PSK and PSY1 is involved in the maintenance of root stem cells and regulation of meristematic activity.

To identify this peptide signal, genes encoding possible sulfated peptides in the *Arabidopsis* genome were screened by an *in silico* approach. Known sulfated peptide hormones, PSK and PSY1, are encoded by multiple paralogous genes whose primary translated products are about 70- to 110-amino acid cysteine-poor (Cys < 6) peptides/polypeptides that contain secretion signal and Asp-Tyr sequences as a minimal tyrosine sulfation motif.[2,6] Based on these criteria, 34 candidate peptides/polypeptides were selected from 31,835 open reading frames in *Arabidopsis*. The RGF family was identified by determining their mature peptide structures followed by testing their activities to recover root meristem defects of *tpst-1* mutant.[8]

STRUCTURE, EXPRESSION, AND BIOLOGICAL FUNCTIONS OF RGF

The RGF family consists of nine gene members that encode peptides/polypeptides with a C-terminal conserved domain containing Asp-Tyr sequences.[8] Mature RGF1 is a 13-amino acid in length, carries a tyrosine sulfation, and derives from the C-terminal conserved domain of the precursor peptide through proteolytic processing (Fig. 2). Chemically synthesized mature RGF1 peptide restores stem cells and meristematic activity of *tpst-1* to a level comparable to that of the wild type when added in the culture medium (Fig. 3). Root meristem activity of *tpst-1* was also recovered, albeit to varying degrees, by the application of the synthetic sulfated peptides corresponding to the 13-amino acid conserved domain of the other members of this RGF peptide family.

RGF1 is specifically expressed in quiescent center cells and columella stem cells in the root tip (Fig. 4A). RGF2 and RGF3 are mainly expressed in the innermost layer of central columella cells. RGF4 shows a diffused expression pattern in the stem cell region. Secreted RGFs diffuse into the meristematic region (Fig. 4B). Although single loss-of-function mutants of RGFs do not exhibit any obvious phenotypes in roots, the *rgf1 rgf2 rgf3* triple mutant shows a short root phenotype characterized by the decrease in meristematic cell number, indicating that RGFs function redundantly.

MOLECULAR TARGET OF RGF SIGNALING

Although RGF receptors remain to be identified, one of the molecular targets of RGF signaling is PLETHORA (PLT) transcription factors. Involvement of PLTs in RGF signaling was identified by analysis of the response of several root-specific transcription factor mutants to RGF1 by exogenous application of RGF1 peptide.[8] The loss-of-function mutant of *PLETHORA* (*PLT*) transcription factors is less sensitive to RGF1. *PLT* genes, specifically expressed in root meristem, encode AP2-domain transcription factors that mediate patterning of the root stem cell niche.[1] PLT proteins display gradient distributions with

maxima in the stem cell area, and this gradient is essential for maintenance of the root stem cell niche and transit-amplifying cell proliferation.[4] High levels of PLT activity promote stem cell identity and maintenance; lower levels promote mitotic activity of stem cell daughters; and further reduction in levels is required for cell differentiation.

In wild-type seedlings, PLT proteins show gradients that extend into the region of transit-amplifying cells or the elongation zone. This expression pattern of PLTs correlates well with the localization of RGF peptides (Fig. 4C). By contrast, PLT protein expression regions were considerably reduced, with weak expression in the meristematic zone in *tpst-1* or *rgf1 rgf2 rgf3* triple mutant seedlings.[8] Importantly, externally added RGF1 restores PLT protein expression levels and patterns in *tpst-1* without affecting *PLT* gene expression levels. Thus, RGF defines PLT expression levels and patterns mainly at posttranscriptional levels, possibly through stabilization of PLT proteins.[4]

Longitudinal auxin concentration gradients generated by the PIN auxin efflux facilitator network have been believed to underlie the gradient distribution of PLTs.[3] Discovery of RGF peptide signals, however, indicates that the regulatory system for PLTs is more complex than was previously thought. It will be very important to unravel how individual cells perceive and integrate the concentration-dependent information provided by RGFs and auxin to generate precise root meristem patterning during root development.

Chapter 11

ROTUNDIFOLIA4

Takahiro Yamaguchi, Momoko Ikeuchi and Hirokazu Tsukaya

ABSTRACT

In *Arabidopsis thaliana* (Arabidopsis), a dominant mutation in the ROTUNDIFOLIA4 (ROT4) gene results in a short-leaf phenotype with decreased cell proliferation, specifically along the proximodistal axis. *ROT4* encodes a peptide of 53 amino acids, which belongs to a plant-specific ROT-FOUR-LIKE/DEVIL (RTFL/DVL) family with 23 members in Arabidopsis. These members share a highly conserved RTF domain in the C-terminus, which serves as the core functional region. We have shown that ROT4 is not subjected to proteolytic processing and acts locally. We also propose that ROT4 is involved in the regulation of positional cues and polarized cell proliferation for multiple aspects of Arabidopsis development.

DISCOVERY

There are more than a dozen plant peptides which function as key players in diverse signaling pathways in plant development.[3] *ROT4* was identified by a gain-of-function genetic screen for genes affecting leaf development in *Arabidopsis thaliana* (Arabidopsis).[11] In an activation-tagging pool, one family displaying short, rounded leaves, and floral organs, and relatively short stems was isolated. Segregation analysis in the T_2 generation indicated a single dominant mutation, which was linked to the enhancer-containing T-DNA insertion. Thus, the mutation was named *rot4-1D*.[11]

Genomic sequence analysis around the T-DNA insertion shows a small potential open reading frame (ORF) of 53 amino acids, which was overlooked by the gene annotation program. Reverse transcription-polymerase chain reaction (RT-PCR) analysis shows that the mRNA corresponding to this small ORF accumulates at a higher level in the *rot4-1D* mutant than in the wildtype (WT). Moreover, overexpression of the full coding region of the ORF under the constitutive *35S* promoter results in the *rot4-1D* phenotype in Arabidopsis. These results indicate that the ORF comprises the *ROT4* gene.[11]

In Arabidopsis, several genes have been identified in the polar control of cell expansion and cell proliferation along the two planer leaf axes, the proximodistal (leaf-length) and the central-lateral (leaf-width) axes. For example, *ROTUNDIFOLIA3* and *ANGUSTIFOLIA* regulate leaf cell expansion along the proximodistal and mediolateral axes, respectively.[7,8,13] In *rot4-1D* mutants, the length of the leaf blades and petioles is severely shortened, while their width is only slightly affected (Fig. 1A, B). Closer observation shows that cell number, but not cell size, is greatly reduced specifically along the proximodistal axis in *rot4-1D* leaves.[11] These observations suggest that *ROT4* negatively regulates cell proliferation along the proximodistal axis when overexpressed.

STRUCTURE OF THE PEPTIDE

The longest *ROT4* cDNA sequence is 430bp and contains a 159-nt ORF encoding a putative 53 amino acid peptide.[11] There is no intron in the *ROT4* gene, and the deduced ROT4 peptide has a molecular mass of 6.2kDa. Database analysis has revealed 23 other putative Arabidopsis proteins homologous to ROT4; they have been designated the ROT-FOUR-LIKE/DEVIL (RTFL/DVL) family.[11,14] *RTFL/DVL* genes are found widely in angiosperm genomes and form a multigene family. For example, 26 *RTFL/DVL* genes (*OsRTFL1-26*) have been identified in the *Oryza sativa* genome. *RTFL/DVL* genes are also present in *Physcomitrella patens* (a moss) and *Selaginella moellendorffii* (a lycophyte) genomes.[2] No homologs were discovered from green algae.

Overexpression of at least six members of the RTFL/DVL family in Arabidopsis produces phenotypes similar to the *rot4-1D* mutant.[15] Overexpression of any of several *O. sativa RTFL/DVL* genes in Arabidopsis also results in the short-leaf phenotype, indicating that RTFL/DVL family members share similar protein function.[16] In *Medicago truncatula*, *MtDVL1* is expressed at the early stages of nodule formation and its overexpression abolishes nodulation.[1] Because the cell cycle is reactivated during nodule formation, *MtDVL1* could also be involved in the regulation of cell proliferation. Thus, the *RTFL/DVL* genes are widely conserved in land plants and may play an essential role in plant life.

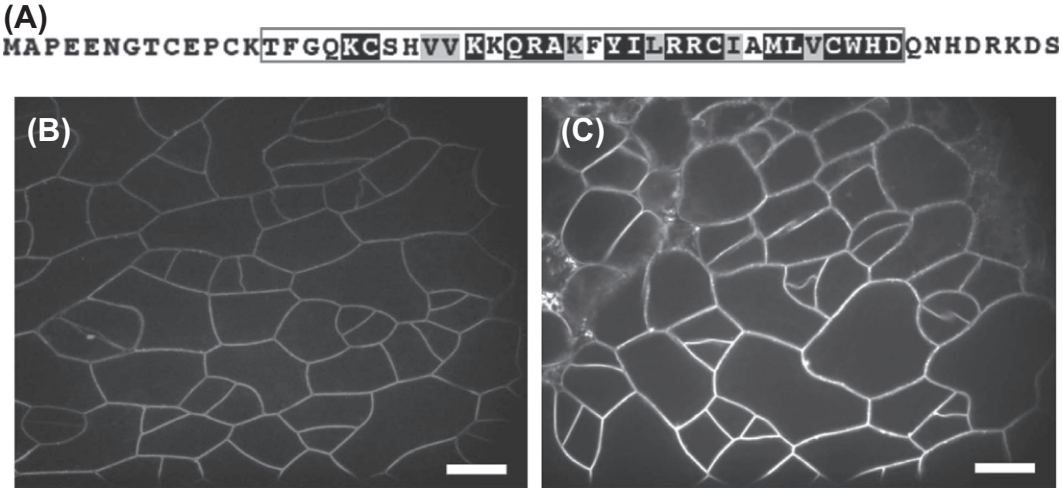

FIGURE 2 Structure of RTFL/DVL protein and intracellular localization of ROT4. (A) Amino acid sequence of ROT4. Black background shows highly conserved residues in the RTFL/DVL family, while gray background shows less-conserved residues. Box indicates the estimated core functional region. (B, C) Subcellular localization of ROT4-GFP (B) and of GFP-ROT4 (C) in Arabidopsis leaves. Scale bars = 10μm. Reproduced from Ref. 6 with permission.

RTFL/DVL proteins share a highly conserved region of approximately 30 amino acids in the C-terminus called the RTF domain, while the N-terminal region is less conserved among RTFL/DVL members and no predictable signal peptide has been identified (Fig. 2A).[11] The RTF domain is rich in basic amino acids, and does not show similarities to other proteins of known function. Overexpression of the conserved domain is sufficient and necessary to reproduce the *rot4-1D* phenotype.[11,15] We identified the precise functional region of ROT4 by overexpressing a series of truncated versions of *ROT4*. The results indicate that the core functional region of ROT4 consists of the 32 amino acid residues surrounding the RTF domain (from T14 to D45), with one or two additional adjacent amino acids required for full ROT4 activity (Fig. 2A).[6]

Plant peptides often undergo posttranslational proteolytic processing, which is essential for their function.[9] The

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

highly conserved single or dibasic residues at the start of the conserved RTF domains have been hypothesized to serve as part of the recognition site for processing RTFL/DVL peptides from the precursor protein.[4,15,16] However, our study suggests that ROT4 is not subjected to proteolytic processing *in planta*. Overexpression of both GFP-ROT4 and ROT4-GFP fusion proteins produces a short-leaf phenotype similar to that of *rot4-1D*. By immunoblotting analysis with an anti-GFP (anti-green fluorescent protein) antibody, we detected the fusion protein (GFP-ROT4 or ROT4-GFP), but not free GFP, in each overexpression line.[6] Thus, ROT4 may be a unique peptide that can function without proteolytic processing.

DISTRIBUTION OF THE mRNA/PEPTIDE

Expression studies using RT-PCR show that *ROT4* is weakly expressed in flowers, shoots, and roots.[11] *ROT4* is expressed in leaves during the early stages of development, but it is not expressed in mature leaves. More precise localization of *ROT4* mRNA remains to be performed because clear signals cannot be obtained by in situ hybridization analysis in WT Arabidopsis plants. Preliminary analysis of a reporter β-glucuronidase (GUS) expression, driven by the 1.2-kb 5′-region of the *ROT4* translation start site, shows strong GUS localization in the petioles of young leaf primordia.[16] GUS expression becomes weaker as a leaf develops, indicating that the *ROT4* gene functions in young leaf primordia, the site of active cell proliferation.

BIOLOGICAL FUNCTIONS

Loss-of-function phenotypes of RTFL/DVL members are unknown. A single loss-of-function mutant did not produce any detectable phenotype in either Arabidopsis or *O. sativa*,[11] probably because of extensive functional redundancy among the more than 20 RTFL/DVL members. Generation of multiple loss-of-function mutants in *RTFL/DVL* genes is necessary to better understand their roles in WT development.

On the other hand, overexpression of *ROT4* inhibits cell proliferation specifically along the proximodistal axis in leaves, which results in the short-leaf phenotype. The effect of *ROT4* overexpression is also observed in other lateral organs, such as petals and carpels. In contrast, the effect is relatively mild in stems.[11] Thus, *ROT4* is more strongly associated with lateral organs that exhibit the development of determinate organ.

Decreases in the number of cells in the leaf could be caused by shortening of the cell proliferation period or by reduction in the cell proliferation rate. To distinguish these possibilities, we performed a time-course analysis of cell proliferation activity during leaf development. Results revealed that the rate of cell proliferation is lower in *rot4-1D* compared with the WT, while the duration of cell proliferation is not shortened in *rot4-1D* (Fig. 1C).[6] To further clarify ROT4 function, we also visualized proliferating cells in leaf primordia using the reporter construct *pCYCB1;1:CYB1;1-GUS*. We found that the size of the meristematic zone is reduced proximally in *rot4-1D* leaf primordia.[6] Therefore, ROT4 negatively regulates the rate of cell proliferation by reducing the size of the meristematic zone along the proximodistal axis during leaf development.

We also examined the effect of local overexpression of *ROT4* in developing leaves using an inducible chimera system.[5] When *GFP-ROT4* is overexpressed on one side of the leaf, the leaf blade–petiole boundary on that side is shifted proximally (Fig. 3A, B).[6] This result suggests that *ROT4* could be involved in the determination of organ boundary and positional cues along the proximodistal axis in leaf primordia.

In addition to the short-leaf phenotype, overexpression of *ROT4* shows an abnormal turning phenotype in pedicels or secondary inflorescence stems (Fig. 3C, D). Closer histological observation revealed that the boundary between pedicels or secondary inflorescence stem and the main inflorescence stem forms at this sharp turning point.[6] This observation has been confirmed using morphogenetic and molecular markers for the boundary. Thus, at the base of pedicels, the main inflorescence stem abnormally protrudes in overexpression of *ROT4*, which results in the turning phenotype seen in pedicels or secondary inflorescence stems. A similar protrusion phenotype is also observed at the base of trichomes during overexpression of some *RTFL/DVL* genes (Fig. 3E, F).[6,15] These phenotypes could be explained by a shift in the boundary or positional cues in inflorescences and at the base of trichomes, similar to the disturbance in positional cues observed upon local overexpression in leaves. Thus, it is possible that *ROT4* is involved in the determination of positional cues during various aspects of shoot development.

RECEPTORS AND SIGNALING CASCADES

Most small peptides are thought to function as peptide hormones, which are secreted into extracellular spaces and interact with specific receptors.[12] The lack of predicted signal sequences in ROT4 protein suggests that ROT4 does not enter the secretory pathway, although some plant peptides with no signal sequences are known to be secreted by non-canonical pathways.[9,12] When GFP-ROT4 is overexpressed on one side of the leaf, the petiole on the induced side is significantly shortened, while the petiole on the opposite side is not (Fig. 3A, B).[6] This result excludes the possibility of the long-distance transport of ROT4, although it is still possible that ROT4 moves locally to the neighboring cells.

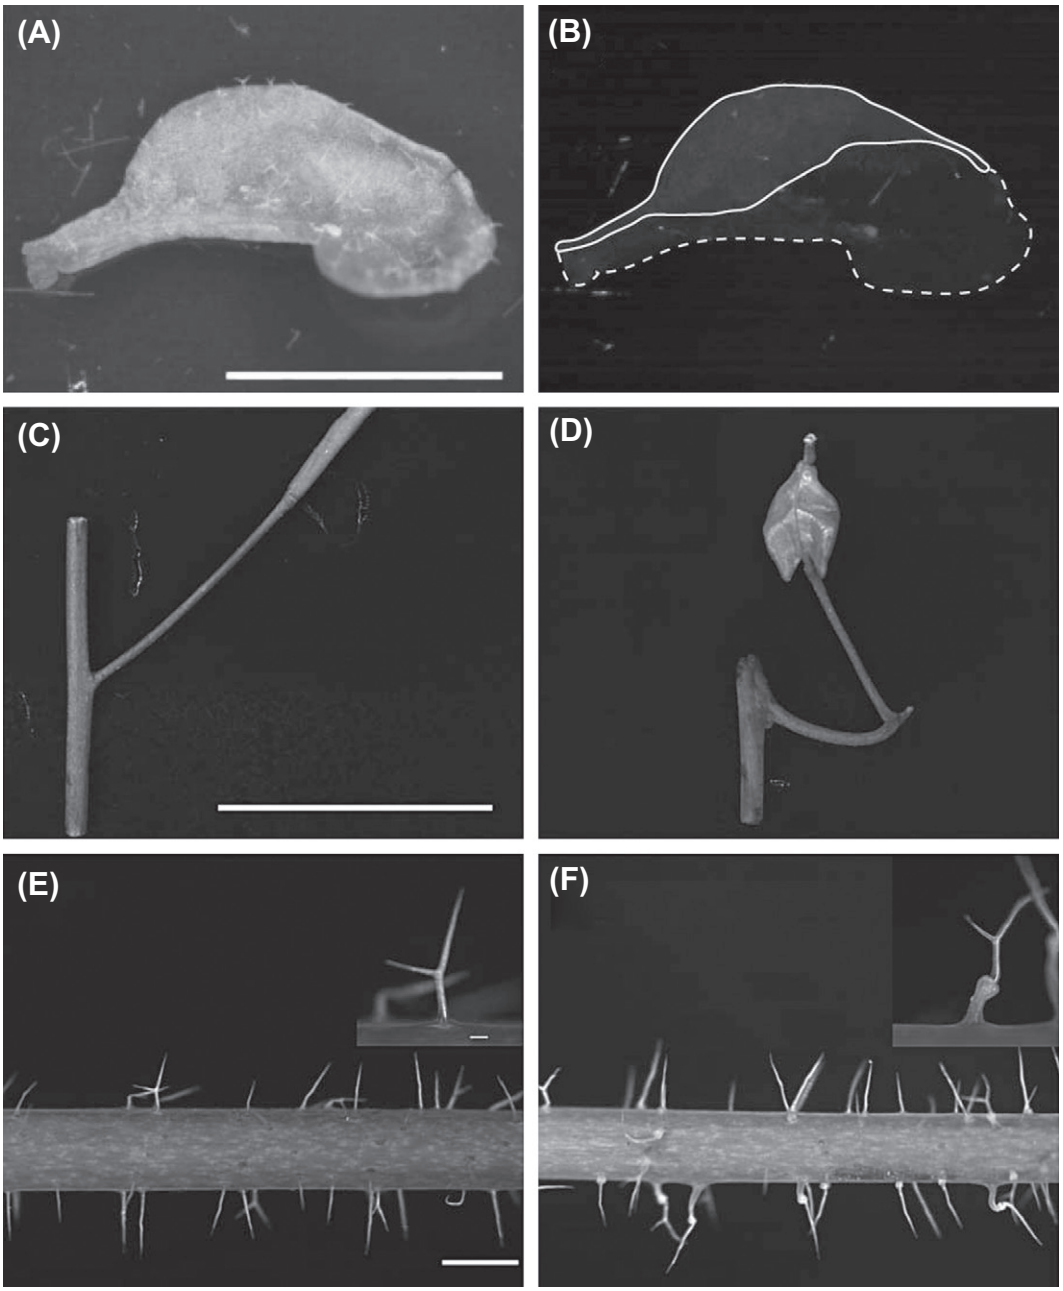

FIGURE 3 Leaf phenotype of localized overexpression of ROT4 and pleiotropic phenotypes of overexpression of ROT4. (A, B) A leaf with a sector overexpressing GFP-ROT4 in the marginal part. (A) A bright field image. (B) A fluorescent image. The sector with GFP fluorescence is outlined by a white line, and the remaining leaf part is outlined by a dashed line. (C, D) A pedicel in the WT (C) and in the overexpression of ROT4 showing a turning phenotype as a result of a protrusion of the inflorescence stem (D). (E, F) Trichome on the stem in the WT (E) and in the overexpression of ROT4 showing a protrusion of the trichome base (F). Bars = 5mm (A), 1mm (C), and 0.1mm (E). Reproduced from Ref. 6 with permission.

On a subcellular level, both the ROT4-GFP and GFP-ROT4 fusion proteins are localized to the plasma membrane and also to a limited number of small foci in the cytoplasm upon overexpression (Fig. 2B, C).[6,11] The appearance of a short-leaf phenotype in both overexpression lines suggests that the observed localization of ROT4 in the plasma membrane and in small cytoplasmic foci reproduces native intracellular localization. Because a transmembrane domain does not exist in ROT4, the protein could be a part of a protein complex localizing to the plasma membrane. Identification of protein partners of ROT4 and their loss-of-function mutants would greatly reveal insights into the role of ROT4 in WT development.

The downstream signaling cascade of RTFL/DVL is also of interest. RT-PCR analysis revealed that overexpression of

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

the *DEVIL1 (DVL1/RTFL18)* gene results in down regulation of the MADS-box gene *FUL/AGL8*.[14] Because *FUL/AGL8* is involved in the regulation of fruit development, down regulation of this MADS-box gene may be related to the abnormal fruit morphology seen in overexpression of *RTFL/DVL* genes. Microarray analysis with inducible overexpression of *DVL4* identified 422 genes whose expression is strongly up or down regulated.[10] Laure et al. reported that, among them, *NAC1* expression is strongly upregulated by the induction of *DVL4*. *NAC1* encodes an NAC-domain transcription factor and is involved in the development of auxin-mediated lateral root in Arabidopsis. When a loss-of-function mutant of *NAC1* is crossed with *dvl1-1D*, all the phenotype characteristics of *dvl1-1D* are largely suppressed in the F1 plants, while the *DVL1* mRNA is still overexpressed. The effect of suppression persists in the F2 and F3 descendants, even in siblings homozygous for the WT *NAC1* allele, suggesting an epigenetic interaction between them.

In summary, the ROT4 peptide represents a unique component required for polarized cell proliferation and determination of positional cues in plant development. Key questions to be addressed include the clarification of the loss-of-function phenotypes, the identification of protein partners, and the elucidation of the signaling cascade downstream and upstream of the RTFL/DVL family. Further studies would greatly improve our understanding of the regulation of polarized growth in plants as well as the diverse roles of plant peptides.

Chapter 12

SCR

Sushma Naithani, Palitha Dharmawardhana and June B. Nasrallah

ABSTRACT

The S-locus cysteine-rich protein (SCR) is a basic protein of about 6kDa that functions in the self-incompatibility (SI) response of the Brassicaceae. SI is a genetic system that prevents self-pollination by disrupting the interaction between pollen grains and the epidermal cells of the stigma, a specialized structure that caps the female reproductive apparatus. *SCR* is genetically and physically tightly linked to the gene for its receptor, the stigma-expressed single-pass transmembrane serine/threonine kinase S-locus receptor kinase (SRK). Like SRK, SCR is highly polymorphic, yet its variants adopt a conserved three-dimensional structure consisting of an α-helix and a triple-stranded antiparallel β-sheet stabilized by four intramolecular disulfide bonds. The allele-specific interactions of SCR with SRK, which underlie specificity in the SI response, trigger a signal transduction cascade within the stigma epidermal cell that leads to the inhibition of pollen tube growth. SCR is the prototypic member of the *SCR*-like (*SCRL*) family of genes, several of which might also function in plant reproduction.

DISCOVERY OF SCR

The *S*-locus cysteine-rich protein SCR, also known as SP11, was discovered in a search for the pollen determinant of self-incompatibility (SI) in the Brassicaceae (crucifer) family. SI is a generic term that encompasses several evolutionarily and mechanistically divergent systems that share one common feature, namely, the inhibition of self-pollination. The information provided here relates specifically to the SI system that operates in the Brassicaceae family, and *SCR* homologs are not expected to be present in families that use a different SI system.

The SI system of Brassicaceae is controlled by a single locus, the *S* (Sterility) locus [for recent reviews, see Refs 17, 32]. In self-incompatible members of the Brassicaceae [such as cultivated *Brassica oleracea* (includes cabbage, broccoli, kale, etc.), *B. rapa* (syn. *campestris*; includes Chinese cabbage, oil seed crops), *B. napus* (includes oil seed crops), as well as *Raphanus sativus* and *Arabidopsis lyrata*], pollinations between plants that express the same *S*-locus variant are prevented by the arrest of pollen tube development at the surface of the epidermal cells of the stigma, which are located at the tip of the female reproductive apparatus. Previous analysis of SI had indicated that the SI specificity-determining *S* locus, although behaving genetically as a single Mendelian locus, was a complex locus consisting of at least two genes, one encoding the stigma specificity determinant and the other encoding the pollen specificity determinant. Molecular analysis of the *S* haplotype had already identified the highly polymorphic *S*-locus receptor kinase (*SRK*) gene as the determinant of SI specificity in the stigma,[27,29] and detailed analyses of DNA flanking the *SRK* gene in various *S* haplotypes were initiated through long-range physical mapping coupled with transcriptional and sequence analyses.[6,21,28] In 1999, Schopfer et al. reported the isolation of *SCR* and provided the first experimental proof through loss- and gain-of-function experiments that *SCR* is required for SI and that it represents the pollen determinant of SI specificity.[21] A self-compatible γ-ray-induced induced mutant of *B. oleracea* that exhibits a pollen-specific defect in the SI response lacks *SCR* transcripts.[21] In addition, transformation of an S_2S_2 plant with an SCR_6 allele confers S_6 specificity on the pollen of transgenic plants.[21] Subsequent verification of these results was provided by additional transgenic experiments[25] and pollination bioassays in which SCR protein, either chemically synthesized or expressed in *E. coli*, was applied to stigmas and found to activate the SI response in an allele-specific manner.[10,31] Additionally, transformation of the self-fertile *Arabidopsis thaliana* with *A. lyrata* SRK_b and SCR_b genes showed that these two genes are sufficient to confer self-incompatibility in a self-compatible species.[15,16]

SCR Sequence Polymorphism

SCR alleles were first cloned from *Brassica* species (*B. rapa* and *B. oleracea*). The DNA sequence is now available for 20 *B. oleracea*, 23 *B. rapa,* 2 *B. napus*, and 10 *Raphanus sativus SCR* variants (http://www.ncbi.nlm.nih.gov/unigene). Additionally, *SCR* variants have been isolated from two other crucifer species [2]: one from *Capsella gradiflora* and a few from *Arabidopsis lyrata*, a self-incompatible close relative of the self-fertile model plant

A. thaliana, which diverged from *Brassica* approximately 15–20 million years ago.[35] The total number of *SCR* alleles within a particular species is predicted to be much higher, because each *S* haplotype must contain an *SCR* variant and *S* haplotypes can number as many as 100 in one species. Consistent with their SI recognition functions, both *SCR* and its receptor *SRK* are highly polymorphic genes that must coevolve to maintain their allele-specific interaction. The diversification of *Brassica S* haplotypes is believed to have taken place over 20–40 million years ago, before speciation in the crucifer family. *S* haplotypes have been grouped into two classes on the basis of sequence similarity of their *SRK* alleles. *SCR* alleles exhibit a particularly high level of intraspecific sequence divergence, as illustrated in Fig. 1 for a representative sample of SCR variants from *Brassica* species and *A. lyrata*. In *Brassica* class-I *S* haplotypes, the mature SCR proteins share between 20 and 76% amino acid similarity while their predicted signal sequences are more conserved.[21] By contrast, *Brassica* class-II SCR proteins exhibit a relatively high degree of similarity (63–94%) in the sequence of both their predicted signal peptide and mature forms.[22] When all available SCR sequences are aligned, it is clear that only eight cysteine residues (designated C1–C8, the glycine in G x C2, and an aromatic residue in C3xxxY/F are conserved in most SCR variants (Fig. 1).

Criteria for Identification of SCR Alleles in Various Species of the Brassicaceae

Because of the extensive polymorphism of *SCR* variants and the existence of *SCR*-like genes in the genomes of Brassicaceae,[34] identification of a cloned sequence as an *SCR* allele is not straightforward. Linkage to the *S* locus and *SRK* is the major and essential criterion for identifying an *SCR*-like sequence as a *bona fide* new *SCR* allele. Accordingly, the isolation of a candidate *SCR* sequence must be verified by genetic analysis of plant populations that segregate for different *S* haplotypes or by physical linkage to *SRK*. When *SCR* alleles are sought from a new Brassicaceae species, the isolation of *SCR* alleles requires the cloning of the *S* locus from large-insert genomic libraries with subsequent "chromosome walking" from *SRK* to the *SCR* gene as was performed for *Arabidopsis lyrata*.[11] This already laborious process is made even more complicated by the fact that *S* haplotypes within one species exhibit extensive structural heteromorphism, a feature that is thought to contribute to the apparent reduced recombination in the *S*-locus region and the maintenance of the tight linkage of the *SRK–SCR* gene pair.[4] Both the orientation of *SCR* relative to *SRK* and its physical distance from *SRK* can vary among *S* haplotypes.[4,11] In *Brassica*, *S* haplotypes range from approximately 10 to >200kb in size, and they

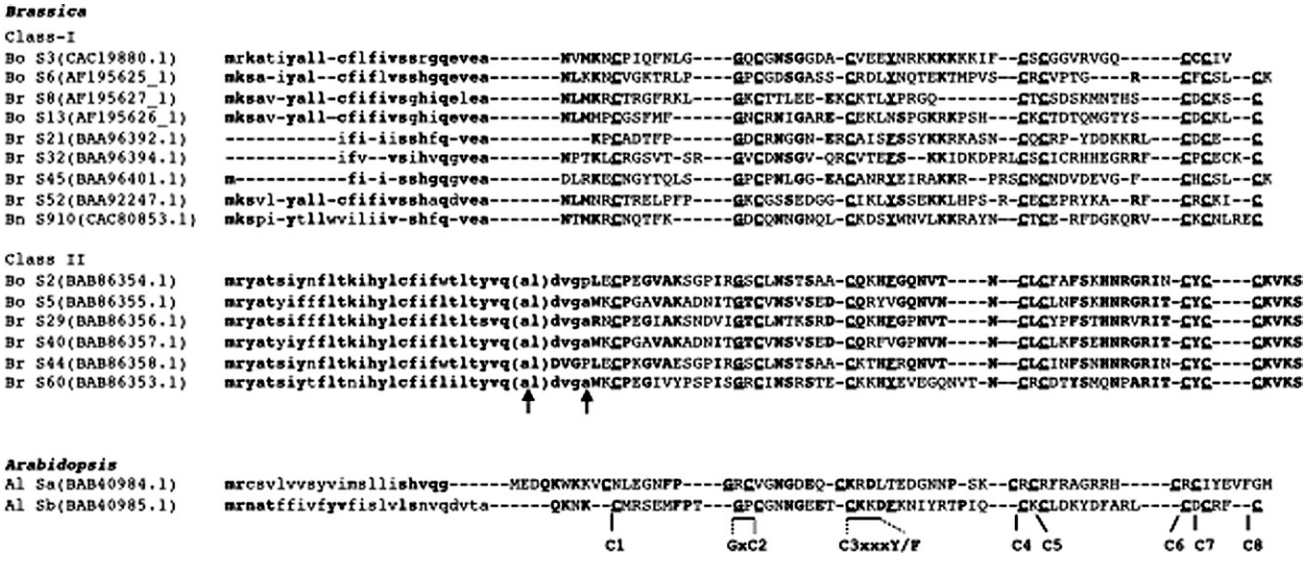

FIGURE 1 Multiple sequence alignment of the predicted amino acid sequences of SCR variants from various *S* haplotypes of different Brassicaceae species. The signal peptide sequence for each *Brassica* SCR variant is shown in lowercase letters. The SCRs from *Brassica oleracea* (Bo), *B. rapa* (Br), and *B. napus* (Bn) are arranged into class-I and class-II alleles, and two variants from *Arabidopsis lyrata* are grouped together. Residues that are conserved in most SCR variants within a group are shown in bold. Residues that are conserved among SCRs in the various groupings are underlined, and the consensus sequence motifs associated with some of these residues are shown below the alignment. In the class-II variants, arrows point to the predicted signal peptide cleavage sites in the proteins predicted from two alternative *Brassica* class-II *SCR* transcripts.[22] One form encodes an open reading frame of 95 amino acids that is predicted to produce a mature SCR protein of 66 amino acids after removal of the signal peptide (left arrow). The second form encodes a 93 amino acid protein that lacks two amino acids ("al" shown in parentheses), which would produce a mature SCR protein of 61 amino acids after cleavage of the signal peptide at an alternative cleavage site (right arrow).

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

also differ in their complement of retroelements and haplotype-specific intergenic sequences.[4,11] Additionally, some *S* haplotypes contain partial or complete duplications of the SI-specificity genes. For example, two identical copies of *SCR* are found in the S_b haplotype of *A. lyrata*[11] and three nonidentical copies were reported in the S_{15} haplotype of *B. rapa.*[24]

SCR Pseudogenes in Self-fertile Brassicaceae

Not all strains within a predominantly self-incompatible species and not all species in the Brassicaceae are expected to have functional *SCR* genes, because the loss of SI that underlies the switch to self-fertility in this family is often accompanied by inactivation of *S*-locus genes. Therefore, the *S* loci of self-fertile species may contain only nonfunctional remnants of these genes. For example, the reference Col-0 accession of the self-fertile model plant *A. thaliana* contains only three truncated *SCR* sequences and an *SRK* pseudogene.[11] Other accessions contain *SRK*-linked *SCR* sequences that are highly diverged from the Col-0 *SCR* sequences and some of these potentially encode full-length open reading frames.[3] However, it is currently not known if their SCR products have retained functionality.

STRUCTURE OF THE PRECURSOR mRNA GENE

Comparison of *SCR* genomic and cDNA sequences indicates that the *SCR* gene consists of two exons separated by an intron. The first exon contains a predicted signal sequence of 29–32 amino acids, and the second exon contains an open reading frame of 50–66 amino acids that corresponds to the mature SCR protein.[21,30] The size of the intron varies among *SCR* alleles from 0.3kb in *B. rapa* SCR_{12} to 4.1 kb in SCR_8.[21,30] A single approximately 450-bp processed *SCR* transcript is observed for some *S* haplotypes that contain either one copy of the *SCR* gene[21,28] or two identical *SCR* genes (e.g., the *A. lyrata* S_b haplotype[11]). However, >1 *SCR* transcript has been reported for the S_{15} haplotype of *B. oleracea*, which contains three nonidentical tandem copies of *SCR* (designated S_{15}-*SP11a*, S_{15}-*SP11b*, and S_{15}-*SP11b'*).[24] Only the first two of these genes are transcribed to produce transcripts of two different sizes, a 0.65-kb transcript resulting from cotranscription of S_{15}-*SP11a* and exon 1 of S_{15}-*SP11b* and a less abundant 1.4-kb transcript containing the full-length S_{15}-*SP11a* and S_{15}-*SP11b* sequences and exon 1 of S_{15}-*SP11b'*.[24] Additionally, two SCR transcripts generated by alternative splicing have been detected for some class-II *SCR* alleles (e.g., S_{29}, S_{40}, S_{60} of *B. rapa*),[22] and these transcripts are predicted to encode two mature protein forms differing by five amino acids (Fig. 1). The biological significance, if any, of these alternative transcripts is not known.

DISTRIBUTION OF THE *SCR* mRNA AND THE BASIS OF ALLELIC DOMINANCE IN HETEROZYGOTES

All *SCR* alleles exhibit anther-specific expression, although the details of this expression vary with the allele being studied. In situ hybridization and reporter gene analyses have shown that all *SCR* alleles examined to date are expressed in the tapetum[11,30] and a subset of *SCR* alleles, such as the *Brassica* class-I *SCRs* and the *A. lyrata SCRb* allele, are also expressed in microspores. *SCR* expression in the tapetum is probably the biologically relevant site of expression: It is clearly sufficient for SI, and it is consistent with the localization of the SCR protein in the pollen coat and with the genetic control of pollen SI phenotype in the Brassicaceae.[11,22,30] The tapetum is a layer of nurse cells that lines the anther cavities in which pollen grains develop, and it serves as a source of many components of the pollen coat. The tapetum degenerates at late stages of pollen maturation, and as a result, tapetum-expressed *SCR* transcripts are lost at late stages of anther development. Furthermore, the tapetum is derived from sporophytic (i.e., 2N) cells of the anther. Expression of *SCR* in the tapetum thus explains the sporophytic control of SI in the Brassicaceae, in which the SI phenotype of a pollen grain is controlled by the diploid genotype of its parental plant rather than by its own haploid genotype. Thus, the pollen grains produced by an S_1S_2 plant will be phenotypically S_1S_2 (assuming codominance of S_1 and S_2) because SCR_1 and SCR_2 are expressed in the tapetum and the SCR_1 and SCR_2 proteins will become incorporated in the pollen coat of all pollen grains, whether they carry the SCR_1 or SCR_2 allele.

A peculiarity of the *SCR* gene is that its expression can be influenced by other *SCR* alleles in heterozygous anthers.[12,22] Some *SCR* alleles exhibit genetic interactions of dominance recessiveness. For example, in *Brassica*, class-II *SCR* alleles are generally recessive to class-I *SCR* alleles, and in *A. lyrata*, SCR_a is recessive to SCR_b. In situ hybridization has shown that the recessive *SCR* allele is silenced in the presence of the dominant *SCR* allele, leading to the absence of recessive *SCR* transcripts and protein in heterozygous anthers.[12,22] The silencing of the recessive SCR allele in heterozygotes results from specific methylation of its promoter region.[23] This methylation is associated with the accumulation of a 24 nucleotide sRNA, termed *Smi* (SP11(SCR)-methylation inducer), which is derived from a noncoding transcript originating within the dominant *S* haplotype.[33] The sequence of *Smi* transcripts derived from the dominant S_9 haplotype (Smi_D) is almost identical to the targeted regions in the promoters of the recessive *SCR* alleles (18 out of 19 nucleotide for SCR_{29}, SCR_{60} and SCR_{44}) but not to the same region in the dominant SCR_9 allele. This observation explains the specific silencing of recessive *SCR* alleles in the presence of the

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

dominant allele. Interestingly, methylation of the promoter of the recessive *SCR* allele extends over approximately 300bp although the region that shares sequence similarity with the Smi_D transcript is only 18 bp long. How this spread of methylation occurs remains to be determined.

PROCESSING OF THE SCR PROTEIN

SCR variants differ in both length and amino acid composition (Fig. 1). Different *SCR* alleles predict open reading frames that range from 71 to 95 amino acids with a predicted signal peptide at their N terminus. For example, the mRNA sequence of the *B. rapa* SCR_8 allele predicts a 74 amino acid protein of approximately 8kDa, but the mature SCR protein extracted from the pollen coat was determined by mass spectrometric analysis to be 5.716kDa, which corresponds to 50 amino acids.[31] The primary SCR translational product is therefore processed by removal of the signal sequence that targets the protein for secretion. Although little biochemical characterization has been performed, the SCR protein is not apparently further processed or modified because SCR variants expressed in *E. coli*[10] or synthetic SCR[31] exhibit biological activity in pollination bioassays.

THE SCR RECEPTOR: THE *S*-LOCUS RECEPTOR KINASE (SRK)

The receptor for SCR, SRK, is encoded by a gene located within the *S* locus in tight genetic and physical linkage to *SCR*. *SRK* mRNA levels attain their highest levels in stigmas just before flower opening, which correlates with the onset of SI in the developing stigma.[27] The full-length *SRK* transcript encodes a protein that is expressed in the stigma epidermal cells and is integral plasma membrane protein.[26] SRK comprises an extracellular region (eSRK) of approximately 430 amino acids, followed by a single transmembrane domain, and a cytoplasmic serine/threonine kinase.[14] *SRK* alleles produce alternative mRNA transcripts[27] that produce a truncated protein equivalent to the eSRK in addition to the full-length SRK.[9] Interestingly, in *Brassica*, most *S* haplotypes contain a third gene, the *S*-locus glycoprotein (*SLG*) gene, which shares a high degree of sequence similarity with the *eSRK* sequence and is coordinately regulated with *SRK*.[7,9] Although SRK is clearly the sole determinant of SI specificity in the stigma, SLG is required for the accumulation of some SRKs to physiologically relevant levels,[7] and it can enhance the SI response in *SRK* transformants.[29] The eSRKs might have a role similar to that of SLG. Homology modeling of the eSRK suggests that this region consists of four structural modules: two N-terminal lectin-like domains (LLD1 and LLD2), followed by an EGF-like domain and a PAN_APPLE domain.[14] *In vitro* studies have suggested that the PAN_APPLE domain function in receptor dimerization.[14]

A major issue in understanding the SRK–SCR interaction is identification of the residues within eSRK that determine allele-specific interaction with the SCR ligand. Statistical analysis of multiple sequence alignments of eSRKs derived from several *Brassica* SRK variants identified three hypervariable regions and a less variable C-terminal region,[18] which were inferred to be targets for positive selection and potential candidates for residues involved in ligand recognition. However, experimental evidence was difficult to obtain because of the lack of efficient transformation methods in *Brassica*. This difficulty was recently overcome by the availability of a transgenic self-incompatible *A. thaliana* model system, which was generated by transformation with *SRK–SCR* gene pairs isolated from the self-incompatible species, *A. lyrata* and *C. grandiflora*.[2,15] Structure–function analysis of the eSRK in this *A. thaliana* model showed that only six residues occurring in two nonoverlapping clusters within the hypervariable regions are essential for allele-specific interaction between SRK and SCR and may form a ligand-binding pocket.[1] High-resolution three-dimensional structural analysis of the eSRK alone or in complex with its SCR ligand is required to confirm this hypothesis.

STRUCTURE OF SCR

The NMR structure of a synthetic SCR variant[13] and modeling of the 3-dimensional structures of several SCR variants are consistent with the conclusion that all SCR variants adopt a similar overall structure despite their extensive sequence divergence (Fig. 2). SCR is thought to fold into a compact α/β barrel structure made of a twisted three-stranded β-sheet backed by another layer formed by an α-helix with flanking loop regions. Four intramolecular disulfide bonds stabilize the structure. The disulfide bridges that link C2 to C5, C3 to C6, and C4 to C7 form the hydrophobic core of the molecule, whereas the C1–C8 bridge tethers the N and C termini. This structure is similar to that of plant defensins, with the difference being that the edges of the loop region between the α-helix and ß2 strand are extensively stabilized by disulfide bonds and hydrophobic packing in SCR. The aromatic (Y/F) residue that is conserved in many, but not all, SCRs (Fig. 1) appears to have a key role in stabilizing this loop, in part through its hydrophobic contact with C7. The conserved glycine in the G x C2 motif apparently facilitates the formation of a stable type-II β-turn in the flanking segment, connecting the β1 strand to the α-helix.

Structure–function Studies of SCRs

Structure–function studies of SCR variants have two aims: (i) to determine which residues, especially those conserved in most SCRs, are important for SCR function and (ii) to identify sequences that determine recognition specificity. While working with proteins encoded by the S_6 and S_{13} haplotypes

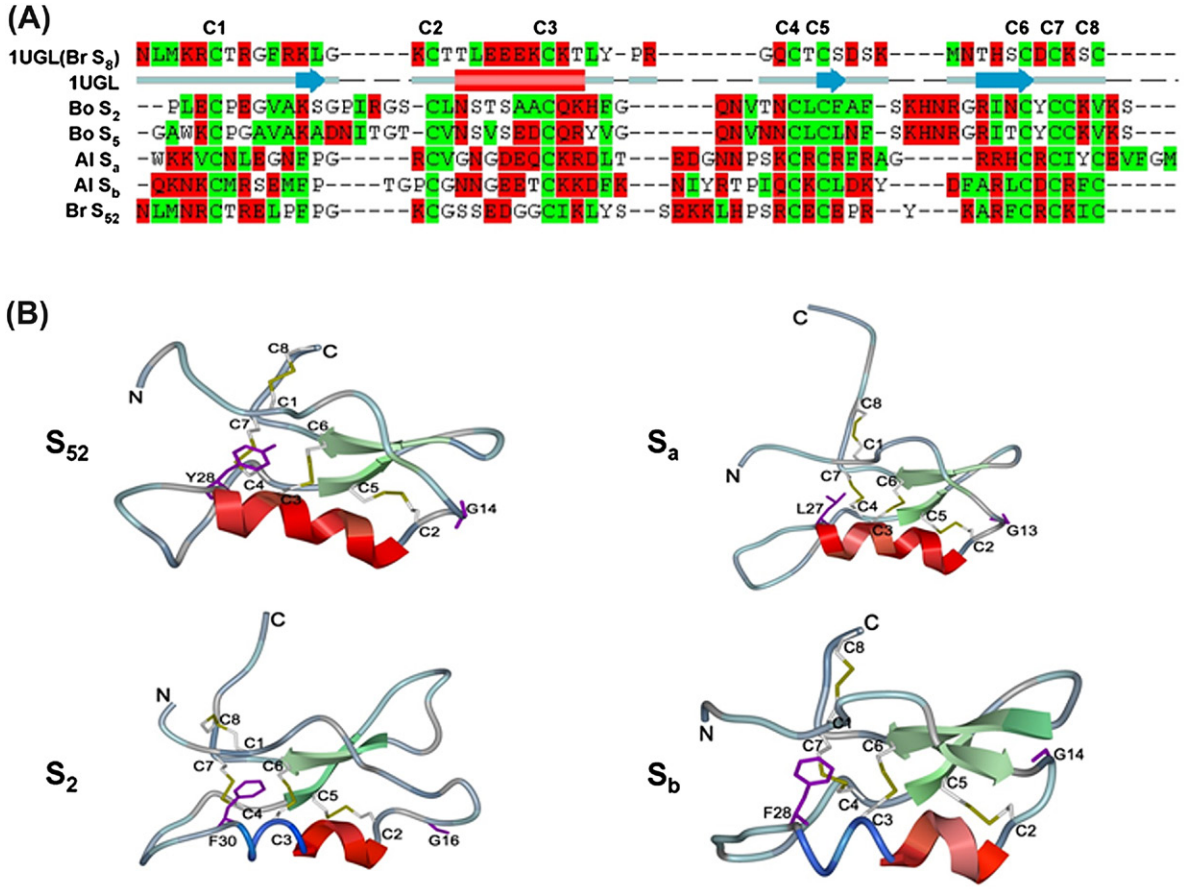

FIGURE 2 Predicted conservation of secondary structure in SCR variants. (**A**) Structure-based sequence alignment of SCR variants from *B. rapa* (Br) S_{52}, *B. oleracea* (Bo) S_2 and *S5*, and *A. lyrata* (Al) S_a and S_b. The NMR structure (model 1) of the *B. rapa* S_8 variant[13] (PDB code: 1UGL) was used as template. The secondary structure of the experimental model was computed by the method of Kabasch and Sanders.[5] The rectangle in the "1UGL" line depicts the α-helix and the arrows show the β-strands. Hydrophilic residues are shaded in dark gray and hydrophobic residues are shaded in light gray. The conserved C1–C8 residues are shown above the alignment. (**B**) Three-dimensional (3D) models of the SCR variants encoded by the *Brassica* S_{52} and S_2 and the *A. lyrata* S_a, and S_b haplotypes. These predicted models were generated with the program MODELLER[5] based on the S_8 SCR NMR structure (PDB code: 1UGL) determined by Mishima et al.[13] and the alignments given in A. The 3D models show the N/C termini and the location of the conserved cysteine residues (C1–C8) and glycine (G) in the G x C2 motif. Lines connecting pairs of cysteines depict the disulfide bridges. The α-helix is shown as a dark gray coiled ribbon and β-sheets are depicted by light gray arrows. The aromatic residue in the C3xxxY/F motif found in most SCRs is shown in stick representation for SCR variants of S_{52} (Y28), S_2 (F30), and S_b (F28). SCR_a contains a lysine (L27) at the corresponding position. See color plate 7.

of *B. oleracea*, SCR sequence variants were generated by site-directed mutagenesis of individual residues in SCR_6 or by swapping one or more regions between SCR_6 and SCR_{13}.[5] The mutated or chimeric SCRs were expressed in *E. coli* and tested *in vitro* for binding to the $eSRK_6$ and $eSRK_{13}$ and *in vivo* for activation of the SI response on stigmas.[5] These studies showed that the SCR function was abrogated by mutations of the conserved cysteine residues and the tyrosine residue in the C3xxxY/F motif, probably because these mutations disrupt the SCR structure. Surprisingly, mutation of the glycine residue in the G x C2 motif was tolerated. Analysis of SCR_6–SCR_{13} chimeras showed that SCR_{13} specificity resides in four contiguous amino acids within the C5–C6 loop.[5] However, the specificity-determining residues of SCR_6 could not be identified by this approach, possibly because noncontiguous residues in this variant determine specificity. These results indicate that residues imparting specificity to SCR can be arranged differently in different SCR variants. This conclusion is supported by *in vivo* studies using transgenic plants, which suggested that the C2–C3 and C5–C6 regions harbor the specificity determinants of the SCR variant encoded by the S_{52} haplotype of *B. rapa*, with some contribution from other regions.[20] Taken together, these studies point to the C5–C6 loop region as an important region for recognition specificity, in at least two SCR variants.

BIOLOGICAL ACTIONS OF SCR AND SI SIGNALING

SCR is the pollen determinant of specificity in the SI response, and it functions as a ligand for the stigma SRK receptor. Although the SCR protein is located in the pollen

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

coat, the outermost surface of the pollen grain that makes initial contact with the stigma, the site of SCR activity is at the plasma membrane of the stigma epidermis, where its specific interaction with its SRK receptor determines the fate of a pollen grain. In self-pollination, the binding of SCR to its cognate "self" SRK results in autophosphorylation of the receptor[31] and activation of the SI-signal transduction pathway within the stigma epidermal cell, resulting in inhibition of pollen hydration, germination, and penetration of pollen tube into the papilla cell wall. In crosspollination, SCR cannot bind nor activate "nonself" SRK (i.e., an SRK encoded in an *S* haplotype different from that which encodes SCR), the signal transduction pathway is not activated, and pollen tube growth proceeds. Thus, SCR may be thought of as the molecular tag on pollen that allows the stigma epidermal cell to perceive, through its SRK, a pollen grain as being a "self" grain that must be arrested and prevented from hydrating, elaborating a pollen tube, and effecting fertilization.

The details of the SI-signal transduction pathway are not fully understood. Three proteins have been proposed to function as downstream effectors of SRK signaling in *Brassica*: the membrane-associated kinase MLPK, the ARM-repeat containing ARC1, which has E3 ubiquitin ligase activity and interacts with the SRK kinase [reviewed in Ref. 32], and the ARC1 interactor, Exo70A1, a component of the exocyst, which might be involved in the secretion of the factors required for pollen tube growth.[19] A model of SI signaling was proposed[19] in which interaction of the SRK ectodomain with its cognate SCR ligand causes autophosphorylation of the receptor, and the phosphorylated SRK, together with MLPK, then interacts with and phosphorylates ARC1. Activated ARC1 would subsequently target Exo70A1 for degradation, thus inhibiting the secretion of "compatibility" factors and preventing pollen tube formation. However, analysis of the *A. thaliana* orthologs of *MLPK*, *ARC1*, and *Exo70A1* failed to show a role for these genes in the SI response of *A. thaliana SRK–SCR* transformants, indicating that if these genes do function as reported in *Brassica*, their requirement for self-incompatibility is not universal.[17]

THE *SCR*-LIKE (*SCRL*) GENE FAMILY IN PLANTS

In most genome annotations of sequenced plants, genes encoding small peptides are routinely ignored. The difficulty in identifying these genes, including genes that encode SCR-like (SCRL) secreted peptides, stems primarily from the fact that gene-finding algorithms often ignore small ORFs (encoding < 50 amino acids) for which empirical evidence of expression is lacking. The identification of *SCRLs* in particular presents two additional difficulties. The first relates to the gene structure of *SCRL* genes, in which the signal sequence with its initiating ATG codon, is separated from the rest of the coding region by an intron. The second difficulty results from the fact that *SCR* alleles exhibit a high degree of sequence polymorphism (Fig. 1) and standard searches based on sequence homology are not suitable for identifying related sequences. Nevertheless, 28 *SCRL* genes that fall into 7 groups on the basis of sequence similarity (Fig. 3), were identified in the *A. thaliana* genome by iterative searches with the tBLASTN program using sequences of the seven most diverse SCR alleles and three pollen coat proteins from *Brassica* species.[34] Most *A. thaliana SCRLs* are predicted to encode ORFs containing a signal peptide, the conserved cysteine residues, the glycine in the G x C2 motif, and the aromatic amino acid in the C3xxxY/F motif found in most SCRs (Fig. 1). Three *SCRLs*, however, lack some of these conserved residues and are inferred to be nonfunctional. A substantial fraction of the *SCRL* genes are arranged in tandem in the genome, and these closely linked genes share relatively high sequence similarity, suggesting that they may have redundant functions.

Of 25 potentially functional SCRLs, none have been assigned a biological function. Furthermore, not much information is currently available regarding their expression patterns and the cells in which they are expressed. A search of ESTs, cDNAs, and microarray datasets available in the public domain identifies cDNAs and ESTs for six *SCRL* genes (At1g60986, At1g60987, At1g60985, At1g60989, At4g15735, At3g27503), most of which exhibit flower-specific expression patterns. Among these genes, only At1g60985 is represented on the ATH1 whole genome array, and expression data again indicate that this gene is expressed preferentially in floral organs, with the highest expression in carpels. Another *SCRL* gene, At1g65113, is represented only by ESTs in the NCBI database (http://www.ncbi.nlm.nih.gov/). A search of the MPSS database (http://mpss.udel.edu/at/), which harbors sequence information for small RNAs generated using Massively Parallel Signature Sequencing (MPSS), confirmed the expression of several *SCRL* genes (At1g65113, At1g60987, At1g60989, At1g60986) and additionally identified four *SCRL* genes (At4g10115, At4g32717, At4g22105, and At2g25685) for which no expression data were previously known. As shown in Fig. 4, these results show that 11 of the 25 apparently functional *SCRL* genes exhibit differential expression in various tissues, with the majority being predominantly expressed in flowers and thus possibly functioning in some aspect of reproduction. Furthermore, several *SCRL* genes have overlapping expression profiles, suggesting possible functional redundancy. Additional information related to gene expression, subcellular localization of the gene product, and mutant phenotypes is required to elucidate the biological function of the SCRL peptides.

Chapter 13

Stomagen/EPFL9

Tomoo Shimada, Shigeo S. Sugano and Ikuko Hara-Nishimura

ABSTRACT

The stomata are valves found on aerial plant organs that are responsible for gas exchange between the atmosphere and the body of the plant. The two-dimensional pattern and the density of stomata are controlled by cysteine-rich peptides of the EPIDERMAL PATTERNING FACTOR (EPF) family. Stomagen/EPFL9 functions as a positive regulator, while EPF1, EPF2, and CHALLAH/EPFL6 function as negative regulators of stomatal development. Stomagen is a 45 amino acid peptide with three intramolecular disulfide bonds. The *STOMAGEN* gene is predominantly expressed in immature organs, including leaves, stems, and flower buds, where stomatal development occurs. Stomagen is produced in internal tissues and migrates to the epidermis, where it acts as an intercellular positive signal. Possible receptors for stomagen are the cell surface TMM and ERf receptors, both of which are also required for response to the negative signaling peptides, EPF1 and EPF2. These findings suggest that stomatal development is finely regulated by competitive binding of positive and negative peptides to the same receptor.

DISCOVERY

Stomagen/EPFL9 is a positive signaling factor for stomatal development. In 2010, the *STOMAGEN/EPFL9* gene was independently discovered by three research groups. Sugano et al.[24] and Hunt et al.[7] identified this gene among genes co-expressed with known stomatal regulators in *Arabidopsis*, while Kondo et al.[11] identified the gene among *Arabidopsis* genes encoding novel secreted peptides that influence plant development. *STOMAGEN*-like genes are found in various plants (Fig. 1A), including poplar, rice, and *Selaginella moellendorffii*, a primitive vascular plant, suggesting that stomagen is a conserved signaling molecule, which regulates stomatal density in vascular plants.

The *STOMAGEN* gene encodes a cysteine-rich secreted peptide that belongs to the EPIDERMAL PATTERNING FACTOR (EPF) peptide family.[6,10,20] In *Arabidopsis*, 11 EPF family peptides have been identified. Three of these family members, EPF1,[5] EPF2,[6,8] and CHALLAH/EPFL6,[1] have been shown to negatively regulate stomatal development. Overexpression experiments indicate that EPFL4 and EPFL5 are also capable of inhibiting stomatal development[6] but their endogenous functions remain to be determined. So far, stomagen is the only known positive signaling factor of stomatal development among EPF family peptides.

STRUCTURE OF THE PEPTIDE

The *STOMAGEN* gene encodes a small polypeptide of 102 amino acids with a putative signal peptide (SP) at the N-terminus (Fig. 1B). The mature form of the *STOMAGEN* gene product, stomagen, is a peptide consisting of the C-terminal 45 amino acids of the precursor protein.[11,24] In the mature peptide, there are six conserved cysteine residues that form three intramolecular disulfide bonds, Cys8–Cys41, Cys13–Cys20, and Cys16–Cys43 (Fig. 1B).[11] Just upstream of the cleavage site of stomagen, a putative dibasic signal (Arg–Arg or Lys–Arg) is well conserved among various plant species (Fig. 1A). Mature stomagen appears to lack posttranslational modifications, such as sulfation or hydroxylation, both of which are often found in other plant signaling peptides, as revealed by mass spectrometry analysis of endogenous stomagen from the apoplastic fluid of *STOMAGEN* overexpressors.[11] Indeed, a chemically synthesized 45 amino acid stomagen polypeptide exhibits stomata-inducing activity.[11,24] It is probable that other EPF family peptides are also subject to similar posttranslational processing, although the mature forms have not been determined. In summary, the *EPF* family genes, including *STOMAGEN*, are predicted to encode a preproprotein that consists of three domains, an SP, a proprotein region, and the mature peptide.

DISTRIBUTION OF THE mRNA/PEPTIDE

The *STOMAGEN* gene is predominantly expressed in immature organs, including leaves, stems, and flower buds,[7,11,24] which enable the gene to be identified by a co-expression analysis. Other stomatal regulators exhibit similar expression patterns. The expression patterns of the *STOMAGEN* gene are consistent with the fact that stomatal development occurs in these immature organs. Relatively low expression of the *STOMAGEN* gene was also observed in the root;[24] however, the physiological function of stomagen in the root is unknown.

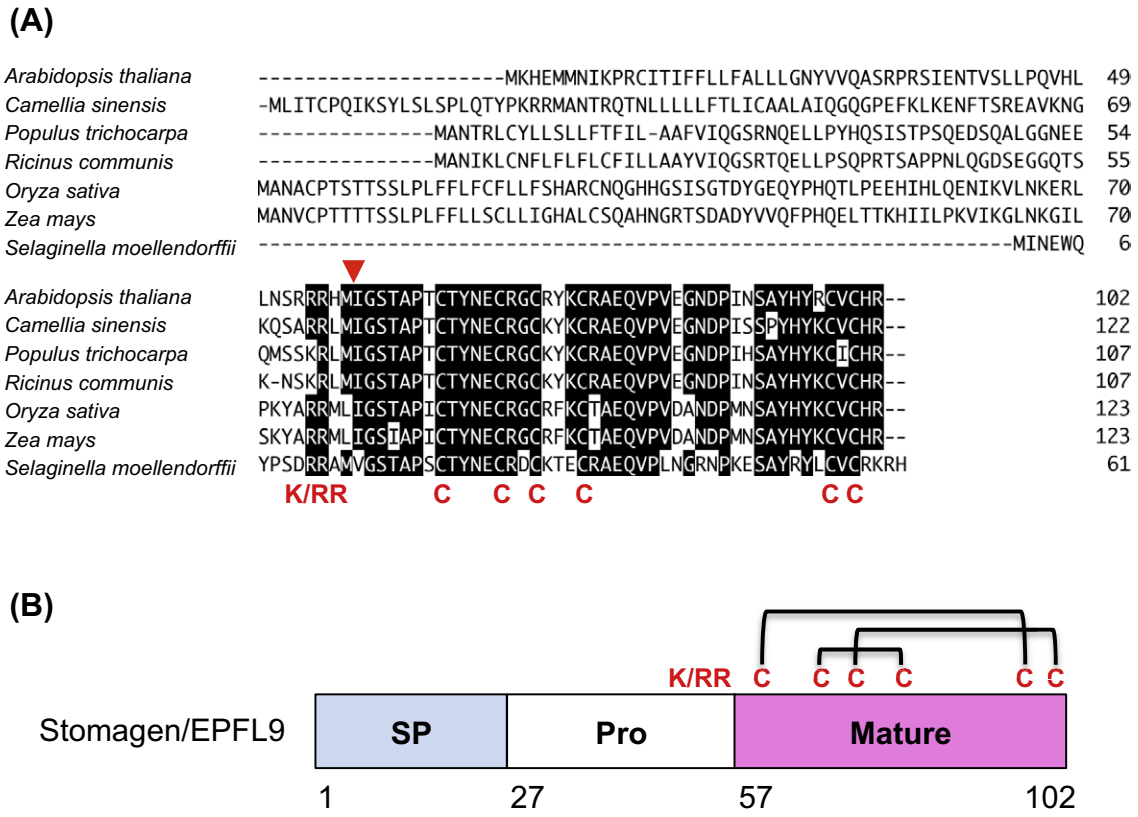

FIGURE 1 Stomagen/EPFL9 is a conserved cysteine-rich peptide. (A) A multiple alignment of stomagen/EPFL9 precursors from various plants, *Arabidopsis thaliana* (GI:15235542), *Camellia sinensis* (GI:330318758), *Populus trichocarpa* (GI:224065439), *Oryza sativa* (GI:115441801), *Zea mays* (GI:195649933), and *S. moellendorffii* (GI:302764960). The N-terminus of *Arabidopsis* mature stomagen is shown by an arrowhead. A putative cleavage signal (K/RR) and six conserved cysteine residues (C) are shown. Sequences are aligned by Clustal W and conserved amino acids among the sequences are shown in reverse. (B) Schematic representation of the domain structure of stomagen/EPFL9 precursor. The precursor is composed of the SP, the propeptide (Pro), and the mature domain. Three disulfide bridges of stomagen are indicated by solid lines. Amino acid positions are indicated below the structure.

Interestingly, the *STOMAGEN* gene is expressed in the internal tissues rather than the epidermis, where the stomata develop.[11,24] This *STOMAGEN* expression pattern is in sharp contrast to the expression of other stomatal regulators, which are expressed primarily in the epidermis or in the stomatal lineage cells. This finding indicates the existence of inter-tissue signaling that regulates stomatal development. Stomagen is predicted to be secreted from cells into the apoplast. In transgenic *Arabidopsis* expressing a STOMAGEN–Venus fusion protein, fluorescence was indeed observed outside the cells.[24] These findings indicate that stomagen is produced in internal tissues and migrates to the epidermis, where it acts as a positive signal for stomatal development.

BIOLOGICAL FUNCTIONS

The biological function of stomagen is to control the stomatal density or the stomatal index (defined as the ratio of the number of stomata to the total number of epidermal cells).[7,11,24] Overexpression of *STOMAGEN* increases the number of stomata, and suppression of *STOMAGEN* decreases the number of stomata in *Arabidopsis* (Fig. 2). A quantitative analysis revealed a positive correlation between the level of *STOMAGEN* messenger RNA and stomatal density.[24] Treatment of *Arabidopsis* seedlings with recombinant or chemically synthesized stomagen can induce the formation of stomata in a dose-dependent manner.[11,24] These findings indicate that stomagen is a positive regulator of stomatal development.

Stomata are formed from a protodermal cell, which is an undifferentiated epidermal cell, through a strict cell lineage in the very early stages of leaf development.[3,16] Stomagen appears to positively regulate several steps in the cell lineage during stomatal development.[21] Stomata in most dicotyledonous plants are separated by at least one non-stomatal cell,[21] which is thought to improve the efficiency of gas exchange. *STOMAGEN* overexpression lines exhibited many clustered stomata in mature leaves, indicating that the orientation of cell division in the stomatal lineage is defective in these lines.[7,11,24] The abnormal clustering, however, may be because of the ectopic expression of the *STOMAGEN* gene in the epidermis.

Differential interference contrast (DIC) images of the abaxial epidermis of mature leaves of wild-type *Arabidopsis*, a *STOMAGEN*-silenced line (STOMAGEN-RNAi), and a *STOMAGEN*-overexpressing line (STOMAGEN-OX). The expected accumulation level of stomagen is illustrated above panels. Stomata were stained with Safranin-O. Scale bars = 100μm. See color plate 8.

RECEPTORS AND SIGNALING CASCADES

Putative receptors for stomagen are predicted to be two classes of cell surface receptors, the receptor-like membrane protein TOO MANY MOUTHS (TMM)[15,26] and three ERECTA family (ERf) receptor-like kinases (ER, ERL1, and ERL2)[23] (Fig. 3). Overexpression or silencing of the *STOMAGEN* gene in a *tmm* mutant did not affect the stomatal density.[24] The application of synthetic stomagen to *tmm* leaves also failed to increase the stomatal density.[11] These results indicate that stomagen requires TMM for the positive regulation of stomatal development. The TMM, ER, ERL1, and ERL2 receptors contain leucine-rich repeat motifs in their extracellular domains. TMM and the ERf proteins are thought to associate with each other in the plasma membrane and, because TMM lacks a cytosolic kinase domain, extracellular peptide signaling is transmitted into the cell by the kinase domain of the ERf.

TMM and ERf receptors have been characterized as negative regulators of stomatal development in leaves, since the loss-of-function of these receptors results in the overproliferation of stomata.[23,26] The possible ligands for these negative receptors are negative signaling peptides, such as EPF1[5] and EPF2.[6,8] EPF1 and EPF2 belong to the same EPF peptide family as stomagen. These observations support an "agonist–antagonist" hypothesis in which the positive peptide, stomagen, and negative peptides, EPF1 and EPF2, act antagonistically on the same receptor(s) during the process of stomatal development (Fig. 3). The *STOMAGEN* gene may have evolved from a negative peptide gene through gene duplication and the alteration of function.[22]

Once extracellular signaling is recognized by cell surface receptors, a mitogen-activated protein kinase (MAPK) cascade within the cell becomes activated, thereby regulating transcription factors (TFs) that promote stomatal development[4] (Fig. 3). A signaling module consisting of YODA (a MAPK kinase), MKK4/5/7/9 (MAPK kinases), and MPK3/6 (MAPKs) has been shown to mediate this signal transduction cascade.[2,12,25] Downstream of the MAPK cascade, two classes of basic helix-loop-helix (bHLH) TFs are involved in the developmental progression of the stomatal cell lineage. One class of bHLH factor contains three paralogous proteins,

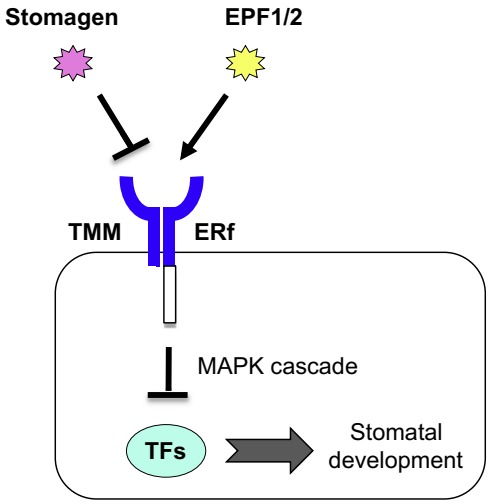

FIGURE 3 A model of peptide signaling for stomatal development in leaves. Stomatal development is promoted byTFs in the absence of receptor signaling and MAPK cascade. The negative peptides, EPF1 and EPF2 (EPF1/2), interact with negative receptors, ERf and TMM, which form a receptor complex at the plasma membrane. The activated ERf receptor transmits negative signal through its kinase domain to the MAPK cascade, which represses the function of TFs. The positive peptide stomagen competes with EPF1/2 for binding the receptor complex to attenuate the negative signal.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

SPEECHLESS (SPCH), MUTE, and FAMA, each of which regulates a distinct step in stomatal development.[14,17,19] The MAPK cascade regulates the phosphorylation status of SPCH, which triggers commitment to the stomatal lineage.[13] Both the overexpression of *STOMAGEN* in an *spch* mutant and the application of purified stomagen to an *spch* mutant failed to induce stomatal formation.[24] These results indicate that the stomata-inducing activity of stomagen is dependent on the SPCH pathway. The second class of bHLH proteins contains SCREAM/ICE1 (SCRM) and SCRM2.[9] The *SCRM* and *SCRM2* genes are expressed throughout the stomatal lineage and their gene products influence stomatal development by forming heterodimers with SPCH, MUTE, or FAMA. Recently, the NMR structure of stomatogen was reported.[18]

Chapter 14

TDIF

Yuki Kondo, Yuki Hirakawa and Hiroo Fukuda

ABSTRACT

The plant vascular system is a crucial network for the transport of water, nutrients, and signaling molecules. Small secretory molecules and plant hormones, play roles in vascular network formation. Here, we summarize the biological functions and signaling cascade of TDIF (tracheary element differentiation inhibitory factor) in vascular development. TDIF, a 12-amino acid peptide containing two hydroxyproline residues, was isolated originally as an inhibitory factor of tracheary element differentiation in a *Zinnia* xylogenic cell culture. Further analysis with *Arabidopsis* revealed non-cell-autonomous action of TDIF. TDIF is produced via processing and hydroxylation in phloem cells and is then perceived by procambial cells, including vascular stem cells, through a TDIF receptor (TDR/PXY). The signal both promotes proliferation of the procambial cells and suppresses their differentiation into tracheary elements. Analysis of downstream events clarified that a putative transcription factor, WUSCHEL-related HOMEOBOX 4 (WOX4), mediates TDIF signaling in the promotion of procambial cell proliferation.

DISCOVERY

Cell culture systems have been widely used to isolate key regulators governing plant cell differentiation and proliferation. Fukuda and Komamine (1980) established a xylogenic cell culture in which single mesophyll cells isolated from *Zinnia* leaves transdifferentiate synchronously and at high frequency into tracheary elements (TEs) without intervening cell division.[8] Detailed analysis of the *in vitro* differentiation process has revealed that not only TEs but also other vascular cells such as procambium-like cells and xylem parenchyma cells differentiate from the mesophyll cells.[9] A possible mechanism that allows differentiation into various cell types involves the interaction between cultured cells via signaling molecules secreted into the culture medium. Xylogen, an arabinogalactan protein, was discovered as such a secretory factor promoting TE differentiation in the *Zinnia* xylogenic culture.[22] Further analysis identified an inhibitor of TE differentiation, named TDIF (Fig. 1A).[14] TDIF was extracted with 20% methanol and purified by a poly Sulfoethyl A ion exchange column, tandem Super SW 3000 columns, and an Inertsil ODS3 reversed-phase column. Mass spectrometry and peptide sequencing clarified that TDIF is a dodeca amino acid peptide containing two hydroxylated proline residues.[14] Indeed, chemically synthesized TDIF peptide strongly inhibits TE differentiation at concentrations as low as 30 pM in the *Zinnia* xylogenic culture.[14] The 12 amino acid sequence was found near the C-terminus of a protein encoded by a *CLAVATA3/EMBRYO SURROUNDING REGION-related (CLE)* family gene in *Zinnia*. TDIF is also encoded at the C-termini of two *Arabidopsis CLE* genes, *CLE41* and *CLE44* (Fig. 1B).[14]

STRUCTURE OF THE PEPTIDE

The CLE family of small secretory peptides is conserved among land plants. In the *Arabidopsis* genome, there are 32 genes encoding CLE peptides.[16] CLE proteins contain an N-terminal signal peptide and a conserved C-terminal 14 amino acid CLE domain(s) from which a mature CLE peptide is produced through proteolytic cleavage (Fig. 1B).[14,17] The first identified natural CLE peptide, TDIF, consists of 12 amino acid residues containing two hydroxylated prolines at fourth and seventh residues.[14] The translated TDIF precursor protein is composed of 132 amino acids. TDIF sequence corresponds to H120 to N131. Addition of the C-terminal arginine residue (R132) to TDIF reduces its activity by 1/7th.[14] Therefore, proteolytic cleavage at both the N and C ends of the peptide is required to produce the mature peptide. In *Arabidopsis*, TDIF was identified from apoplast fluid of *CLE44*-overexpressing plants,[25] confirming that TDIF is a product of *CLE44* (Fig. 1B). Secretion of TDIF is shown *in vivo* by an immunohistochemical study using an anti-TDIF antibody.[11]

To deduce the chemical basis of TDIF function, TDIF derivatives were synthesized, and their activities were examined in the *Zinnia* xylogenic culture. Alanine substitution for H_1, V_3, G_6, N_8, P_9, and N_{12} within the 12 amino acid sequence all caused a severe loss of TDIF activity in the *Zinnia* xylogenic culture.[14] By contrast, replacement of the amino acids at positions E_2, S_5, Hyp_7, I_{10}, and S_{11} do not affect TDIF activity.[14] These alanine scanning experiments indicate that H_1, V_3, G_6, N_8, P_9, and N_{12} are the essential

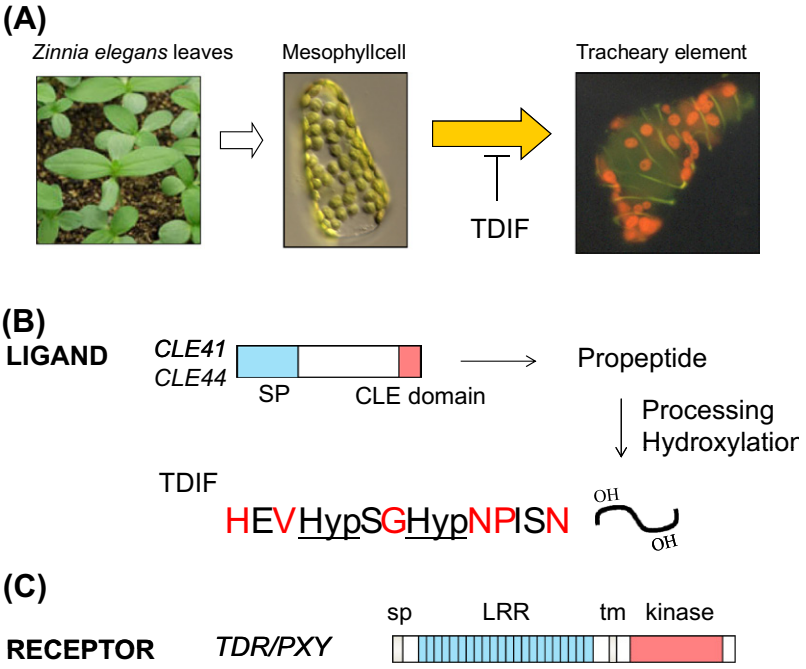

FIGURE 1 Identification and characterization of TDIF. (A) TDIF was isolated as a factor inhibiting TE differentiation from the *Zinnia* xylogenic culture. (B) Maturation of TDIF peptide through translation as a propeptide, processing, and hydroxylation. TDIF is produced as a 12-amino acid peptide with two hydroxyproline residues. Bold characters indicate indispensable amino acids for TDIF activity. (C) Structure of *TDR/PXY* encoding a TDIF receptor, which consists of a signal peptide (sp), leucine-rich-repeat domains (LRR), a transmembrane domain (tm), and a kinase domain. See color plate 9.

residues for TDIF activity (Fig. 1B).[14] Consistently, CLE42 peptide, which differs from TDIF at only one amino acid at the second position, also has an inhibitory effect on TE differentiation.[14]

All CLE peptides isolated so far have hydroxylation of proline residues at the 4th and 7th positions. In addition, CLV3 and CLE2 peptides are further modified with three arabinose residues on Hyp_7.[26] The glycosylation greatly increases the efficiency of binding of the CLE peptides to their receptors, indicating the importance of glycosylation for their biological activities.[26] By contrast, TDIF does not need glycosylation for its full activity. Indeed, alanine scanning analyses of TDIF synthetic peptide indicate the hydroxylation is dispensable for TDIF activity.[14]

DISTRIBUTION OF THE mRNA/PEPTIDE

The vascular system consists of two types of tissue, xylem and phloem, which are spatially separated by the intervening procambium/cambium/vascular meristem. Procambial/cambial cells, which give rise to xylem and phloem cells, behave as stem cells in the vascular meristem (Fig. 2). To ascertain where TDIF is produced *in vivo*, promoter activities of *CLE41* and *CLE44* were examined by use of the β-glucuronidase (GUS) reporter gene in *Arabidopsis*. In roots and hypocotyls, *pCLE41::GUS* activity is restricted to the phloem and the neighboring pericycle cells. *pCLE44::GUS* is expressed in endodermal cells as well as cells in the phloem and the adjacent pericycle.[11] Immunohistochemical analysis using an anti-TDIF antibody showed that TDIF accumulates in the apoplast of phloem cells and their surrounding cells.[11] By contrast, transcripts for *TDR,* which encodes a TDIF receptor, accumulate specifically in procambial cells.[11] These

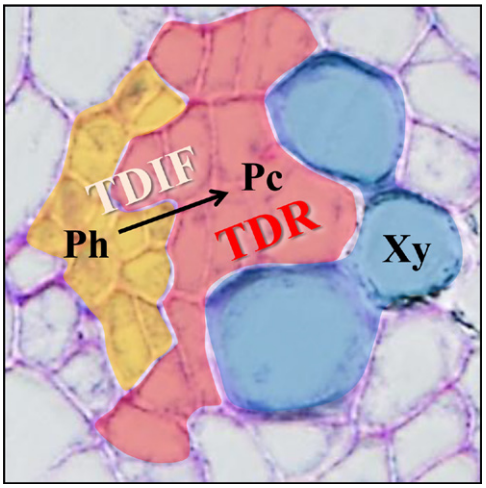

FIGURE 2 Non-cell-autonomous function of the TDIF signal TDIF is secreted from phloem cells and functions in procambial cells in a non-cell-autonomous fashion. Ph, Pc, and Xy indicate phloem, procambium, and xylem, respectively. See color plate 10.

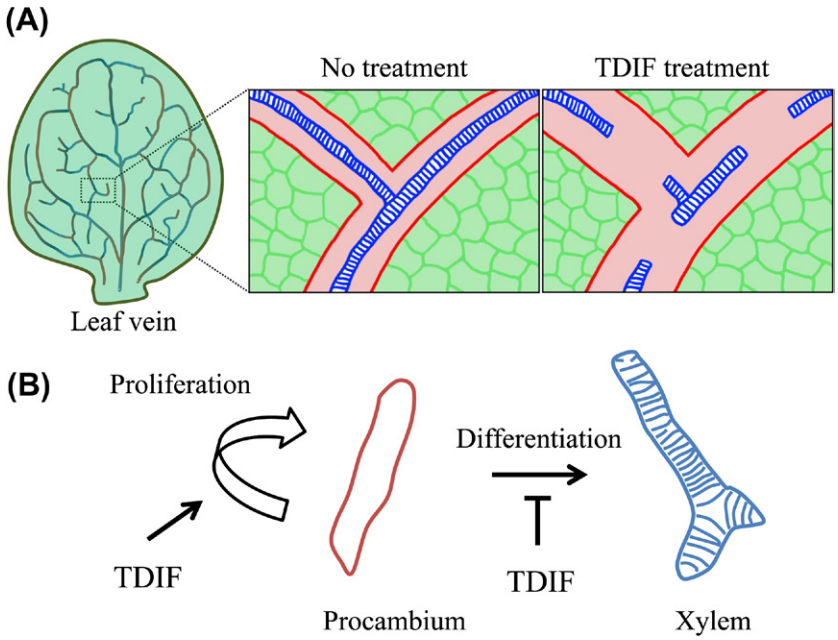

FIGURE 3 Biological functions of TDIF *in vivo*. (A) TDIF inhibits xylem strand formation but not phloem or procambium strand formation in leaf veins. (B) In a cellular level, TDIF promotes procambial cell proliferation and inhibits xylem cell differentiation from procambial cells.

results indicate that TDIF is produced in and secreted from the phloem cells, and then functions in the procambial region in a non-cell-autonomous fashion via the receptor, TDR (Fig. 2).

Interestingly, ectopic expression of *CLE41* under a xylem-specific promoter or the cauliflower mosaic virus 35S promoter leads to disorder of vascular tissues although *CLE41* overexpression under phloem-specific SUC2 promoter did not.[5] This result indicates that the location of TDIF production is essential for correct vascular patterning. Thus, TDIF diffusing from the phloem conveys positional information within the vasculature.

BIOLOGICAL FUNCTIONS

In *Zinnia* xylogenic culture, TDIF strongly inhibits TE differentiation at very low concentrations.[14] Similarly, TDIF application inhibits xylem vessel formation in leaves and hypocotyls in *Arabidopsis*, but it does not affect phloem strand formation.[11] In the region where xylem vessel formation is inhibited, procambial cells are formed normally (Fig. 3A).[11] These results indicate that TDIF specifically inhibits xylem differentiation of procambial cells. TDIF also promotes the proliferation of cells in the *Zinnia* culture[14] and of procambial cells in *Arabidopsis* hypocotyls.[11] These findings strongly suggest that functions in the maintenance of procambial cells by two different mechanisms: inhibiting differentiation of procambial cells into xylem cells and promoting proliferation of procambial cells (Fig. 3B). Indeed, *cle41* mutants often cannot maintain vascular stem cell activity in hypocotyls, resulting in the formation of xylem cells directly adjacent to phloem cells, an arrangement that does not occur in wild type.[12] This TDIF activity for procambial proliferation is greatly enhanced by the simultaneous application of TDIF with some CLE peptides belonging to groups A, B, and D, according to the previous classification.[13,30] CLE42 peptide, containing only one amino acid difference compared with TDIF also has TDIF activity. However, *CLE42* is not expressed in vascular tissues, but rather is expressed strongly in the shoot apical meristem (SAM) and axillary meristems.[31] Overexpression of *CLE42* and *CLE41* (encoding TDIF) enhanced axillary bud formation in leaf and cotyledon axils, in addition to causing xylem vessel discontinuity.[11,29–31]

RECEPTORS AND SIGNALING CASCADES

CLV1 and *CLV3* were identified genetically as key regulators of the SAM organization.[2,7] CLV3 peptide directly binds to the CLV1 receptor, which belongs to class XI of the leucine-rich repeat receptor-like kinase (LRR–RLK) family.[24] In *Arabidopsis*, there are >200 LRR–RLK members.[28] Based on the structural similarity between CLV3 peptide and TDIF, Hirakawa et al. (2008) predicted that TDIF may be recognized by an LRR–RLK.[11] To identify the receptor(s) for TDIF, they first selected about 60 LRR–RLK genes that are predicted to be expressed in procambium/cambium according to the expression data from the public database AtGenExpress and from the *Zinnia* xylogeninc culture and *Arabidopsis* xylogenic culture.[4,19] Screening T-DNA insertion lines for the 60

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

LRR–RLK genes resulted in three lines being identified as mutants resistant to TDIF when assayed for xylem differentiation.[11] Each of these lines has a T-DNA insertion in the same gene, which was named *TDR*. TDR, previously designated as PHLOEM INTERCALATED WITH XYLEM (PXY), is a member of the class XI of the LRR–RLK family.[6] TDR protein comprises extracellular LRR domains, a transmembrane domain, and an intracellular kinase domain (Fig. 1C).[11] TDR localizes at the plasma membrane when overexpressed transiently in *Arabidopsis* cultured cells.[11] TDIF but not CLV3 binds to the extracellular LRR domain of TDR produced in BY-2 cells.[11] Loss-of-function mutants for *TDR* show abnormal polarity of vascular tissues and exhaustion of vascular stem cells, similar to the phenotype of *cle41*.[6,11,12]

The CLV3–CLV1–WUS (WUSCHEL) module is a well-known pathway in maintenance of the SAM.[1,21,27] *WOX4*, a member of the *WUSCHEL-related HOMEOBOX* (*WOX*) gene family, is upregulated within an hour upon TDIF application, suggesting that *WOX4* acts downstream of the TDIF–TDR signaling pathway.[12] *wox4* mutants exhibit resistance against TDIF treatment in terms of the promotion of vascular stem cell proliferation but not of inhibition of xylem differentiation.[12] Together with the observation that *WOX4* is expressed specifically in procambial cells,[12,15] it is concluded that *WOX4* is required for TDIF-dependent enhancement of procambial cell proliferation but not for TDIF-dependent suppression of their xylem differentiation (Fig. 4). This idea is supported by the observation that the vascular phenotype of *wox4* mutants differs from that of *tdr* mutants: in *wox4* mutants, procambial cell proliferation is reduced, whereas vascular stem cells still exist at least one cell layer between xylem and phloem cells.[12] These findings indicate that maintenance of vascular stem cells requires not only promotion of procambial cell proliferation but also suppression of xylem cell differentiation, both of which are regulated by TDIF–TDR. Further analysis is required to identify a putative transcription factor that functions in xylem cell differentiation downstream of the TDIF–TDR signaling pathway.

Plant hormones play crucial roles in vascular formation.[9] Cytokinin promotes the proliferation of procambium/cambium,[10,20,23] whereas brassinosteroids are capable of enhancing xylem differentiation.[3,32] A recent study on CLE peptides revealed that group-A CLE peptides including CLE9/10 inhibit protoxylem vessel formation in roots by modulating intracellular cytokinin signaling,[13,18] indicating crosstalk between CLE peptides and plant hormone signaling. Promising future work will help in understanding the crosstalk between the TDIF/CLE signaling pathways and plant hormones in the control of vascular cell differentiation and proliferation (Fig. 4).

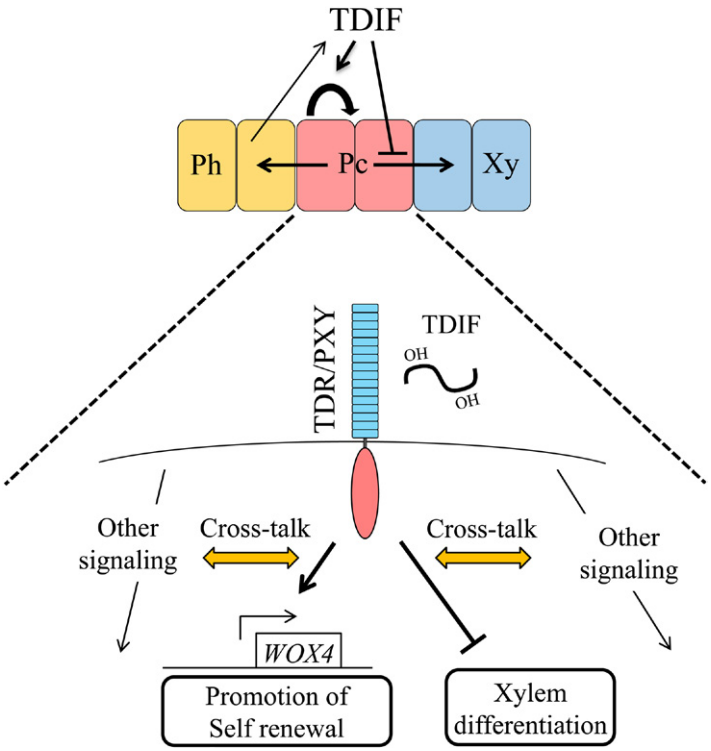

FIGURE 4 Intercellular and Intracellular TDIF–TDR signaling. TDIF is secreted from phloem cells and functions in procambial cells to maintain stem cell activity by both promoting cell division and suppressing differentiation into xylem cells. The former is regulated by a putative transcription factor WOX4.

Chapter 15

Cathelicidins

Neeloffer Mookherjee, Kelly L. Brown and Robert E.W. Hancock

ABSTRACT

Cathelicidins are members of a family of protective, anti-infective peptides, also known as host defense or antimicrobial peptides, and are defined by the high degree of conservation of their "pre–pro" precursor sequences and exceptional diversity of sequence and structure in the mature peptide. These endogenous cationic peptides play a key role in innate immune responses and are widely distributed in mammalian species and being recently observed in nonmammalian vertebrates including hagfish, trout, and chicken. They exhibit a variety of functions ranging from direct antimicrobial activity against bacteria, fungi, eukaryotic parasites, and viruses, through to immunomodulatory and anti-inflammatory activities.

DISCOVERY

Cathelicidins are small cationic, amphiphilic peptides consisting of 12–97 amino acids. This family of peptides was first discovered in bovine neutrophils by Zanetti and collaborators in the early 1990s.[35] The term cathelicidin was coined in 1995 to describe this family of cationic, bipartite peptides sharing a conserved DNA and pre–pro protein sequence at the N-terminus that is highly homologous to that upstream of the coding sequence for the protein cathelin, a 96-amino-acid, cathepsin L protease inhibitor from porcine neutrophils. Thus, cathelicidins are paradoxically named based on this homology in the part of the precursor protein involved in secretion and processing, despite the fact that this family has become better known for the anti-infective properties of the mature (processed) protein, and potential protease inhibitory roles of cathelicidins are rarely investigated. Thus, all cathelicidins have a prosequence at their N-terminus as a part of the precursor protein, that is highly homologous, followed by a heterogeneous C-terminal mature peptide (Figure 1).[35]

Cathelicidins were originally described as antimicrobial peptides and include proteins such as pig protegrins and cattle indolicidins that served as templates for some of the most clinically advanced antimicrobial peptide drugs.[22,29] Cathelicidins have some direct antimicrobial activity in dilute media, but there is a broad range of potencies and in some cases antimicrobial activity is almost completely antagonized at the concentrations and salt conditions found physiologically.[1] Cathelicidins also exhibit a wide range of immunomodulatory and anti-inflammatory activities.[3,15,22] Therefore, the term "host defense peptides" can be used for cathelicidins to encompass their diverse biological functionality. Ongoing research to further understand the complex myriad of biological functions of cathelicidins has captured the interest of researchers, particularly in the health sciences.

STRUCTURE OF THE PRECURSOR mRNA/ STRUCTURAL GENE

The cathelicidin gene family can be traced back 300–500 million years,[30] showing the early evolutionary origin of these peptides. Like the defensin family, these peptides are encoded by a single gene that belongs to a gene family with three highly conserved exons. Cathelicidin encoding genes have a homologous 5′ region that encodes for the characteristic conserved cathelin prodomain, enabling the discovery of new cathelicidins by homology. Cathelicidin encoding genes contain four exons.[29] Exons 1–3 encode the conserved signal peptide (29–30 amino acids) and the cathelin-like domain (94–114 amino acids). By contrast, exon 4 is hypervariable, encoding the heterogenous mature peptide (12–100 amino acids) with very limited sequence similarity between species, in addition to the processing site and 3′ UTR (Figure 1). The 5′ flanking sequences upstream of the coding sequence and the promoter region have several consensus sequences for potential binding of transcription factors involved in hematopoiesis and inflammation.[9,29] Therefore, cathelicidin mRNA expression is, where studied, coregulated with (or by) inflammatory responses and other entities of innate immunity. Recent studies have demonstrated several mechanisms for the regulation of cathelicidin gene expression including the presence of splice variants,[9] possible interactions with

the histone deacetylase complex,[27] and mediation via the vitamin D receptor complex.[31]

DISTRIBUTION OF CATHELICIDINS

Cathelicidins are extensively found in nature in both invertebrates such as hagfish and vertebrates such as fish, birds, reptiles and mammals.[15,29,30] Cathelicidin mRNAs and precursor or mature proteins are widely distributed in different mammalian species (Table 1) and in a variety of tissue types and cellular lineages. In mammals, cathelicidins are widely distributed among various tissue types, including the skin, intestine, oral cavity, cervix, lungs, mucosa, etc., and are found largely in their unprocessed (pre–pro) form in the granules of neutrophils as well as in myeloid precursors, epithelial cells, mast cells, keratinocytes, and lymphocytes. They are found in their processed forms in several bodily fluids including gastric juice, saliva, semen, sweat, plasma, airway surface liquid, and breast milk.[8,22]

The expression of cathelicidin mRNA can be constitutive or inducible and seems to be differentially regulated depending on the lineage and/or differentiation state of particular cell types. For example, the levels of expression of the genes encoding the precursors of human LL-37 and mouse CRAMP peptides are affected by infection (or the inflammation accompanying infection) and/or

injury in skin keratinocytes.[15] Conversely, infection of the intestinal epithelium with particular pathogens, such as *Shigella*, leads to the downregulation of the expression of cathelicidin.[12] Expression of human cathelicidin LL-37 can also be upregulated in inflammatory diseases but is apparently not directly induced by microbial products. For example, LL-37 is found to be elevated in chronic inflammatory diseases such as rheumatoid arthritis,[25] Crohn's disease,[14] and eczema.[17] Similarly, the precursor protein of human LL-37 has recently been shown to

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY
Copyright Elsevier 2024

be induced by vitamin D[31] and in endoplasmic reticulum stress via NF-κB activation.[24]

PROCESSING

Cathelicidins need to be proteolytically processed to be biologically active. Initially, they are synthesized as precursor peptides containing both a leader sequence (for secretion) and the pro (cathelin) domain (Figure 1). In neutrophils, these inactive pre-propeptides are stored at high concentrations in granules and upon neutrophil activation undergo processing by appropriate proteases to release the mature peptide that is found extracellularly. Various studies, including crystallographic analysis, have shown that mammalian cathelicidins are processed by serine proteases such as elastase, with the protease-sensitive sequence in a β-hairpin loop, and proteinase 3.[28] Another serine protease, kallikrein, was also recently shown to control the processing of cathelicidin precursor protein.[21] The exact function of the cathelin domain is still uncertain. It has been suggested that the cathelin-like domain exhibits antimicrobial and protease inhibitor activities, although these have not been proven to be relevant *in vivo*. Once released, the mature peptide often demonstrates resistance to proteolytic degradation by ubiquitous proteases resulting from mechanisms such as high proline content or posttranslational modifications such as bromination or C-terminal amidation.[28] The mature cationic peptide domain shows a broad range of an antimicrobial and immunomodulatory activities (discussed below).

RECEPTORS

The ligand–receptor interactions of cathelicidins are not well understood, with human cathelicidin LL-37 representing the most studied peptide in this regard. Overall LL-37 has been shown to have a variety of receptors according to the function being studied and the cell type. For example, LL-37 directly mediates chemotaxis of human peripheral blood neutrophils, monocytes, and T cells, and induces production of IL-8 in epithelial cells, through formyl peptide-receptor-like 1 (FPRL1),[6,16] whereas two alternative (as yet uncharacterized) receptors are involved in chemotaxis of mast cells by LL-37.[3] By contrast, it has been demonstrated that LL-37-mediated phosphorylation of mitogen-activated protein kinases (MAP kinases) p38 and Erk1/2 in human peripheral blood-derived monocytes is independent of FPRL1[2] and LL-37 activates MAP kinases in epithelial cells via the transactivation of epidermal growth factor receptors.[3] LL-37 has been shown to mediate IL-1β secretion from human monocytes by activating the P2X7 nucleotide scavenger receptor, but conversely porcine protegrins mediate IL-1β secretion independently of P2X7 receptors.[10] In addition, intracellular GAPDH has also been described as a functional receptor for LL-37 induction of chemokines (see Figure 2 for model).[19] One hypothesis to explain these results is that there are multiple

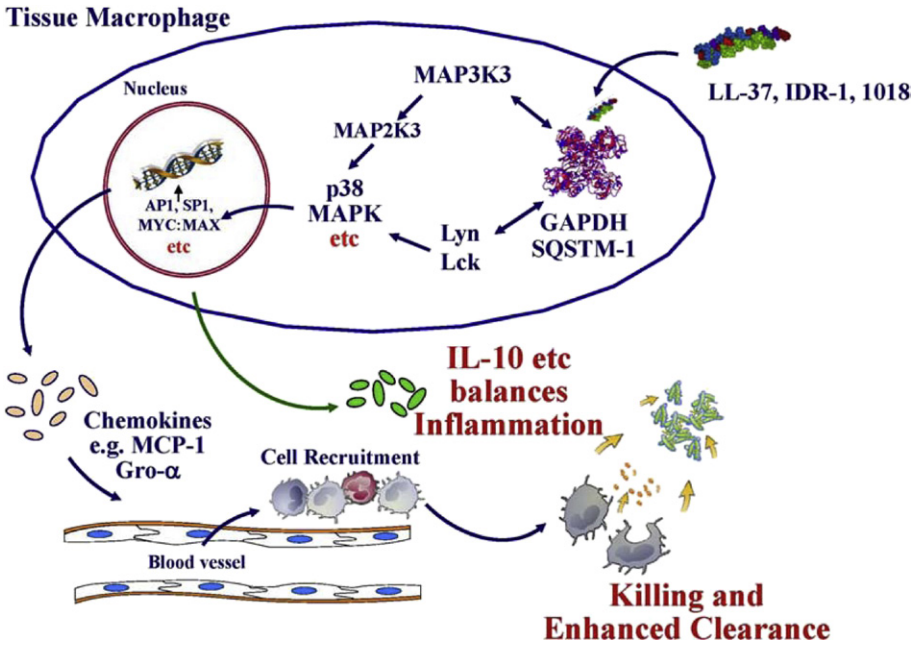

FIGURE 2 Proposed mechanism for cellular activation by LL-37: internalization of the peptide is facilitated by an atypical endocytic uptake, followed by interaction with the intracellular receptors. These interactions appear to facilitate modulation of various immune signaling pathways, mediates various immunomodulatory responses and overall results in the "selective" modulation of inflammatory responses (modified from *J Immunol* 2009;**183**:2688, and *Mol Biosystems* 2009;**5**:483).

receptors for LL-37 that mediate different events in particular cells, but the issue of cathelicidin receptor interactions and their function(s) in mediating biological activity is not yet completely resolved.

INFORMATION ON ACTIVE AND/OR SOLUTION CONFORMATION

Peptides of the cathelicidin family include representatives of all known secondary structure groups into which antimicrobial peptides are classified. Indeed they exhibit a remarkable variety of sizes, sequences, and structures. They typically have a net positive charge at neutral pH of +2 to +7 resulting from excess lysine and arginine basic residues, and contain around 50% hydrophobic amino acids. This permits them to fold into amphipathic or amphiphilic structures (often upon membrane contact), which is important in their mechanisms of action.[4,29] Mature (processed, biologically active) cathelicidins fold into one of four structural classes: (i) amphipathic α-helices (that form after interaction with membranes), (ii) β-hairpin molecules with two β-strands interconnected by intramolecular disulfide bonds, (iii) extended structures (upon membrane interaction) including peptides enriched in one or two amino acids such as proline and arginine, or tryptophan, and (iv) peptides such as bactenecin (dodecapeptide) that are cyclized by a single disulfide bond and contain a β-turn structure (Figure 3, Table 1). Their distinct antimicrobial and immunomodulatory functions have been localized to different regions of the peptide, and it is probable that these functions have different (but perhaps somewhat overlapping) structural determinants. Several studies have indicated that the amino acid sequence of natural cathelicidins can be modified to obtain much more potent synthetic antimicrobial peptides with reduced undesirable properties, such as mast cell degranulation, hemolysis and cytotoxicity. The quantitative structure–activity relationships (QSAR) approach, based on sequences of natural cathelicidins, together with computational structural modeling has yielded biologically active peptides with potential therapeutic use.[11] Further structure–function studies will fuel the synthesis of peptides with potent and perhaps selective activities.

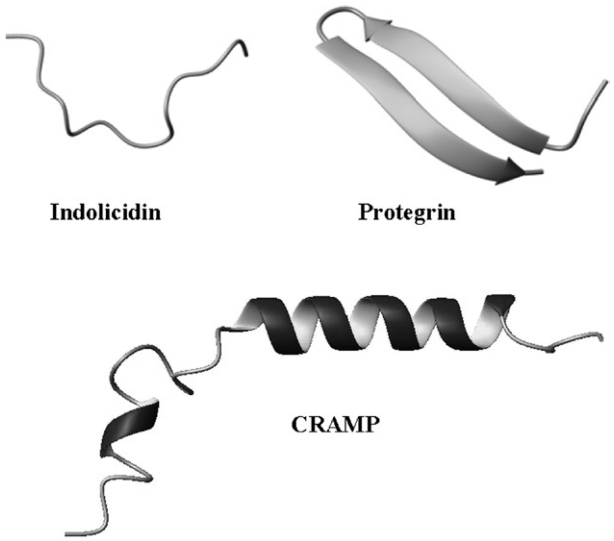

FIGURE 3 Ribbon structures of cathelicidin mature peptides bovine indolicidin (extended structure), porcine protegrin 1 (β-hairpin structure) and murine CRAMP (amphipathic α-helical structure).

BIOLOGICAL FUNCTIONS

Cathelicidins can function as immunomodulators and/or microbicidal agents in the innate immune system. The biological effects exerted by cathelicidins at a given time and place are probably determined by the specific activities of the peptide and the physiological setting, including the concentration of the peptide, cellular environment, and soluble components of the extracellular milieu. Although many publications refer to LL-37 as an antimicrobial peptide, in the presence of physiological salt, heparin, and serum conditions, LL-37 is not antimicrobial at the concentrations (generally 2 μg/ml) normally found in adults at mucosal surfaces, although it does exhibit immunomodulatory functions under these conditions. It is possible that the release of LL-37 during degranulation from neutrophils can considerably elevate local concentrations.

The most studied cathelicidin peptides, human LL-37, porcine PR-39, and bovine BMAP-28, have been shown, when added exogenously, to control bacterial load and prevent sepsis and mortality in rats and mice after bacterial challenge (Table 2). Mice deficient in the murine cathelicidin CRAMP also exhibit significant but moderate defects in defense against bacterial infections of the skin and respiratory tract as well as decreased angiogenesis and delayed wound closure. In humans with atopic dermatitis, low expression of LL-37 (and possibly other peptides) in skin lesions from patients coincides with their enhanced susceptibility to skin infections, while individuals with Morbus Kostmann, suffer from frequent oral bacterial infections and severe periodontal disease that correlates most with a deficiency in LL-37. Conversely, LL-37 is highly expressed in psoriatic skin and rosacea. Together, these observations demonstrate, *in vivo*, a significant role for cathelicidins in mucosal host defenses and wound healing.[3,15,22]

Anti-infective

The protective effects of cathelicidin peptides against different microorganisms (bacteria, viruses, yeast, fungi) have often been attributed to their direct antimicrobial killing properties, which can be mediated by bacterial cytoplasmic membrane disruption.[3,15] Indeed, some cathelicidin peptides have exceptionally good antimicrobial

activity (e.g., pig protegrin 1). Most cathelicidins, however, are not nearly as potent as protegrin yet may exert microbicidal action by other mechanisms, for example, LL-37 inhibits microbial attachment capabilities and biofilm formation.[5] LL-37 also exhibits antiviral effects by attacking viral membranes,[7] or targeting the reverse transcriptase of HIV.[32] Mouse cathelicidin CRAMP maintains colonic integrity and prevents inflammatory disease and infection in part by suppressing apoptosis and stimulating mucin gene expression and mucous production in the colon.[34]

Immunomodulatory

In addition to being antimicrobial, host defense peptides stimulate a broad range of biological effects in a innate immune cells (including neutrophils and epithelial cells), adaptive immune cells (T- and B-lymphocytes), and in cells that are involved in and bridge the innate and adaptive immune systems such as monocytes/macrophages and dendritic cells[3,8,15,22] (Table 2). They promote effector mechanisms that initiate and support innate and adaptive immune responses, yet they also protect the host against the detrimental effects of excessive inflammatory responses and support the subsequent resolution of inflammation.

Immune Activation

Cathelicidins promote chemotaxis of effector cells, induce the transcription and secretion of chemokines and cytokines, and induce mast cell activation and degranulation. Together these effects enhance vascular permeabilization, promote leukocyte extravasation, and regulate cellular responses at the site of infection/injury. Human cathelicidin LL-37 activates effector monocytes through many signaling pathways (IκB-α/NF-κB, PI3 K and the MAP kinases p38, ERK1/2 and JNK) and transcription factors (including NF-κB, AP-1, AP-2, SP-1, E2F1, CREB, and EGR) that induce the expression of nearly 500 immune-related genes.[18] LL-37 can also activate effector cells synergistically with proinflammatory stimuli (IL-1β, CpG, LTB_4), cellular differentiation factors (GM-CSF) and some TLR agonists (e.g., flagellin, polyI:C, and viral and microbial self-DNA/RNA); the latter synergy is in line with the observed adjuventicity of cathelicidins LL-37 and CRAMP.[1,3,22]

Inflammatory Control

In a diverse range of cells exposed to proinflammatory bacterial products, cathelicidins suppress gene transcription and the release of proinflammatory mediators. The antiendotoxin (LPS) effect of cathelicidins has been well described in numerous immune cells and correlates with protection in

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

several animal models of sepsis.[20] Recently, it was shown that LL-37 inhibited both innate and adaptive cellular responses to IFNγ, the key cytokine of Th1-polarized immunity.[23] Cathelicidins exert these effects through intracellaular and/or surface receptors that trigger intracellular signaling pathways that influence MAP kinases, Ca^{2+} moblilization and NF-κB.[18] Cathelicidins can also directly bind to negatively charged microbial components (e.g., LPS) and can also control inflammation by preventing the release of toxic cellular components that cause excess tissue damage and inflammation. For example, PR-39 inhibits the production of reactive oxygen species and BMAP-28 induces cell death via apoptosis of activated (infected) lymphocytes, which, unlike necrosis, occurs without releasing toxic cytoplasmic molecules. LL-37 also modulates apoptosis, necrosis and secondary necrosis with differing effects that are cell type specific; affected cells include neutrophils, keratinocytes, epithelial cells, endothelial cells, $CD4^+$ $CD25^+$ $FoxP3^+$ regulatory T cells, and cytotoxic, but not helper, T cells.[3]

Immune Resolution

Cathelicidins are strongly expressed during wound healing and have been shown to promote reepithelialization of human skin wounds and rat gastric ulcers. These effects may be mediated by cathelicidin-induced angiogenic effects, induction of epithelial cell migration and proliferation, and inflammatory modulation. LL-37-induced migration of keratinocytes and proliferation of epithelial cells is mediated by pathways involving EGFR/STAT3 and GPCR/EGFR/ERK.[34]

The neutralizing and resolving effects of cathelicidins provide a balance between the protective and destructive components of inflammation, protecting against lethal conditions, while promoting responses to eradicate the infectious agent. These neutralizing activities also implicate cathelicidins in maintaining homeostasis, particularly in regions of the gut rich in commensals that contain the same bacterial molecules that activate the innate immune response through TLRs.

THERAPEUTIC POTENTIAL

Recent advances in understanding the bioactivity of cathelicidins suggest a broad use of optimized derivatives of these peptides as therapeutic interventions. The most prominent therapeutic potential of cathelicidins is established in the protection against infections.[3] There has been considerable interest in developing synthetic peptide derivatives with enhanced therapeutic potential, for example, against drug-resistant pathogens, while eliminating undesirable cytotoxic properties associated with natural cathelicidins. For example, a bovine cathelicidin derivative, peptide Omiganan, has been shown to be effective against infections and in inflammatory conditions in clinical trials.[22] Recent studies have also explored the use of cathelicidin peptides in wound healing by promoting reepithelialization and angiogenesis, and in controlling inflammation.[34] Similarly, the immunomodulatory functions of these peptides have lead to their potential use as vaccine adjuvants.[22] The human cathelicidin LL-37 is now known to be a modulator of tumor growth, which seems to be tissue-specific. For example, LL-37 can promote breast and lung cancers and in contrast suppress tumor growth in gastric cancers.[33] Thus fragments derived from LL-37 are being developed as anticancer agents.[33] Another area for the use of these peptides is as biomarkers for disease diagnosis. Recent studies have demonstrated that human LL-37 may serve as a biomarker in inflammatory disorders such as eczema and chronic obstructive pulmonary disease.[13,17] Despite extensive proof-of-principle studies and some clinical trials, development of these peptides as therapeutics has several challenges,[11] primarily pharmacokinetics, peptide stability, possible side effects of systemic administration and associated production costs.

In summary, cathelicidins actively participate in the regulation of host defenses, exerting antimicrobial activity through the stimulation of biological functions in immune effector cells during the inflammatory and immune response and/or direct killing. The functional redundancy between species, the antiseptic activities, and adjuvant properties of cathelicidins make them attractive anti-infective therapeutic agents. The ability of cathelicidins to reduce proinflammatory mediators, induce chemotaxis and enhance the adaptive immune response *in vivo* validates these as key functions of cathelicidins in protection against bacterial challenge. However, the vast number of reports under varying conditions illuminates the need for experiments to confirm that *in vitro* activity is physiologically relevant *in vivo*.

Chapter 16

Class II Non-Lantibiotic Bacteriocins

Ingolf F. Nes, Dag A. Brede and Dzung B. Diep

ABSTRACT

The Class II bacteriocins, which often are termed non-lantibiotic and heat stable bacteriocins, encompass a larger group with high diversity with respect to structure and antimicrobial activity. Modifications have been identified in some new bacteriocins, and there are formylated methionines in the leaderless bacteriocins. It is becoming increasingly evident that Class IIa bacteriocins need a receptor for targeting bacteria. So far, only the Class IIa bacteriocins and a few non-related one-peptide bacteriocins have been experimentally proven to need a receptor. Despite there being no sequence homology between lactococcin A and the Class IIa bacteriocins, they are recognizing the same receptor, the membrane embedded part of the mannose PTS transport system. The two membrane proteins ManC and ManD that constitute the receptor and are needed for exerting antimicrobial activity are differently recognized by lactococcin A and the Class IIa bacteriocins. It seems probable that the target specificity of most Class II bacteriocins rely on a receptor.

BACKGROUND

Bacteriocins are defined as ribosomally synthesized antibacterial peptides/proteins that either kill or inhibit the growth of closely related bacteria. These bacteriocins are divided into two major classes: the Class I lantibiotics (see the chapter by Dischinger et al. in this section of the book) and the Class II non-modified bacteriocins, with the latter also being called the non-lantibiotics. The Class II bacteriocins, which are the focus of this chapter, are presently divided into: (a) the anti-listeria, pediocin-like bacteriocins that have very similar amino acid sequences at their N-terminus, (b) the two-peptide bacteriocins whose activity depends on two different peptides, (c) the cyclic bacteriocins, and (d) the linear nonpediocin-like one-peptide (LINPLOP) bacteriocins (Table 1). In addition, there is a group named leaderless bacteriocins because they are synthesized without an N-terminal leader peptide. Most bacteriocins are cationic and contain 30–70 amino acid residues, and their mode of killing is through membrane permeabilization of the target cells. Class II bacteriocins were originally defined as non-modified bacteriocins. However, during the last few years, it has been shown that some bacteriocins that are included in the Class II bacteriocins may have modifications such as formylation of the N-terminal residue[21] and glycosylation.[34] The classification of bacteriocins is still a matter of controversy, though there is a general agreement as to how certain subclasses are defined.

New Class II bacteriocins are frequently identified, and they are found among bacteria, mostly lactic acid bacteria (LAB), in a great variety of ecological niches such as cereal, milk, and meat-based foods and feeds, different kinds of silage and plants, and the intestinal tract of animals including humans. Class II bacteriocins have not been found in many applications to date. However, starter cultures for food fermentation (dairy and meat products) use bacteriocin-producing strains, and several commercial starter cultures are known to produce bacteriocins.

In recent years, probiotic bacteria have attracted an increased awareness among consumers. Such "health-promoting" bacteria are used in numerous food products and dietary supplements. Several probiotic cultures produce bacteriocins, and there is good circumstantial evidence that they contribute to a healthy gut microflora. Among the many ecological niches studied for the presence of bacteriocin-producing LAB, the fecal flora of babies, seem to represent an environment enriched with bacteriocin-producing LAB. In particular, bacteriocin-producing enterococci, the dominant LAB in the colon, are found at a high frequency. The role of bacteriocin-producing probiotic LAB was convincingly shown when a bacteriocin producer efficiently prevented the development of pathogenic *Listeria* in infected mice.[6]

NON-LANTIBIOTIC BACTERIOCINS: PROPERTIES AND STRUCTURAL FEATURES

Class IIa: Pediocin-like Bacteriocins

Class II bacteriocins are generally synthesized as a prebacteriocin with an N-terminal leader, which is removed during the process of secretion.[19] The leader is almost exclusively

a so-called double-glycine type with exceptions for some bacteriocins that use a common signal sequence for secretion (Sec leader).[4] To understand the antimicrobial activity of bacteriocins, it is important to understand their structure. Structural studies have provided important information and new ideas as to how such peptides kill target bacteria. Class IIa bacteriocins are the most thoroughly studied Class II bacteriocins.

The present model of how such bacteriocins interact with the target membrane is partly based on investigation of their three-dimensional structures in dodecylphosphocholine (DPC) micelles and in trifluoroethanol (TFE) by the use of nuclear magnetic resonance spectroscopy (NMR) and circular dichroism (CD), mutation analysis, and construction of hybrid molecules that have been studied in the groups of Vederas (Canada), Nissen-Meyer, (Norway), and others.[32] A common structural feature of Class IIa bacteriocins is their N-terminal consensus sequence (KYYGNGL/VXCXKXX-CXVDW) that is organized into an S-shaped antiparallel β-sheet structure stabilized by a disulfide bridge. In the absence of this bridge, the antimicrobial activity is drastically reduced.

The C-terminus of Class IIa is less conserved and comprises a more hydrophobic or amphiphilic α-helical-structure that has been proposed to interact with the hydrophobic core of target-cell membranes. The N-terminal and C-terminal regions seem to be linked together by a flexible hinge. Figure 1 shows the structures of some Class IIa bacteriocins. The C-terminus seems to be folded back, and in enterocin A and pediocin PA1, this structure is forced by a second disulfide bridge. This folded back structure seems to enhance the antimicrobial activity because introducing a similar disulfide bridge in sakacin P significantly improves the activity with respect to both potency and broadening the inhibitory spectrum.[11] Also temperature studies show that the bacteriocins without the second C-terminal disulfide bond are 30–50 times less active at 37 °C compared with the activity at 25 °C. Such heat instability is not observed for the bacteriocins with a second N-terminal disulfide bond.[16]

Class IIa bacteriocins are structured in membrane-mimicking solvents, and for a long time, the killing mode of such bacteriocins was based on the formation of a barrel-stave bacteriocin-based pore that provided a channel in the target-cell membrane for free diffusion of ions and/or small molecules. Even early experiments suggested that this was a simplified model and that more specific targets (receptors) were probably involved in the killing.

A detailed picture of target-specific interaction was first obtained for the lantibiotic nisin, which uses lipid II as a specific docking site to interact with target cells.[3] Years later, it was conclusively shown that many one-peptide bacteriocins including Class IIa bacteriocins target the membrane-located part (MptCD proteins) of the phosphoenolpyruvate:mannose phosphotransferase system (Man-PTS), which is the major transport system for glucose in bacteria.[8] Based on this and other studies, it was conclusively shown that such bacteriocins lead to permeabilization of targeted bacteria that encode a phylogenetically defined subgroup of Man-PTS. Particularly, a defined region of 40 amino acids that encompasses an extracellular loop of the membrane-located protein MptC is responsible for the specific target recognition by the Class IIa bacteriocins.[20]

The present model on how Class IIa and other one-peptide bacteriocins use ManCD (homologs of MptCD) as a receptor is depicted in Fig. 2. The mechanism of killing includes specific binding to or interaction with MptC (ManC) in the presence of MptD (ManD) by triggering an irreversible opening of the transporter which in effect permits a free diffusion of ions across the membrane that eventually kills the target cell.

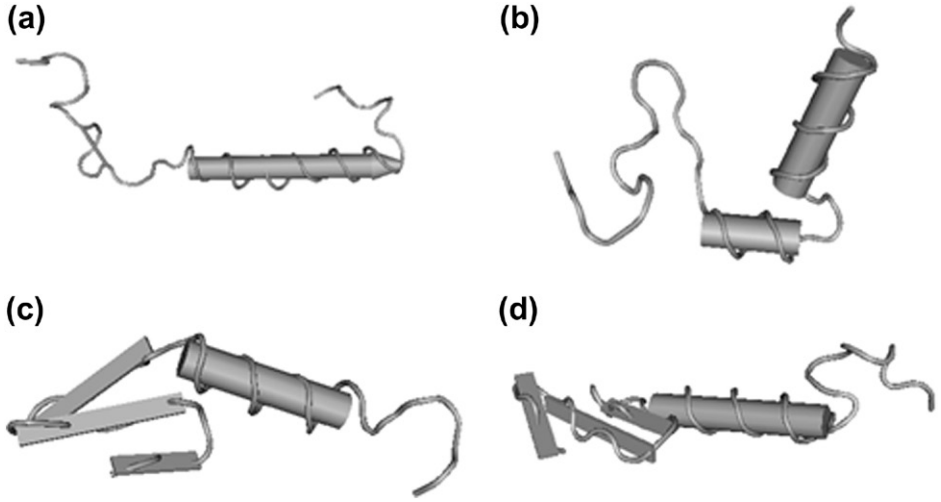

FIGURE 1 Structure of Class IIa bacteriocins. a, Carnobacteriocin B2; b, Curvacin A; c, Leucocin; d, Sakacin P. In A the conserved N-terminal disulphide bridge is shown. In c and d the N-terminal conserved S-shaped reminiscence of a three-stranded antiparallel β-sheet structure is shown.

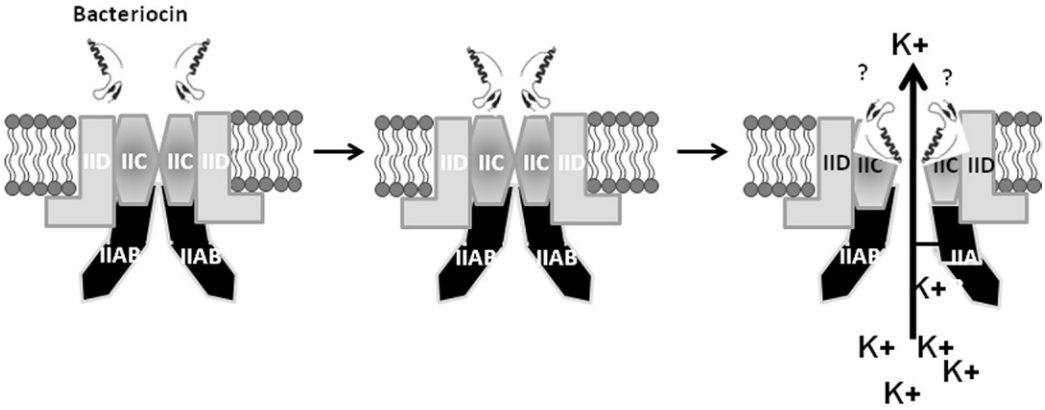

FIGURE 2 The model of killing by Man-PTS targeting bacteriocins. Shown here is the binding of a Class IIa bacteriocin to its receptor and the membrane embedded component ManCD (IIC and IID) of the Man-PTS transporter. This binding irreversibly opens the pore of the transporter and allows free diffusion of ions (such as potassium ions) from the targeted bacterium. Subunits IIA and IIB, which are domains reversibly associated with their membrane-located partners at the cytosolic side, are required for the sugar transport function but not for the bacteriocin receptor function.

Despite the observation that these bacteriocins target the membrane-located constituents of the Man-PTS transporter, it is not possible to exclude direct interaction between the bacteriocin and the hydrophobic membrane of the targeted bacterium as contributing to bacterial killing.

Class IIb: The Two-Peptide Bacteriocins

The two peptides that constitute a two-peptide bacteriocin are normally synthesized as precursor peptides each with a 15- to 30-residue double-glycine-type N-terminal leader sequence. The leader is cleaved at the C-terminal side of the two glycine residues by a dedicated ABC-transporter that concomitantly transfers the mature peptides across the cell membrane, as observed for most Class II bacteriocins and some lantibiotic bacteriocins. The features that identify a two-peptide bacteriocin are: (i) the bacteriocin comprises two non-identical peptides that are encoded by two separate genes located adjacent to one another, (ii) the individual peptides pose little or no antibacterial activity, (iii) the two peptides act together in a one to one molar ratio, and (iv) only one immunity protein is required to protect the producer.

Like other bacteriocins, two-peptide bacteriocins also attack the integrity of the target membrane thereby causing leakage of intracellular compounds such as potassium ions. But the mechanism behind the permeabilization is still poorly understood.

The individual peptides of lactococcin G bind independently to the membrane/target cells, but the antimicrobial activity is manifested only when both peptides are present concurrently.[26] It also seems that there is no diffusion of peptides between cells, and that the peptides seem to be immediately and irreversibly bound by the membrane/cell surface of the target cells.

Ion selective efflux is also observed among two-peptide bacteriocins. In the plantaricin system where 2 two-peptide bacteriocins are colocalized in the same gene cluster, plantaricin EF causes leakage of monovalent cations while plantaricin JK preferentially permits efflux of anions.[22]

The three-dimensional structures of some two-peptide bacteriocins have been elucidated by both CD and NMR spectroscopy in DPC micelles and in TFE.[27] These peptides contain long amphiphilic α-helical-structures, and the two peptides interact in a way that enhances their structuring in membrane-mimicking solvents. Experiments also suggest that the beta-peptide of lactococcin G or enterocin 1071 is important for the target specificity.[27] Structure–function studies and sequence analysis suggest that the two peptides form a membrane-penetrating stacked helix structure involving helix–helix-interacting GxxxG motifs that are present in virtually all characterized two-peptide bacteriocins.

In a study addressing the importance of the ends of the alpha and beta peptides of lactococcin G, selected N- and C-terminal L-amino acid residues were replaced with the D-isomeric counterparts.[29] Activity studies show that when the D-amino acid containing peptides are combined with their wildtype peptide counterparts, antimicrobial activities are partly retained. Studies combined with structural analysis of peptides modified at the C-terminal region of the alpha-LcnG peptide and at the C- and N-terminal regions of beta-LcnG peptide suggest that these terminal regions are not crucial in maintaining antibacterial activity.[29] The results indicate that these regions are not structurally essential for interpeptide interactions or in their interactions with cellular components. In addition, the immunity protein of lactococcin G also retains its function when the D-amino acid containing bacteriocin peptides are tested.[29]

Based on structural information, genetic, mutagenic, and complementary studies, a model as to how a two-peptide bacteriocin can form a pore in a membrane has

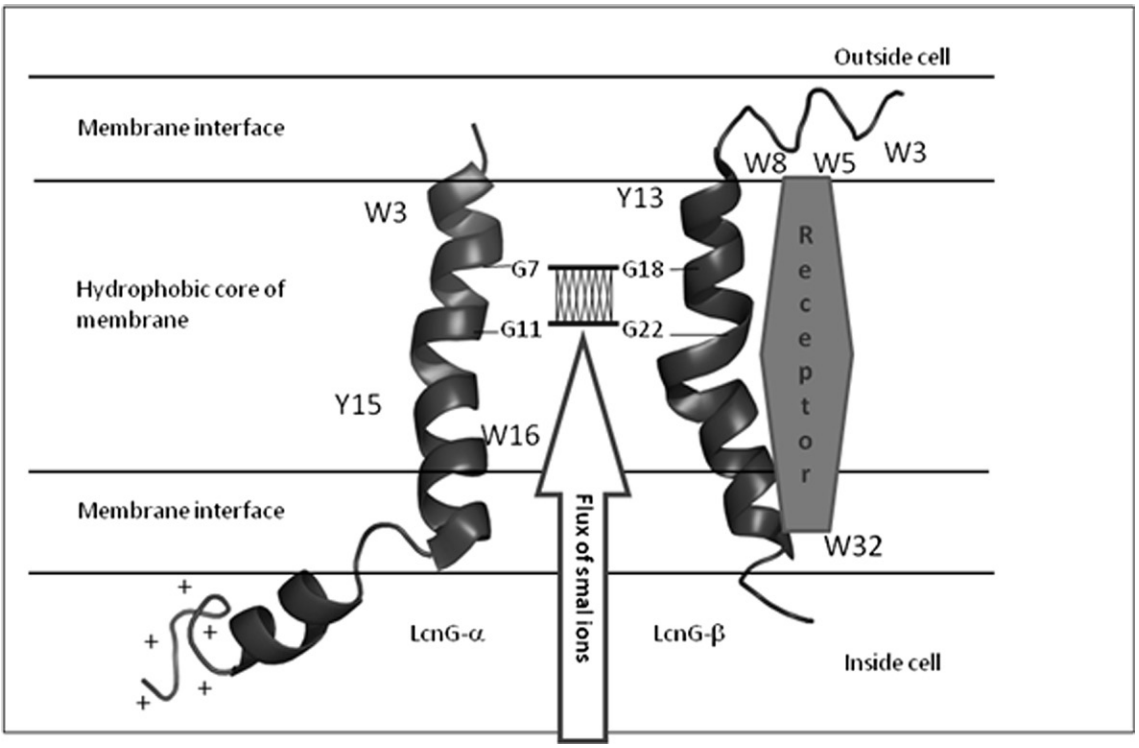

FIGURE 3 The model of how lactococcin G causes permeabilization in a bacterium. The two lactococcin G peptides become structured when they contact and insert into the target membrane. The two peptides interact with each other presumably when they become structured within the membrane and form a stacked helix structure involving the two GxxxG motifs (G7–G11 and G18–G22). A putative receptor molecule is included in the model.

been proposed by Nissen-Meyer and collaborators (Fig. 3). This model proposes that the two individual peptides in a two-peptide bacteriocin form a helix–helix structure when embedded in the membrane creating an open pore for free migration of ions between the cell and its environment. This model does not include any specific receptor, though such a target has been suggested. If one considers the narrow target specificity of the two-peptide bacteriocins, it seems probable that a receptor is involved in the killing as seen with many one-peptide bacteriocins, including the Class IIa ones, but such a target is yet to be identified.

It is proposed that many membrane-active peptide bacteriocins kill target cells through basically the same mechanism; such a common theme includes the concept that a membrane-penetrating part of the bacteriocin binds to a membrane embedded region of an integrated membrane protein (receptor) thereby causing conformational alterations in the structure of the target protein and/or membrane that in turn leads to membrane-leakage and eventually cell death.[27]

Class IIc: Circular Bacteriocins

Circular bacteriocins are antimicrobial peptides produced by a variety of Gram-positive bacteria. They are part of a growing family of ribosomally synthesized peptides that are circularized by an amide bond between the N and C termini of the linear propeptide. Circular bacteriocins adopt a four- or five-α-helix structure encompassing a hydrophobic core.[33] They are exceptionally stable and show increased resistance to proteases.

A cyclic bacteriocin is synthesized as a prebacteriocin with a defined leader, but the length of leaders and their sequences vary between the different bacteriocins. The cyclic bacteriocins are presently divided into two groups: (i) those with long (>20 amino acid residues) and (ii) those with very short (2–6 amino acid residues) leader sequences. Although the mechanisms behind their biosynthesis, including the cyclization process have not been disclosed, the minimum number of genes required for production has been determined for several cyclic bacteriocins.[33]

Cyclic bacteriocins permeabilize the membrane of sensitive bacteria, causing loss of ions and dissipation of the membrane potential. Carnocyclin A forms anion selective pores as seen with the two-peptide plantaricin JF.[12] Still most of the studies concerning mechanisms of action have been performed on *in vitro* systems where non-physiological concentrations of the bacteriocin are used. Because of the physicochemical properties of bacteriocins (e.g. cationic, hydrophobic, skewed composition of amino acids), such studies do not give a valid picture of the mechanism behind killing as seen with early studies of other bacteriocins such as nisin, where additional complexity is involved in receptors

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

(lipid II) and cell wall inhibition. Because of their stability and inertness to protease activity, the circular bacteriocins should have great potential in various applications from food to medical treatment.

Classification of bacteriocins can be a problem as seen with the head-to-tail cyclic bacteriocin subtilosin A that posttranslationally links cysteine sulfurs to alpha-carbons of certain amino acids as seen for the sactibiotics (see below).[17]

Class IId: LINPLOP Bacteriocins

This group of bacteriocins has sometimes been referred to as a miscellaneous group because it comprises a diverse group of bacteriocins with characteristics that do not fit them into any of the other subclasses. Some members of the LINPLOP subclass are lactococcins A and B, and enterocin B. Although the LINPLOP bacteriocins share no sequence similarity to the pediocin-like bacteriocins, some members of this group (lactococcins A and B) seem, surprisingly, to share some common mechanistic features with them in cell targeting and immunity.[8] Like the pediocin-like bacteriocins (Class IIa), lactococcin A uses the membrane-located components (ManCD) of the Man-PTS as receptor (Fig. 2). In both types of bacteriocins, their immunity proteins seems to exist in two different settings: one setting involves a soluble and/or loosely membrane-associated form in the absence of the cognate bacteriocins, and the second, which occurs when they confer immunity, involves a protein complex tightly associated with the Man-PTS (receptor) and the cognate bacteriocin. However, they differ greatly from each other in their inhibitory spectra. The lactococcal bacteriocins target basically only cells of lactococcal species while the pediocin-like bacteriocins, as a group, target cells of diverse bacterial genera but not cells of the *Lactococcus* genus. This substantial difference in target specificity relies mainly on small differences in the primary sequences of the membrane-located components of Man-PTS of the lactococcal cells and the non-lactococcal cells.[19,20]

Leaderless Bacteriocins

Leaderless bacteriocins have been found in the lactococci, enterococci, staphylococci, and others.[5,7,14,15,25] Historically, these bacteriocins have been grouped in the same subclass as the LINPLOP bacteriocins, but recent findings regarding their distinct genetics and biosynthesis suggest a separate subclass for these bacteriocins. The leaderless bacteriocins are synthesized without N-terminal signal peptide extensions, and consequently need no activation during excretion. Thus, they have several inherent traits distinct from other types of bacteriocins. They are not subject to posttranslational modifications or processing, although in 2002 the presence of an *N*-formyl-methionine residue (normally removed in bacteria during protein synthesis) was reported in aureocin A53.[24] Since then, another study confirmed formylation of the N-terminal methionine in such a leaderless bacteriocin,[21] and now it seems quite probable that such leaderless bacteriocins all have formylated N-terminal methionine residues. However, whether the formyl group is required for the antimicrobial activity or not has not been disclosed.

How the producer avoids being harmed by a leaderless bacteriocin before secretion is not understood, but it seems plausible that bactericidal activity is only possible from the outside of the cell. Evidence for a dedicated immunity gene/protein has been found in certain systems such as the enteriocin Q and aureocin 70.[7]

There are two different mechanisms by which leaderless bacteriocins are secreted. Some leaderless bacteriocins are exported by dedicated ABC-transporters, which lack domains typical for the recognition of Sec- or double-glycine leaders. Notably, the primary sequences of the four (A–D) aureocin 70 peptides are recognized by a single transporter. For other peptides, the transport mechanisms remain to be confirmed, although there is some evidence for members of *Staphylococcus* hemolytic protein family peptides (PF05480) that the transport is facilitated by the general secretion pathway. The primary structure of some leaderless bacteriocins shows homology to *Staphylococcus* hemolytic protein family peptides, which include phenol-soluble modulins (PSMs). PSMs are amphipathic, α-helical peptides found in *Staphylococcus aureus*, *Staphylococcus epidermidis* and other staphylococci. A subclass of these peptides also has bacteriocin activity.

Genes of leaderless bacteriocins can be found as clusters in the genomes, and up to four such genes have been found located next to each other, although single genes have also been identified. When more than two bacteriocins are found, they share strong sequence homology, suggesting that gene duplications have taken place. It is also surprising that they act synergistically, and the potency is increased and the spectra widened when these homologous peptides act together.[5,25]

In vitro experiments revealed that the four peptides of aureocin 70 oligomerize to enable pore formation. It has been shown that the leaderless aureocin A53 permeabilizes the bacterial membrane; its activity leads to cell death within minutes, and it was suggested that the bactericidal activity of aureocin A53 develops through a generalized membrane destruction rather than by formation of discrete pores within the membrane.

The most challenging aspect of the leaderless bacteriocins is their apparent structural similarity to hemolytic peptides and toxins found among certain pathogens.[9] Some of these toxins also possess antibacterial activity; consequently, leaderless bacteriocins should always be thoroughly scrutinized for toxic properties before being considered as antimicrobial remedies.

Antimicrobial Peptides Derived from Larger Proteins by Proteolytic Processing

An increasing number of bacteriocins derived from large precursor proteins are being characterized. *Propionibacterium jensenii* and *P. thoenii* secrete large amounts of the pro-PAMP protein, which on encountering proteases in its resident milieu is specifically processed into the protease-activated antimicrobial peptide.[10] It seems that propeptide is a microbial booby trap that targets proteolytic bacteria. Propionicin F is a 4.4-kDa bacteriocin derived from a 29-kDa precursor, which undergoes both N- and C-terminal proteolytic processing. In contrast to most bacteriocins, this peptide is negatively charged but displays bactericidal activity at nanomolar concentrations. In the intestinal isolates of *Lactobacillus reuteri*, the mucus adhesion protein MapA is degraded by the producer into specific peptides with antimicrobial activity.[2] This pleiotropic function of the MapA protein offers a new perspective on how bacteria gain a competitive edge in the gut epithelium. Presently, the mechanism behind the production of MapA-derived antimicrobial peptide, and whether it plays a role in defenses against pathogenic bacteria in the gastrointestinal tract is unknown.

OTHER NON-LANTIBIOTICS BUT MODIFIED BACTERIOCINS

In 1996, a new bacteriocin was found to be produced by a *Lactobacillus plantarum* strain.[18] Subsequently, it was shown that this bacteriocin (named glycocin F) was posttranslationally glycosylated in two amino acid residues.[34] An N-acetylglucosamine was linked to the oxygen atom in Ser18, and an *N*-acetylhexosamine was S-linked to the cysteine in position 43. Glycocin F is synthesized with a double-glycine leader as found in many bacteriocins. Some bacteriocins such as plantaricin ASM[13] were previously classified as lantibiotics, but now there is a good reason to believe that such bacteriocins are not lantibiotics but belong to the group of glycosylated bacteriocins. The glycosylated bacteriocins may include, in addition to glycocin F and sublancin 168[28] (originally classified as a lantibiotic), bacteriocins such as plantaricin ASM, and enterocin 96 though the last two have not been experimentally proven to contain such modifications.

Thuricin CD, produced by *Bacillus thuringiensis*, is another posttranslationally modified bacteriocin that does not fit into the class of lantibiotics and has been allocated to a new class of bacteriocins named sactibiotics.[23] The sactibiotics have a unique modification wherein sulfur atoms are covalently linked to the α-carbon backbone of amino acids. Thuricin CD is a bacteriocin that consists of two peptides, each having three sulfur to α-carbon bridge modifications and these peptides share 45.3% sequence similarity.[31] The individual peptides exhibit some antimicrobial activity but when combined they exhibit much stronger activity. Optimal activity is achieved when the two peptides are mixed in a one to one molar ratio. In addition, the two peptides are synthesized in a prepeptide form with typical double-glycine leaders, as found for many other bacteriocins within Classes I and II. The circular subtilosin A can also be classified as a sactibiotic because it covalently links sulfur to certain α-carbon-amino acids.

A bioinformatic search in bacterial genome databases identified 15 novel thuricin CD-like gene clusters, based on the presence of homologs of thuricin-like bacteriocin genes.[23] Thus, sactibiotic-like bacteriocins seem to be abundant in Gram-positive bacteria. Thuricin CD seems to have a great potential for use in the treatment of *Clostridium difficile* infections resulting from its unique anticlostridial activity with little or no impact on the commensal gut flora. In contrast, other antimicrobial agents greatly affect the composition of the human microflora of the gut.[30]

CONCLUDING REMARKS

Over the years, we have seen an increasing number of new bacteriocins with different properties. New classes of bacteriocins are found with new and interesting structures and antimicrobial activities, which will make them useful for combating pathogens. Bacteriocins are among the most potent antimicrobial compounds known, but they are limited by their narrow specific activity. Many bacteriocins do not target all bacteria within a species, whereas others are able to kill selected isolates from different genera. Although several reports claim that Gram-positive bacteriocins are able to kill Gram-negative bacteria, this is largely by a combined action with other antimicrobial or chemical entities. On the other hand, it is interesting to note that not just the Class IIa bacteriocins need the Man-PTS system as a receptor as certain Gram-negative bacteriocins also require membrane components of the Man-PTS to exert their antimicrobial effects.[1] The Man-PTS system is ubiquitous in bacteria but not found in eukaryotes, and therefore, it should be possible to develop a strategy to fight all bacteria with peptide drugs targeting at the Man-PTS.

The greatest genetic diversity is found among bacteria, and we will certainly, in the future, discover a large number of new and chemically diverse bacteriocins with specificities against different bacterial targets. This will give us a great opportunity to develop new and potent antimicrobial compounds to fight pathogens. Such an effort is a human necessity because the antibiotic era is slowly but surely coming to a halt.

Chapter 17

Colicins

O. Sharma, S.D. Zakharov, M.V. Zhalnina, E. Yamashita and W.A. Cramer

ABSTRACT

The functions of receptor binding, cytotoxicity, and translocation across the cell envelope, which are necessary for colicins to enter the cell to exert their lethal effect, are encoded in defined domains. Import into the cell is guided by a transenvelope network of "tol" or "ton" proteins. The crystal structures of several colicins or one of their domains are known. Structures have also been obtained for the outer membrane vitamin B_{12} (BtuB) and CirA receptors, in complex with the receptor (R)-domain of the nuclease E-colicins and the channel-forming colicin Ia, respectively. Both extended (>100 Å) colicin receptor–binding domains protrude obliquely from the membrane plane at a 45° angle, resembling a "fishing pole." The disordered colicin E3 N-terminal peptide inserts into an OmpF pore, as shown by crystal structures. Occlusion of OmpF channels by the unfolded colicin E3 C-terminal cytotoxic nuclease domain supports the premise that the colicin C–terminal domain is cotranslocated through OmpF.

DISCOVERY AND CLASSIFICATION

Colicins are plasmid-encoded bacteriocins, produced by *Escherichia coli* under stress conditions, which are cytotoxic to closely related strains that contain the required outer membrane receptor(s) but do not produce the cognate immunity protein. Colicins were first discovered in 1925 by Gratia who showed that one strain of *E. coli* ("V" for virulent) released a substance found in the filtrate that was toxic to a sensitive strain.[3] Gratia also showed that colicin-resistant mutants could be derived from sensitive strains. Fredericq later suggested that resistance to colicins involved the loss of a surface receptor specific for that type of colicin.[3] Indeed, as was confirmed later, colicins enter cells by parasitizing outer membrane receptors that have the physiological purpose of binding and import of metabolites (e.g., vitamins, sugars, metals such as iron). Subsequently, several colicins differing in their mode of action and the receptors they parasitize to gain entry into target cells have been identified. The domain organization of colicins, with each domain performing a distinct function in colicin uptake,[1] is shown (Fig. 1A). Ribbon diagrams of those colicins (Ia, N, B, which are pore formers, and E3, an rRNase) for which the 3-D structure has been solved, are shown in Fig. 1 B–F. Colicins have also been classified according to the translocation system that they appropriate to enter the bacteria. Group A colicins use the bacterial Tol-dependent translocation system consisting of the proteins TolA, TolB, TolQ, TolR, and Pal (Table 1). The "Tol" nomenclature is derived from the observation that mutants of such gene products are "tolerant" to colicin action. Group B colicins use the ton-dependent system, consisting of TonB and ExbB–ExbD (Table 2). "Ton" mutants are so named because they are resistant to the phage T1. As can be seen from the tables, the lethal action of most known colicins is exerted either by cellular deenergization[8,19] that results from the formation of a highly conducting pore in the cytoplasmic membrane or by an enzymatic nuclease digestion mechanism (reviewed in Ref. 3).

COLICIN, IMMUNITY, AND LYSIS PROTEINS

Cells are themselves protected from the action of the colicins they produce by coordinate synthesis of an immunity protein that acts specifically against that colicin. Immunity proteins are small (MW ~10kDa) polypeptides that protect the colicin-producing cells from both endogenous and exogenous colicins. Immunity proteins bind tightly to the enzymatic colicins and prevent them from acting on the colicin-producing cell. In the case of the pore-forming colicins, a small number of immunity molecules (~10^2–10^3) in the cytoplasmic membrane are able to provide immunity against the formation of a single functional and lethal channel in that membrane. Regions of homology between the immunity proteins of pore-forming colicins A, B, and N have suggested that extramembrane loops L1 and L3 of the 3-4 TM helix immunity protein interact with the respective colicins. A "lysis protein," localized in the periplasmic space, functions to release colicin from producer cells to the extracellular medium, both for the colicin-immunity protein complex of enzymatically active colicins and for pore-forming colicins. The gene encoding the colicin, its cognate immunity protein, and the lysis protein form an operon that

TABLE 2 Colicins that are Imported via the Ton System. Although the Mechanism of Import of the Various Colicins into the Target Cells is Similar, the Cytotoxic Activity Differs. A Common Feature of these Colicins is the Presence of a TonB Box that Interacts with the TonB Protein, which Transduces Energy from the Inner Membrane to these Import Processes[3]

Colicin	Activity protein[1]	Immunity protein[1]	Receptor protein	Activity
B	510	175	FepA	Channel
D	697	87	FepA	Protein synthesis[2]
Ia	626	111	Cir	Channel
Ib	626	115	Cir	Channel

Ton-dependent colicins Js, M, 5, and 10 have not been included in the table.
[1]Length in amino acids.
[2]Inhibits protein synthesis by cleavage of arginine tRNAs.

is regulated by an SOS (DNA-damage–induced) promoter. In the absence of induction, the immunity gene is expressed by a constitutive promoter that provides basal levels of immunity protein for protection against exogenous colicins (reviewed in Ref. 3).

THE DOMAIN CONCEPT

There are three defined steps in the killing of sensitive *E. coli* by most colicins, each of which is carried out by a separate domain of the colicin that occupies approximately one-third of the polypeptide (Fig. 1A). The first step involves the central "R" (receptor) domain, which mediates the binding of colicin to its outer membrane receptor. The N-terminal "T" (translocation) domain mediates the second step of translocation from the outer membrane receptor to the colicin target in the cell. Finally, the carboxy-terminal "C" (catalytic) domain functions in cytotoxicity.

CRYSTAL STRUCTURES OF COLICINS (FIG. 1B–E)

(A) The four complete or incomplete structures of colicins that have been solved by X-ray diffraction of three-dimensional crystals and their major properties are summarized: (i) The structure of residues 23–39 and 83–624 of the 626 residue pore-forming colicin Ia ("B-type," translocated by the Ton system) has been resolved to 3.0 Å resolution (Fig. 1B[29]) and (ii) that encompassing residues 84–551 of the 551 residue endoribonuclease colicin E3 ("A-type," translocated by the Tol system) to 3.0 Å (Fig. 1C[24]). The crystal structure of a complex of the BtuB receptor and bound coiled-coil R-domain of colicins E2[21] and E3,[16] relevant to the mechanism of their cellular import through the outer membrane, is discussed below. (iii) A 3.1-Å structure of a 292 residue segment, of a 321 residue chymotryptic fragment of the 387 residue pore-forming colicin N, contains the globular channel domain (Fig. 1D) but is missing a substantial part (N-terminal 90 residues) of the T- (and possibly of the R-) domain.[27] (iv) The structure of most of the 511 residue pore-forming colicin B (ton dependent) (Fig. 1E) was solved at a 2.5-Å resolution.[11] The X-ray and NMR structures of the C-domains of pore-forming colicins A[18] and E1[7] show a bundle of ten α-helices with a hydrophobic helical hairpin anchor at the core. The structures of the endonuclease domain of colicins E3, E7, and E9 (tol dependent), and ton-dependent colicin D, in complex with Imm or nucleic acids, have also been solved.[9,15,26]

The T-, R-, and C-domains in colicins E3 (RNase; tol dependent) and Ia (pore forming; ton dependent) are structurally defined (Fig. 1B, C) and connected by long α-helices that form coiled coils, whereas in colicin B (pore forming; ton dependent; Fig. 1E), and probably in colicin N (pore-forming; tol-dependent; Fig. 1D), the T- and R-domain functions are located in a globular domain that is separated from the C-domain by a single long helix, forming the shape of a dumbbell. These two distinct shapes are not related to either the import pathway (tol or ton dependent) or to the mechanism of cytotoxicity (pore formation or endonuclease). It has been proposed that the extended coiled-coil structure ("fishing pole") in nuclease colicins such as E3 is necessary for delivery of T- and C-domains of a receptor-bound colicin to the outer membrane porin OmpF, through which it is translocated to the periplasm.[16] Outer membrane porins do not seem to be involved in the import of the ton-dependent colicin Ia.[13]

(B) *T-domains.* The N-terminal T-domain of colicin Ia contains a "TonB box" (E23–V27) that is necessary for translocation across the periplasm as part of an antiparallel helix bundle. This secondary structure of the T-domain of colicin Ia contrasts with the β-sheet "jelly roll" that forms most of the colicin E3 T-domain. The N-terminal region of the nuclease E colicin T-domain contains an extended "TolB box" needed for translocation,[10] and is glycine-rich

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

(34 of 79 residues), accounting for the disorder in this region of the structure. A possible reason for the difference in the T-domain structures of colicins Ia and E3 is that the immunity protein is tightly bound to the T-domain in the latter. The N-terminal domain of colicin B is composed of 17 β-strands, 2 α-helices, and long loops. The central region (residues 130–291) of its sequence shares some similarity with the T-domain of colicin E3, but the folding pattern does not fit to a jelly roll motif. In both colicins Ia and B, the N-terminal segments, containing the TonB box (residues 23–27 and 17–21 in Ia and B, respectively) are folded back and interact with antiparallel helices of the coiled-coil and T-domain in colicin Ia and with the N-terminal lobe (TR-domains) of colicin B.

(C) *R-domains.* The 104 residue region at the tip of the 160-Å coiled coil, consisting of an amphipathic two-stranded β-hairpin folded around the tip-terminal helix of the coiled coil was proposed to bind to the colicin Ia Cir receptor.[29] The R-domain of colicin N was proposed to consist of a 65 residue (residues 97–161) six-stranded β-strand wrapped around the C-terminal end of a 45 residue extended helix (65 Å) that would be part of the pore-forming domain.[27] The receptor-binding function of colicin B was attributed to two antiparallel β-strands (residues 262–282) of the same N-terminal lobe that contains the T-domain.

Comparison of the structure of colicin Ia (Fig. 1B) with genetic and functional analysis of the pore-forming colicins implies that the entire coiled coil might be a good fit to the receptor-binding R-domain. Subsequent studies of the minimum receptor-binding domain in the A type colicins E9 and E3 that inhibit intracellular protein synthesis have indicated that a large part of the coiled-coil, but perhaps only its distal half, might be necessary for recognition and effective binding to the receptor. The coiled-coil nature of the receptor domain in the structure of intact colicins Ia and E3 implies that this is a necessary structural motif for interaction with the receptor that initially sequesters the colicin.

The markedly smaller length of the extended helices of colicins N and B is suggestive of a mechanism that is different from those used by colicins Ia and E3 for receptor binding and translocation across the outer membrane and periplasmic space.

(D) *Cytotoxicity domains.* The isolated soluble pore-forming 20-kDa domain of colicins A[18] and E1,[7] along with these domains in the intact colicins B, Ia, and N, have a similar 10 helix globular structure with a tightly packed apolar core formed by a hydrophobic helical hairpin consisting of helices VIII and IX. This hairpin is surrounded by 8 hydrophilic helices, some of which are amphipathic. The average length of the two hairpin helices is 15–16 residues, shorter than usually considered necessary (~20 residues) to span the membrane bilayer. The average length of the surrounding 8 helical segments is 12–14 residues. Beyond the implied role of the buried helical hydrophobic hairpin as a potential membrane anchor, the structure of the soluble channel domain provides few clues about the mechanism of pore formation and insertion into the membrane, particularly since the one-hit mechanism of cell killing implies that the channel is formed by a single colicin molecule. In addition, the channel-forming domain of the soluble colicin must undergo large voltage-dependent conformational changes to accomplish insertion of the channel.[17,33,34]

The function of the hydrophobic helical hairpin is to serve as an anchor during pore-forming domain insertion into membrane bilayer. This interaction is dependent on the anionic lipid content, that is, and is optimal at approximately 20–30% anionic lipid and a negative membrane surface potential of approximately −60 mV.[34] Electrostatic interactions with the negatively charged membrane surface (i) guides binding of the C-terminal pore-forming domain to the membrane surface and (ii) induces unfolding that results in the formation of a surface-bound prepore state.[17,33]

The ability of pore-forming colicins to form ion channels in planar bilayer membranes was demonstrated for the first time by Schein et al.[19] The transition of the colicin from a closed-to-open state requires the presence of a transmembrane potential, negative on the side of the membrane opposite (*trans*) to the side of protein binding and insertion. The electrical field across the cytoplasmic membrane (*in vivo*) created by the electrochemical proton gradient thus favors pore formation. The structure of the open channel state is not known. The one-hit killing first described by F. Jacob implies that the channel is formed by a single colicin molecule or unit. In the open state of the channel, a significant part of the C-domain (68 residues, helices II–V of colicin Ia) becomes accessible to ligand binding from the *trans* side of the membrane.[23] The dependence of channel formation by colicins on the lipid content of membrane points to the involvement of lipids in the formation and a structure of the ion channel that has been characterized as a "toroidal pore."[32]

The cytotoxic activity of endonuclease colicins also resides in the C-terminal domain. The size of the C-terminal cytotoxic domain of these colicins ranges from 96 to 135 residues. The immunity proteins bind to these domains with very high affinity ($K_d < 10^{-13}$M[28]; Zakharov et al., unpublished), efficiently blocking the interaction of colicins with their substrates, DNA or ribosomes. Extensive, highly complementary interaction surfaces in endonuclease–Imm complexes that involve hydrophobic and polar side chains of both proteins, account for the high-affinity nature of binding of Imm. Active sites in both DNase and rRNase colicins involve residues on the C-terminal side relative to the residues involved in Imm binding. This can allow Imm binding to an incompletely translated colicin to afford protection to host cells during the toxin synthesis.

CRYSTAL STRUCTURES OF COLICIN–RECEPTOR COMPLEXES (FIG. 2)

Crystal structures of complexes formed by polypeptide fragments of (i) the receptor-binding domain of colicins E2, E3, and Ia with the outer membrane primary receptor, BtuB[16,21] or Cir[2] and (ii) the N-terminal T-domain of colicins E3 and E9 with OmpF[12,30] have provided an insight into the initial molecular events that concentrate the colicin from three-dimensional solution space to the two-dimensional cell surface. Here, we discuss these structures together with the information they provide regarding the mechanism of colicin translocation across the *E. coli* outer membrane.

Colicin R Domain and the Primary Receptor

(A) Comparison of E2R135–BtuB and E3R135–BtuB, and with apo-BtuB –Crystallization of colicin E2[21] (Fig. 2B) and E3[16] (Fig. 2A) R-domains (135 residues) in complex with their primary receptor, BtuB, yielded crystal structures at 3.5- and 2.75-Å resolution, respectively. The two crystal structures showed the colicin R domain bound peripherally and at an oblique angle of 45° to the membrane plane. There was no disorder seen in the plug domain of either crystal structures, implying that the colicins do not translocate through the BtuB central pore. Further evidence in this regard comes from planar bilayer studies that did not show an opening of the BtuB pore upon addition of colicin E3 R-domain.[16] The oblique angle of the R-domain is thought to be physiologically relevant and is hypothesized to position the T-domain of the colicin in close proximity to the outer membrane where it enables a search for the secondary receptor/translocator, OmpF, or OmpC. The ample abundance of OmpF and/or OmpC (~10^5/cell) ensures that at least one of these porins can be found within easy reach of the obliquely bound colicin. The natively unstructured N-terminal 83 residues of colicins E2 and E3 have been inferred to enable the colicin to bind to and traverse the outer membrane to reach the periplasmic TolB protein. The two structures were found to be remarkably similar with the main difference being that the R domain in E2R135–BtuB was two and five residues longer, respectively, on the N- and C-termini. Although the R-domain was bound peripherally, the interaction between the R-domain and BtuB is surprisingly strong. The K_d of the interaction was estimated to be approximately 10^{-9}M, implying a binding energy of approximately −12kcal/mol.[16] This strong interaction suggests that the C-domain of colicin reaches its cytosolic target not by dissociation of the colicin from its tightly bound receptor but by separation of the C-domain from the rest of the colicin. The cleaved C-domain then enters the cell cytosol.

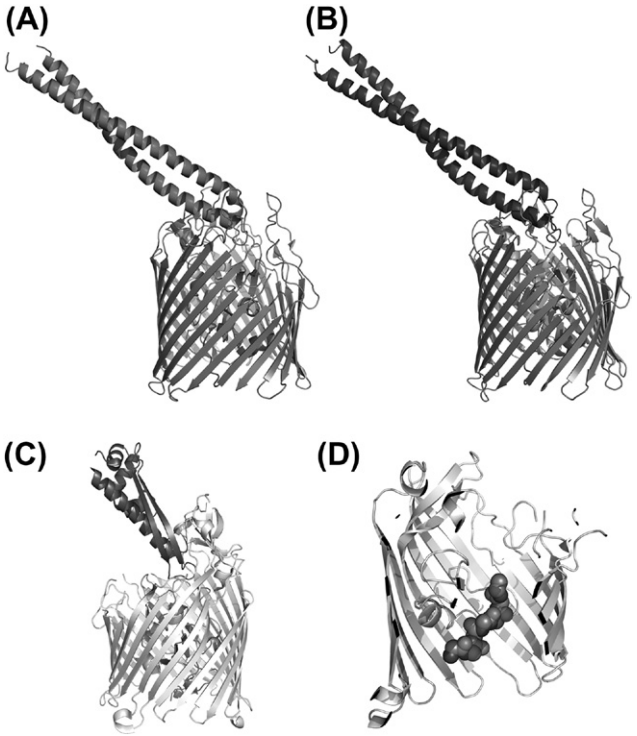

FIGURE 2 Crystal structures of receptor-binding R135 fragment of colicin (A) E3 and (B) E2 (residues 313–447) in complex with the high-affinity outer membrane vitamin B12 receptor at 2.75 and 3.5 Å, respectively. (C) A 2.5-Å resolution structure of colicin Ia R104 (aa 282–385) fragment bound to its Cir receptor showing the colicin Ia bound at the same 45° angle to membrane plane, as seen for colicin E2 and E3R135–BtuB structures above. (D) A 3.0-Å structure of OmpF porin with a small fragment of the translocating N-terminal peptide segment of colicin E3, corresponding to carbon backbone of a string of 7 residues, bound in the central pore.

At least some degree of colicin unfolding is required for its entry into the cell. The structure of E2R135–BtuB and E3R135–BtuB has revealed unwinding of intertwined coiled-coil R-domain and unfolding of the ends of the alpha-helices suggesting that the binding energy of BtuB and colicin R-domain can be used for colicin unfolding.[16] The binding of colicin E2 and E3 R-domain causes some changes in the BtuB structure, too. Most of the changes are in the extracellular loops of BtuB, some of which become ordered on binding of the R-domain. Two residues, Ser4 and Pro5 of the TonB box, become ordered up binding of the R-domain.

(B) Ia R104-Cir complex (Fig. 2C) – The structure of the R-domain (104 residues, aa 282–385) of the pore-forming Group B colicin Ia in complex with its Cir receptor has been solved to 2.5-Å resolution.[2] The structure revealed the Ia R-domain to be bound at a 45° angle to the membrane plane, an orientation very similar to that seen in the E2R135–BtuB and E3R135–BtuB structures. The Ia R-domain binds peripherally, yet tightly (dissociation constant, ~10^{-10}M) to Cir. As in the structures of nuclease colicin R-domains with BtuB, no significant disorder was seen in the plug domain

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

of the Cir receptor, suggesting that Ia translocates across the outer membrane through a secondary receptor/translocator. This secondary receptor/translocator was inferred to be another Cir molecule.[13] Superimposition of the complete colicin Ia structure onto the structure of Ia–Cir complex reveals that because of the long 160-Å helices connecting R-domain to the C- and T-domain, the C- and T-domains are suspended approximately 100 Å above the membrane surface. It is unclear how these domains of the colicin would traverse this distance to reach the membrane surface.

(C) Binding of Colicin N to OmpF – Electron microscopic analysis of 2-D crystals of colicin N along with its receptor/translocator OmpF revealed the colicin to be bound at the periphery of OmpF trimer where it could displace LPS molecules bound to OmpF.[5] Neutron scattering indicates that the pore-forming domain of colicin N binds in the interstices of the OmpF trimer, inserting into an OmpF–lipid interface.[5] Interaction of the colicin with LPS is further corroborated by the results of genomic screening that identified LPS biosynthesis genes to have a function in the cytotoxicity of colicin N.[20] Genes *gmhA*, *gmhB*, gmhC, *gmhD* that function in synthesizing the ADP-L, D-Hep moiety, *waaC*, and *waaF* that use the ADP-L, D-Hep to form the LPS inner core and *waaG* and *galU* that, in concert, add the first glucose to this inner core, were all identified to be required for colicin cytotoxicity. These results imply that the LPS inner core together with the first added glucose forms the minimum binding site for colicin N.

It is unclear whether colicin N translocation across the outer membrane occurs through the central OmpF lumen or at the OmpF-lipid interface. There is evidence to suggest that the colicin T-domain interacts with the OmpF lumen.[14,31] One of the possible mechanisms of colicin N entry that can accommodate these findings is that the colicin T-domain interacts and traverses the outer membrane through OmpF to reach the periplasm. In the periplasm, the TolB box in the colicin T-domain interacts with the TolB protein that is a part of the Tol complex. This interaction together with the colicin N–OmpF binding energy causes partial unfolding of the colicin, enabling the C-domain to traverse the outer membrane at the membrane-OmpF interface. In this model, the colicin R-domain remains anchored to the outer membrane through its interactions with OmpF, whereas the C-domain reaches the inner membrane where it forms channels killing the cell. Support for this model also comes from planar bilayer studies that show that the T-domain of colicin N can occlude OmpF channels, whereas the RC domain does not.[31]

Colicin E3 T-domain and OmpF (Fig. 2D)

Subsequent steps in the import of the nuclease colicins E2, E3, and E9 across the outer membrane include facile lateral diffusion across the outer membrane[25] and formation of a transient complex with the OmpF porin to which the colicin N-terminal T-domain binds and inserts. The latter inference is based on structure data derived from diffraction data at 3.0-Å resolution obtained from cocrystals of OmpF with N-terminal peptides of colicins E3[30] or E9.[12] Electron density was consistent with a seven residue segment of the colicin E3 T-domain, the sequence of which was not determined in the original study but overlapped a 15 residue peptide T-domain peptide of colicin E9 that spans the aqueous channel running through OmpF. These structures define the anchor formed by these colicins with the OmpF pore protein through which their cytotoxic C-terminal segment must be inserted. Although a structure has not yet been obtained of the latter complex, it has been shown that the C-terminal peptide of colicin E3 will occlude OmpF channels in planar bilayer membranes.[35]

MECHANISM OF IMPORT ACROSS THE OUTER MEMBRANE (FIG. 3)

Several steps have been identified in the uptake and subsequent cytotoxicity of the colicins. These steps have been hypothesized in both Group A and B colicins. In the first step (Fig. 3, Step 1), colicins bind tightly to their primary receptor, through their R-domain. This binding is at an oblique angle to the plane of the membrane, as seen in the crystal structures of E2R135–BtuB, E3R135–BtuB, and Ia R104–Cir. This allows the T-domain of the colicin to potentially scour the neighboring area for the secondary receptor/translocator, OmpF/OmpC in the case of nuclease E colicins and Cir in the case of colicin Ia (Fig. 3, Step 2). The T-domain then interacts with either the Tol or the Ton network (Fig. 3, Step 3). This interaction leads to the release of the immunity protein[6] (Fig. 3, Step 4). Release of

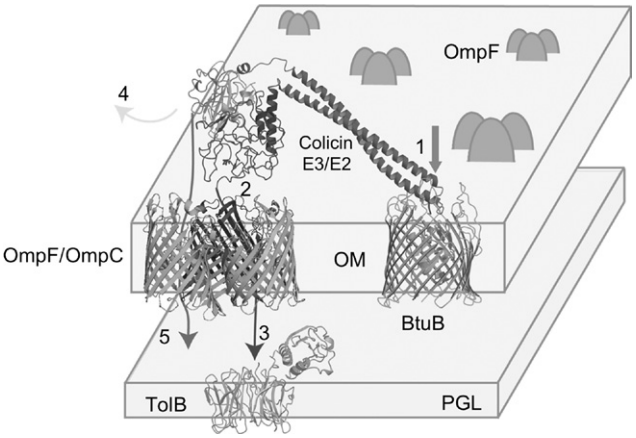

FIGURE 3 Events occurring during the import of colicin E3/E2: **(1)** High-affinity binding to the primary receptor BtuB; **(2)** interaction with and insertion through the secondary receptor/translocator OmpF/OmpC; **(3)** binding to TolB; **(4)** release of Immunity; **(5)** proteolytic cleavage of the cytotoxic C-domain followed by its insertion into the cell where it exerts its cytotoxic effects.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

immunity protein has been shown to cause a partial unfolding of the colicin E3 C-domain allowing it to interact with OmpF[35] (Fig. 3, Step 5). Concomitantly, a protease then functions to separate the C-domain from the rest of the colicin by cleaving at the junction between the C- and the R-domain[22] (Fig. 3, Step 5). In contradiction to an earlier work that found the protease to be periplasmic for colicin E7,[22] a recent work has identified the protease to be an inner membrane protein, FtsH,[4] in the case of colicins D and E3. The mechanism of translocation of C-domain into the cell across the inner membrane is yet to be elucidated but is widely believed to be mediated by the Tol or the TonB–ExbBD complexes.

AREAS OF RESEARCH ENCOMPASSED BY COLICIN STUDIES

As described above, colicin studies span a broad range of general interests that include mechanisms of protein secretion, protein import, protein–receptor interactions, high-affinity protein–protein interactions, ion channel structures and function, and intracellular nuclease activities.

Chapter 18

Defensins

Nikolinka Antcheva, Filomena Guida and Alessandro Tossi

ABSTRACT

The term defensin relates to a set of host defense peptides (HDPs) in vertebrates, invertebrates, plants, and molds that display structural similarities based on a cystine stabilized antiparallel β-sheet core, with an α-helical stretch also present in some members. Defensins of different origins exhibit structural and functional similarities, with phylogenetic relationships between invertebrate and plant defensins and between different types of vertebrate defensins, and a possible common bacterial ancestor. Most defensins demonstrate a direct antimicrobial action *in vitro* with varying activity spectra. This requires interaction with the components of the microbial cell wall, and often involves membrane permeabilization, although the mode of action differs markedly for defensins both within and from different families. Defensins also play important regulatory roles in the immune system of animals and plants, acting as a bridge between innate and adaptive immunity in vertebrates. Roles outside of host defenses have also been reported.

DISCOVERY

Defensins were among the first HDPs to be discovered. α-Defensins were first identified in the early 1980s as cationic, cysteine-rich components of mammalian neutrophil phagocytes, by Lehrer et al., who coined the name "defensin."[14,15] Analogous molecules termed "cryptdins" were later found in specialized host defense cells of the intestinal crypts (see the chapter on Paneth cell defensins in the Gastrointestinal Peptides section of this book). The ability to inhibit adrenocortical steroidogenesis also led to the alternative definition "corticostatin."[32] In the early 1990s, "β-defensins," with a different cysteine-bridge connectivity, were identified in mammalian epithelia and neutrophils, as well as in avian leukocytes,[3,13–15,23,26] and more recently also in reptiles and teleost fish.[4,35] In the late 1980s, isolation of the inducible peptides from insect hemolymph[5] with a significant similarity to the mammalian peptides is what prompted them to be named "insect defensins." Cysteine-rich peptides with antimicrobial properties—the "thionins"—were known in plants since the early 1950s,[2] but it was only in the midnineties that the γ-thionins, based on their resemblance to the insect and mammalian defensins, were redefined as "plant defensins" (see also the chapter on Plant Antifungal Peptides in the Plant Peptides section of this book).[13] A backbone circularized peptide that is structurally quite different from that of defensins was isolated in Old World monkeys but was found to derive from the head-to-tail ligation of two truncated α-defensins, so it was assigned the name "θ-defensin" with reference to its cyclic structure.[8,14,23] Finally, the recent discovery of a several families of defensin-like peptides in a fungus underlines the antiquity of this peptide superfamily of innate immune effectors.[34]

The term "defensin" thus defines several peptide families based on functional (host defense) and structural (a compact cysteine-stabilized β-sheet structure) similarities[1,10,26,27] that seem to span a vast phylogenetic continuum. There is evidence that fungal, invertebrate animal and plant defensins form an evolutionarily related group,[5,7,19,34] and all the vertebrate defensins form another.[29] These two groups may be phylogenetically related through ancient prokaryotic ancestors as evidenced by the discovery of defensin-like peptides in some bacteria.[1,27,31,33]

STRUCTURE OF PRECURSOR mRNA AND GENE

Analysis of defensin gene organization in numerous species indicates that they occur in multigene families, as a result of numerous duplication and diversification events. They are synthesized as prepropeptides (Fig. 1) and processed to varying degrees depending on the context.

The mammalian α- and β-defensins are products of distinct gene families that probably derive from an ancestral β-defensin gene, as only this latter type are found in non-mammalian vertebrates.[25,26,28] Primate θ-defensin precursors are truncated α-defensin paralogs from which fragments are excised and spliced head to tail to give the mature, backbone cyclized, homodimeric or heterodimeric peptide (Fig. 2).[8,14,23] Their genes are active in Old World monkeys and Orangutans, not present in New World monkeys or prosimians, and present only as pseudogenes in chimpanzees and humans.

In humans, a gene cluster for both α- and β-defensins was mapped to a structurally variable region of chromosome

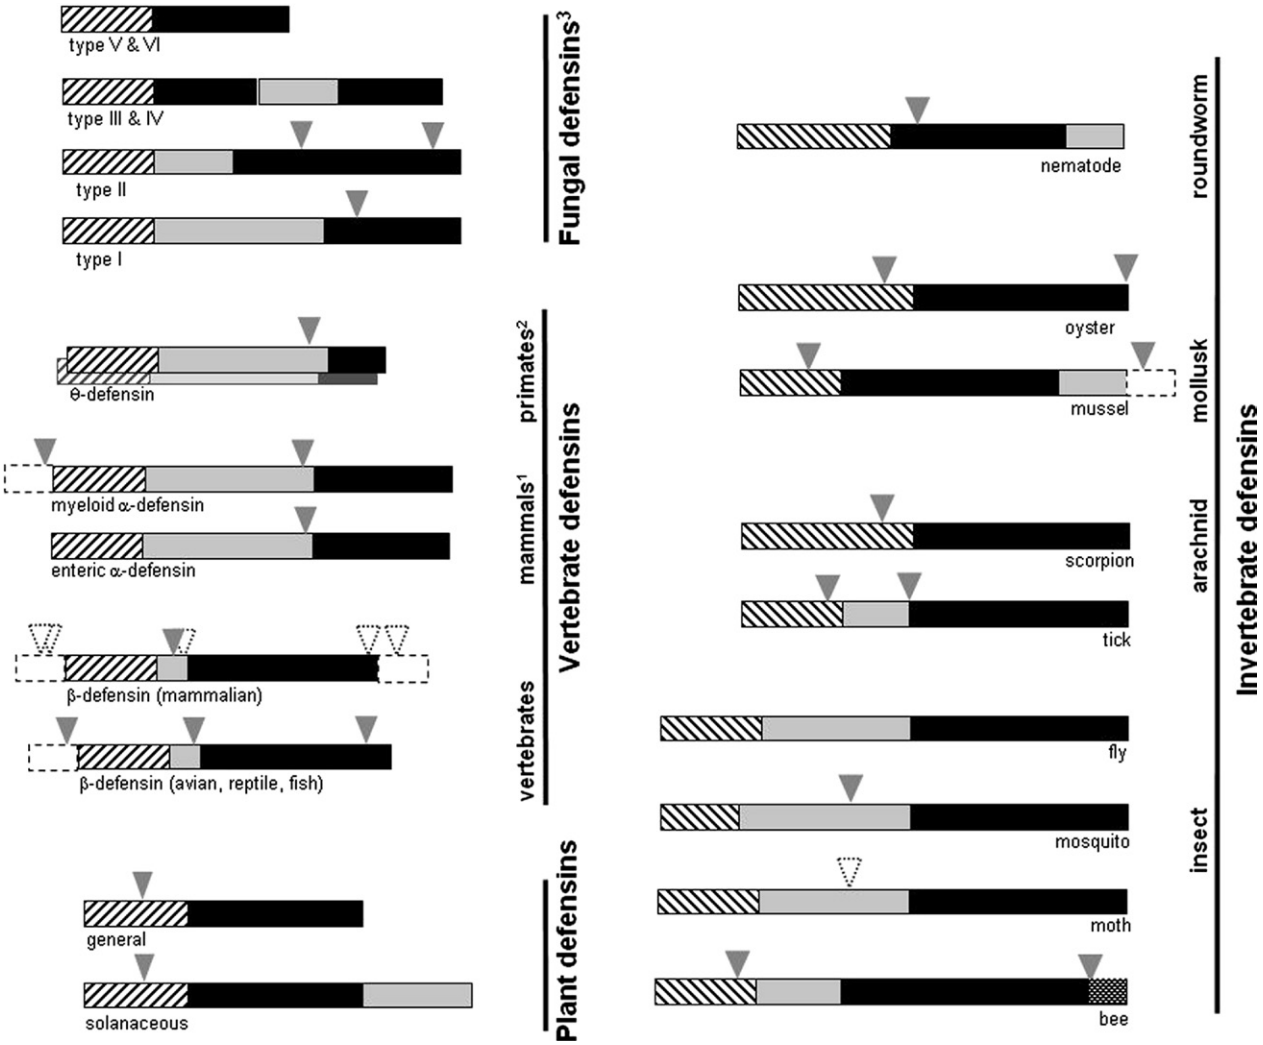

FIGURE 1 Gene organization of different defensin families. The coding region for the mature peptide is in black. The signal or leader sequences are hashed. The proregions are in gray. Broken rectangle indicates the 5′- or 3′-UTR regions, only when introns fall into them. Introns are indicated by triangles. Full gray triangles represent introns normally present, whereas dotted triangles represent additional introns present only in some members. Coding region relative sizes are only indicative. For θ-defensin, two different genes provide precursors as indicated in the circle that are subsequently trimmed and spliced head to tail into a single backbone-cyclized molecule. The dotted part of the bee defensin mature peptide region represents a C-terminal extension found only in hymenopterans defensins.[1,2] For vertebrate defensins, β-defensins are present in all vertebrates, whereas α-defensins are present in all tested mammals except in artiodactyls. θ-Defensins are present in Old but not in New world monkeys, and also in orangutans, but only as pseudogenes in humans and chimpanzees.[3] Fungal defensin gene families are as indicated by Zhu.[34] Adapted from Refs. 4, 7, 11, 13, 18, 20, 21, 23, 29, 34.

8 (8p21–p23[22]), and there is evidence for a similar arrangement in syntenic chromosomal locations in other mammals confirming the homology between these gene families. Clusters of β-defensin-like peptides of unknown function map to other chromosomal locations in humans, mice, rats, and dogs.[18,22] In nonmammalian vertebrate species, only β-defensin genes have been identified; 14 and 22 genes are clustered, respectively, on chicken and finch chromosome 3 (3q3.5–q3.7 in chicken).[11] Mammalian β-defensin genes have at least two exons, the first encoding for the signal and the propiece, and the second for the HDP (Fig. 1), separated by an intron of variable size, just before the mature peptide coding region. Myeloid α-defensins have a third exon in the 5′-UTR, as do avian, reptile, and fish but only a few mammalian β-defensins.[4,18,23,35]

Invertebrate defensins exhibit a more varied gene organization (Fig. 1). In addition to presenting diverse coding regions, the presence, number, and location of introns also vary.[7,20] Defensin genes from related species, or even the same species, can show significant homology in the mature HDP region but little in that coding for the leader and propeptides.

Plant defensins show two types of gene organization (Fig. 1),[13] the most common consisting of only signal peptide and the mature defensin domain, the other, found in

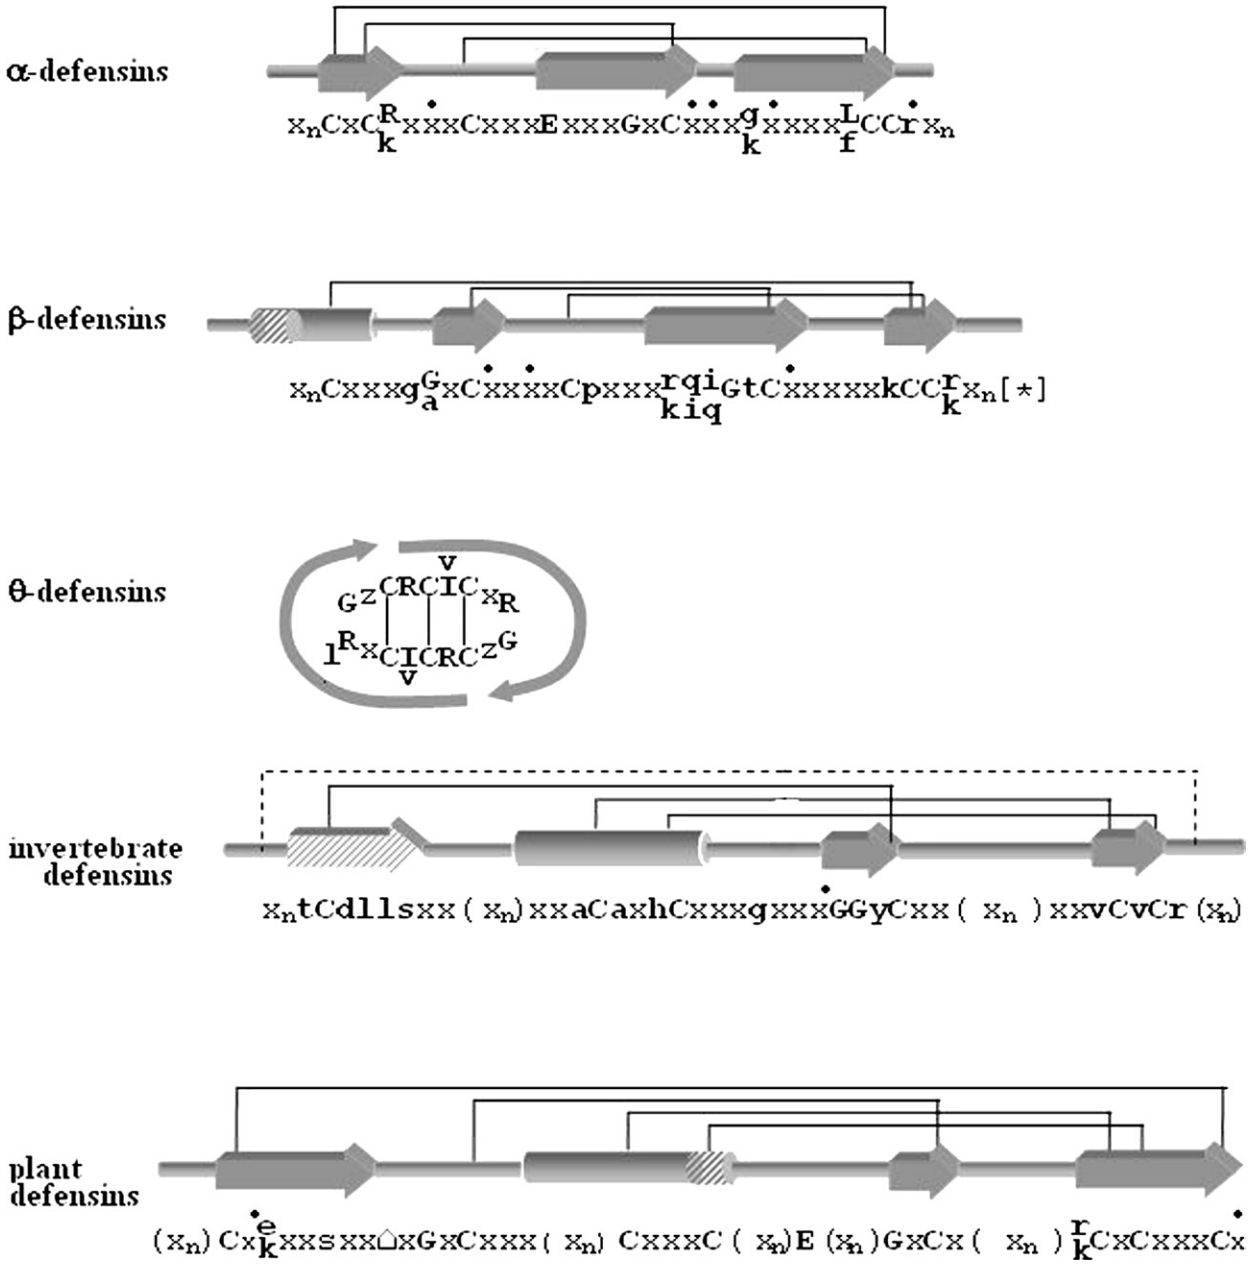

FIGURE 2 Schematic representation of the primary structure, topology, disulfide connectivities, and residue variation in defensin families. Highly conserved residues are in uppercase, conserved residues are in lowercase, x indicates variable residues, and stretches of variable size are indicated by x_n; dots above the sequence indicate positions of possible residue deletions in some family members with respect to others. For β-defensins, * indicates a long C-terminal extension present in some members (e.g. epididymis hBD25-29). For θ-defensins, z indicates variable but hydrophobic residues; the only known fungal defensin structure is very similar to the six cysteine mussel defensin structure. For plant defensins, ⌂ indicates aromatic residues. Gray arrows represent β-strands. Cylinders represent α-helical segments. Hashed segments are present in some family members but not in others.

solenaceous species, presenting a C-terminal propiece. Only one intron is present.

The propiece in plant, invertebrate, and vertebrate defensins is often anionic, in contrast to the cationic mature HDP. This may be required for folding, subcellular trafficking, or processing, or may serve to render the HDP nontoxic until needed, protecting the producer cell.

DISTRIBUTION AND EXPRESSION OF THE mRNA

Defensins are expressed at sites where the producer organism encounters pathogens or needs to control the natural microbial flora, namely, in phagocytic cells and at epithelial surfaces. Mammalian defensins are stored in the granules of

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

neutrophils or paneth cells or are generated by monocytes, macrophage, keratinocytes, or mucosal epithelial cells of the respiratory, digestive, urogenital, or reproductive system. α-Defensins were originally isolated from the cytoplasmic granules of polymorphonuclear phagocytes, where they are present at high concentrations (>10 mg/ml).[15,23] Human and mouse Paneth cells also store α-defensins in secretory granules for release into intestinal crypts, where a concentration of 10 mg/ml can be reached. In both situations, expression seems to be constitutive. β-Defensins have a wider tissue distribution, involving barrier and secretory epithelial cells in particular and can also be produced at quite high concentrations. Expression is in some cases is constitutive and in others induced by bacteria or their components (e.g. LPS, LTA) or by proinflammatory cytokines (interferons-γ and -1β, TNFα), and is often mediated by Toll-like receptors, induction being NF-κB dependent.[10,15]

The distribution pattern in both granulocytes and epithelial cells varies considerably among vertebrate species, as well as within each species.[10,15,23] α-Defensins have been isolated from the leukocytes of primates and various rodents but not from mice. In humans, the expression of defensins has been reported in monocytes, NK, and T-cells, but only rabbits have appreciable amounts in alveolar macrophages. Only certain primate species express θ-defensins in monocytes and neutrophils.[8,23] Artiodactyls express numerous β-defensins, but apparently not α-defensins, and in avian species, only the more ancient β-defensins are expressed in a specific manner in the heterophils, epithelia, and eggs.[26] However, as α-defensin genes are present in monotremes and in basal mammals they developed early in mammalian evolution.

Invertebrate defensins have mainly been isolated from the hemolymph of insects, arachnids, and mollusks.[5,7,28] In insects, they are induced by bacterial components, in the fat body for release into the hemolymph, in surface epithelia, and in the midgut. In the latter case, they may serve both to prevent infection of blood-sucking insects by blood-borne pathogens and parasites, and to protect the stored blood meal from microbial attack. Curiously, a similar role has been proposed for the avian β-defensin spheniscin, isolated from the preserved stomach contents of the king penguin.[26]

The distribution of plant defensins also is consistent with their defensive role,[13,24] as they are mainly found in vulnerable tissues or at entry points for pathogens, where they are constitutively produced in a tissue- or organ-specific manner, or induced in peripheral cell layers, and in cells that line cavities such as stomata. Most of the plant defensins identified are seed derived and sufficiently abundant to provide seedlings with protection against soil fungi. They have also been identified in other tissues, such as leaves, tubers, roots, flowers, pods, and fruits with a wide distribution in species throughout the plant kingdom.[13]

A common feature of many defensins in animals and plants is their induction by pathogen-associated molecular patterns (PAMPs) interacting with Toll or Toll-like receptors.[6,10,13,15,23] The regulatory mechanisms show a remarkable analogy, although it is uncertain whether they represent an ancient evolutionary relationship or a case of convergent evolution. Invertebrate defensins are principally selective for Gram-positive bacteria and fungi, and activation occurs via NF-κB-like signaling pathways initiated by Toll receptors, which respond to cytokines produced after activation of pattern recognition receptors for different types of PAMPs.[6] Induction of mammalian defensins can be mediated by Toll-like receptors (TLRs), which directly recognize PAMPs, or by receptors for chemokines induced by bacterial components,[10,15,23] and is often under NF-κB control. Plants have also acquired the ability to recognize PAMPs via receptors that resemble animal TLRs, and several components of the resulting signaling cascades leading to the transcriptional activation of immune response genes are shared among the two kingdoms.[16]

PROCESSING

Defensins are synthesized as precursors with an N-terminal signal or leader sequence necessary for secretion or storage, and usually also with a prosequence that can be either N- or C-terminal to the mature peptide region (Fig. 1). The posttranslational processing steps are well understood for myeloid and enteric α-defensins, which are transferred into the ER by the signal peptide, where it is removed leaving a relatively long anionic propiece. This may serve as an intramolecular chaperone for folding, and/or to neutralize the activity of the mature peptide region preventing cell damage.[14,15,23] The myeloid defensins are stored as the mature, active form, on removal of the propiece during granulogenesis. In mice, enteric α-defensins are also stored in granules in the mature form, after processing by the matrix metalloproteinase 7 (matrylisin), whereas they are stored in the proform in humans, with processing by Paneth cell trypsin during or after release.

β-Defensin precursors are simpler, having a shorter propiece or lacking it altogether, and their biosynthesis and intracellular trafficking seem quite different from that of the α-defensins.[15,23] Human β-defensin 1 (hBD1) is constitutively produced in many epithelial cells and is present in plasma and urine, where several N-terminal truncated forms indicate continued processing. hBD2 lacks a propiece and is processed to the mature form by signal peptidases in the ER, ready for secretion. The biosynthesis of ovine neutrophil β-defensins is completed early in myelopoiesis, and the peptides are stored in the dense granules in the mature form.

θ-Defensins are derived from the processing of α-defensin isoforms in which a premature stop-codon interrupts

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

translation of the mature peptide after 12 residues. Although the intermediate processing steps are unknown, in monkey PMN two of these truncated peptides are trimmed and spliced head-to-tail to give the mature, eighteen-residue cyclic peptide.[8,23]

Invertebrate defensins are also synthesized as precursors composed of a hydrophobic signal peptide and a relatively long prosequence, joined to the C-terminal mature HDP by a dibasic processing site.[5] This overall organization resembles that of vertebrate and plant defensins. The prodomain, similarly to the vertebrate α-defensins, shows a high content of anionic residues and likely has similar chaperone or protective functions. In contrast to animal systems, there is little information about proteolytic processing of defensins in plants.

RECEPTORS

The antimicrobial activity of mammalian defensins derives from both direct and indirect mechanisms. With respect to direct mechanisms, they act as immune effectors via a direct interaction with the microbial cell-surface and/or membrane components, leading to a breach of the membrane or a compromise of essential cell membrane enzymes involved in processes such as cell wall synthesis or cell division, as part of the killing mechanism, or to translocation into the cytoplasm where they can access intramolecular targets. Membrane lysis is not necessarily a receptor mediated process, although the ability to recognize specific membrane components can be important. In particular, the antifungal activity of insect and plant defensins requires either direct interaction with specific sphingolipids and related glucosylceramides in lipid rafts, or with phosphatidyl inositol anchored proteins associated with these rafts.[11,13,27] The antiviral activity of θ-defensins has been related to their capacity to act as lectins and bind viral glycoproteins or glycolipids.[15] More recently, it has been reported that different classes of defensins, including fungal plectasin, invertebrate defensins, and plant defensins can all interact specifically with and block lipid II, thereby inhibiting cell wall biosynthesis in susceptible bacteria.[27]

Indirect antimicrobial action involves an immune regulatory role as shown for some mammalian defensins that act as signaling molecules to recruit or activate cellular components of innate or adaptive immunity. They have variously been shown to chemoattract leukocytes, antigen presenting cells, and lymphocytes.[12,15,17,30] Human and mouse β-defensins are chemotactic for a broad spectrum of leukocytes via the CCR2 or CCR6 receptors. Certain α-defensins selectively chemoattract T-cells and iDC by G-protein-coupled receptors, as this activity is pertussis toxin sensitive. Mouse β-defensin 2 has the ability to stimulate iDC maturation, acting through TLR4. The capacity of certain α-defensins to interfere with the production of immunosuppressive glucocorticoids, possibly by blocking ACTH receptors, was also recognized very early.[32] They have a large variety of other immune regulatory functions, and many of these are probably receptor-mediated including cytokine/chemokine induction, regulation of IL-1β secretion and homeostasis through the P_2X_7 nucleotide scavenging receptor, regulation of cell death mechanisms, and effects on cellular growth and wound repair.[19]

ACTIVE CONFORMATION

Defensins have variable primary structures, not only by comparison of members of different families but also for members within each family (Figs 2 and 3). Effectively, only the cysteine residues involved in disulfide bonding, and few other residues are conserved, whereas the remainder show varying degrees of variability, as do the number of residues separating the cysteines (Fig. 2). The connectivities differ between families but are conserved within each family, being C1-C6, C2-C4, C3-C5 for α-defensins; C1-C5, C2-C4, C3-C6 for β-defensins; C1-C4, C2-C5, C3-C6 for invertebrate defensins; and C1-C8, C2-C5, C3-C6, C4-C7 for plant defensins. Some insect defensin-like peptides such as drosomycin also show an added C0-C7 disulfide bridge.[5,10,13,25,26,28,34]

Despite the differences in sequence and connectivities, molecules from the different families fold into quite similar tertiary structures (Fig. 4). This involves a core formed by a twisted antiparallel β-sheet, generally comprising two or three strands connected to each other and to the rest of the molecule by the disulfide bridges. In insect and plant defensins, the presence of a helix gives rise to the cysteine-stabilized α/β fold (CSαβ), which defines a superfamily in the SCOP classification that also includes scorpion and spider toxins and protease and amylase inhibitors. Vertebrate α- and β-defensins share an overall similar fold, although not all peptides have a C-terminal α-helical segment. This segment, when present, makes the fold similar to the CSαβ fold, but they have been placed in a separate "defensin-like" SCOP superfamily. Thus, defensins have in common a conserved scaffold that seems to be insensitive to sequence variations. The distribution of cationic and hydrophobic residues on this scaffold tends to be arranged so as to result in amphipathic structures that favor interaction with microbial membranes, which are rich in anionic components, and can also account for more specific receptor/based interactions. The lack of sequence constraints and the fact that these peptides are involved in host:pathogen interactions has ensured their rapid evolution and explains the heterogeneity of their sequences.

FIGURE 3 Sequences of members of different defensin families. Sequences are aligned and gaps inserted so as to maintain as far as possible a constant cysteine residue spacing. Residues or types of residues that are significantly conserved are shaded. For θ-defensins, only a hemisequence is shown. The full peptide is formed by the head to tail homo- or heterodimeric ligation of two hemisequences in a circular structure (see Fig. 2). Defensin nomenclature has not yet been fixed, so that the peptide names are either those present in the literature or in the UniProt database. The beginning of the mature peptide region is often inferred or unknown, in which case it is indicated by ….

BIOLOGICAL ACTIONS

Defensins have an undeniably important role in host defense, as both effectors and regulators.[2,3,5,10,13–15,19,23–28] As effectors, most defensins show a direct activity, *in vitro*, against bacteria and fungi, which is however quite medium and salt sensitive. α- and θ-Defensins tend to have a broader spectrum of activity than β-defensins do, whereas the canonical insect defensins tend to be more active against Gram-positive bacteria and the four cystine insect defensin-like peptides and plant defensins tend to be principally active against fungi. The precise mechanisms of action of these peptides, regarding this direct microbicidal activity, are still undefined. For many of them, interaction with the microbial membrane seems to be a crucial step, although the mode of action can vary remarkably. Membrane disruption would lead to the loss of the transmembrane potential gradient and release of cytoplasmic contents and may contribute to the microbicidal activity.

For the vertebrate defensins and the canonical three cystine invertebrate defensins, bacterial membrane interaction was proposed to occur principally with anionic phospholipids such as phosphatidylglicerol or cardiolipin.[2,5,10,12,23,25] This could then lead to pore formation by barrel stave, toroidal or aggregate mechanisms or membrane disruption by a detergent-like "carpet mechanism." However, although the relevance of initial membrane interactions is undisputed, that of membrane disruption may be overestimated. It is now apparent that bacterial membranes demonstrate considerable functional organization of their protein machinery, whose assembly requires patches of anionic phospholipids, so that HDPs could preferentially target these regions and affect coordinated processes required for bacterial survival. Further, for fungal, mollusk, and mammalian defensins, it has been shown that the lipid II, which carries cell wall building blocks, is also an important target, especially for Gram-positive bacteria.[27] By binding to it, these peptides impede cell wall biosynthesis, analogously to some clinically used antibiotics. It is interesting to note that the affinity for mammalian α-defensin HNP1 and β-defensin hBD3 is an order of magnitude lower than for the fungal defensin, and in their case, pleiotropic effects on membrane localized processes may act in conjunction with cell wall inhibition. The lower affinity probably also correlates with the broader activity spectrum of these peptides, which also includes Gram-negative bacteria, and that requires affinity for additional targets.

For the four cystine antifungal insect and plant defensin that are principally antifungal, a common membrane target has been identified in fungal sphyngolipids or related glucosylceramides (see above).[1,13,27] These sphingolipids colocalize in fungal membranes with ergosterol in lipid-rafts rich in membrane proteins, and may represent high-affinity binding sites for the defensins. Different antifungal defensins bind in different manners with one or more different subsequent effects, including membrane disruption, inactivation of calcium channels, activation of signaling cascades, induction of ROS production, and induction of apoptosis.[1,27]

For mammalian defensins in particular, roles as regulators of innate and adaptive immune cells have been amply demonstrated.[10,12,15,17,19,30] These variously include the capacity to chemoattract monocytes, neutrophils, immature dendritic cells, mast cells, and T-cells; to stimulate the maturation of antigen presenting cells; to induce or suppress proinflammatory mediators; to activate phagocytes; to regulate the function of complement components, to inhibit the production of immunosuppressive adrenal glucocorticoids, and to act as adjuvants for antigen presenting cells. Some mammalian defensins also play other roles outside immunity, which include the stimulation of wound healing, reproduction, and curiously the determination of the fur color in dogs. Certain plant defensins act as inhibitors of proteinases, α-amylase, or protein translation. These are structurally and functionally distinct from antifungal defensins and serve to protect from predators.[26] Plant defensins are also implicated in plant growth and development.[24]

ACKNOWLEDGMENTS

N. Antchera and F. Guida, respectively, acknowledge postdoctoral and doctoral grants from the University of Trieste. The FVG regional R3A2 network and EU IAPP project NAM are acknowledged for support.

Chapter 19

Lantibiotics

Jasmin Dischinger, Imke Wiedemann, Gabriele Bierbaum and Hans-Georg Sahl

ABSTRACT

Lanthionine-containing antibiotic peptides (lantibiotics) have been known for >60 years, and the prototype peptide nisin has been used safely in food preservation for half a century. Lantibiotics derive from ribosomally synthesized prepeptides through unique post-translational modifications involving serine, threonine, and cysteine residues. About 80 lantibiotics are known to date, and even more gene clusters, containing the determinants for prepeptides, modification, processing, export, and producer self-protection, have been sequenced or detected by genome mining. Recent progress in *in vitro* modification and insights into multiple antibiotic mechanisms combined in a single molecule make lantibiotics attractive model compounds for design of novel antiinfective drugs.

DISCOVERY

The most prominent lantibiotic nisin was first described as a group-**N** streptococci **i**nhibiting **s**ubstance in the 1920s and identified as a lanthionine-containing peptide by Berridge in 1949. Its structure was elucidated by Gross and Morrel. The designation "lantibiotics" was introduced to emphasize the occurrence of lanthionine and the antibiotic nature of these peptides (**lan**thionine-containing an**tibiotics**)[7] (Fig. 1). Since 1985, a significant number of new lantibiotics have been discovered,[3,7] among them numerous natural variants. "Prototype" peptides, such as nisin, mersacidin, lacticin 481, Pep 5, and lacticin 3147 were defined for various subgroups, which are shown in Table 1. Genomic mining shows that putative lantibiotic gene clusters are widespread among many genera and even present in phyla, for example, the cyanobacteria that had previously not been associated with lantibiotic production.[20,22]

STRUCTURAL *lanA* GENES

Lantibiotics are expressed as prepropeptides, with an N-terminal leader sequence and a C-terminal propeptide part, which is posttranslationally modified. Biosynthesis starts with enzymatic dehydration of serine and/or threonine residues in the propeptide part yielding the unusual amino acids 2,3-dehydroalanine (Dha) and 2,3-dehydrobutyrine (Dhb). To some of these dehydroamino acids, the thiol group of a neighboring cysteine residue is added resulting in the characteristic lanthionine (from Dha) and methyllanthionine (from Dhb) residues. The stable, thioether-based intramolecular rings determine the three-dimensional structure of the peptides and are essential for biological activity. The substrate recognition of the modification enzymes seems to reside in the leader peptide, for example, it is possible to synthesize pneumococcin using the nisin modification enzymes after a fusion to the nisin leader.[21]

BIOSYNTHETIC GENE CLUSTERS

For a long time, lantibiotic production was exclusively associated with Gram-positive bacteria; however, genetic determinants for lantibiotic synthesis are also present in other genera and phyla and can be located on either chromosomes or mobile elements such as plasmids and transposons. Nearly always, the prepeptide structural genes (*lanA*) are part of gene clusters that also contain the genes responsible for modification (*lanB*, *lanC*, *lanM*, *labKC*, *lanL*, and *lanD*), proteolytic processing (*lanP* and *lanT*), transport (*lanT*), immunity (*lanI*, *lanFEG*) and biosynthesis regulation (*lanK*, *lanR*, *lanQ*) (Fig. 2) (reviewed in Refs. 3, 7, 35). By contrast, in the marine cyanobacterium *Prochlorococcus*, one LanM enzyme is able to modify a plethora of LanA precursor peptides that are encoded all over the chromosome.[20] Currently, lantibiotics are classified according to their modification machinery and antibiotic activity: Type I and II lantibiotics show antibacterial activity and are distinguished by their modification enzymes as discussed below, whereas type III lantibiotics show only little antibiotic activity and, for example, may be involved in morphogenesis of the producer strain.[35]

BIOSYNTHESIS OF THE RING STRUCTURES

Several different biosynthetic machineries have been identified. The first requires two separate enzymes (LanB and LanC) to synthesize lanthionines and – by definition – is

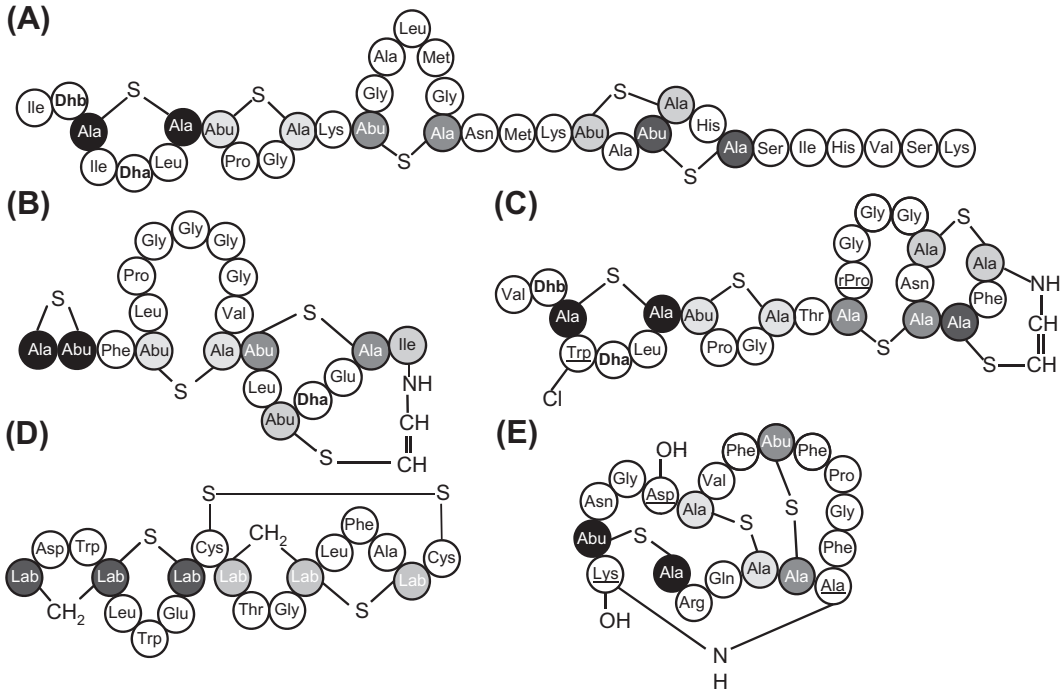

FIGURE 1 Structures of the lantibiotics nisin A (A), mersacidin (B), microbisporicin (C), labyrinthopeptin A2 (D), and cinnamycin (E). Residues involved in (Me)Lan or labionin formation are highlighted by shades of gray, and residues that contribute to one thioether are marked in the same shade of gray. Additionally, serine and threonine residues that are dehydrated to Dha and Dhb in the mature peptide are in bold. Additional modifications are underlined.

found in gene clusters of the type I lantibiotics (Table 1).[7] In this pathway, the LanB enzyme dehydrates the Ser and Thr residues of the C-terminal core propeptide or propeptide sequence. The LanC enzyme then catalyzes the cyclization reactions to form the thioether structures. The structure of NisC has been well studied; the enzyme coordinates a zinc ion that is involved in the activation of the thiolate.[3] In type II lantibiotics (Table 1), only one enzyme, LanM, is necessary to form the thioether bridge and catalyzes both reactions.[3,7] Several LanM enzymes are active in *in vitro* modification assays, and the dehydration of the hydroxy amino acids is mediated via an ATP-dependent phosphorylation.[3,20,23] The

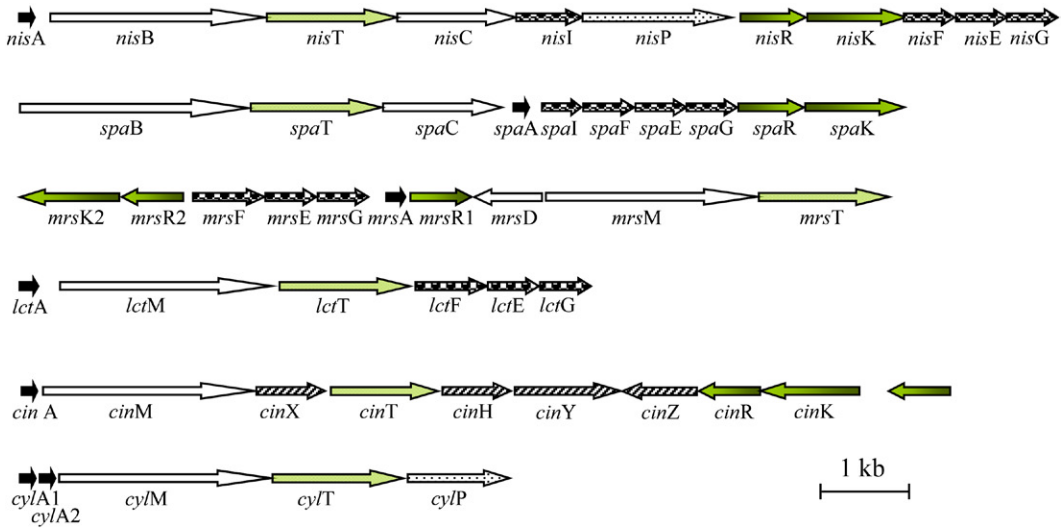

FIGURE 2 Examples for lantibiotic biosynthesis gene clusters. *lanA* genes encode the lantibiotic prepeptides; *lanB*, *lanC*, *lanM*, and *lanD*, modification enzymes; *lanP*, proteolytic enzymes; *lanT*, transporters; *lanI*, *lanE*, *lanF*, and *lanG*, immunity determinants; *lanR*, *lanK*, and *lanQ*, regulators of biosynthesis. Gene nomenclature has been unified for clarity and is not consistent with the original publications. From the top to the bottom, the gene clusters of nisin (*nis*), subtilin (*spa*), mersacidin (*mrs*), lacticin 481 (lc*t*), cinnamycin (*cin*), and cytolysin (*cyl*) are shown.

LanD enzymes catalyze the oxidation of the C-terminal Cys residue present in epidermin and its analogs and in mersacidin.[7,31] The labyrinthopeptins contain a novel modified amino acid, labionin, a quaternary α,α-disubstituted amino acid and are modified in a yet different biosynthetic mechanism that involves a GTP-dependent phosphorylation step by the LabKC enzyme.[24,25] Because an antibiotic action has not yet been reported and the LabKC enzyme displays similarities to RamC, which modifies the type III lantibiotic SapB, these peptides are grouped with the type III lantibiotics. A further novel thioether biosynthesis pathway, catalyzed by the LanL enzyme, was described for venezuelin.[12]

PROCESSING

After posttranslational modification, lantibiotics become activated by removal of the leader peptide segment. Genetic determinants for dedicated proteases are present in most gene clusters.

LanP proteases are associated with the LanBC modification system of type I lantibiotics and show sequence similarity to subtilisin-like serine proteases (reviewed in Refs. 3, 7). Peptides that are processed by such LanP proteases have leader sequences with a number of charged residues and relatively conserved motifs at position −15 and −20 (FNLD) and at the cleavage site. NisP and EpiP are synthesized as preproproteins, that is, with a signal peptide for export and a prosequence, which possibly functions as an intracellular chaperone. NisP possesses, in addition, a C-terminal extension that might act as membrane anchor to attach the enzyme to the cytoplasmic membrane; EpiP lacks the C-terminal anchor. No details are known for MutP proteins (from mutacins I and III) that have strong similarity to NisP and EpiP. PepP, ElkP, and LasP seem to be located in the cytoplasm.[7]

Type II lantibiotic peptides resulting from LanM biosynthesis machineries, such as mersacidin, lacticin 481 (and analogs), and many two-peptide lantibiotics such as lacticin 3147 A1/A2 are processed concomitantly with export by bifunctional ABC transporters LanT.[7] Such LanT transporters possess an N-terminal extension that contains a cysteine protease domain. The cleavage site of these peptides is usually preceded by a "double-Gly" motif, referring to conserved GG (GA or GS) residues in positions −1 and −2 (Fig. 1); bifunctional transporters are also found with many nonlantibiotic bacteriocins.[15]

RECEPTORS

The antimicrobial activity of lantibiotics does not involve receptors *sensu strictu*, although specific targets have been identified (see Biological Activities). However, lantibiotic biosynthesis may be autoregulated through a quorum-sensing process, in which the respective lantibiotic acts as an upregulating signal. In this case, the lantibiotic binds to a receptor that is the histidine kinase of a dedicated two-component regulatory system (LanRK).[3]

PRODUCER SELF-PROTECTION

Lantibiotic producers always contain peptides or proteins that confer producer self-protection or "immunity." Usually, ABC transporters (LanEFG), single proteins or peptides (LanI), or accessory proteins are involved (LanH). For a recent review, see Ref. 26.

INFORMATION ON ACTIVE AND/OR SOLUTION CONFORMATION

The antibiotic activity is strictly associated with the fully modified lantibiotic, that is, lanthionine ring structures and dehydroresidues provide structural features that are essential for activity. The distinction between the two groups of antibacterial peptides, type I and II lantibiotics, is also reflected in their overall structures.

Typical type I lantibiotics such as nisin, subtilin, gallidermin, and Pep5 are elongated and flexible in solution. Defined conformations can only be found within or close to the rings. In membrane mimicking solvents, these peptides adopt rod-shaped structures with pronounced amphiphilicity.[7]

The type II lantibiotics adopt a more globular conformation than type I lantibiotics, and they possess much less conformational freedom than the type I peptides. Cinnamycin, duramycins, and ancovenin have an intertwined bridging pattern including a head-to-tail thioether. Studies on the conformation of cinnamycin and duramycins in water and water:acetonitrile (1:1) have shown that these peptides present a U-shaped topology, with the hydrophobic residues clustered in the U-bend area of the molecule and the hydrophilic side chains located in the terminal segments.[7]

The solution conformations of the type II lantibiotics mersacidin and actagardine were determined in methanol and acetonitrile:water (7:3), respectively. Both peptides adopt an overall globular structure with neutral side chains pointing outwards. The hydrophilic residue Glu, which belongs to a highly conserved motif in mersacidin, actagardine and many of the α-peptides of the two-peptide lantibiotics, is directed to the center of the molecule. Mersacidin is the only lantibiotic for which a crystal structure is available.[30]

As shown for the solution structure of plantaricin C, the type II lantibiotics of the lacticin 481 group[9] share features from both groups. The first six N-terminal residues, four of which are lysines, are structurally undefined; the remaining part of the molecule is globular because of a bridge connecting residues 7 and 27 and the presence of three internal rings.[32]

BIOLOGICAL ACTIVITIES

Most lantibiotics are active against Gram-positive bacteria and exert multiple activities at the cytoplasmic membrane.[3,7] Resistance of Gram-negative bacteria results from the protective effect of the outer membrane that is impenetrable to these peptides. Microbisporicin is a particularly active agent against pathogenic Gram-positive bacteria (methicillin-resistant staphylococci and enterococci).[6]

Numerous studies performed with intact bacterial cells, membrane vesicles, and artificial liposomes have shown that nisin and other type-A lantibiotics in μM concentrations are able to destabilize membranes by forming nonselective, transient pores, which leads to dissipation of the membrane potential, rapid efflux of small metabolites, and cessation of cellular biosynthetic processes (reviewed in Ref. 3).

The membrane-bound peptidoglycan precursor lipid II was identified as a specific target for many lantibiotics. These substances belong to the nisin group (nisin and subtilin), the epidermin group (epidermin, gallidermin, mutacin 1140, and clausin[5]), or the lacticin 481-group (lacticin 481[4] and plantaricin C), the mersacidin group (mersacidin and actagardine) and the α-peptides of the two-peptide lantibiotics (lacticin 3147). Binding of lipid II blocks the precursor from incorporation into the bacterial cell wall. Although this seems to be the only bactericidal activity of mersacidin, the nisin-type lantibiotics and the two-component lantibiotic lacticin 3147 combine this activity with a unique, target-mediated pore formation.[3] Such a combination of two killing mechanisms may explain the potent *in vivo* activity (minimal inhibitory concentration in the nanometer range) of nisin and related lantibiotics.

The molecular basis of the interaction between nisin and lipid II was intensively investigated. Genetically engineered nisin variants and NMR spectroscopy identified structural features of nisin, which are important for its biological activities. The first two rings in the N-terminal part of the peptide are responsible for interaction with lipid II, whereas the C-terminal and the central flexible hinge region are essential for pore formation. Obviously, the pyrophosphate moiety of the lipid II molecule contributes significantly to binding nisin. The N-terminus of nisin was found to form a cage-like structure, which allows the formation of five intermolecular hydrogen bonds between the backbone amides of nisin and the pyrophosphate linkage group of lipid II.[18] These structural elements are also found in a complex of nisin and undecaprenylpyrophosphate; however, for target-mediated pore formation, nisin seems to need a second docking site on the Mur-NAc-pentapeptide moiety present in lipids I and II. Eight nisin molecules and four lipid II molecules are intrinsic parts of the pore.[13] Furthermore, nisin is able to sequester lipid II from the division septum and form large nisin–lipid II aggregates in the membranes.[14]

Mersacidin and actagardine also bind to lipid II and thus inhibit the cell wall biosynthesis at the level of transglycosylation. It was shown that the binding site of these peptides differs from that of the glycopeptide antibiotic vancomycin. NMR studies of the interaction of lipid II and mersacidin identified a hinge region between residues 12 and 13, which serves in opening and closing of the adjacent rings during lipid II binding. Moreover, Glu-17 is indispensable for antibiotic activity.[17] The two-peptide lantibiotic lacticin 3147 and its relatives like haloduracin seem to be interesting cases in which the two functions, lipid II binding and pore formation, are attributed to two individual peptides, rather than being combined in one molecule.[3,28]

In both cases, nisin and mersacidin, the structural elements that are predicted to be directly involved in the interaction with lipid II, that is, the first two rings in nisin and the intertwined rings in mersacidin with the conserved negative charge are also found in many other peptides. In Table 1, lantibiotics were grouped according to their ring patterns. It seems probable that peptides that possess these conserved structural features exert the same mechanism of action as the respective prototype lantibiotics, at least regarding their interactions with lipid II.

The cinnamycin-like lantibiotics display bactericidal activity against a few bacterial strains, in particular *Bacillus* strains. The basis for the antibiotic activity seems to be specific binding of phosphoethanolamine, which causes increased membrane permeability, impaired ATP-dependent protein translocation and calcium uptake, and phospholipase inhibition (reviewed in Ref. 3).

The structure–function relationships of several lantibiotics have been addressed by extensive engineering of site-directed mutants, and these investigations have recently been systematically reviewed.[29]

The lanthionine-containing peptides of the group III lantibiotics probably have non-antibiotic functions, and the designation lantipeptides has been proposed.[11] For example, SapB does not display antibacterial properties but functions as biological surfactant. It is important for aerial mycelium formation by the filamentous bacterium *Streptomyces coelicolor*. The functions of other lantipeptides, for example, from the cyanobacterium *Prochlorococcus*, are still unknown.[20] Cytolysin is another two-peptide lantibiotic produced by some enterococci, has cytotoxic activity, and has been shown to represent a significant virulence factor in clinical cases of enterococcal infections.

Chapter 20

Microcins

Sylvie Rebuffat

ABSTRACT

Microcins are gene-encoded antimicrobial peptides (molecular weights <10 kDa) produced by Gram-negative bacteria, essentially Enterobacteria. They belong to a large class of bacteriocins and are involved in microbial competition. Microcins are highly stable peptides that display heterogeneous structures arising from various and complex posttranslational modifications acquired through specific enzyme machineries. These modifications include heterocycles (thiazole, oxazole), and nucleotide, or siderophore entities that contribute to the potent activity exerted by microcins toward bacterial species generally closely related to the producing bacteria. Most microcins use subtle Trojan horse strategies to kill sensitive bacteria: they either hijack iron siderophore receptors to enter cells or require processing when inside target bacteria to generate the toxic species. Subsequently, some inhibit strategic intracellular enzymes and functions (DNA gyrase, RNA polymerase, ATP-synthase, mRNA translation); others act at the cytoplasmic membrane level. Therefore, microcins provide fascinating models for novel antimicrobial strategies that evade common resistance mechanisms.

DISCOVERY AND CLASSIFICATION

Most bacteria and archaea produce an arsenal of toxic peptides and proteins, which are major actors of microbial competition. They are called bacteriocins, a term first introduced by François Jacob in the 1950s and further used to define proteinaceous compounds of bacterial origin that are lethal to bacteria differing from the producing strain. This term is today currently applied to antimicrobial peptides, polypeptides, and proteins that are ribosomally synthesized by bacteria, have most often a narrow spectrum of antibacterial activity, and against which the producing strains are protected by a dedicated immunity system. In the literature, the term bacteriocin very often applies to antibacterial peptides from Gram-positive bacteria and particularly lactic acid bacteria, but the first bacteriocin to be discovered was produced by the Gram-negative bacterium *Escherichia coli* and was a microcin.[25] Microcins are different from colicins, which are large proteins (between 30 and 80 kDa), in their lower molecular masses (<10 kDa) and especial resistance to proteases, extreme pH, and temperature.[1] They are essentially hydrophobic and form a very restricted, but highly heterogeneous, class of bacteriocins, with only 14 representatives identified to date,[6] among which only 8 have been isolated and structurally characterized (Figure 1). Because of this restricted number of representatives, classifying microcins appears difficult in contrast with bacteriocins from Gram-positive bacteria and with colicins, where identification of a larger number of representatives sharing common structural features and mechanisms of action helps in identifying classes.[25] Most microcins are plasmid-encoded peptides. They arise from biosynthetic pathways that may include the acquisition of complex and diverse posttranslational modifications, exhibit a high diversity in structures and mechanisms of action, and display various mechanisms of uptake. Therefore, the classification adopted presently, which divides microcins into two classes (Figure 1), takes into account these criteria.[6,25] Class I encompasses three plasmid-encoded peptides with molecular mass <5 kDa that have extensive backbone posttranslational modification: microcins B17, C (also called C7, C51 or C7/C51), and J25.[6,30] More precisely, microcin B17 is a 43-amino-acid peptide that carries four thiazole and four oxazole heterocycles, which arise from the modification of six glycine, four serine, and four cysteine residues among the 69 amino acids that form the microcin precursor. Microcin C is a nucleotide-peptide. It is an N-formylated heptapeptide that is covalently linked to a modified adenosine monophosphate by its C-terminal aspartate through an N-acyl phosphoramidate linkage; a propylamine is attached to the phosphate group, thus modifying adenosine. Microcin J25 is a 21 amino acid lasso peptide. It consists of a macrolactam ring closed between the N-terminal amino group and the side-chain carboxylate of an aspartate at position 8 through which the tail is threaded and trapped by steric interactions, thus forming a lasso. Class II contains higher molecular mass peptides, in the 5- to 10-kDa range and is itself further subdivided into two subclasses, IIa and IIb. (Figure 1). Class IIa consists of three plasmid-encoded peptides,

microcins L, V,[6] and N (previously named microcin 24)[4] that are devoid of posttranslational modifications and have two, one, and no disulfide bond(s), respectively. Class IIb includes those chromosome-encoded linear microcins that carry a C-terminal siderophore posttranslational modification, thus forming a small family of related peptides: microcins E492, M, H47, and presumably I47 and G492, which have been hypothesized through genome analyses but have not been isolated and characterized to date.[21,34] The structure of microcin E492 has been

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

examined in detail. It consists of an 84-amino-acid peptide that can be either unmodified as primarily described,[23] or modified as a siderophore peptide.[32] Indeed, the modified microcin E492 carries a C-glucosylated linear trimer of N-2,3-(dihydroxybenzoyl)-L-serine (DHBS) linked to the C-terminal serine carboxylate through an O-glycosidic bond. With enterobactin (a cyclic trimer of DHBS) and salmochelin (the C-glycosylated counterpart of enterobactin), DHBS is one of the major catechol siderophores used by Gram-negative bacteria to bind iron and import it into cells via high affinity receptors. The modified form of microcin E492 that carries a salmochelin-like siderophore was the first natural siderophore peptide to be isolated.[32] It is the mature form of the microcin that displays improved activity.[33,17,18]

Therefore, because of their diversity of structures and mechanisms of action, microcins appear as attractive models for the design of novel bioactive peptides with antiinfective or antitumor properties.[5,6,12,22,26]

GENETIC SYSTEMS AND BIOSYNTHESIS

Although they share with colicins a common gene cluster organization, microcins have more complex genetic systems that include several genes encoding auxiliary proteins or modification enzymes, and in this regard are more similar to bacteriocins from Gram-positive bacteria. All microcins are synthesized by ribosomal machinery and share a common maturation process. They are translated from their respective mRNAs as precursor peptides containing an N-terminal leader peptide extension and a core peptide, which eventually undergoes more or less complex posttranslational modifications before becoming the mature active microcin.

Microcins are encoded by gene clusters, generally carried by plasmids and in certain cases (microcins of class IIb) by the chromosome. These clusters include a variable number of genes, but show a conserved organization (Figure 2).[6,30] The minimal structure of the gene clusters consists of (i) a structural gene encoding the precursor of the microcin, (ii) the self-immunity gene, which is generally adjacent to the former and encodes the factors that protect the producing strain against its own toxic peptide (immunity protein or/and system connected to the export system), and (iii) genes encoding the microcin export system required for secretion of the antimicrobial peptide outside the cells. A variable number of genes coding for posttranslational modification enzymes are found additionally for modified microcins (Figure 2). Gene clusters encoding unmodified class IIa microcins only contain four genes among which two are involved in export. By contrast, the siderophore microcins (class IIb), which are chromosomally encoded, exhibit very complex gene clusters that contain at least ten genes, as exemplified by microcin E492 (*mceA* to *mceJ*), *mceC*, *D*, *I*, and *J* being involved in the acquisition of the siderophore posttranslational modification (Figure 2). For class I, production of, immunity to, and export of microcin B17 require seven genes forming an operon: *mcbA*, *mcbB*, *mcbC*, *mcbD*, *mcbE*, *mcbF*, and *mcbG*. The genes *mcbC*, *D*, *E* encode the three components of the microcin B17 synthetase that provide the posttranslational modifications, that is, the thiazole and oxazole rings. The main cluster of genes encoding microcin C (*mccABCDE*) allows acquisition of the nucleotide and propylamine parts linked to the heptapeptide via the phosporamidate bond, while the structural gene *mccA* that encodes the 7-amino-acid precursor, is one of the shortest genes known (24 bp).[9] By contrast, microcin J25 production only requires four genes *mcjA* (structural gene), *mcjB, mcjC* (modification enzymes), and *mcjD* (export), although the precursor must undergo cleavage of the leader and cyclization to the macrolactam ring, together with adequate folding to enable adoption of the unique threaded lasso structure.

All microcins are produced as inactive precursor peptides endowed with leader peptide extensions of various sizes and sequences that are located N-terminal to the mature peptide region. Leader peptides of class II microcins are approximately 15 amino acids in length, whereas posttranslationally processed microcins of class I have longer leaders of 19–37 amino acids (58 for microcin J25, 69 for microcin B17).[6,30] Microcin C does not possess a leader peptide and is the only one to be secreted without cleavage of a precursor. Similarly to bacteriocins from Gram-positive bacteria, cleavage of the microcin leaders most often occurs at a specific cleavage site. Class II microcin leader peptides contain a conserved sequence MRXI/LX(9)GG/A (X = any amino acid) that ends with the typical double-glycine motif or glycine-alanine motif that is found in proteins exported through ABC (ATP-binding cassette) transporters as an alternative to the GG motif.[6] Leader peptides of class I microcins do not display common features, either in length or in amino acid sequence. The roles of the leaders have not been clarified to date for microcins and bacteriocins, and differ for the different classes and subclasses of peptides considered. However, they probably contribute to the maturation, the secretion, the protection of the precursor against degradation, or to keeping the precursor inactive inside the host cells during biosynthesis.[6,19]

Export of the mature microcins generally occurs on cleavage of the leader peptides. Similar to bacteriocins from Gram-positive bacteria, secretion of class II microcins into the extracellular medium uses ABC transporters,[26] which cleave the typical GG-containing leader sequences of the precursors, concomitantly with translocation of the microcins across the membrane. The machineries in charge of the secretion of these microcins have a canonical organization consisting of three components, an ABC transporter and its

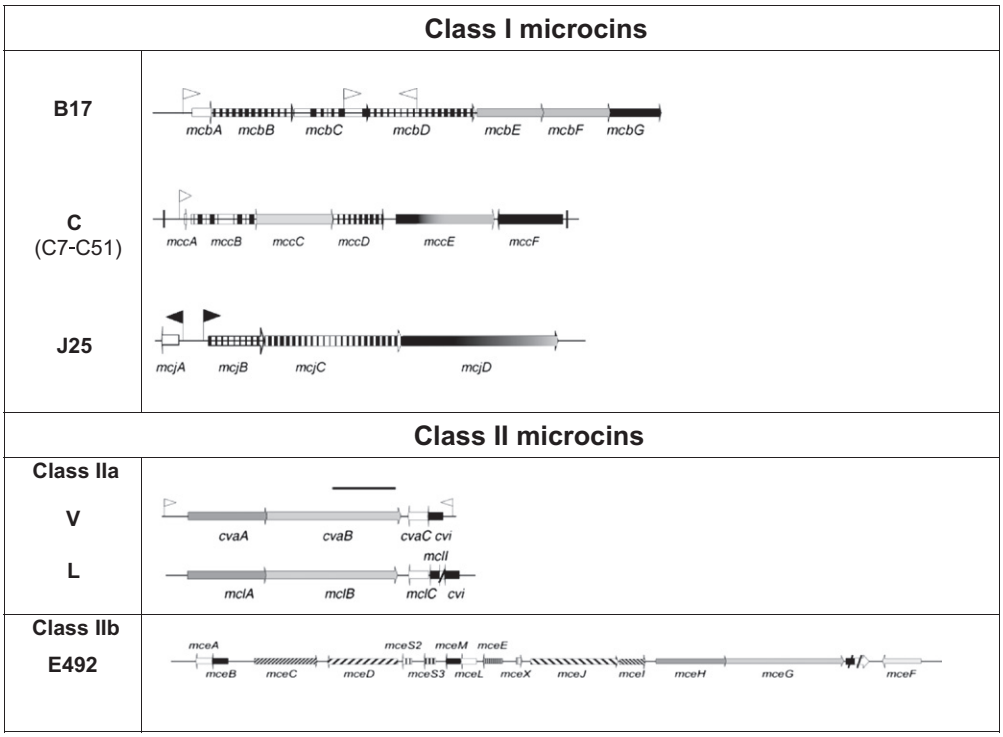

FIGURE 2 Typical gene clusters characterizing microcins of classes I and II. Genes encoding the microcin precursors are indicated in white; those required for self-immunity, export and for both immunity and export are labeled in black, gray and shaded tones, respectively; those required for post-translational modifications are labeled in vertical hatching and in right- and left-inclined hatching for class I and class II microcins, respectively.

accessory protein, both of which are encoded by the microcin gene cluster, and the protein TolC, which is located at the outer membrane and is encoded outside the microcin gene cluster.[34] There is no standard export machinery for class I microcins. They use either ABC transporter-like systems (microcins B17 and J25) or efflux pumps (microcin C), which are encoded by their genetic systems, in association with outer membrane components. Before proteolytic cleavage, some precursors are posttranslationally modified, particularly the class I and IIb microcins.

Most results on microcin B17 maturation were published in the 1990s, coincident with the isolation of the McbBCD enzyme complex[12] and reviewed in two articles published in 2007.[6,30] Microcin B17 was the first microcin to be reconstituted *in vitro* from its precursor McbA in the presence of the modification enzymes McbB, McbC, and McbD that form the microcin B17 synthetase complex.[12] The oxazole and thiazole heterocycles that take part in the final structure of the active microcin result from a series of cyclization, dehydration, and dehydrogenation reactions occurring from Gly–Ser (oxazoles) and Gly–Cys (thiazoles) dipeptides or Gly–Cys–Ser (thiazole-oxazole) and Gly–Ser–Cys (oxazole-thiazole) tripeptides displayed in the sequence of the 69 amino-acid precursor McbA. The McbBCD synthetase recognizes the leader peptide extension that has a helical structure. On removal of the N-terminal 26 amino acid leader peptide by the dedicated ABC transporter McbEF, mature microcin B17 is then exported outside the cells. Severinov's group showed that a major portion of the posttranslationally modified mature microcin contains an additional unusual modification, a backbone ester bond connecting residues Cys51 and Ser52.[8] The formation of the depsipeptide bond very probably results from an N–O acyl rearrangement that occurs during cyclization at Ser52 located immediately C-terminal to one of the thiazole rings. It is postulated that this novel modified microcin is therefore possibly an intermediate form in the biosynthesis pathway of microcin B17.

The maturation process of microcin C is particularly original in the sense that the last cleavage step leading to the toxic entity does not occur in producing cells, but in target cells.[14] Before this last processing step, three modifications of the precursor MccA are required to link the modified nucleotide to the heptapeptide: (i) conversion of Asn7 to a derivatized isoAsn7, (ii) formation of an N–P bond between the amide group of isoAsn7 and Pα of ATP, facilitating the peptidyl–AMP linkage via a phosphoramidate bond, which is ensured by a specific enzyme MccB encoded by the microcin gene cluster *mccABCDE*,[28] and (iii) aminopropylation of the phosphoramidate by two enzymes encoded by genes *mccD* and *mccE*. The aminopropyl chain increases activity several fold, indicating

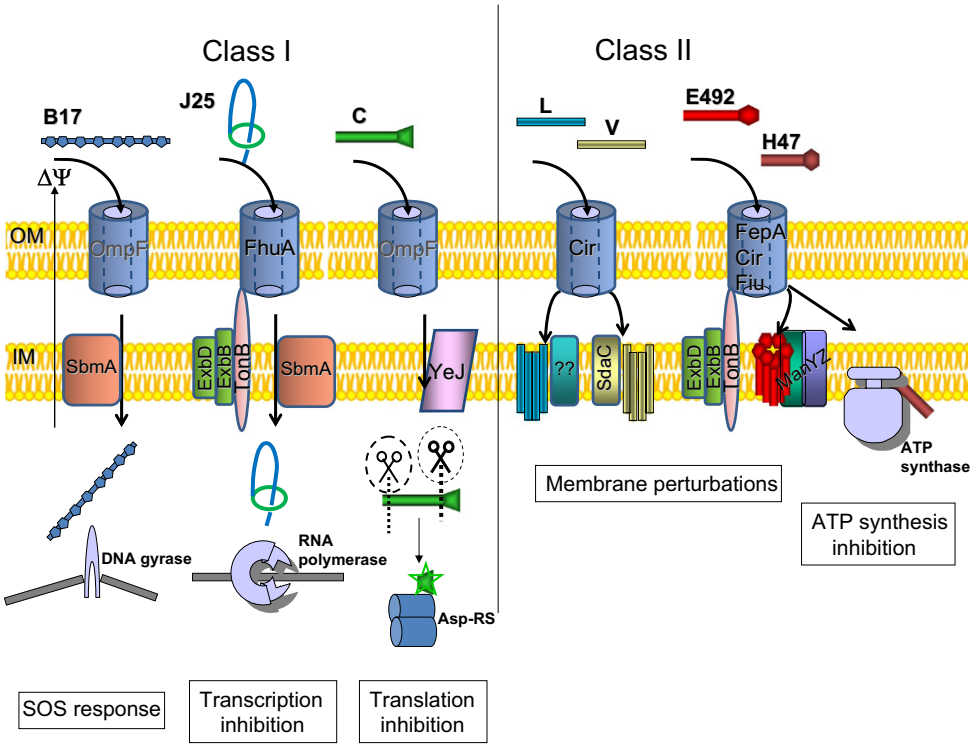

FIGURE 3 Synthetic scheme of the mechanisms of action of microcins of classes I and II. See color plate 12.

its importance for antibacterial activity.[31] The modified precursor itself (i.e., the N-formylated heptapeptide nucleotide) is exported out of the producing cells and enters into the target bacteria using OmpF and Yej. The final maturation steps required for MccC activity (i.e., deformylation and cleavage of the peptide part) happen in target cells[31] (see "Receptors and Biological Activity" and Figure 3).

Microcin J25 is the archetype of lasso peptides. Lasso peptides form a growing class of bioactive peptides synthesized by bacteria that differ most often from enterobacteria, and particularly by actinomyocetes.[10,24,29] They have attracted considerable interest based on the high stability of the fascinating lasso structure, which can be used as a template for peptide bioengineering,[11] as well as the biological activities of known lasso peptides that inhibit enzymes or antagonize receptors.[24] In microcin J25, the amino group of Gly1 is linked to the side-chain carboxylate of Glu8 by a lactam bond, forming an N-terminal ring that is threaded by the C-terminal tail, thus forming the lasso (Figure 1). This particular structure is maintained by the two bulky side chains of two aromatic residues at the end of the tail, Phe19 and Tyr20 that straddle the ring and prevent the tail escaping from the ring. With microcin B17,[12] microcin J25 is the sole microcin that can be produced by *in vitro* reconstitution of an enzyme complex capable of modifying an exogenously supplied precursor peptide.[7] This pioneering work in the connected fields of microcins and lasso peptides showed that the two proteins McjB and McjC encoded in the *mcjABCD* gene cluster are the two enzymes that control the acquisition of the lasso structure from the 58 amino acid precursor. Only the presence of ATP and Mg^{2+} is additionally required to produce the mature and active lasso microcin.[7] Following hypotheses arising from gene sequence comparisons,[7,30,31] recent evidence obtained in my laboratory (Yan K-P, et al. *ChemBioChem* 2012) indicates that McjB is a cysteine protease that cleaves off the leader peptide, whereas McjC is a lactam synthetase responsible for the formation of the amide bond between the glycine at position 1 generated upon proteolytic cleavage of the leader and the Glu8 side chain. McjB and McjC are two interdependent enzymes that mutually need the physical presence of their partner to fulfil their enzymatic function, probably acting as a protein complex. Moreover, the leader peptide with a basic character plays a role in the maturation process, being implicated in the recognition of the precursor McjA by the maturation machinery.

Microcin E492 is the most studied siderophore microcin. The modification anchored at its C-terminal serine is a C-glucosylated linear trimer of DHBS, which is a linear breakdown product of the cyclic catechol-type siderophore enterobactin. Biosynthetic pathways of siderophore microcins (E492, M, H47, and presumably I47 and G492) are dependent on the enterobactin and salmochelin synthesis pathways.[17,34] These pathways use nonribosomal peptide synthetases (NRPS), and their initial steps involve

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

the shikimate pathway that starts from phosphoenol pyruvate and erythrose-4-phosphate. Four genes *mceCDIJ* in the siderophore-microcin gene clusters are required for modifying the peptide at its C-terminal serine. For microcin E492, proteins MceC and MceD ensure enterobactin glucosylation and linearization,[17] whereas MceI and MceJ are responsible for the formation of the O-glucosidic bond between the glucosylated enterobactin and the C-terminal serine of the microcin.[18]

Thus, it seems that the elucidation of microcin biosynthetic pathways points to specific, and in some cases novel, bacterial enzymes that could be either targets for antibiotics or tools for peptide bioengineering.

IMMUNITY OF PRODUCING BACTERIA TO MICROCINS

Contrary to Gram-positive bacteriocins for which several three-dimensional structures of immunity proteins have been determined, assisting in the elucidation of their immunity mechanisms, no immunity protein from a microcin-producing bacterium has been characterized. Although the mechanisms by which microcinogenic strains acquire self-immunity to their own microcin remain largely unexplained, it seems that at least one resistance-conferring gene is associated with the production of a given microcin. Immunity to class I microcins principally involves efflux pumps. Indeed, self-immunity to microcin B17 involves three genes in the microcin gene cluster. However, only strains harboring the three *mcbEFG* genes are fully resistant to the toxic peptide, while those having only two of these genes are only partly resistant to the microcin.[6] In addition to the McbEF export pump, the protein McbG, which is a member of the growing family of pentapeptide repeat proteins, contributes to the immunity of the producing cells to microcin B17.[31] Similarly, self-immunity of the producing strains to microcin C involves at least two proteins, MccC and E, the first one being an efflux pump. In addition, a third protein, MccF contributes to self-immunity of the producing strains.[30,31] The mechanism by which the producing strains are protected against microcin J25 also involves efflux pumps.[6,31] One, McjD, encoded by one of the genes of the microcin biosynthesis cluster, is also involved in the export of the microcin out of the producing bacteria. The other, YojI, is an ABC transporter. Both McjD and YojI require TolC to export microcin J25. By contrast and more similarly to Gram-positive bacteriocins, immunity to class II microcins involves dedicated peptides/polypeptides that range from 51 to 144 amino acids in length. Generally, these small proteins are membrane associated.[6] No three-dimensional structures of these microcin immunity proteins have been determined, and further studies are required to elucidate the mechanisms involved. They should be taken into account in the context of the elaboration of novel strategies against bacterial resistance.

RECEPTORS AND BIOLOGICAL ACTIVITIES

Similar to colicins, microcins have receptor-mediated mechanisms of antimicrobial activity. Such a mechanism is reflected in their low minimal inhibitory concentrations that are found in the nanomolar range, contrasting with antimicrobial peptides of eukaryotic origin that act through a direct interaction with phospholipid membrane bilayers and exert their activity in the micromolar range. It also explains the narrow spectrum of activity generally exhibited by microcins, which are essentially active against bacterial strains very similar to the producing Gram-negative bacteria. Thus, microcin J25 that is produced by *E. coli* mainly targets *Salmonella* sp., whereas microcin E492 produced by *Klebsiella pneumoniae* preferentially kills *Escherichia* sp. To improve uptake into sensitive bacteria, microcins hijack receptors involved in the uptake of essential nutrients, which therefore constitute an Achille's heel for the bacteria (Figure 3). Many microcins parasitize iron siderophore receptors, either of the catechol- (FepA, Cir, Fiu), in the case of microcins E492, H47, L, M, V, or the hydroxamate-type (FhuA) for microcin J25, whereas others (microcin B17 and C) use the porin OmpF. However, the affinity of the receptors for the microcins varies, as microcins E492, M, and H47 are recognized essentially by FepA and also to a lesser extent by Cir and Fiu, whereas microcin L and V on the one hand and J25 on the other hand are specifically and exclusively recognized by Cir and by FhuA, respectively.[6,15] Translocation of many microcins (E492, M, H47, J25) requires the TonB-ExbB-ExbD inner-membrane protein complex,[3,6,15] which uses the proton-motive force from the cytoplasmic membrane for energy transduction to the outer membrane and its receptors. After having crossed the outer membrane through porin OmpF, microcin B17 and C require the proteins SbmA and the ABC-transporter YejABEF, respectively, to be transported through the inner membrane.[26,31]

Microcins exhibit very heterogeneous, complex and subtle bacteria killing mechanisms (Figure 3). Class I microcins mainly inhibit vital bacterial enzymes.[31] Microcins B17 targets DNA gyrase (a topoisomerase essential for ATP-dependent negative supercoiling of DNA, similarly to clinically important quinolones but through a different mechanism). Microcin B17 can inhibit both the DNA supercoiling and relaxation reactions of gyrase.[20] It induces accumulation of covalent complexes of DNA gyrase with cleaved DNA, leading to the formation of double stranded DNA breaks, inhibition of DNA replication, and triggering of the SOS response.[20,31] The intracellular target of microcins J25 is RNA polymerase (RNAP). The lasso microcin binds in the secondary channel that directs NTP substrates

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

toward the RNAP active site, provoking its obstruction in a cork-in-the-bottle fashion[16] and therefore blocking transcription. However, in addition to this enzyme inhibition, microcin J25 targets mitochondria and the respiratory chain at higher concentrations.[6,31] To become active, microcin C requires a cleavage step inside target bacteria to generate the toxic entity.[14] Once inside the cells, it is processed in two steps, first by peptide deformylase, which removes the N-terminal formyl group and second by several broad-specificity aminopeptidases that are able to target the ultimate peptide bond Ala6–Asp7 and cleave off the peptide part.[31] As a result of intracellular processing, the active compound, a modified nonhydrolyzable aspartyl adenylate, is released (Figures 1 and 3). The processed molecule, which is a mimic of aspartyl adenylate, is a potent inhibitor of aspartyl tRNA synthetase, which therefore blocks protein synthesis at the translation step.[13,14]

Class II microcins, however, target the inner membrane or their components.[6] Microcin H47 targets the F_0 proton channel of ATP synthase.[27] Microcins V and E492 both permeabilize the inner membrane. However, microcins also require proteins in the inner membrane for activity. Microcin E492 not only forms channels in the inner membrane, but it also requires the ManYZ inner-membrane components of the mannose permease,[2] which is involved in the active uptake of mannose and related hexoses, to exert its bactericidal activity. Similarly, microcin V needs SdaC, which is involved in serine uptake, and both microcins B17 and J25 need SbmA, a protein of unknown function,[6,30,31] whereas microcin L does not require the inner-membrane proteins ManYZ or SdaC.[15] These proteins presumably help microcins pass through the inner membrane.

STRUCTURE/ACTIVITY RELATIONSHIPS

Except for microcin J25, which has been the subject of extensive structural analysis leading to the clear description of its lasso structure,[24] the three-dimensional structures of other microcins remain poorly identified. Detailed structure–activity relationships of class I microcins, however, have been undertaken, while such studies are not described for class II microcins. A single study from M. Laviña's group, which constructed chimeric peptides with exchanged C-terminal sequences of microcins V and H47, has clearly shown that the C-terminus is involved in recognition by the receptors and therefore in the uptake of the microcin, whereas the N-terminus is responsible for toxicity and specificity.[6]

The unique mode of action of microcin C, for which final processing steps occur inside target bacteria, makes it an attractive model for elaborating analogs targeting other aminoacyl-tRNA synthetases than the aspartyl-tRNA synthetase naturally inhibited by the natural microcin. As saturating mutagenesis of the *mcjA* gene failed, a chemical strategy was developed to prepare a series of microcin C analogs, which retain the initial Trojan horse mechanism of antibacterial activity displayed by the natural microcin (i.e., similar import by YejABEF into target bacteria and processing by aminopeptidases inside cells), while targeting different aminoacyl-tRNA synthetases specified by the last amino acid located proximal to the adenosine part.[35] This synthetic approach is the first step to further create new compounds derived from microcin C and inhibiting different targets. There is no systematic structure–activity relationship analysis of microcin B17, but some point mutation studies indicate that the number and position of the thiazole and oxazole heterocycles in the microcin structure are important and that the C-terminal bis-heterocycle is critical, the activity being completely lost on complete destruction of these two cycles.[31] A systematic structure–activity relationship study of microcin J25 has been performed in Severinov's laboratory, leading to 380 singly substituted variants and paving the way for the future design of strategic variants.[31] The most remarkable conclusion is that the production and activity of the lasso microcin are both tolerant to amino acid substitutions at most of the positions in the 21-amino-acid sequence. Ongoing site-directed mutagenesis studies in my group aiming at deciphering the residues that are critical for both the lasso fold and the antibacterial activity are in progress and point out particularly the stringent roles of Tyr20, which traps the tail into the ring, and of Gly21. The stable lasso structure of microcin J25 is an efficient scaffold for epitope grafting,[11] affording proof of concept of the capacity to provide novel biological functions to the lasso fold and thus very promising tracks for future drug design.

CONCLUDING REMARKS

Bacteriocins exert their potent and selective antimicrobial activities through original, sometimes unique, mechanisms of action that show them to be excellent models for scientists to mimic their strategies. Many bacteriocins from Gram-positive bacteria target components or intermediates in the synthesis of peptidoglycan. Microcins from Gram-negative bacteria, however, use Trojan horse mechanisms to kill target bacteria. Either they use molecular mimicry to bind receptors involved in vital bacterial functions, such as iron import or sugar transport, and to cross the outer or inner membrane, or they enter freely into target bacteria as a harmless entity, which is then processed inside target bacteria to generate a toxic compound. It now becomes clear from structure–activity relationship studies that scientists can take advantage of these elegant and sophisticated strategies to generate potent and selective drugs. The rapid development of bioinformatics provides powerful tools to assist in the discovery of novel microcins or related peptides endowed with interesting biological properties, either inhibiting specific enzymes or perturbing essential bacterial functions. In this regard,

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

posttranslationally modified microcins and particularly class I microcins, seem particularly suitable for drug design, because of their lower molecular masses and unusual posttranslational modifications. Moreover, the mechanisms of immunity developed by the microcin-producing bacteria to evade the toxic peptides they synthesize should provide powerful models for circumventing bacterial resistance. Taken together, this shows that microcins, and bacteriocins in general, could become important tools in the rational design and engineering of biologically active peptides.

Chapter 21

Nonribosomal Peptide Synthesis

Jan Grünewald and Mohamed A. Marahiel

ABSTRACT

Nonribosomal peptides (NRPs) are highly diverse natural products of bacterial and fungal origin. In contrast to ribosomally produced peptides, which are diversified by posttranslational modification events (analogous to postsynthetic modifications of NRPs, which will be not discussed here), complexity-generating structural transformations of the NRP scaffold occur at several additional levels within the biosynthetic pathway. First, the biosynthetic enzymes of NRPs, the nonribosomal peptide synthetases (NRPSs), are able to process at least 25-fold more monomers than the ribosomal biosynthetic machinery. Second, NRPs are further diversified during chain initiation and elongation by a variety of NRPS condensation domain subtypes that integrate D-amino acids, heterocyclic elements, fatty acids, and other moieties into the peptide backbone. Third, complexity-generating chain release from the NRPS multienzyme complex often aims to rigidify the NRP scaffold. This step is mainly catalyzed by thioesterase and reductase domains and is discussed at the end of this chapter.

INTRODUCTION

Diversity is the key characteristic of nonribosomal peptides. The Norine database currently includes >1120 of these highly complex natural products (http://bioinfo.lifl.fr/norine/). NRPs are mainly derived from the secondary metabolism of microorganisms such as bacteria and fungi.[6,21] Their proteolytic stability and highly selective bioactivity have made the diverse scaffolds of NRPs an attractive source of novel drugs for the pharmaceutical industry. For instance, cyclosporin is an efficient immunosuppressive agent that down regulates T cells by binding to cyclophillin,[2] and daptomycin is an antibiotic against multiresistant Gram-positive bacteria that acts through rapid depolarization of the bacterial cell membrane.[1] These are just two examples of the numerous biological applications of NRPs. Hence, the chemical and structural diversity of these secondary metabolites correlates with a large set of highly diverse biological targets with which NRPs can interact. "What determines the high diversity of NRPs?" The answer to this question lies in the biosynthetic logic of NRP production. NRPs are synthesized by large multidomain enzymes, the NRPSs, which catalyze the formation of these natural products in a templated assembly-line fashion.[6] Unlike ribosomal translation of mRNA, NRPS assembly lines can process >520 monomers (http://bioinfo.lifl.fr/norine/, September 2011) for the biosynthesis of NRPs. In addition to high molecular diversity at the monomer level, additional diversification of NRPs occurs during chain assembly on the NRPS multienzyme complex. For instance, on-template heterocyclization significantly increases the rigidity of NRPs and protects them against proteolytic degradation. Chain termination is another diversification step during NRP biosynthesis. For example, full-length NRPs can be cleaved from NRPS enzymes as linear peptides, as peptide amides, as peptide alcohols, and as cyclic or branched-cyclic macrocycles, such as macrolactones, macrolactams, and cycloimines.[4] Finally, another diversification step is achieved by postassembly-line tailoring reactions[33] that are analogous to posttranslational modifications (PTMs) of ribosomally synthesized peptides such as the lantibiotics, microcins, cyanobactins, cyclotides, and linaridins. While PTMs are chemical modifications of peptides after the release from the ribosome, postassembly-line tailoring occurs after the cleavage of NRPs from the NRPS assembly line. In contrast to the PTM machinery, which is the only complexity-generating tool for ribosomally synthesized peptides, postassembly-line tailoring is only one of several steps to generate diversity in nonribosomal peptide synthesis. Further, genomic databases contain thousands of NRPS gene clusters that have not been biochemically characterized to date.[34] Thus, it is expected that many more NRP diversity-generating tools will be discovered in the future. The scope of this chapter is to provide a brief overview of the biosynthesis of NRPs, and to describe how the NRPS machinery is

optimized to introduce a high degree of chemical diversity into peptides that rarely exceed 20 monomers in length.

MONOMER DIVERSITY

The biosynthetic genes for NRP assembly are usually physically clustered within the respective bacterial or fungal genome. This also applies to the genes that encode for the biosynthesis of the numerous monomers of NRPs. For example, the 82-kb gene cluster of the calcium-dependent antibiotic (CDA) from *Streptomyces coelicolor* contains at least 40 genes, 17 of which are predicted to encode enzymes for the biosynthesis and tailoring of monomers such as the 2,3-epoxyhexanoyl fatty acid and the nonproteinogenic amino acids 3-methylglutamic acid (3-MeGlu), 3-hydroxyasparagine, 3-phosphohydroxyasparagine, and 4-hydroxyphenylglycine (Hpg).[8] Further, the high flexibility in monomer selection combined with the NRPS machinery's lack of an efficient proofreading mechanism often leads to inhomogeneous mixtures of NRP natural products. One example is the depsipeptide daptomycin. This approved last-resort antibiotic was originally isolated as a minor component of the A21978C group of acidic lipopeptides derived from the fermentation of *Streptomyces roseosporus*.[1] A21978C is a complex mixture of depsipeptides that differ in the nature of the fatty acyl groups N-terminally attached to an identical peptide core. The major components A21978C_1, A21978C_2, and A21978C_3 contain branched chain C_{11}, C_{12}, and C_{13} fatty acyl groups, respectively. The ratio of these components can be easily manipulated by precursor-directed biosynthesis. Addition of valine to *S. roseosporus* fermentations leads to the production of mainly A21978C_2, whereas feeding with isoleucine dramatically shifted the production toward A21978C_1 and A21978C_3.[1] Analogously, the production of daptomycin containing a straight chain C_{10} fatty acyl group could be significantly optimized by adding decanoic acid to the *S. roseosporus* fermentation medium,[1] thereby illustrating how the diversity of NRP biosynthesis can be easily manipulated to produce a desired peptidic compound. Hence, the monomer diversity of NRPs is a great opportunity for natural-product-based drug discovery efforts.

According to a bioinformatic study based on the Norine database, proteinogenic L-amino acids form only 40% of the total number of NRP monomers.[3] Most of the NRP monomers are of nonproteinogenic origin, such as D-amino acids, noncanonical amino acids, lipids, sugars, and polyketide building blocks. Although both bacterial- and fungal-derived NRPs contain a similar degree of monomer complexity, bacteria and fungi show profound differences in monomer preference. Bacterial NRPs often contain D-serine, D-alanine, 2,4-diaminobutyric acid (Dab), and Hpg as nonproteinogenic building blocks, which are rarely found or even absent in fungal NRPs. By contrast, fungal NRPs are unique in preferring nonproteinogenic monomers such as 2-aminoisobutyric acid (Aib), phenylalaninol, leucinol, and isovaline.[3] Besides monomer-based differentiation between fungal and bacterial NPSs, bioinformatics may also prove useful to assign specific NRP monomer compositions to certain biological activities. By using the Norine database in combination with the known monomeric compositions of the NRPs orfamide, fuscachelin, and aibellin, Jacques and coworkers were able to correctly predict their biological activities as being surfactant, siderophoric, and antibiotic, respectively.[3] Together, bioinformatics in combination with NRP monomer manipulation, such as precursor-directed biosynthesis and mutasynthesis, offer an enormous potential to precisely engineer peptidic natural products with desired biological activities.

INITIATION OF NRP ASSEMBLY

The selection of a highly diverse set of monomers for peptide synthesis is only one aspect that contributes to the overall complexity of NRPs. Further diversification occurs during chain initiation, chain elongation, and chain termination of NRP biosynthesis. All these steps are catalyzed by the NRPS multienzyme complex that covalently binds both the monomers and the nascent peptide chain as thioesters to highly flexible 4′-phosphopantetheine (4′-PP) cofactors.[6] This covalent mode of peptide synthesis minimizes side reactions and eliminates diffusion limitations of single enzyme pathways. The 4′-PP cofactor is posttranslationally attached via a phosphodiester bond to a conserved serine residue of the peptidyl carrier protein (PCP) also referred to as thiolation (T) domain. During NRP biosynthesis, the α-amino group of a covalently attached monomer nucleophilically attacks the electrophilic thioester of a peptidyl or aminoacyl group that is tethered to the upstream PCP. Hence, peptide chain growth by one monomer unit per catalytic cycle is accompanied by the transfer of the nascent oligomer from an upstream to a downstream PCP, thereby also ensuring peptide chain elongation from N- to C-terminus. Besides unidirectionality of peptide synthesis, the prosthetic 4′-PP group of the PCP provides the basis of diversification during NRP biosynthesis. Substrates tethered to this flexible 18 Å long 4′-PP cofactor can reach various domains within the NRPS multienzyme complex that catalyze transformations such as the heterocyclization of serine and cysteine residues, N-methylation of amide bonds, and epimerization of L- to D-amino acids. The importance of the PCP for biosynthesis and diversification of NRPs has led to a "PCP-centered view" of NRPS multienzyme complexes.[12] Structural biology efforts have focused on elucidating the molecular interaction of PCPs with the various catalytic domains of the NRPS machinery. A major breakthrough was the solution

structure of the entire 144-kDa termination module of the *Bacillus subtilis* surfactin synthetase.[31] The 2.6 Å X-ray structure shows the PCP in the context of a fully functional NRPS module containing the complete catalytic machinery necessary for chain elongation by one monomer.

N-Acylation is a common strategy in nonribosomal peptide biosynthesis to increase the hydrophobicity of intrinsically hydrophilic NRP natural products. This initiation step in NRP biosynthesis also significantly contributes to the diversification of the peptide scaffold. For example, most of the daptomycin-related acidic lipopeptide antibiotics are naturally produced as mixtures composed of various N-terminal fatty acid chains.[1] Because of its potential importance for the bioengineering of novel lipopeptide drugs, the mechanism of NRPS-mediated lipoinitiation has been the object of intense research. Initially, Baltz et al. proposed a three-step pathway for the N-terminal lipidation of NRPs.[1] First, fatty acyl-CoA ligase (FACL) catalyzes the formation of acyl-CoA from ATP and the respective fatty acid, which is either recruited from primary metabolism or is synthesized or derivatized by enzymes encoded by the respective biosynthetic gene cluster. Second, the activated acyl moiety of the CoA thioester intermediate is transferred to the holo form of a dedicated acyl carrier protein (ACP) in a transthioesterification reaction. Third, the interaction of this acyl-S-pantetheinyl-ACP intermediate with the NRPS multienzyme complex leads to the transfer of the lipid moiety to the tethered monomer of the NRPS initiation module. This final step of nonribosomal lipoinitiation is assumed to be catalyzed by the N-terminal condensation (C) domain of the NRPS megaenzyme, which is also referred to as "starter" C domain or as type C^{III} domain. The suggested mechanism is supported by the presence of both ACP and FACL in several biosynthetic gene clusters of the acidic lipopeptide antibiotics, namely, A54145, friulimicin, and daptomycin.[1] However, two studies on the glidobactin and the surfactin biosynthetic pathways shed light on an alternative mechanism of NRP lipoinitiation[10,16] (Fig. 1). Interestingly, although no ACPs could be located in either of the two biosynthetic gene clusters, *in vitro* studies show that the respective starter C domains catalyze amide bond formation between the respective PCP-tethered aminoacyl acceptor substrate and the acyl-CoA donor substrate. Further, knockouts of FACL genes in the genome of the surfactin producer *Bacillus subtilis* and enzymatic assays with recombinant FACLs indicate direct recruitment of the acyl-CoA donor substrate from primary metabolism, thereby also explaining the absence of a dedicated FACL gene in the surfactin biosynthetic gene cluster.[16] In glidobactin biosynthesis, the acyl-CoA donor is presumably recruited from the catabolism of fatty acyl-CoA precursors[10] Moreover, although the dissected starter C domain of the surfactin synthetase exhibits stringent substrate specificity for the 3-hydroxy tetradecanoic acyl-CoA donor substrate, the corresponding domain of the glidobactin synthetase tolerates various lipid donors for chain-initiating N-acylation that structurally significantly differ from the cognate 2(E),4(E)-diene fatty acids. Overall, the example of the fatty acid diversity in the acidic lipopeptide antibiotics indicates that many more of such starter C domains with relaxed acyl-CoA donor specificity may exist. Such promiscuous starter C domains would serve as ideal tools for NRPS reengineering efforts to generate novel NRPs with custom-made N-terminal fatty acid moieties, thereby allowing the fine tuning of the hydrophobicity of these natural products.

Besides catalyzing lipoinitiation of NRP synthesis, starter C domains are also responsible for the N-terminal incorporation of aromatic or heteroaromatic carboxylic acids into NRPs. In the biosynthesis of the siderophore enterobactin, the starter C domain catalyzes amide bond formation between serine-S-pantetheinyl EntF and upstream 2,3-dihydroxybenzoate (2,3-DHB), which is tethered to the 4′-PP group of an aryl carrier protein (ArCP) in the two-domain protein EntB.[23] Other examples include starter C domain-mediated chain initiation reactions with 4-methyl-3-hydroxyanthranilic acid (4-MHA) in actinomycin D biosynthesis and 3-hydroxypicolinic acid (3-HPA) in pristinamycin I biosynthesis.[23] A special case is observed in the biosynthesis of the siderophore vibriobactin. In this instance, the starter C domain VibH is a stand-alone domain that catalyzes amide bond formation between two nonproteinogenic building blocks: 2,3-DHB as the donor substrate and norspermidine as the acceptor substrate.[11] Hence, the examples discussed thus far show that starter C domains are versatile biocatalysts capable of processing highly diverse monomeric building blocks for the initiation of NRP assembly. However, one exception is the N-formylation of anabaenopeptilides and linear gramicidins. This NRP initiation reaction is suggested to be catalyzed by formylation domains. For the linear gramicidins, *in vitro* enzymatic assays reveal that the formylation domain of the first module LgrA1 uses both N^{10}-formyltetrahydrofolate and N^{5}-formyltetrahydrofolate as cofactors to catalyze N-formylation of PCP-tethered valine, and, to a lesser degree, leucine and isoleucine.[29]

ELONGATION DURING NRP ASSEMBLY

While the nascent peptide is covalently tethered to the NRPS assembly line, chain elongation is another opportunity to diversify the NRP scaffold. Common diversifying modifications during chain assembly include the epimerization of distinct monomers of the peptide chain, the introduction of heterocyclic structural elements, the N-methylation of peptide bonds, and the reduction of α-keto acids leading to ester bond formation.[34] These complexity-generating

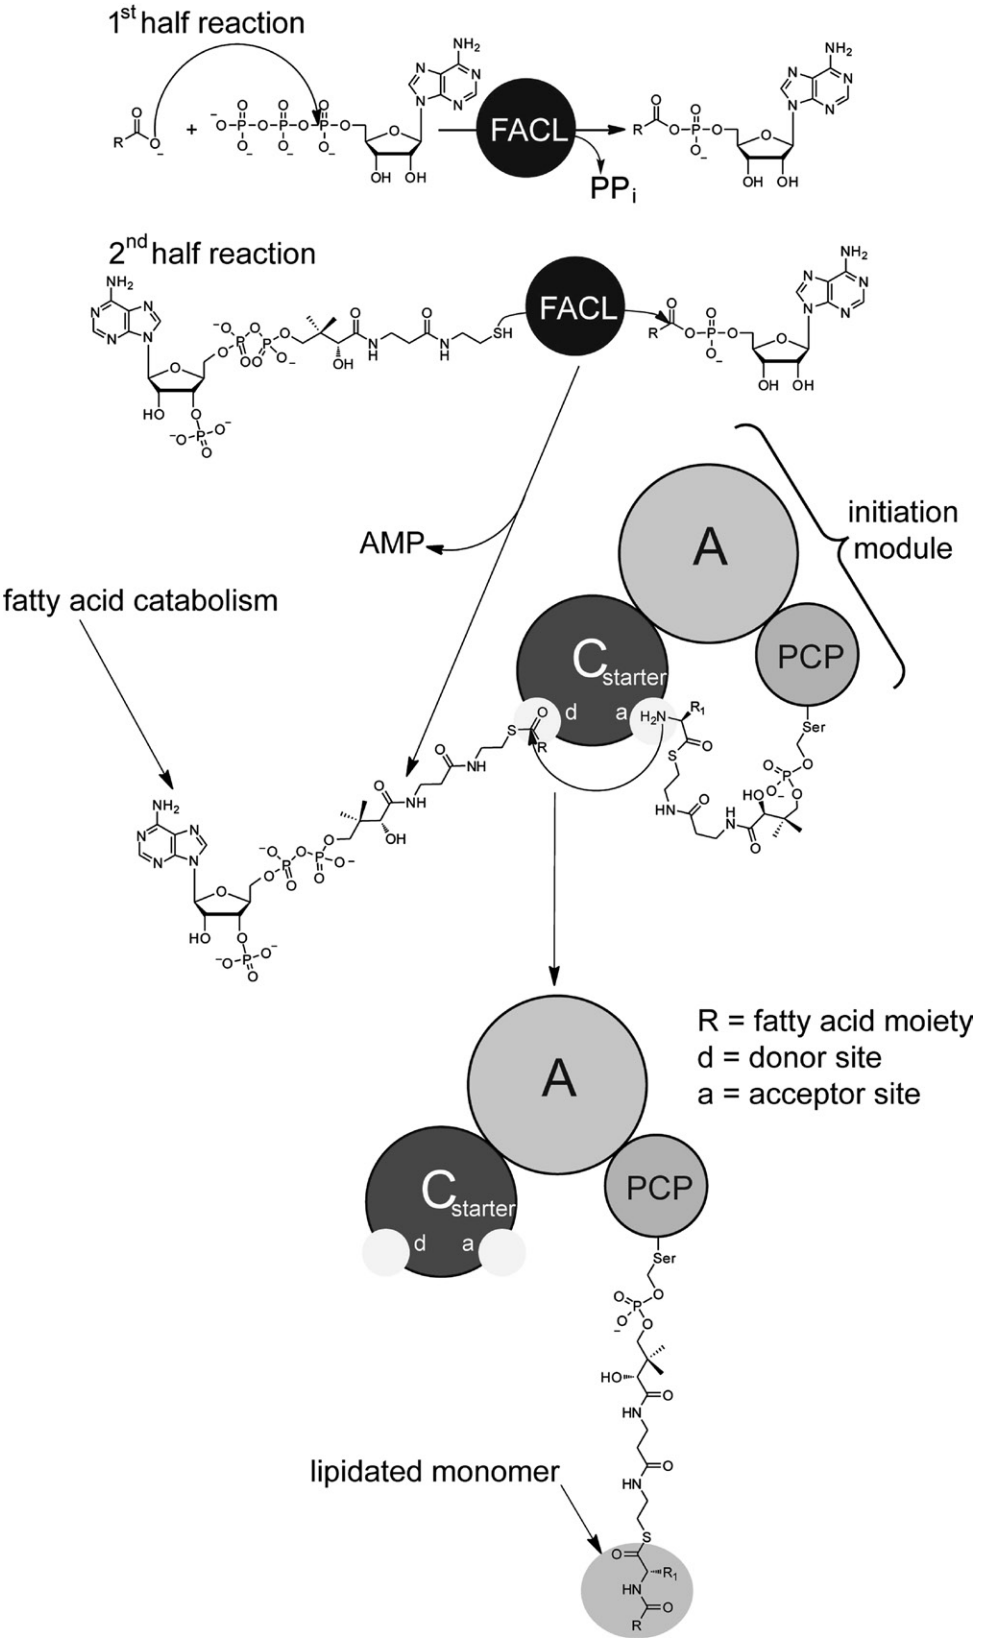

FIGURE 1 Proposed mechanism of NRP lipoinitiation. Acyl-CoA donor substrates are directly recruited from primary metabolism. In the surfactin biosynthetic pathway, formation of the lipid-CoA donor substrate is catalyzed by FACLs.[16] The respective fatty acid is first activated as an adenylate (first half reaction), which is then converted into an energy-rich CoA thioester (second half reaction). Alternatively, the acyl-CoA donor substrate can also be derived from the catabolism of acyl-CoA precursors,[10] as suggested for the glidobactin biosynthetic pathway. In either case, the dedicated acyl-CoA donor directly serves as a substrate for the starter C domain, which catalyzes the transfer of the activated fatty acyl moiety to the PCP-bound aminoacyl acceptor via amide bond formation.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

transformations during peptide assembly, combined with the high diversity of NRP monomers, pose a significant challenge to the enzymatic machinery of the NRPS. Besides lipoinitiation, the C domain is the key enzymatic element accounting for efficient peptide elongation with highly diverse NRP building blocks. Further, it even contributes to several "on-assembly-line" modifications that further increase the complexity of NRPs. To better accommodate the variety of enzymatic transformations, the C domain is split into several functional subtypes. Phylogenetic studies carried out by Rausch et al. reveal the existence of six C domain subtypes in NRPSs: the already mentioned starter C domain, the $^{L}C_{L}$ domain, the $^{D}C_{L}$ domain, the epimerization (E) domain, the dual E/C domain, and the heterocyclization (Cy) domain[23] (Fig. 2). A solid understanding of the catalytic functions and substrate specificities of this diverse set of C domain subtypes will be beneficial for the design of future bioactive NRP derivatives by NRPS reengineering efforts. The major functional and structural aspects of C domain subtypes in peptide elongation will be discussed in the following section.

In nonribosomal peptide elongation, the C domain catalyzes the nucleophilic attack of the α-amino group of the PCP-tethered monomer on the electrophilic thioester of the nascent peptidyl-S-pantetheinyl intermediate of the upstream PCP. X-ray crystallographic studies reveal that the

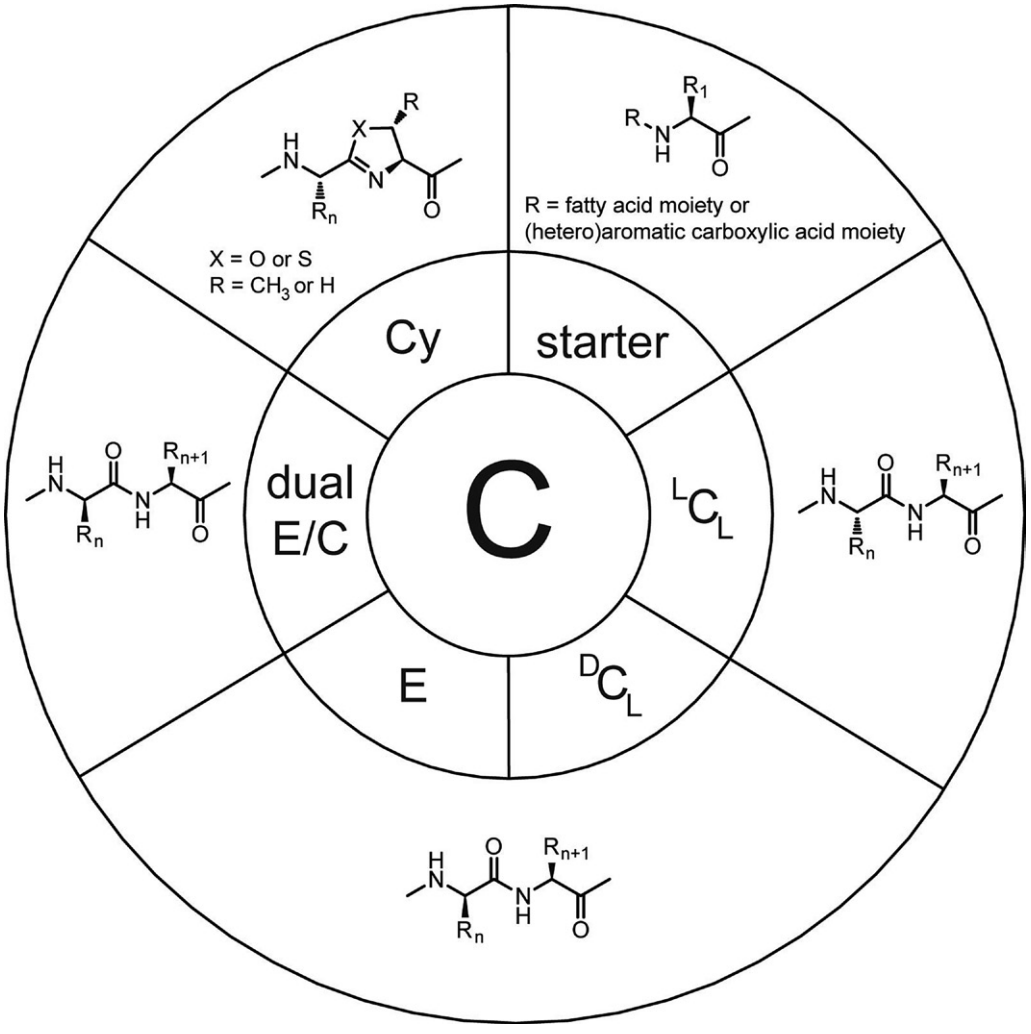

FIGURE 2 NRP diversification during peptide assembly by various C domain subtypes. According to Rausch et al.,[23] the C domain can be subdivided into six different functional subtypes: starter C domain, $^{L}C_{L}$ domain, $^{D}C_{L}$ domain, E domain, dual E/C domain, and Cy domain. The starter C domain is involved in the attachment of a diverse set of fatty acid moieties or (hetero)aromatic building blocks to the N-terminus of the nascent NRP natural product. The $^{L}C_{L}$ domain catalyzes amide bond formation between two L-configured amino acid monomers, whereas the two-domain E/$^{D}C_{L}$ system and the dual E/C domain stereospecifically catalyze amide bond formation between an upstream D-configured amino acid monomer and a downstream L-configured amino acid monomer. The major difference between the dual E/C domain and the two-domain E/$^{D}C_{L}$ system is that in the latter amino acid epimerization is catalyzed by an autonomous catalytic domain, the E domain. Finally, the Cy domain catalyzes both peptide bond formation and its subsequent cyclodehydration to generate thiazoline (X = S; R = H) or oxazoline heterocycles (X = O; R = CH_3 or H).

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

C domain has a V-like structure, in which two sub-domains are separated by a groove containing the putative active site HHXXXDG of the C3 core motif (His-motif).[31] The groove provides enough space for the 4′-PP-tethered condensation substrates to reach the highly conserved motif from two opposing faces, the donor and the acceptor sites. Initially, the second histidine residue of the His-motif was postulated to function as a catalytic base in the deprotonation of the positively charged α-amino group of the acceptor monomer.[26] However, mutational studies on the VibH C domain show that the conserved histidine residue is not essential for the catalysis of amide bond formation.[11] Further, pK_a value calculations of the respective histidine residue in the C domain of the 6th module of the tyrocidine synthetase TycC indicated complete protonation of the histidine side chain under physiological conditions.[28] Essen and coworkers therefore suggested that the protonated residue is involved in the stabilization of the tetrahedral oxyanion intermediate during the nucleophilic attack on the thioester bond. Similar to the still elusive mechanism of amide bond formation, the interdomain dynamics involved in nonribosomal peptide elongation are currently far from being understood. Despite the availability of X-ray crystallographic information on a PCP-C didomain[28] and even an entire NRPS termination module,[31] X-ray crystallography can only provide static snapshots of distinct conformational states and crystal-packing effects may alter the NRPS interdomain interactions in a nonphysiological way. However, in contrast to this, nuclear magnetic resonance studies on the PCP indicated that NRPS assembly-line synthesis is a highly dynamic process that is driven by major conformational changes of this small protein domain.[12] Hence, a better understanding of nonribosomal peptide elongation would require alternative structure solution methodologies that better capture the native dynamic processes involved in amide bond formation. In addition, as suggested by Strieker et al., a yet to be determined 3-D structure of a multimodular NRPS fragment containing the C domain together with its interacting upstream and downstream partner PCP domains would give better insights into the underlying interdomain interactions.[31]

One striking feature of the C domain, which has not yet been rationalized on a structural basis, is its stereoselectivity for both condensation substrates. The $^{D}C_{L}$ domain catalyzes the stereospecific condensation of a D-configured donor substrate with an L-configured acceptor substrate, whereas the $^{L}C_{L}$ domain exhibits strict L-specificity on both donor and acceptor sites. Switching between both C domain subtypes by rational mutagenesis would allow complete control over the stereochemistry of the final NRP natural product. Although reprogramming of C domain subtypes would be highly desirable for the engineering of novel NRPs, stereospecificity-determining key residues have not been identified yet. Further, phylogenetic studies indicate no significant differences between the putative catalytically or structurally relevant residues, for example, both subtypes contain the highly conserved His-motif.[23] However, profound differences between the two subtypes could be detected within and downstream of core motif C4. Mutually nonconserved residues in these regions may serve as a promising starting point for future mutational studies aiming to alter the stereospecificity of the C domain donor site.

Besides its stereospecificity, the C domain also exhibits significant selectivity toward the side-chain structure of the acceptor monomer. Hence, the acceptor site of the C domain is a second selectivity filter that acts downstream of monomer selection and activation by the adenylation (A) domain. This tight functional interaction between both domains ensures the incorporation of the correct monomer into the nascent peptide chain. Both the C domain and its downstream A domain also tightly interact at a structural level. According to the X-ray crystal structure of the termination module of the surfactin NRPS, both domains share a large surface area to form a rigid catalytic platform with their active sites aligned on the same side of the platform.[31] This close functional and structural association of both domains explains the difficulty of reengineering NRPSs by domain swapping. Reprogramming of NRPSs by swapping, deletion, or insertion of entire modules is preferable as the structural integrity of this catalytic platform is maintained. Moreover, the low side chain specificity of the C domain donor site, which is part of the module–module interface, increases the chances of success of such reengineering efforts.

The $^{D}C_{L}$ domain is closely related to the dual E/C domain, which was first characterized by Walsh and Fischbach.[6] Both C domain subtypes act as stereoselective $^{D}C_{L}$ catalysts that share significant similarities in the C5 core motif.[23] However, analysis of the primary sequence of the dual E/C domain reveals the existence of a unique N-terminal extension that contains another elongated His-motif, HH[I/L]XXXDG. This second His-motif is believed to exhibit epimerization activity toward the C-terminal L-amino acid of the nascent peptide chain, which is tethered to the preceding module. Specifically, E/C domain-catalyzed epimerization results in the generation of a diastereomeric mixture of the donor peptidyl chain containing the C-terminal monomer in both D- and L-configurations. Interestingly, biochemical studies with recombinant NRPS components of the arthrofactin synthetase indicate that this epimerization activity is triggered by the presence of the downstream monomer-*S*-pantetheinyl-PCP intermediate.[6] Epimerization is then followed by stereoselective peptide bond formation, in which only the D-configured C-terminal monomer of the upstream peptidyl-S-pantetheinyl moiety is transferred to the downstream L-aminoacyl-S-pantetheinyl

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

acceptor. The strict order of the dual catalytic activity of this C domain subtype ensures unidirectionality of peptide synthesis and the stereoselective incorporation of D-configured monomers.

D-Configured building blocks diversify NRPs and contribute to the exceptional stability of these natural products by conferring resistance to naturally L-specific proteases. Further, they allow the NRP scaffold to adopt unique structural conformations, which play an important role in their bioactivity. For the vast majority of characterized NRPSs, the incorporation of D-configured monomers is mediated by two distinct C domain subtypes, namely, E and $^{D}C_{L}$ domains. By analogy to the catalytic activity of the dual E/C domain subtype, E-domain-catalyzed epimerization is followed by $^{D}C_{L}$-domain-mediated condensation of the downstream L-aminoacyl-S-pantetheinyl acceptor with the thioester-bound D-configured monomer of the upstream donor substrate.[6] Mutational studies have indicated that epimerization is catalyzed by the second histidine residue of the E domain's HHXXXDG motif,[30] which is supposedly involved in the rapid deprotonation and reprotonation of the Cα atom of the aminoacyl- or peptidyl-S-pantetheinyl donor.

Heterocyclization is another tailoring step in nonribosomal peptide synthesis that occurs while the nascent peptide chain is tethered to the NRPS assembly line. In addition to further diversification of the NRP natural product, the introduction of heterocyclic structural elements increases resistance to proteolytic degradation and also significantly contributes to the rigidity of the peptide scaffold. Moreover, five-membered heterocyclic rings, such as thiazolines, oxazolines, and their oxidized derivatives, are important binding motifs that allow NRPs to chelate metal ions and to specifically interact with DNA, RNA, and proteins.[27] In NRP biosynthesis, the formation of oxazoline and thiazoline heterocyclic moieties is catalyzed by the heterocyclization (Cy) domain. Similar to the dual E/C domain, this C domain subtype catalyzes multiple catalytic transformations. The first catalytic step is mechanistically identical to C-domain-mediated peptide bond formation in which the nascent peptidyl-S-pantetheinyl donor is transferred to the downstream monomer-S-pantetheinyl-PCP intermediate. Specific to the Cy domain, the acceptor substrate is always a 4′-PP group-tethered serine, threonine, or cysteine moiety, because the nucleophilic side chains of these amino acids attack the carbonyl carbon atom of the newly formed amide bond in the second catalytic step. Dehydration of the cyclization product then leads to the formation of the final oxazoline (derived from serine or threonine) or thiazoline (derived from cysteine) ring systems.[5] Overall, the Cy domain is a dual-functioning C domain subtype that catalyzes the cyclodehydration of its own generated peptide bond. In common with the dual E/C domain, the Cy domain has a unique sequence motif. The His-motif HHXXXDG is replaced by the conserved signature motif, DXXXD, which is believed to be crucial for the catalysis of amide bond formation.[11] Further, mutational studies of the Cy domain of the bacitracin synthetase identified two conserved residues, Asn^{900} and Ser^{984}, which seem to be essential for cyclodehydration catalysis.[5] Interestingly, the corresponding residues are absent in the Cy2 domain of the VibF subunit of the vibriobactin synthetase, and the catalytic activity of Cy2 is restricted to amide bond formation.[18] By contrast, the adjacent Cy1 domain of the VibF subunit, which contains both key residues, is mainly involved in the catalysis of the cyclodehydration reaction. Hence, in analogy to the two-domain E/$^{D}C_{L}$ system, Cy1 and Cy2 are believed to act in tandem with Cy1 restricted to the catalysis of cyclodehydration and Cy2 restricted to the catalysis of amide bond formation. The cyclodehydration-specialized Cy domain may therefore be regarded as the evolutionary counterpart of the epimerization-specialized E domain.

In many cases, Cy-domain-catalyzed cyclodehydration of peptide bonds is followed by subsequent oxidation or reduction of the resulting oxazoline, β-methyl oxazoline, and thiazoline heterocyclic ring systems.[6] This further increases the number of possible heterocyclic elements in NRPs to a total of nine different species. Heterocycle diversification is either catalyzed by oxidation (Ox) or reduction (R) domains (Fig. 3). The Ox domain, which is integrated into the NRPS multienzyme complex, uses the cofactor flavin mononucleotide (FMN) to oxidize oxazoline and thiazoline to oxazole and thiazole moieties, respectively.[6] Conversely, the R domain acts as a free-standing enzyme by catalyzing the NADPH-cofactor-dependent reduction of oxazoline to oxazolidine rings or thiazoline to thiazolidine

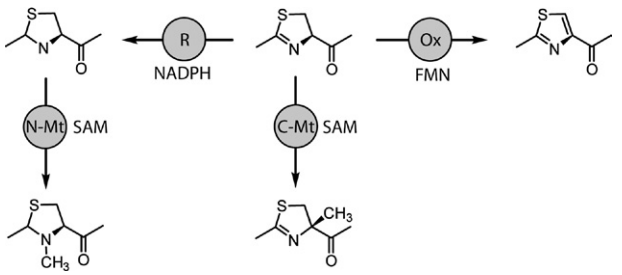

FIGURE 3 Heterocycle diversification in NRP biosynthesis as exemplified for the thiazoline moiety. Peptide bond formation and subsequent cyclodehydration to form a thiazoline heterocycle is the starting point of several complexity-generating catalytic transformations. The FMN-dependent Ox domain can carry out a two-electron oxidation resulting in the generation of an aromatic thiazole moiety. Conversely, two-electron reduction by the NADPH-dependent R domain yields a thiazolidine heterocycle. Because of the high basicity of the nitrogen atom in the thiazolidine ring, this moiety can undergo N-methylation by an SAM-dependent N-Mt domain as observed in pyochelin biosynthesis.[22] Alternatively, SAM-dependent C-methylation of the thiazoline heterocycle occurs in yersiniabactin biosynthesis.[19] This regiospecific methylation of the C2 atom is catalyzed by a C-Mt domain via a putative carbanion intermediate.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

heterocycles.[24] Because both Ox and R domain could be heterologously expressed in *Escherichia coli* as catalytically active enzymes, they may be used as versatile catalytic tools for the *in vivo* production of novel peptides using engineered NRPSs expressed in this genetically most-manipulable microorganism.

Besides oxidation and reduction, heterocyclic moieties can be C-methylated by an S-adenosylmethionine (SAM)-dependent C-methyltransferase (C-Mt) domain (Fig. 3). In the synthetase of the siderophore yersiniabactin, the C-Mt domain is located downstream of a Cy domain that catalyzes the cyclization of a cysteine side chain onto the preceding amide carbonyl group.[19] The resulting thiazoline moiety is then regiospecifically methylated at the C2 atom by the C-Mt domain. Mechanistically, C-methylation is believed to involve C-Mt-domain-mediated deprotonation of the C2 hydrogen atom, leading to a delocalized carbanion intermediate that nucleophilically attacks the electron-deficient methyl group of the enzyme-bound SAM cofactor. Similar to Ox and R domains, C-Mt domain catalysis requires the substrate to be covalently tethered to the 4′-PP cofactor of the PCP. Hence, all these complexity-generating tailoring steps on heterocyclic elements occur during chain elongation of the NRP nascent product. The same applies to the N-methylation of these rigidifying moieties (Fig. 3). For instance, *in vitro* reconstitution of the biosynthetic pathway of the siderophore pyochelin indicated that N-methylation of the C-terminal thiazolidine heterocycle occurs during NRPS assembly-line synthesis.[22] The enzymatic cascade reaction is initiated by a Cy domain, which catalyzes both peptide bond formation and cyclodehydration. An *in trans*-acting R domain then converts the resulting C-terminal thiazoline into a thiazolidine moiety. This imine reduction renders the heterocyclic amine nitrogen more basic, thereby facilitating the final nucleophilic attack onto the SAM electrophile. This final step in heterocycle tailoring is catalyzed by an *in cis*-acting N-Mt domain, which is an embedded catalytic entity of the pyochelin synthetase. N-methylation may prevent opening of the reduced thiazolidine ring, which is assumed to be involved in the siderophore chelation of ferric iron.[22] However, more common than N-methylation of heterocyclic moieties is the N-methylation of noncyclized peptide bonds in nonribosomal peptide biosynthesis. N-Methylation of peptide bonds is an important *in cis* tailoring step that renders NRPs more hydrophobic and inhibits proteolytic cleavage of the peptide backbone. For example, the cyclosporin synthetase contains six embedded N-Mt domains that contribute to the N-methylated peptide bonds of the undecapeptide.[32] In contrast to the N-methylation of heterocyclic elements, SAM-dependent N-methylation occurs before amide bond formation resulting from the higher basicity of the free amino group of the 4′-PP-bound aminoacyl acceptor substrate. Further, molecular modeling studies on the C domain of the second module of cyclosporin synthetase reveal specific recognition of the N-methyl group of the downstream N-MeLeu^3-S-PCP acceptor nucleophile by the acceptor site.[32] Specifically, the N-methyl group is involved in hydrophobic interactions with Phe^{1399}, which is part of a hydrophobic pocket in the C domain acceptor channel. This key residue is only conserved among C domains in the cyclosporin synthetase that catalyze the formation of N-methylated peptide bonds.

Diversification of NRPs during chain elongation is mainly generated by the C domain and its various subtypes. Interestingly, instead of catalyzing amide bond formation, several C domains of bacterial and fungal NRPSs supposedly act as chemoselective ester synthases. For example, the terminal C domain of the CesA module of the cereulide NRPS has been proposed to use the α-hydroxy moiety of the 4′-PP-bound L-α-hydroxy isovaleric acid (L-HIV) as the incoming nucleophile.[17] Ester bond formation is proposed to occur with $^{D}C_{L}$ stereospecificity, leading to the observed D-Ala-L-HIV connectivity of the cereulide molecule.

Diversification of NRPs by the various C domain subtypes usually occurs *in cis*. However, as already exemplified for heterocycle reduction in pyochelin biosynthesis, many additional tailoring reactions during chain elongation are catalyzed by *in trans*-acting enzymes that interact intermolecularly with the NRPS-tethered peptide substrate. According to Walsh and Fischbach, these enzymatic transformations can be classified into two categories: group transfer reactions and oxidative transformations.[34] Tailoring enzymes involved in group transfer reactions catalyze the conjugation of an electrophilic moiety of a cosubstrate to a nucleophilic center of the NRP scaffold. One example is the N-methylation of 4′-PP-bound 2,3-diaminobutyric acid (2,3-DABA) by the external SAM-dependent methyltransferase PacV in pacidamycin biosynthesis.[35] By contrast, oxidative transformations are catalyzed by tailoring enzymes that use molecular oxygen as a cosubstrate. For instance, nonheme Fe^{II} halogenases of various biosynthetic gene clusters were discovered that use molecular oxygen and α-ketoglutarate to oxidatively activate halogen atoms such as bromine and chlorine. As shown for the syringomycin E biosynthetic pathway, these enzymes regiospecifically halogenate unactivated carbon centers on 4′-PP-tethered aminoacyl moieties.[20] Another example of oxidative transformations is the crosslinking of aromatic side chains of vancomycin-type glycopeptide antibiotics by cytochrome P450 monooxygenases. In vancomycin biosynthesis, the three enzymes OxyA, OxyB, and OxyC catalyze these rigidifying oxidative transformations on the PCP-tethered aglycone in a highly regiospecific fashion.[34] However, most of the enzymatic group transfer reactions and oxidative transformations occur postsynthetically after the release of the peptide from the NRPS multienzyme complex. These postsynthetic tailoring reactions show parallels

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

to the diversifying posttranslational modifications found in ribosomally produced peptides. A comprehensive review of these complexity-generating modifications has been provided by Walsh et al.[33]

TERMINATION OF NRP ASSEMBLY

Chain termination in NRP biosynthesis combines peptide release from the NRPS assembly line with further diversification of the peptidic scaffold. In most cases, diversification is directed toward the rigidification of the short peptide chain consisting of usually <20 monomers. Chain release by macrocyclization is the most common strategy in NRP biosynthesis to constrain the peptide backbone in a biologically active conformation. According to the Norine database, 64% of all nonribosomally produced peptides consist of at least one cyclized form.[3] Besides being important for bioactivity, these nonlinear structures significantly contribute to the proteolytic resistance of the NRP natural products, thereby increasing their half-lives. Interestingly, although the biologically active conformation of most ribosomally produced peptides is stabilized by cystine disulfide bonds or lanthionine thioether bridges, cysteine constitutes a rare monomer in NRPs. The role of cysteine in the rigidification of the NRP scaffold is mainly confined to thiazoline, thiazole, and thiazolidine heterocycle formation. Instead, covalent linkage between nonadjacent residues of the NRP chain occurs mostly via macrolactonization and macrolactamization. This final step in templated NRP synthesis is typically catalyzed by a thioesterase domain (TE domain), which usually constitutes the most downstream domain of the NRPS assembly line.[13] TE domains belong to the superfamily of α/β hydrolases, which use a catalytic triad of serine, histidine, and aspartate for catalysis. Specifically, the reactive hydroxyl moiety of the triad serine residue nucleophilically attacks the thioester of the 4′-PP cofactor-bound full-length peptidyl chain of the most downstream PCP domain. The resulting peptidyl-O-TE oxoester intermediate then undergoes regioselective attack by an amine or hydroxyl group of the tethered peptide moiety, thereby triggering the release of the macrocyclic product from the NRPS template.[13] For instance, daptomycin is released as a macrolactone, whereas bacitracin A is released as a macrolactam (Fig. 4). Valuable insights into the mechanistic aspects of TE-domain-catalyzed peptide cyclization have been gained from X-ray crystallography and NMR spectroscopy, as well as *in vitro* enzymatic assays with recombinant TE domains.[7,13] These studies conclude that substrate recognition by the TE domain is basically limited to the peptide's C-terminal residues and the residue containing the cyclization nucleophile. The active site of the TE domain allows hydrogen bond-assisted folding of the bound peptide into a precyclic conformation, which orients the cyclization nucleophile for the subsequent attack on the transient oxoester linkage. In a minority of NRPSs, this TE-domain-mediated chain termination step involves hydrolysis or aminolysis of the peptidyl-O-TE intermediate, leading to the release of a linear NRP product. For example, the glycopeptides of the vancomycin family are hydrolytically released from the NRPS multienzyme complex as linear peptide acids (Fig. 4). As mentioned earlier, scaffold rigidification of these NRPs by oxidative side-chain cross-linking takes place before chain termination. In a third variant of chain termination, the peptidyl-O-TE intermediate is nucleophilically attacked by several species of nucleophiles. As shown in the biosynthesis of gramicidin S, the TE-bound pentapeptidyl oxoester is cleaved by the N-terminal α-amino group of a second pentapeptidyl moiety as a pseudoexternal nucleophile, which is tethered to the most downstream PCP domain.[9] The resulting 4′-PP cofactor-bound head-to-tail dimerized decapeptidyl moiety is then transferred back to the TE domain, which catalyzes the release of the final ten-residue macrolactam ring via nucleophilic attack of the internal N-terminal α-amino group. Such cyclooligomerization reactions have been observed for both macrolactone- and macrolactam-forming TE domains.[13] In addition, as shown in Fig. 4, cyclooligomerization involving the generation of two thioester bonds has been described for the TE domain of the thiocoraline synthetase.[25] Even more remarkable, iterative TE domain-mediated diversification of NRP scaffolds also includes C–C bond formation (Fig. 4). Such a chain termination strategy was discovered during the reconstitution of the terrequinone A biosynthetic pathway *in vitro*. Specifically, Balibar et al. showed that TE domain-catalyzed release of a terrequinone A precursor is coupled to two tandem Claisen condensations. These two sequential C–C bond formations generate the quinone core which bridges the two indole moieties of terrequinone A.[4] Further, in some NRPSs, a chain releasing C domain can functionally substitute a TE domain. Examples are C-domain-catalyzed macrolactamization of cyclosporin A[13] and C domain-catalyzed aminolytic release in vibriobactin biosynthesis[11] (Fig. 4). Hence, the C domain is the most versatile catalytic entity of NRPSs, because it can contribute to all three biosynthetic phases of NRP biosynthesis, namely, initiation, elongation, and termination.

In NRP biosynthesis, chain release can also be triggered by an NAD(P)H-dependent reductase domain (R domain), which typically constitutes an integrated domain at the C-terminal end of the NRPS assembly line. Both two-electron and four-electron reductions of the PCP-bound peptidyl thioester have been observed. Two-electron reductive release via formation of a peptide aldehyde intermediate occurs in the biosynthesis of saframycin A, anthramycin, and linear gramicidin A.[4] For the latter NRP, the two-electron reductive release is followed by another two-electron reduction, which is catalyzed by an external R domain, leading to the observed C-terminal ethanolamine moiety of the final product (Fig. 4). By contrast, lyngbyatoxin A is reductively released from the biosynthetic template as a peptidyl

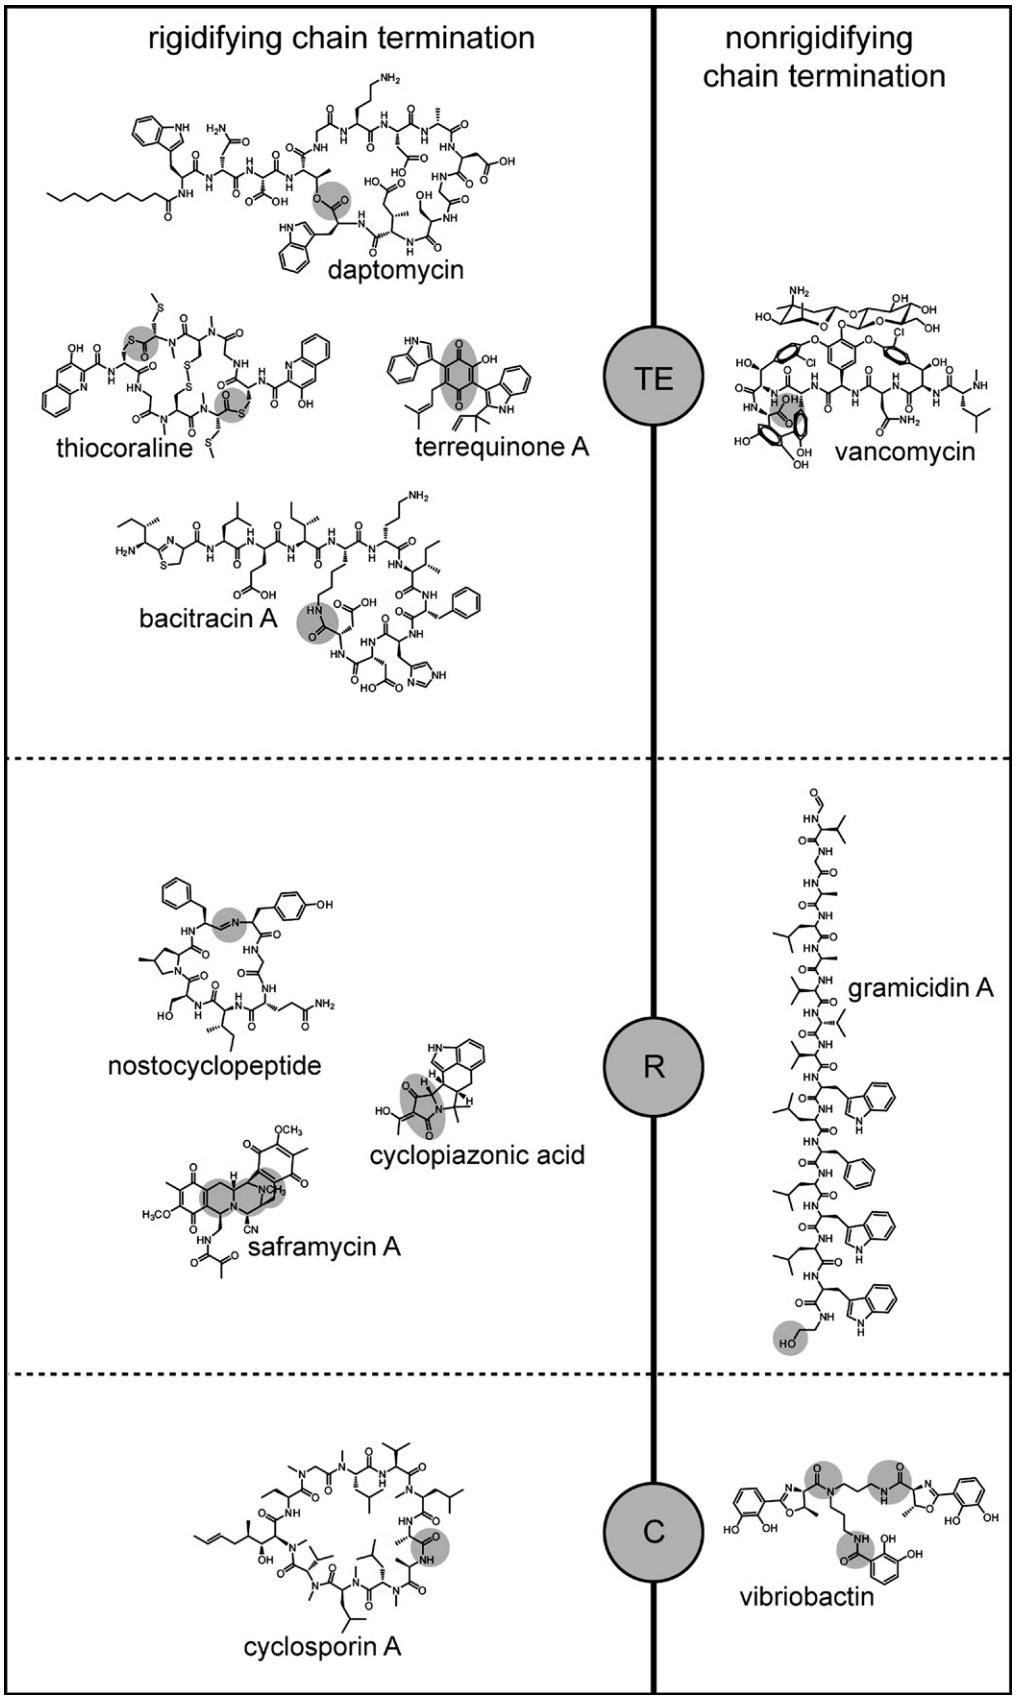

FIGURE 4 NRP diversification by chain termination. An overview of characteristic NRPs that represent specific chain termination strategies in NRP biosynthesis is shown. These chain termination strategies are subdivided into rigidifying (left) and nonrigidifying (right). Further, the NRPs are categorized by the termination domain that is involved in the chain release of the respective peptidic product. Finally, the structural motif that is associated with NRP chain release is highlighted by shading.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

alcohol by the catalytic action of a single integrated R domain that carries out a four-electron reduction.[4]

In many cases, R domain-catalyzed reductive release is followed by various crosslinking events that lead to a substantial rigidification of the initially released linear product. For example, in saframycin A biosynthesis, the reductively released aldehyde species form the substrates of the iterative Pictet–Spengler reactions that build up the rigid polycyclic tetrahydroisoquinoline core of the antibiotic (Fig. 4).[14] Even peptide macrocyclization can be triggered by an R domain as shown for the cytotoxin nostocyclopeptide.[15] After product release via a two-electron reduction of the PCP-bound peptidyl thioester, the linear heptapeptide aldehyde undergoes spontaneous formation of a macrocyclic imine (Fig. 4). Experiments with synthetic peptide aldehydes indicate that cyclic imine formation occurs in the absence of the R domain and is solely driven by the autonomous folding of the linear precursor into a precyclic conformation.[15] By contrast, direct involvement of the R domain in chain-terminating cyclization reactions occurs in the biosynthesis of equisetin, tenellin, and cyclopiazonic acid.[4] Here, chain release is mediated by a redox-inactive R domain that catalyzes the formation of a five-membered ring via Dieckmann condensation (Fig. 4). The nonrequirement of a reducing cofactor for this type of chemistry also rationalizes the existence of TE domains that act as Dieckmann cyclases as observed in the biosynthesis of the polyketide aflatoxin.[4] In addition to the aforementioned chain termination strategies, diversifying NRP off-loading mechanisms also include chemistries such as diketopiperazine formation and α-oxoamine formation, which have been reviewed by Du and Lou[4] as well as Walsh and Fischbach.[34]

The biotechnological potential of chain-terminating NRPS domains is enormous. Bypassing the selectivity restrictions imposed by A and C domains, researchers have used excised TE domains in combination with solid phase peptide synthesis to create large libraries of macrocyclic peptides.[13] This chemoenzymatic approach is ideal for the high throughput screening of NPSs for improved bioactivity. Lead peptides could then be translated back into reengineered NRPSs for large-scale production by fermentation.

In conclusion, the enormous structural complexity of NRPs originates from a total of five biosynthetic events: 1. Enzymatic pathways that contribute to monomer diversification; 2. Starter C-domain-mediated complexity generation during the initiation of NRP biosynthesis; 3. Diversification by various C-domain subtypes while the peptide is elongated on the NRPS assembly line; 4. Chain-terminating complexity generation by various enzymatic peptide release mechanisms; 5. Postsynthetic tailoring to complete the biosynthesis of the released peptide. These many levels of complexity generation make this biosynthetic system a unique tool for the generation of tailored drug scaffolds. By using methods such as precursor-directed biosynthesis, mutasynthesis, directed protein evolution, domain/module swapping, and chemoenzymatic NRP reengineering, researchers have already begun to rationally manipulate each of these biosynthetic steps with the eventual goal to improve the pharmacological properties of NRP natural products.

Chapter 22

Peptaibols

César de la Fuente-Núñez, L. Whitmore and B.A. Wallace

ABSTRACT

The peptaibols are a large family (>440 members identified to date) of homologous linear peptides isolated from soil fungi, ranging in length from 5 to 20 amino acids. They are characterized as having a high content of α-Aminoisobutyric acid (Aib) residues and generally have both N-terminal (mainly acetyl groups) and C-terminal modifications in the form of amino alcohol groups rather than amino acids. Peptaibols are nonribosomally synthesized on large protein complexes that permit the incorporation of nonstandard amino acids. During the process of peptide chain elongation, some of the synthetase modules are not absolutely specific for amino acid type, resulting in a diversity of isoforms being produced by a single organism. Most members of the family show antibacterial or antifungal activity, which has been attributed to their ability to induce membrane permeability by forming multimeric helical bundle ion channels. Some peptaibols possess antiviral and antitumor activities and promote wound healing.

INTRODUCTION

The naturally occurring peptaibols are a family of short peptides isolated from soil filamentous fungi, especially from members of the genus *Trichoderma*. This chapter represents an update of the previous version found in the first edition of this Handbook.[30] The name peptabiol derives from the chemical composition of these molecules: pept<u>ides</u> containing <u>Aib</u> (α-Aminoisobutyric acid) residues and ending in a C-terminal alcoh<u>ol</u>. They are mainly distinguished by compositions consisting of a large number of "nonstandard" amino acid residues, with Aib accounting for a high proportion of all residues in each of the sequences (for examples of some peptaibol sequences, see Fig. 1). Peptaibols are synthesized on large protein synthetase complexes rather than ribosomally, which permits the inclusion of nonstandard, noncoded residues. As would be expected for a family of peptides with a single dominant residue, there is considerable sequence identity between different peptaibols, especially between peptides isolated from the same biological source. It is possible to group the peptaibol sequences from a range of biological sources into subfamilies according to their sequences. At present, >440 peptaibol sequences have been identified,[8,28,30] although high-resolution structures are only available for a few of them.[1,29] All those structures are primarily helical, as would be expected because Aib is a strongly helix-promoting residue. The helical nature of these peptides plays a key role in their biological activity, which seems to be primarily based on their ability to form helical bundles that facilitate ion transport/leakage across membranes. This activity can be harmful to organisms and can cause cell death. Some authors argue that fungi produce peptaibols as a passive defense mechanism. As a result, many peptaibols are effective antibiotics, with varying degrees of activity against different target microbes. An online searchable database of natural peptaibol sequences, structures, nomenclature, and literature references[28] may be found at http://peptaibol.cryst.bbk.ac.uk although these have not been updated recently. The numbers presented in this chapter have been updated based on recent literature searches.

CHARACTERISTIC FEATURES OF THE PEPTAIBOLS

An important feature of peptaibol sequences is the presence of a high proportion of α,α-di-substituted amino acids, primarily Aib. The Aib residue, also known as α-methylalanine, has two methyl groups attached to its α-carbon atom, making it more hydrophobic and conformationally constrained than the standard (ribosomally encoded) L-alanine and thus promoting the formation of helical structures (Fig. 2). Another disubstituted residue found in peptaibols is isovaline (Iva), which is also known as methylethylalanine. Percentages and locations of Aib residues in peptaibol sequences vary among different members of the same family.[29,30] However, no peptaibols have as yet been discovered with a C-terminal hydroxylated Aib residue. Similarly, in the longer sequences, Aib has not yet been found at positions 18, 19, or 20. On average, almost 40% of peptaibol residues in the currently known peptaibols are Aib, and >3% are isovaline (Iva) or α-ethylalanine; the upper and

lower ranges for Aib composition of individual sequences are 56% and 14%, respectively. Some trends regarding Aib content have been identified. Thus, shorter peptaibols tend to contain greater proportions of Aib than do longer ones. The distribution of residues Aib-neighboring residues is not random, as certain pairs of residues occur more frequently than expected statistically. A prime example of this is that virtually all proline residues in peptaibols (>98%) have Aib as their N-terminal neighbor; the Aib–Pro peptide bond forms the characteristic kink that is often seen in the peptaibol structures. Furthermore, 100% of nonproteinogenic hydroxyproline (Hyp) residues are preceded by disubstituted amino acids (75% Aib and 25% isovaline).

Although Aib is the most common noncoded residue to occur in peptaibols, it is not the only one. The imino acid hydroxyproline comprises >2% of all residues, and etnorvaline

(α-amino-α-ethyl-n-pentanoic acid) and 2-amino-6-hydroxy-4-methyl-8-oxodecanoic acid (AHMO) are also rarely found (in <10 examples across all known peptaibols).

In addition to containing these nonstandard amino acids, peptaibol sequences also have a distinctive lack of many charged and polar amino acids.[29] Although the functionally important glutamine is abundant in peptaibol sequences, constituting around 6% of the residues and featuring in >65% of the sequences, there are as yet no known peptaibols containing arginine, asparagine, cysteine, histidine, lysine, or methionine residues, and there is only one example of a tyrosine-containing peptaibol. Glutamines (or occasionally glutamic acids) are found at specific locations, primarily at position 6 or near the C-terminus; the position and number of these polar residues seem to be related to their functional properties as ion channels.

Prolines are also frequently found, accounting for >7% of all peptaibol residues and are often located near the middle of the sequences. These residues tend to break helical structures because of the absence of the amino protons needed to form intramolecular hydrogen bonds. It has been proposed that they may be responsible for producing kinks or bends in helices or β-turns, which may be related to their ion channel gating properties.[5]

Aromatic residues are found infrequently in peptaibols, comprising approximately 4% of the total amino acid residue content. They tend to cluster at the termini, where they are thought to contribute to stabilize the transmembrane orientations of the peptide chains within the bilayer, in a manner similar to the mechanism proposed for the transmembrane segments of membrane proteins.[27]

A further sequence feature of peptaibols is that both their N- and C-termini tend to be modified. The N-terminal amino acids are typically attached to an acyl group, although other aliphatic groups, such as octyl groups in the trikoningins,[29,30] have also been reported. The C-terminal residues, however, generally have their carbonyl groups reduced to hydroxyl groups, explaining why they are amino alcohols rather than amino acids. Interestingly, clonostachin is a peptaibol that has an ester-linked sugar alcohol terminal group.[4]

Sequence length is often considered to be a defining feature of peptaibols. The shortest known natural peptaibol, peptaibolin, is five residues long.[13] The longest ones are 20 residues long. Of all known peptaibols, a substantial proportion of sequences (>30%) have 20 residues, and the distribution of sequence size shows a decreasing trend with decreasing peptide size (Fig. 3). The predominance of longer sequences probably results from the role of these peptides as transmembrane permeabilizers. Remarkably, even-numbered members predominate over odd-numbered ones, with the exception of the highly populated 11-residue group (which might be found more frequently than expected because its size corresponds approximately to a half-bilayer spanning helix).[29]

BIOLOGICAL ORIGINS AND BIOSYNTHESIS OF PEPTAIBOLS

All known peptaibols have been isolated from soil fungi or molds. The majority (>50%) have been isolated from various *Trichoderma* species.[6,16,18–20,24] Others come from other fungal species, including *Hypocrea peltata*,[28]

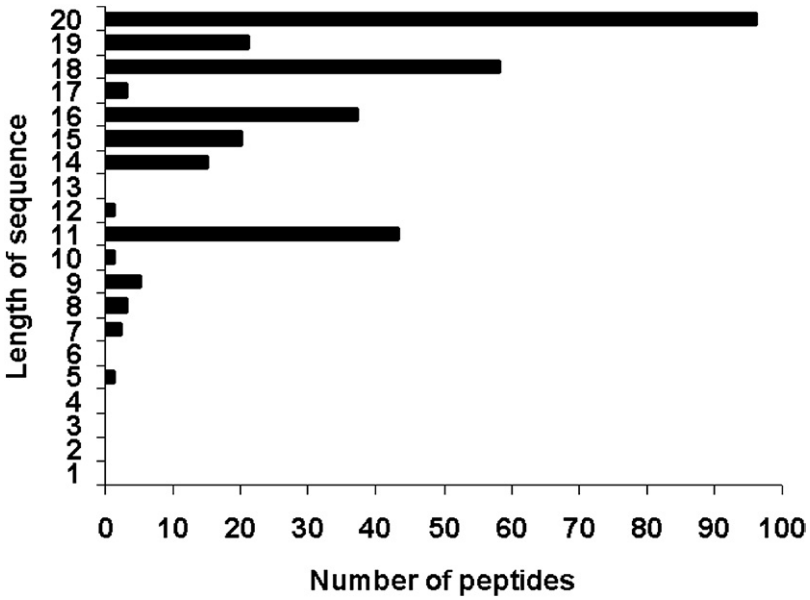

FIGURE 3 Distribution of peptaibol sequence lengths as of 2004 (after Ref. 29).

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Clonostachys,[4] *Apiocrea chrysosperm*,[9] *Sepedonium ampullosporum*,[21,30] *Acremonium tubakii*,[25] *Mycogone cervina*,[32] *Mycogone rosea*,[30] and *Verticimonosporium ellipticum.*[28] Some particular sequences are known to be produced by different organisms. Antiamoebins, for example, have been isolated from at least three different species: sequences I–V are from *Emericellopsis poonensis*, *Emericellopsis synnematicola*, and *Cephalosporium pimprina*,[30] whereas sequences VI–XVI are obtained from *Stilbella erythrocephal*, *Stilbella fimetaria*, and *Gliocladium catenulatum.*[15]

Peptaibols are not formed ribosomally. Instead, they are synthesized by multidomain enzymes on large nonribosomal peptide synthetase (NRPS) complexes[30] (Fig. 4). The peptaibols are assembled by these NRPSs from various precursor units, responsible for adding both standard and nonstandard amino acids to the peptide sequence. The synthetases have a modular structure, with different modules independently responsible for recognizing, activating, and modifying specific consecutive residues. Each module can be further organized into different adenylation, thiolation, and condensation domains depending on the specific reaction they catalyze. The number of modules usually correlates with the number of amino acid residues present in the peptide sequence. Synthetase complexes have been cloned and expressed, and depending on the modules present, used to produce defined peptaibol molecules.[31] Some modules seem to be specific for particular residues, whereas others have two or three specificities and will attach residues according to their availability within the growth medium.[21] This variable specificity leads to the microheterogeneity of the peptaibols extracted from a given organism. Also, there are indications that other factors may modify the peptaibol sequence. Raap et al.[23] showed that zervamicins produced in a medium with labeled isovaline contained both labeled isovaline and labeled Aib residues. The tendency of these multidomain complexes to synthesize peptaibols with an even number of residues, pairwise distribution of amino acids and longer sequences, indicates that the biological role of these peptides is dictated by these large nonribosomal complexes.

Postsynthesis modifications of peptaibols may also contribute to define specific characteristics. Sharman et al.[28] have shown that XR586, a peptaibol-like peptide from *Acremonium persicinum*, is sequentially very similar to the zervamicins, although it terminates in the sequence Phe–Gly (i.e., with an extra Gly), rather than the Phe residue common to the zervamicins. This might suggest that the final stage of synthesis of some peptaibols could include a cleavage enzyme that is not present in all organisms.

PEPTAIBOL STRUCTURES

Various methods have been employed to group peptaibols according to their sequences. The original classification method was based on sequence length and terminal groups.

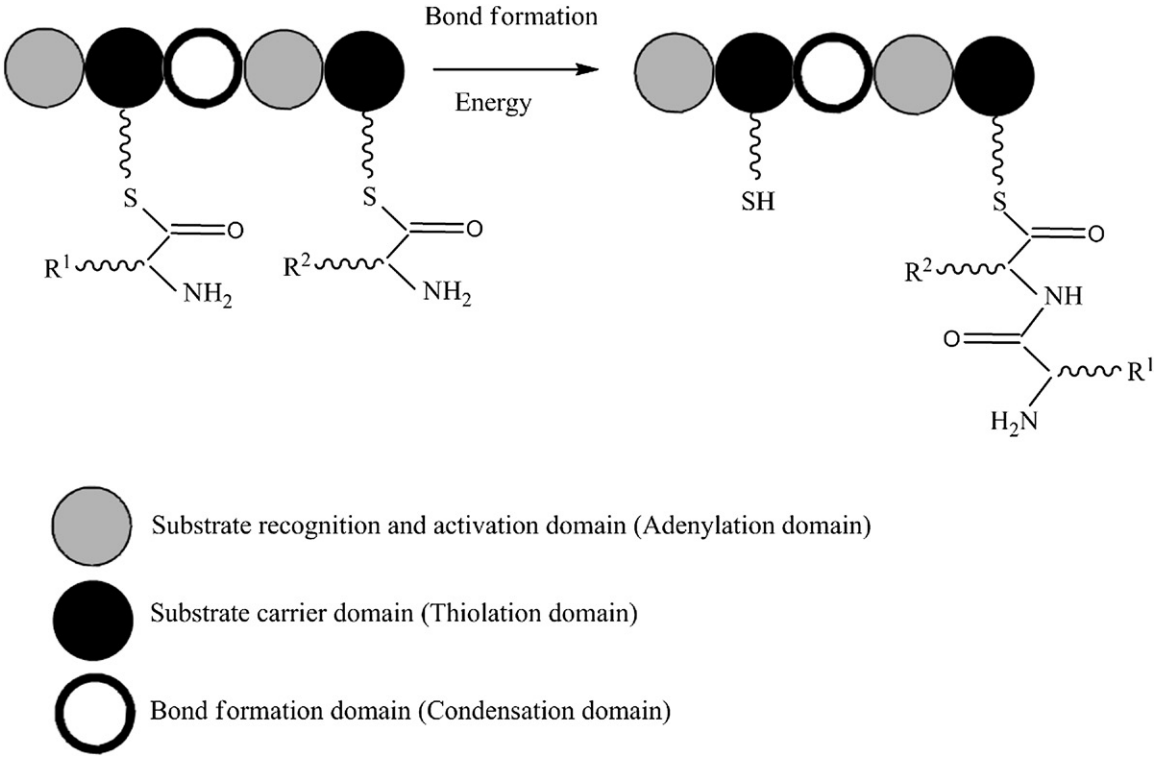

FIGURE 4 *In vivo* posttranslational synthesis of peptaibols by nonribosomal peptide synthetases (NRPS), after Ref. 17.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Accordingly, groupings were established as "long," "short," and "lipopeptaibol." The long peptaibols are characterized by a sequence length of 18–20 residues (e.g., saturnisporins). Short peptaibols have sequence lengths in the range of 11–16 residues and include the trichorovins[28] (11 residues) and heptaibin[14] (15 residues). It should be noted that this classification was made before the identification of 17 residue peptaibols such as cephaibols P and Q.[25] Lipopeptaibols are 11 residues or shorter and have fatty acids such as octanoic acid at their N-termini, as exemplified by trichogin A IV.[2]

A classification method based on sequence homology was devised by Chugh and Wallace in 2001.[5] Homology grouping into subfamilies, with special attention to functionally important residues, had the advantage of being relatively sequence length-independent, and tended to cluster family members with similar functional properties. A total of nine distinct subfamilies with sequence identities of >50% were identified. This classification makes it clear that closely related sequences reflect a naturally occurring pool of "mutants" with slightly modified functional properties, which can be used in structure/function studies.

In contrast to the wealth of information available about peptaibol sequences, there are relatively few published peptaibol structures with complete coordinates. This is probably related to the fact that peptaibols fall in the intermediate size category, smaller than the macromolecular structures traditionally found in the Protein Data Bank, and larger than the small molecule structures deposited in the Cambridge Structural Data Bank. There are only a limited number of X-ray structures and even fewer deposited NMR structures (http://peptaibol.cryst.bbk.ac.uk/structure.htm). For one of the peptaibols, antiamoebin I, two crystal structures (in different solvents) and an NMR structure have been identified. For zervamicin IIb, there are two NMR structures in different environments (one from an isotropic solvent and one in micelles) and a crystal structure for a modified version of this peptaibol. The observation that different peptaibol structures occur in different environments suggests flexibility and adaptability. The dearth of structures may reflect difficulties for crystallizing membrane-active peptides and solving intermediate-sized crystal structures,[28] as well as for determining structures of peptides with high redundancy of residue types from NMR data.

Less detailed structural information under various solvent conditions and/or in lipid bilayers or micelles has been frequently obtained using circular dichroism (CD) spectroscopy. CD information is available for hypelcins, trichorzianines, alamethicin,[3] paracelsin, trichogins, trikoningins, trichotoxin A-40, chrysospermins, trichosporins, saturnisporins, harzianins, trichologins, antiamoebin, and XR586, a peptaibol-like antibiotic molecule [http://peptaibol.cryst.bbk.ac.uk/singlerecords/XR586.html]. They all have common spectral shapes typical of helical structures, featuring negative peaks at approximately 205–209 and 221–226 nm and positive peaks at approximately 192–198 nm. These broad ranges reflect the total span of peak positions quoted in the literature. As the structures are highly constrained by extensive hydrogen-bonded networks, they tend to show little solvent dependence, although their spectra (especially the peak positions) do exhibit a significant dependence on solvent permanent dipole (dielectric constant).

All the peptaibol structures determined to date include helical conformations, although they exhibit considerable structural diversity in the type of helix present (3_{10} or α) and in whether they are straight or bent. The bending tends to be the result of the number and position of the proline or hydroxyproline residues present. Nonetheless, not all imino acid-containing peptaibols are bent. For example, the structure of trichotoxin, which has a central proline, is essentially a straight helix [http://peptaibol.cryst.bbk.ac.uk/trichotoxin1.htm].

FUNCTIONS AND ACTIVITIES OF PEPTAIBOLS

Functionally, most peptaibols exhibit varying antibacterial and antifungal properties against different target organisms. Thus, for example, although chrysospermins display activity against a range of bacteria, including Gram-negative *Escherichia coli*,[9] trikoningins inhibit the Gram-positive bacterium *Staphylococcus aureus*.[30] Antifungal behavior includes that of hypelcin A, which prevents the growth of *Lentinus edodes*, a Japanese edible mushroom and other fungi.[30]

The physical basis of peptaibol antibiotic properties seems to lie in their ability to permeabilize lipid bilayers. They form transmembrane pores and carriers and can also modify the membrane surface in a surfactant-like mode. When pores are formed in membranes, they generally take the form of voltage-gated ion channels.[10,11,22] Typically, voltage-dependent activity is usually associated with the longer peptaibols (that can directly span a bilayer) and has also been observed in peptaibols as short as 14 residues. The channels themselves are thought to be formed by several peptaibol molecules coming together to form a bundle,[10] which is then inserted into the membrane, creating a hydrophilic channel through its center[3] (Fig. 5). The longer peptaibols (16–20 residues), when in a helical conformation, have the appropriate length to span a lipid bilayer.[5,26] The number of peptide chains in the bundle differs depending on the peptaibol type, ranging from 6 to >12. The basis for the antimicrobial activity of these compounds can be explained by the leakage of cytoplasmic material through the peptaibol-induced channels.

Somewhat surprisingly, the membrane activity of peptaibols is as pronounced in some short peptides as it is in longer ones. Auvin-Guette et al.[2] reported that among the trikoningins, the 11-residue lipopeptaibols KB I and

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

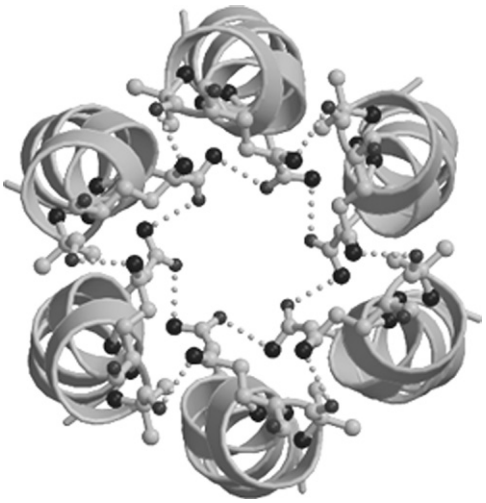

FIGURE 5 End-on view of the hexameric bundle pore structure of trichotoxin, after Ref.10.

KB II show similar antibacterial activity against *Staphylococcus aureus* as does the 19- residue kA V. Similarly, the 11-residue trichogin A IV was shown to have significant membrane-perturbing properties in experiments measuring carboxyfluorescein leakage from egg phosphatidylcholine unilamellar vesicles.[2] Clearly, the shorter peptaibols could not span a membrane in the same way as the longer ones. There are a variety of potential mechanisms for these short peptides as discussed previously.[1,12] Two possible mechanisms of action could occur in these cases: either the shorter peptaibols form end-to-end bundles within the bilayer, thus effectively doubling up their length perpendicular to the bilayer, or, as suggested for the antimicrobial peptides, form membrane-associated aggregates, surface-associated "carpets," membrane spanning toroidal channels or act via a detergent-like mechanism.

Finally, although membrane permeabilization is clearly a feature common to all peptaibols, it remains uncertain whether this is their true biological function within the native organism. Hypothetically, they could act as an *in vivo* defense mechanism against other organisms with different membrane characteristics to their own. In fact, many of them exhibit differential activity when targeting different membrane lipid types.[10,11]

In summary, the peptaibols are a naturally occurring family of hydrophobic nonribosomally produced peptides that seem to have the capability of altering membrane permeability. They show considerable sequence diversity because of their multiple specificities displayed by nonribosomal peptide synthetases[5,7,31] and represent an excellent natural resource of "mutant" peptides, allowing the study of structure–activity relationships. The antibiotic properties of peptaibols seem to be related to ion channel formation.[5,22]

ACKNOWLEDGMENTS

This work was supported, in part, by grants from the UK Biotechnology and Biological Sciences Research Council to B.A. Wallace. C de la Fuente-Núñez received a scholarship from the Fundación "la Caixa" and Fundación Canadá (Spain). The original idea of creating a Peptaibol Database was suggested by Dr. Chris Snook, when he was a student in the Wallace Laboratory. The database was designed and is curated by Dr. Whitmore. Some updates of the database and curation were the work of Dr. Jasveen Chugh. We thank both Drs. Chugh and Snook for helpful discussions and Dr. Chugh for Fig. 4.

Chapter 23

Antifungal and Antibacterial Peptides of Fungal Origin

Tzi Bun Ng

ABSTRACT

Many diseases in humans, livestock, and agricultural crops are caused by fungi. Nonproteinaceous and proteinaceous/peptidic molecules are produced by humans and other living organisms to combat fungal assault. Much effort has been directed at isolating antifungal proteins and peptides from living organisms and making use of them in antifungal strategies such as producing transgenic crops overexpressing the antifungal proteins and peptides and thus acquiring enhanced resistance against pathogenic fungi. Antifungal peptides produced by fungi comprise peptaibols, which also display antibacterial activity, cyclic peptides, and linear peptides. Proteins with antifungal and antibacterial activities are also produced by fungi.

INTRODUCTION

Antifungal proteins are produced by humans, animals, plants, and microbes for protection against pathogenic fungi. A spectacular array of antifungal proteins with a diversity of molecular masses, N-terminal or complete amino acid sequences, and specificity, and mechanism of antifungal action exist. Some of the antifungal proteins also possess antibacterial activity. The intent of this chapter is to review antifungal peptides and antibacterial peptides of fungal origin (Table 1).

Peptaibols with Antifungal and Antibacterial Activities

Nine membrane-active peptaibols, designated as trichorzianines A, were isolated from *Trichoderma harzianum* cultures. They are characterized by an acetylated N-terminal amino acid, and L-tryptophanol or L-phenylalaninol at the C-terminal, and possession of seven to eight alpha-aminoisobutyric acid residues. The isovaline residue present has the D-configuration.[10] Two nonadecapeptide peptaibols, tricholongins BI and BII, expressing antifungal and antibacterial activities, have been isolated from *Trichoderma longibrachiatum* cultures. They possess mostly hydrophobic L-amino acids, eight to nine 2-aminoisobutyric acid residues, an acetylated N-terminal residue, and a C-terminal leucinol. Both peptides adopt a similar alpha-helical conformation with a hinge around Pro13 resulting from two 3(10) bonds. The results suggest that the N-terminus contains mixed alpha/3(10) bonds.[20] Four nonadecapeptide peptaibols with antibacterial and antifungal activities, designated as chrysospermins A, B, C, and D, were isolated from *Apiocrea chrysosperma* mycelia.[9] Ampullosporin was isolated from *Sepedonium ampullosporum* mycelia as a peptaibol with narrow-spectrum antibacterial and antifungal activities. It induced pigment formation by *Phoma destructiva*, elicited hypothermia and inhibited spontaneous locomotor activity in mice.[21]

Two linear 19-amino-acid peptaibols with antifungal and antibacterial activities, septocylindrin A and septocylindrin B, which are peptides with a modified phenylalanine C-terminus related to the membrane-channel-forming peptaibol alamethicin, were isolated from an isolate of the fungus *Septocylindrium* sp. The 18th residue, was Glu in septocylindrin A and Gln in septocylindrin B.[25] From liquid culture of a cork oak endophytic strain of *Trichoderma citrinoviride*, a mixture of peptaibols, 20-residue antifungal peptides with N-terminal acetylation and C-terminal phenylalaninol, was isolated. The peptide mixture shows remarkable toxicity in a brine shrimp bioassay.[18]

Trichogin GA IV from the fungus *Trichoderma longibrachiatum* is a protease-stable lipopeptaibol with attenuated hemolytic activity. It exhibits folding in a mixed 3(10)-/α-helical conformation with an amphiphilic character, possibly accounting for its ability to perturb bacterial membranes and to induce cell death. It displays antibacterial activity toward Gram-positive bacteria, especially methicillin-resistant *S. aureus*.[31]

Peptaibols trichorzianines A1 and B1, chitobiohydrolase, endochitinase, and beta-1,3-glucanase activities were found in culture supernatants of *Trichoderma harzianum*

TABLE 1 Amino Acid Sequences of Peptides With Antifungal, Antibacterial and HIV-Reverse Transcriptase Inhibitory Activities

Peptide	Amino acid sequence
Ampullosporin[21]	Ac-Trp-Ala-Aib-Aib-Leu-Aib-Gln-Aib-Aib-Aib-Gln-Leu-Aib-Gln-Leuol
Russula paludosa peptide[27]	Lys-Arg-Glu-His-Gly-Gln-His-Cys-Glu-Phe
Cicadapeptin I[16]	Hyp-Hyp-Val-Aib-Gln-Aib-Leu
Cicadapeptin II[16]	Hyp-Hyp-Val-Aib-Gln-Aib-Ile
Penicillium canescens antifungal peptide	D-Phe-L-Val-D-Val-L-Tyr
Ulocladium atrum cyclopeptolide[29]	HPA-homoPro-NMeVal(1)-Val-NMeAsp-NMeIle(1)-NMeIle(2)-Gly-NMeVal(1)-OMeTyr
Isarfelin A[11]	Pro-Leu-Phe-Gly-Ala
Isarfelin B[11]	Pro-Val-Phe-Gly-Ala
Aspergillus clavatus antimicrobial peptide[3]	D-Phe-L-Val-D-Val-L-Tyr
Trichogin GA IV[31]	n-Oct-Aib-Gly-Leu-Aib-Gly-Gly-Leu-Aib-Gly-Ile-Lol
Cordycommunin[13]	Thr-Ala-Ala-Gln-Tyr-Val
Alternaramide[14]	Pro-Phe-Hiv-Pro-Phe
Septocylindrin A[25]	Ac-Aib-Pro-Aib-Ala-Gln-Aib-Val-Aib-Gly-Leu-Aib-Pro-Val-Aib-Aib-Glu-Gln-Phaol
Septocylindrin B[25]	Ac-Aib-Pro-Aib-Ala-Gln-Aib-Val-Aib-Gly-Leu-Aib-Pro-Val-Aib-Aib-Gln-Glu-Phaol
Aspergillus giganteus antifungal peptide[17]	Asp-Glu-Ser-Ala-Val-Leu-Ala-Thr-….

mycelia cultivated on glucose as the only carbon source and transferred to fresh medium with *Botrytis cinerea* cell walls. The culture supernatants impede spore germination and hyphal elongation of *B. cinerea*. Culture supernatants from mycelia cultured in fresh medium in the absence of *B. cinerea* cell walls do not show hydrolase activities, synthesis of peptaibol-like compounds, or suppression of fungal growth. Purified trichorzianines A1 and B1, chitobiohydrolase, endochitinase, or beta-1,3-glucanase inhibited spore germination and hyphal elongation. There is a synergism between the antifungal actions of the enzymes and peptaibols.[23] Also see the peptaibol chapter in the Bacterial/Antibacterial Peptides section of the book.

Cyclic Antifungal Peptides

Isarfelin, a cyclic peptide with inhibitory activity toward the fungi *Rhizoctonia solani* and *Sclerotinia sclerotiorum* and insecticidal activity toward *Leucania separata* but devoid of antibacterial activity, was isolated from *Isaria felina* mycelia. The isolation procedure involved ethanol extraction, adsorption on YPR II macropore adsorption resin, ethyl acetate extraction, petroleum ether precipitation, and recrystallization from ethyl acetate.[11]

The saprophytic fungus *Ulocladium atrum Preuss*, promising for biocontrol of *Botrytis cinerea* on crops cultivated in the greenhouse and the field, produces a cyclopeptolide characterized by an abundance of N-methylated amino acids and potent antifungal activity against *Botrytis cinerea* and moderate activity against *Alternaria alternata* and *Magnaporthe grisea.*[29]

A cyclic depsipeptide, eujavanicin A, which suppresses growth in the human pathogenic filamentous fungus *Aspergillus fumigatus*, was isolated from *Eupenicillium javanicum.*[19]

The filamentous soil fungus *Coleophoma empetri* F-11899 produces a water-soluble echinocandin type 1 antifungal lipopeptide FR901379, the original source of micafungin used in therapy of deep-seated mycoses. FR901379 consists of a cyclic hexapeptide nucleus with a sulfonated and fatty acid acylated N-terminus. FR901379 exerts its activity against *Aspergillus* and *Candida*

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

species by inhibiting 1,3-b-glucan and hence fungal cell wall synthesis.[28]

A novel cyclodepsipeptide, cordycommunin, with growth retarding activity toward *Mycobacterium tuberculosis* H37Ra and weak cytotoxicity toward KB cells, was isolated from the entomopathogenic fungus *Ophiocordyceps communis.*[13]

Other Antifungal Peptides

A thermostable 5773-Da antifungal peptide was purified from an indigenous fungal strain (VR) of *Aspergillus clavatus* by ultrafiltration and reverse phase-HPLC on a C18 column. It inhibits mycelial growth of *Alternaria solani*, *Aspergillus niger*, *Botrytis cinerea*, *Fusarium oxysporum*, and *F. solani*, but it has no effect on growth in yeasts and bacteria.[24]

A new tetrapeptide D-Phe-L-Val-D-Val-L-Tyr, with antifungal activity similar to that of the commercial product benomyl against the soybean pathogen *Fusarium virguliforme*, was isolated from a *Penicillium canescens* culture collected from beehive pollen.[3]

Penicillium antifungal protein (PAF) from *Penicillium chrysogenum* is a small cationic protein devoid of toxicity on mammalian cells and is thus a drug candidate for treating the usually fatal Aspergillus infections in humans. Its mechanism of antifungal action entails G-protein-coupled signaling followed by apoptosis of sensitive fungi. Its solution structure has been determined by nuclear magnetic resonance. PAF comprises five beta-strands forming two orthogonally packed beta-sheets that share a common interface. Its highly conserved and positively charged lysine-rich surface region contributes to an augmented toxicity.[2]

A killer toxin with a molecular mass <3 kDa and antifungal activity against *Penicillium expansum* strain #2 was partially purified by normal phase HPLC, using TSK-gel Amide-80 analytical and preparative columns from cell-free culture supernatants of *Pichia ohmeri 158* and *Candida guilliermondii P3*.[8] The basic, low-molecular-weight antifungal protein from *Aspergillus giganteus* is secreted as an inactive precursor with a six amino-acid extension at the NH_2-terminal and shows antifungal activity against phytopathogens *in vitro* and *in vivo*.[17]

The (2–10) kDa protein fraction of the culture supernatant of *Saccharomyces cerevisiae* CCMI 885 contained antimicrobial peptides with fungistatic effect against *Hanseniaspora guilliermondii, Kluyveromyces thermotolerans,* and *Torulaspora delbrueckii,* and fungicidal activity against *Kluyveromyces marxianus.*[1]

A 6.0-kDa thermostable, protease-sensitive, cysteine-rich, basic antimicrobial peptide from *Aspergillus clavatus* ES1 with antifungal and antibacterial activities, designated as AcAMP, shows high sequence homology to other ascomycete peptides. It might find application in biocontrol of plant diseases and food preservation.[12]

A 9.5-kDa antifungal protein, with N-terminal amino acid sequence homology to *Clostridium thermocellum* ribonuclease H and antifungal activity against *Flammulina velutipes*, was purified from the mushroom *Hypsizygus marmoreus*.[26] A 6.6-kDa basic and cysteine-rich antifungal peptide, with homology to similar proteins from *Aspergillus clavatus*, *A. giganteus*, *A. niger*, and *Penicillium chrysogenum*, was isolated from the culture supernatant of the mold, *Neosartorya fischeri* (anamorf: *Aspergillus fischerianus*). Its in silico presumed tertiary structure including the presence of five antiparallel β-sheet connected with filaments and stabilized by three disulfide bridges, closely resembles those of defensin-like peptides. It is protease resistant and stable within broad pH and temperature ranges.[15]

Aspergillus giganteus produces a cationic cysteine-rich defensin-like antifungal protein AFPNN5353, which suppresses the germination and growth of filamentous ascomycetes, such as human and plant pathogens and the model organisms *Aspergillus nidulans* and *A. niger*. Binder et al.[4] determined an AFPNN5353 hypersensitive phenotype of nonfunctional *A. nidulans* mutants in the protein kinase C (Pkc)/mitogen-activated protein kinase signaling pathway and the induction of α-glucan synthase A promoter in a transgenic *A. niger* strain, which point at the stimulation of the cell wall integrity pathway and cell wall remodeling in response to the antifungal protein. Stimulation of the cell wall integrity pathway by the antifungal protein operates independently from RhoA, which regulates signal transduction of the fungal cell wall integrity pathway. Calcium signaling has an essential role in the mechanism of action of this antifungal protein, which elevates the cytosolic free calcium ion concentration of a transgenic *A. niger* strain expressing codon optimized aequorin. Calcium chloride supplementation of the growth medium antagonizes toxicity of the antifungal protein, reduces perturbation of the cytosolic free calcium ion concentration, and inhibits protein uptake into *Aspergillus* cells.[4]

Hybrid Peptide Polyketides

Five hybrid peptide polyketides, curvularides A–E, were isolated from the endophytic fungus *Curvularia geniculata* obtained from the limbs of *Catunaregam tomentosa*. Curvularide B shows antifungal activity against *Candida albicans* and synergistic activity with a fluconazole drug.[6]

Antibacterial Peptides

A cyclic pentadepsipeptide designated as alternaramide, with slight antibacterial activity toward *Bacillus subtilis* and *Staphylococcus aureus*, has been isolated from an ethyl acetate extract of the fungus *Alternaria* sp. SF-5016.[14] Fermentation extracts of *Cordyceps heteropoda* (ARSEF #1880) isolated from an Australian cicada yielded two major peptides, cicadapeptins I and I, both with N-terminal acylation by *n*-decanoic acid and C-terminal amidation by 1,2-diamino-4-methylpentane. The cicadapeptins display antibacterial activity and slight antifungal activity.[16]

HIV-1 RT Inhibitory Peptide

From the hot water extract of *Russula paludosa*, a 4.5-kDa peptide with the N-terminal amino acid sequence KREHGQHCEF and HIV-1 RT inhibitory activity (IC50 = 11 μM) was isolated by anion exchange chromatography on DEAE cellulose and gel filtration on Superdex 75. The peptide is devoid of antifungal activity.[27]

Antifungal and Antibacterial Proteins

Two forms of the 31-kDa chitosanase PgChP produced by *Penicillium chrysogenum* AS51D, which differ in the extent of glycosylation, exhibit antifungal activity against toxigenic molds. PgChP manifests pronounced sequence homology to fungal chitosanases and high catalytic activity on chitosan. Thus, the possible applications of PgChP include the use as a food preservative against toxigenic molds and a tool for obtaining chitosan oligomers for food additives and neutraceuticals.[22]

A 44-kDa dimeric antibacterial protein from the wild mushroom *Clitocybe sinopica* exhibits antibacterial activity against a variety of bacteria including *Agrobacterium rhizogenes*, *A. tumefaciens*, *A.vitis*, *Xanthomonas malvacearum*, and *X. oryzae* but not against *Erwinia herbicola*, *Escherichia coli*, *Pseudomonas batatae*, and *Staphylococcus aureus.* It has no antifungal activity.[30]

The yeast *Kluyveromyces siamensis* HN12-1 isolated from mangrove ecosystem produces a 66.4-kDa killer toxin against the pathogenic yeast (*Metschnikowia bicuspidata* WCY) in crabs.[5]

Mushroom Antifungal Peptides and Proteins

Antifungal peptides and proteins designated as agrocybin, alveolarin, eryngin, ganodermin, hypsin, lyophylin, Lyophyllum antifungal protein, *Hypsizygus marmoreus* antifungal protein, lentin, and pleurostrin have been isolated from mushrooms. They inhibit mycelial growth with an IC50 value at micromolar concentrations. They manifest a range of molecular masses (9–28 kDa) and a variety of N-terminal sequences.[7,26]

Chapter 24

Fungal Peptides with Ribonuclease and Ribosome Inactivating Activities

Tzi Bun Ng

ABSTRACT

Fungi including molds and mushrooms produce a variety of proteins and peptides with ribonuclease- and ribosome-inactivating activities. In addition to their ability to inhibit protein synthesis, they may have other effects such as antiproliferative activity toward tumor cells and inhibitory activity toward viral enzymes. They manifest a diversity of structures and molecular sizes.

MUSHROOM UBIQUITIN-LIKE PEPTIDES

Ubiquitin-like peptides with RNase activity have been isolated from *Agaricus cylindracea*, *Catharellus cibarius*, *Calvatia caelata*, *Pleurotus ostreatus*, *P. sajor-caju*, and *Termitomyces globulus*. Most of them have a molecular mass of 8–9 kDa and are unadsorbed on DEAE-cellulose but adsorbed on Affi-gel blue gel, Mono S and CM-Sepharose/CM-cellulose. However, they differ in polyhomoribonucleotide specificity, optimum pH, and optimum temperature. They exhibit marked sequence similarity to human ubiquitin.[16]

MUSHROOM RNases

RNases were isolated from mushroom fruiting bodies by a combination of ion exchange chromatography on cationic and anionic exchangers and gel filtration. Sometimes, affinity chromatography on Affi-gel blue gel was used. They are unadsorbed on DEAE-cellulose, adsorbed on Affi-gel blue gel and CM-Sepharose and Mono S.[7,16–19,21,24,25] RNases have been reported from different Pleurotus species including *P. eryngii*, *P. pulmonarius*, *P. sajor-caju*, *P. tuber-regium*, and *P. ostreatus*. They exhibit a range of molecular masses running from 9 to 29 kDa, with most of them in the range of 9–14 kDa. They have an optimum pH of approximately 7. They differ in their N-terminal sequence, optimum temperature, and polyhomoribonucleotide specificity. RNases have also been isolated from non-Pleurotus species including *Clitocybe maxima*, *Dictyophora indusiata*, *Ganoderma lucidum*, *Irpex lacteus*, *Lentinus edodes*, *Russula virescens*, and *Volvariella volvaceae*. They display a molecular mass in the range of 17.5–43 kDa. They differ from one another in their optimum temperature, optimum pH, and polyhomoribonucleotide specificity. *C. maxima* RNase displays some sequence homology to *P. ostreatus* RNase. *I. lacteus* and *L.edodes* RNases are very similar, whereas *P. pulmonarius* RNase and black oyster mushroom RNases are somewhat similar.[16]

Ganoderma lucidum RNase and *Volvariella volvac*ea RNases have the largest molecular mass (42.5–43 kDa), followed by RNases from *Boletus griseus* (29 kDa)[16] and *Dictyophora indusiata* (28 kDa).[16] *Clitocybe maxima*[16] and *Agaricus bisporus*[19] RNases have an intermediate molecular mass (17.5 and 14 kDa, respectively).

B. griseus RNase expresses maximal activity at pH 3.5.[16] RNase from *G. lucidum*, *R. virescens*, *D. indusiata*, and *P. djamor* demonstrate an optimum pH at 4–4.6. RNase from *R. delica*, *A. bisporus*, and *H. marmoreus* display maximal activity at pH 5. RNase from *V. volvaceae*, *P. tuber-regium*, *C. maxima*, *T. ganbajun*, and *L. shimeiji* have an optimum pH between pH 6 and pH 7. The following RNases have an optimum pH between pH 7 and pH 8: *P. eryngii, P. ostreatus,* and *P. pulmonarius.*[16,21,25] All the following RNases express maximal activity at 60 °C: *D. indusiata*, *G. lucidum*, *R. virescens*, *R. delica*, *P. djamor*, and *A. bisporus.* RNases from *P. eryngii* and *B. griseus* have an optimum temperature between 60 °C and 70 °C. RNases from *C. maxima*, *H. marmoreus*, and *L. shimeiji* have maximal activity at 70 °C. *T. ganbajun* RNase has an optimum temperature at 40 °C.[7,16,18,19,21,24,25] *P. pulmonarius* RNase has optimum activity at 55 °C.[16]

Different RNases from different Pleurotus species display different specificities for polyhomoribonucleotides.[16] The

same phenomenon is observed when the pairs *R. virescens* and *R. delica* RNases and *L. shimeiji* and *H. marmoreus* are compared. *P. djamor* RNase[21] and *L. shimeiji* RNase[24] resemble in their polyhomoribonucleotide specificity to some extent. *P. pulmonarius* RNase[16] and *H. shimeji* RNase is another pair with similar polyhomoribonucleotide specificity. *C. maxima* RNase[16] and *P. eryngii* RNase[16] is yet another pair with similarity. The others exhibit different specificities.

RNases from *H. marmoreus*, *L. shimeiji*, *R. delica*, and *P. djamor* exert antiproliferative activity toward tumor cells. RNases from *L. shimeiji* and *T. ganbajun* but not that from *R. delica* inhibit HIV-1 reverse transcriptase.[7,21,24,25]

Saccharomyces cerevisiae RNases

In *Saccharomyces cerevisiae*, RNase MRP is composed of an RNA subunit and ten proteins. Thirty-one direct protein–protein interactions are found. Each protein interacts with three or more others. Seven proteins exhibit self-interaction. Six protein subunits interact directly with MRP RNA and four protein subunits interact with pre-rRNA.[1]

Saccharomyces cerevisiae RNase H2 is a complex of three proteins [Rnh2Ap (Rnh201p), Ydr279p (Rnh202p), and Ylr154p (Rnh203p)] all of which are required for RNase H2 activity. Deletion of the gene encoding any protein or mutations in the catalytic site in Rnh2A abolishes RNase H2 activity. The multisubunit nature of the RNase may have structural importance and play a role in interaction with other proteins involved in DNA replication/repair and transcription.[10]

Aspergillus niger RNase

A 40.1-kDa extracellular RNase, with the N-terminal amino acid sequence TIDTYSSDSP, designated as *A. niger* SA-13-20 RNase, was isolated from a mutant of *Aspergillus niger.* It differs in molecular weight and pI value from RNase produced by the wildtype.[22]

FUNGAL RIBONUCLEOLYTIC TOXINS

Fungal ribotoxins, such as mitogillin and the related *Aspergillus* toxins restrictocin and alpha-sarcin, are ribonucleases that bring about enzymatic inactivation of the ribosome by cleaving 28S RNA of the large ribosomal subunit, at a site between G4325 and A4326, present in a 14-base sequence (the alpha-sarcin loop) conserved among the large subunit rRNAs of all organisms. Consequently, elongation factor binding is disrupted, and protein synthesis is suppressed. Because the His-49Tyr, Glu-95Lys, Arg-120Lys, and His-136Tyr mutations adversely affect the ribonucleolytic activity of mitogillin, these residues seem to be the active site residues.[11]

Restrictocin has two disulfide bonds, one between Cys 5 and Cys 147 and another between Cys 75 and Cys 131. The presence of the two disulfide bonds is essential for ribonucleolytic and protein synthesis inhibitory activities.[12]

The putative catalytic site of restrictocin includes Tyr47, His49, Glu95, Arg120, and His136. Intact N- and C-termini are required for restrictocin to express full activity.[13]

In restrictocin, P112 is crucial for maintaining the functionally active conformation. Prolines at positions 112, 118, and 126 are not directly involved in the membrane interaction activity of restrictocin.[5]

A total of 93 out of 149 (62%) of the amino acid residues in restrictocin are not essential for the action of the toxin. Of the five proposed active site residues, three can be deleted without loss of activity, possibly because the loss of these three residues is compensated for by a residue in the vicinity that fills the structural space produced by the larger amino acid deletions.[6]

The loop L4 in restrictocin spanning residues 99–117 is more important than loop L2 spanning residues 36–48 for interaction with the specific substrate.[4] To elucidate the molecular basis of toxin sarcin action, Correll et al.[3] determined three cocrystal structures of the sarcin homolog restrictocin bound to analogs that mimic the target sarcin/ricin loop (SRL) structure of the rat 28S rRNA. In these structures, restrictocin contacts the bulged G motif and an unfolded form of the tetraloop of the SRL RNA. In one structure, toxin loops guide selection of the target site by contacting the base critical for recognition (G4319) and the surrounding S-shaped backbone. In another structure, base flipping of the tetraloop enables cleavage by placing the target nucleotide in the active site with the nucleophile nearly inline for attack on the scissile bond. These structures provide the views of how a site-specific protein endonuclease recognizes and cleaves a folded RNA substrate.[23]

Sarcin targets a universal RNA structure in the ribosome designated as the sarcin/ricin loop. A resolution structure of a minimal sarcin/ricin loop RNA substrate reveals that the loop portion of the substrate folds into two common building blocks of RNA structure: a bulged-G motif (recognition site) and a GAGA tetraloop (cleavage site). Site selection by the toxin depends on direct base and shape recognition of the sarcin/ricin loop RNA, and cleavage by the toxin depends on a base flipping mechanism that positions the nucleophile for in-line attack on the scissile bond.[3]

All species assigned to *Aspergillus* section Clavati carry ribotoxin genes classified into different groups including the alpha-sarcin, gigantin, c-sarcin, and mitogillin/restrictocin families. *A. longivesica* and *N. acanthosporus* produce ribotoxins only slightly related to gigantins and c-sarcins, respectively. All of them possess the cysteine residues, and the two Trp residues of alpha-sarcin conserved in ribotoxins.[17]

N-terminal sequences from Refs. 2–8, 21–25.

MUSHROOM RIBOSOME INACTIVATING PROTEINS (RIPs)

Mushroom RIPs that have been isolated from mushrooms comprise flammin, velin, flammulin, velutin, hypsin, lyophyllin, pluturegin, calcaelin, and volvarin. They are unadsorbed on DEAE-cellulose, and adsorbed on Affi-gel blue gel, and CM-Sepharose/CM-cellulose. Hypsin and lyophyllin closely resemble each other in amino acid sequence. They display a molecular mass in the range of 13.8–40 kDa. They inhibit translation in a cell-free rabbit reticulocyte lysate system with an IC50 in the range 0.24–7 nM[14]

The teratogenicity of three fungal ribosome-inactivating proteins, hypsin from *Hypsizigus mamoreus*, lyophyllin from *Lyophyllum shimeji*, and velutin from *Flammulina velutipes*, has been studied using microinjection and post-implantation whole embryo culture. The results show that hypsin and lyophyllin induce abnormal embryonic development at 2.5 μM during the organogenesis period from E8.5 to E9.5. The total number of abnormal embryos showed a dose-dependent increase, accompanied by a reduction in the final somite number, and an increase of abnormal structures including open cranial neural tube, abnormal branchial arches, absence of forelimb buds, and twisted body axis. The otic and optic placodes, however, are affected to a lesser extent. Histological study disclosed a correlation of increased cell death with abnormal structures, indicating that induction of cell death by hypsin and lyophyllin may explain its teratogenicity. By contrast, velutin does not have any adverse effect on mouse development.[2,15]

A 9567-Da RIP with a novel N-terminal sequence from fresh fruiting bodies of the mushroom *Hypsizigus marmoreus*, designated as marmorin, inhibits proliferation of hepatoma Hep G2 cells and breast cancer MCF-7 cells, HIV-1 reverse transcriptase activity, and translation in the rabbit reticulocyte lysate system with an IC50 of 0.15, 5, 30 μM, and 0.7 nM, respectively. Compared with RIPs from hairy gourd, bitter gourd, ridge gourd, garden pea, and the mushroom *Flammulina velutipes*, marmorin is more potent in its antiproliferative activity toward hepatoma (HepG2) and breast cancer (MCF-7) cells, similar in inhibitory potency toward HIV-1 reverse transcriptase (with the exception that it was more potent than ridge gourd RIP and bitter gourd RIP), and less potent in translation-inhibitory potency. Marmorin is devoid of antifungal, protease, RNase, mitogenic, antimitogenic, nitric-oxide-inducing, hemagglutinating, and trypsin inhibitory activities.[20]

The N-terminal amino acid sequences of some fungal ribonucleases and ribosome inactivating proteins are presented in Table 1.

Chapter 25

Fungal Toxins

Jack Ho Wong

ABSTRACT

Fungi exist in a diversity of habitats, encompassing oceans, rocks, deserts, very salty environments, and areas of extraordinarily high or low temperatures. They acquire their nutrition by absorbing nutrients from the surroundings. Many fungi play a crucial role in decomposition and returning nutrients to the ecosystem. They are also exploited in medicine, a well-known example being the antibiotic penicillin, as well as in industry and cuisine preparation. There are two sides of a coin. Many fungi produce toxic materials that threaten the health and safety of human beings and livestock. In this chapter, toxic peptides such as amatoxins and phallotoxins produced by higher fungi (mushrooms) and depsipeptides from phytopathogenic molds are reviewed.

INTRODUCTION

Fungi have a wide geographical distribution. A countless number of fungal species have been identified. Fungi produce a spectacular array of toxins for counteracting predators or minimizing competition from other organisms. Based on the phylogenetics, fungal toxins can be categorized into (1) mycotoxins formed by hyphae of common molds; and (2) mushroom toxins formed in the fruiting bodies of higher fungi. Based on their molecular structure, fungal toxins can be divided into two groups: nonpeptidic toxins and toxic peptidic toxins. Examples of nonpeptidic toxins include orellanine, gyromitrin, and coprine from mushrooms[1,4,7] and other toxins from molds comprising aflaxonin produced by *Aspergillus niger*,[5] ergot alkaloids from *Clarviceps* spp,[6] zearalenone from *Fusarium* species,[13] and trichothecenes from a variety of molds.[16] In this chapter, toxic peptides such as amatoxins and phallotoixns from higher fungi (mushroom) and some depsipeptides from phytopathogenic fungi (molds) are discussed.

STRUCTURAL FEATURES OF THE PEPTIDIC FUNGAL TOXINS

Amatoxins and phallotoxins constitute the two major groups of peptidic mushroom toxins. Different amatoxins including alpha-, beta-, and gamma-amanitins have been isolated. They are octapeptides with a molecular weight in the vicinity of 900 Da. In addition, a D-amino acid is present in phallotoxins. Amatoxins and the related phallotoxins are bicyclic peptides that possess a distinctive Trp–Cys crossbridge (having the name tryptathionine) and several hydroxylated amino acids.[10] The detailed structures of amatoxins and phallotoxins were presented in the first edition of Handbook of Biologically Active Peptides in Chapter 20. Depsipeptides are nonribosomal peptides. Their biosynthesis is facilitated by the biosynthetic programming of the nonribosomal peptide synthetases, the deployment of non-proteinogenic amino acid precursors, and the synthesis of straight-chain, macrocyclic or branched macrocyclic structures with amide, ester or even thioester or imino ring closures.[11,2] In the nonribosomal depsipeptides, at least one bond of the peptide backbone is substituted by an ester bond. These link carboxy groups of amino acids with a 2-hydroxycarboxylic acid, or furnish another routing of the chain through side chain hydroxy groups of amino acids and the C terminal region of the peptide.

Different from depsipeptides, the synthesis of amatoxins and phallotoxins takes place on ribosomes.[3] The gene coding for alpha-amanitin yields a proprotein with 35-amino-acid residues, and then the mature toxin (IWGIGCNP). Genes coding for beta-amanitin (IWGIGCDP), phallacidin (AWLVDCP), and phalloidin (AWLATCP) have also been detected in *Amanita* species. It is believed that *Amanita* species synthesize a much greater number of cyclic peptides than those reported in the literature, because their genomes harbor a minimum of 30 sequences.[3]

BIOSYNTHESIS OF PEPTIDIC FUNGAL TOXINS

The biosynthesis of amatoxins and phallotoxins occurs on ribosomes. The genome of *Amanita bisporigera* encompasses a sizable family of related genes, which is designated as the MSDIN family. The genes were revealed by genomic survey sequencing using 454 pyrosequencing of *A. bisporigera*, AMA1 (for alpha-amanitin) and PHA1 (for phallacidin). The proproteins of the family members consist of 34–39 amino

Handbook of Biologically Active Peptides. http://dx.doi.org/10.1016/B978-0-12-385095-9.00025-7

Copyright Elsevier 2024

acids and are devoid of signal peptides. In the mature toxins, 6–10 amino acids are present, and the amino acid sequences are hypervariable in comparison with that of adjacent sequences. These compounds have the smallest size of all known cyclic peptides that are synthesized on ribosomes. A proline (Pro) residue is the immediate upstream amino acid and also the last amino acid in the predicted hypervariable regions. All reported amatoxins and phallotoxins and all predicted MSDIN peptides possess a minimum of one Pro residue. Only amatoxins and phallotoxins have Trp and Cys residues and thus tryptathionine can be formed only by these toxins. Several monocyclic hexapeptides and decapeptides have been isolated from *A. phalloides*. All 20 proteinogenic amino acids are present at least once in one of the MSDIN family members of *A. bisporigera*. PCR has been used to amplify members of the MSDIN family from *A. phalloides* and *A. ocreata*.[17]

The steps in *Amanita* toxin biosynthesis after translation comprise proteolytic excision, cyclization, hydroxylation, Trp–Cys (tryptathionine) crosslinking, and epimerization of one amino acid in the case of phallotoxins. These steps do not always take place in the above sequence. *Amanita* toxin biosynthesis might also necessitate genes coding for export and regulatory proteins. Cyclization might be effected before or after tryptathionine biosynthesis.

Together with the complete amino acid sequence deduced from a cDNA, a protein was identified as a member of the prolyl oligopeptidase (POP) family of serine proteases[15] involved in the synthesis of mushroom toxins. The enzyme excises at both Pro residues in the synthetic phalloidin peptide to liberate the mature linear peptide.

Most probably, a protease or protease-like enzyme catalyzes the cyclization of the *Amanita* toxins. However, no evidence from chromatographic or mass spectrometric experiments has been reported for the formation of cyclized product during incubation of toxin precursors with POP and thus catalysis of the cyclization by POP is very probable. With respect to the sequence of processing steps, cyclization might take place subsequent to the formation of the Trp–Cys crossbridge (tryptathionine), because this would promote cyclization by bringing the N and C termini of the nascent peptide into proximity of each other.

The biosynthesis of fungal depsipeptides is accomplished with the catalytic help of cyclooligomer depsipeptide synthetases (CODS), which have modules with a role in the programmed iterative synthesis of the peptide/peptidol monomer units. Their cyclooligomerization mechanisms entail the participation of various domains

In comparison with other fungal CODSs, the 10 known full-length CODS have approximately 3150 amino acid residues and display a molecular mass of 350 kDa. They exhibit 55–74% amino acid sequence identity. The two *Fusarium oxysporum* CODSs, FolCODS and FoCODS, show 68% identity. All identified CODS, notwithstanding their involvement in the formation of hexa- or octadepsipeptides, manifest identical extended bimodular architecture with the same domain arrangement: C1A1T1–C2A2M2T2aT2b–C3.[14]

PROPOSED USAGE OF FUNGAL TOXINS

Riede showed that amanitin suppresses the activity of leukemia cells and advocated a new mode of tumor therapy using amanitin. Amanitin not only interrupts growth of cancer cells but also is capable of modifying antigen expression, and hence the immune system may be able to combat the cancer cells with augmented efficacy. The dosage of amanitin given is determined by monitoring the leukocyte cell count in blood. When the cell count rises, and the general condition of the patient is optimal, a higher dose is administered and vice versa.[12]

ANTIDOTES TO FUNGAL TOXINS

Mortality arising from poisoning by amanitin-producing mushroom species is escalating. The toxicity of alpha-AMA results from the arrest of protein synthesis in hepatocytes. Amanitin intoxication is as yet a problem that is difficult to tackle in the absence of a specific and effective antidote. A reduction of cell viability of human hepatocytes, an elevation of lactate dehydrogenase (LDH) activity, and decreased cell spreading and attachment were detected after exposure for 12, 24, and 36 h to 2 microM alpha-AMA. Benzylpenicillin (BPCN), acetylcysteine (ACC), and silibinin (SIL) added as antidotes to hepatocyte cultures promote cell proliferation and attachment. In hepatocyte cultures exposed simultaneously to alpha-AMA and the aforementioned antidotes, MTT and LDH (parameters indicating cytotoxicity) do not differ significantly from the control.[8]

Additionally, alpha-AMA exhibits prooxidant properties that may contribute to its severe hepatotoxicity. In human hepatocyte culture, alpha-AMA causes an elevation in superoxide dismutase activity and a rise in lipid peroxidation. The introduction of antidotes (ACC or SIL) to the culture medium more effectively protects against lipid peroxidation in human hepatocytes treated with alpha-AMA than BPCN, which has no antioxidant activity.[9]

Chapter 26

Plant Antifungal Peptides

Suzana Meira Ribeiro, William Farias Porto, Osmar Nascimento Silva, Marcelo de Oliveira Santos, Simoni Campos Dias and Octávio Luiz Franco

ABSTRACT

A large number of peptides isolated from different plant species seem to play an important role in plant defense against fungi. The antifungal activities of these compounds have been associated with interaction with components from walls, membranes, or nuclei of fungal cells. According to this view, antifungal peptides may cause physiological, morphological, and molecular disorders and in some cases kill the fungal cell, being dependent on several factors, including chemical and structural properties from peptides and genetic aspects of fungal host species, which consequently may determine susceptibility or resistance to peptides. In this chapter, the structural and functional properties of multiple plant antifungal peptide families, including defensins, cyclotides, and several others, will be analyzed, relating structural parameters with fungicidal activities. Moreover, the potential biotechnological use of these molecules for the treatment of fungal infections in humans and mainly in the protection of economically important crops will also be examined.

DISCOVERY

In 1942, the first antimicrobial peptide (AMP) was isolated by Ball and Hale in the wheat plant and named α-purothionin. Decades later, a large number of antifungal peptides have already been explored and described in many plant species in diverse parts of the world. They have been grouped into several families, and many of them display similar features according to their chemical parameters and mode of action. In short, plant peptides can target bacteria, virus, and fungi, although antifungal activity has been much more commonly reported.[11] The diversity of peptides with antifungal activity is enormous, where different classes have been identified and divided into distinct classes: cyclotides, defensins (previously named γ-thionins), lysine-rich, hevein-like, impatiens, knottins, lipid transfer proteins (LTPs), snakins, and thionins, among others (Table 1). Peptides can be constitutively produced or induced by the host plant in response to fungal infections. They have been reported in different plant species and different plant tissues (Figure 1), having been isolated from roots, corms, stems, bulbs, leaves, fruits, seeds, and flowers (Table 1). Because these peptides form the first barriers against a microorganism's infections, a really wide variability of structures and functional properties has been observed between these compounds.[5,23]

THREE-DIMENSIONAL STRUCTURES OF PLANT ANTIFUNGAL PEPTIDES

Over the years, many three-dimensional structures of antifungal peptides have been solved through X-ray crystallography or NMR.[23] Structural elucidation is extremely important for providing a better definition of protein families and also for understanding the mechanism of action of each class of biologically active peptides. It is difficult to establish a clear relationship between structure and activity in peptide classes with only a few members due to the absence of homologous structures or mutants with different activities. In these cases, the main explanation for activity has been related to the amphipathic surface of the peptide. Two examples are MiAMP1[17] and PAFP-S.[10] MiAMP1 was isolated from the nut kernels of the native Australian plant *Macadamia integrifolia* and is the only antifungal peptide that has been classified in the β-barrelins family. Its structure is unique among antifungal peptides and is comprised of a Greek key β-barrel with eight β-strands arranged into two Greek key motifs, stabilized by three disulfide bonds (Figure 2),[17] being its activity is restricted to plant pathogens. Structural analysis suggests that its activity may be related to its amphipathic and cationic surface, through electrostatic interactions with the membrane's anionic portion, followed by hydrophobic interactions. This is partially confirmed by bioassays in the presence of different concentrations of potassium and calcium salts. High salt concentrations deplete the inhibitory effects in plant pathogens. However, yeasts remain sensitive to MiAMP1, independently of salt concentrations, suggesting that this peptide may have a different target in yeasts, because the interaction between the cationic residues and the membrane is obstructed by high salt concentrations.[17]

Similar results were observed for PAFP-S, an antifungal peptide from *Phytolacca americana* seeds. PAFP-S is the only knottin antifungal peptide with a solved structure,[10]

TABLE 1 Overview of the Wide Distribution, Localization, and Fungus Target of Antifungal Peptides

Class	Plants species	Tissue localization	Organism target
α-Helical hairpin	*Echinochloa crus-galli*	Seeds	*Alternaria alternata, Alternaria solani, Aspergillus niger, Bipolaris sorokiniana, Colletotrichum graminicola, Diplodia maydis, Fusarium graminearum, Fusarium oxysporum, Fusarium solani, Fusarium verticilloide, Phytophtora infestans, Phytophtora debaryanum, Polymyxa betae, Trichoderma album*
β-Barrelin	*Macadamia integrifolia*	Fruits	*Saccharomyces cerevisiae*
Cyclotides	*Chassalia parviflora, Oldenlandia affinis, Psychotria longipes, Viola hederacea*	Leaves, stems and lower in roots	*Candida albicans, Candida kefyr, Candida tropicalis*
Defensins	*Aesculus hippocastanum, Arabidopsis thaliana, Capsicum annuum, Nicotiana tabacum, Petunia hybrida, Pisum sativum, Raphanus sativus, Sinapis alba, Vigna radiata*	Epidermis and vascular bundles of pods, stems, roots, leaves, flowers and wet or dry seeds	*Alternaria brassicola, Aspergillus niger, Aspergillus versicolor, Botrytis cinerea, Cercospora beticola, Cladosporium sphaerospermum, Fusarium culmorum, Fusarium moniliforme, Fusarium oxysporum, Fusarium solani, Leptosphaeria maculans, Neurospora crassa, Penicillium digitatum, Pyricularia oryzae, Rhizoctonia solani, Saccharomyces cerevisae, Septoria tritiei, Trichophyton mentagrophytes,Trichoderma viride, Verticilium alboatrum*
Hevein-like	*Amaranthus caudatus, Amaranthus retroflexus, Beta vulgaris, Euonymus europaeus Eucommia ulmoides, Eutrema wasabi, Ipomoea nil, Fagopyrum esculentum*	Leaves, roots and seeds	*Alternaria brassicola, Alternaria consortiale, Alternaria nicotianae, Ascochyta lycopersici, Ascochyta pisi, Botrytis cinera, Cercospora beticola, Colletotrichum gossypii, Colletotrichum lindemuthianum, Fusarium culmorum, Fusarium moniliforme, Fusarium oxysporum, Fusarium solani, Geotrichum candidum, Gibberella zeae, Helminthosporium sativum, Magnaporte grisea, Mycosphaerella eumusae, Neurospora crassa, Phoma exigua, Phytophthora capsici, Phytophthora cryptogea, Phytophthora infestans, Phytophthora parasitica, Pythium ultimum, Rhizoctonia solani, Saccharomyces cerevisiae, Sclerotinia sclerotiorum, Trichoderma hamatum, Verticillium dahliae*
Impatiens	*Impatiens balsamina*	Seeds	*Alternaria longipes, Botrytis cinerea, Cladosporium sphaerospermum, Fusarium culmorum, Penicillium digitatum, Trichoderma viride, Verticillium alboatrum*
Knottins	*Mesembryanthemum crystallinum, Mirabilis jalapa, Phytolacca americana*	Leaves	*Alternaria brassicola, Alternaria panax, Ascochyta pisi, Botrytis cinerea, Cercospora beticola, Colletotrichum lindemuthianum, Fusarium culmorum, Fusarium oxysporum, Fusarium oxysporum, Nectria haematococca, Phoma betae, Pyrenophora tritici-repentis, Pyricularia oryzae, Rhizoctonia solani, Verticiliium dahliae, Venturia inaequalis*
Lipid transfer proteins	*Allium cepa, Leonurus Artemisia, Phaseolus aureus*	Seeds, cotyledons, shoot meristem, inter-cotyledon space, primary xylem and immature vascular elements	*Alternaria alternate, Alternaria brassicola, Ascockyta pisi, Aspergillus niger, Bipolaris maydis, Botrytis cinerea, Cerospora personata, Colletotrichum gloeosporiodes, Colletotrickum lindemutkianum, Fusarium culmorum, Fusarium graminearum, Fusarium oxysporum, Nectria haematococca, Penicillium digitatum, Pythium aphanidermatum, Phoma betae, Pyrenopkora tritici-repentis, Pyricularia grisea, Pyricularia oryzae, Rhizoctonia cerealis, Rhizoctonia solani, Saccharomyces cerevisiae, Sclerotinia sclerotiorum, Sclerotium rolfsii, Trichoderma harzianum, Verticillium dahliae*
Snakins	*Solanum tuberosum*	Tubers, stems, flowers, shoot apex and leaves	*Aspergillus flavus, Bipolaris maydis, Botrytis cinerea, Colletotrichum graminicola, Colletotrichum lagenarium, Fusarium solani, Fusarium culmorum, Fusarium oxysporum, Plectosphaerella cucumerina*
Thionins	*Aesculus hippocastanum, Arabidopsis thaliana, Beta vulgaris, Capsicum annuum, Hordeum vulgare, Medicago sativa, Nicotiana tabacum, Petunia hybrida, Phyllostachys pubescens, Pisum sativum, Raphanus sativus, Sinapis alba, Triticum aestivum, Triticum kiharae, Tulipa gesneriana, Vicia faba, Viscum album*	Leaves, flowers, roots and seeds	*Aspergillus niger, Aspergillus versicolor, Alternaria brassicola, Botrytis cinérea, Cercospora beticola, Cladosporium sphaerospermum, Fusarium moniliforme, Fusarium oxysporum, Fusarium solani, Geotrichum candidum, Leptosphaeria maculans, Neurospora crassa, Penicillium digitatum, Phytophtora infestans, Pyricularia oryzae, Saccharomyces cerevisiae, Sclerotinia sclerotiorum, Septoria tritiei, Trichoderma viride, Trichophyton mentagrophytes, Verticilium alboatrum, Verticillium dahliae*

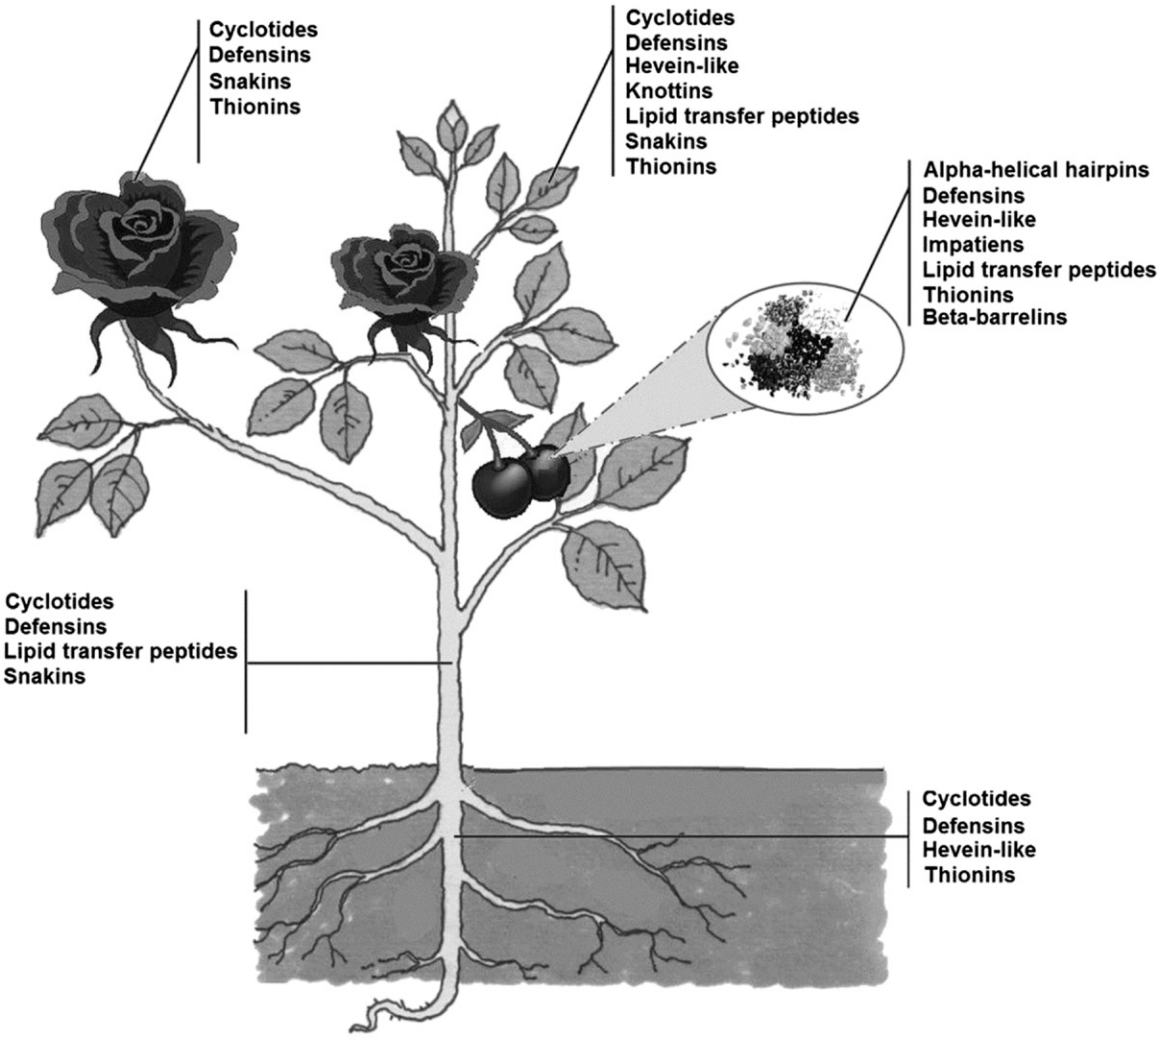

FIGURE 1 Illustrative figure showing the different plant tissues where antifungal action has been found.

comprising an antiparallel β-sheet with three β-strands, stabilized by three disulfide bonds (Figure 2). As well as MiAMP1, PAFP-S has an amphipathic surface, and its activity is also restricted to plant pathogens.

Even in cases where there are several three-dimensional structures available, the elucidation of regions or features responsible for antifungal activity is sometimes not completely possible, as observed for the cyclotides kalata B1, circulin A, and circulin B, extracted from plants of the Rubiaceae family[29] (Figure 2). The cyclotide family consists of multi-functional cyclic peptides with approximately 29 amino acid residues and a typical cysteine knot motif, showing an extremely conserved disulfide bonding pattern (Cys^{I}–Cys^{IV}, Cys^{II}–Cys^{V}, and Cys^{III}–Cys^{VI}). Cyclotides can be split into two subfamilies, bracelets and Möbius. The main difference between them is a cis-proline in the fifth loop, only observed in Möbius. Both subfamilies have members with elucidated structures and antifungal activity. Circulins A and B belong to the bracelet group, while B1 belongs to the Möbius one. Despite knowing these three structures, the mechanisms of antifungal activity have not been fully understood. Similar to that observed for MiAMP1 and PAFP-S, bioassays with high salt concentrations practically abolish the antifungal activity of cyclotides, suggesting once more the essentiality of ionic forces and also the amphipathic surface.

The α/β-thionins were the first class of antimicrobial peptides described in plants.[23] Like the classes reported so far in this section, α/β-thionins also show an amphipathic surface.[23] However, like cyclotides, α/β-thionins have a wide range of biological activities in addition to their antifungal property. These proteins also have bactericidal, insecticidal, and immunomodulatory functions and can inhibit protein synthesis in cell-free systems.[23] The overall shape of α/β-thionins resembles a capital letter L, where the α-helixes define the long arm and the short antiparallel β-sheet the short arm (Figure 2).[23] Besides having a probable electrostatic interaction with membranes, DNA binding has been

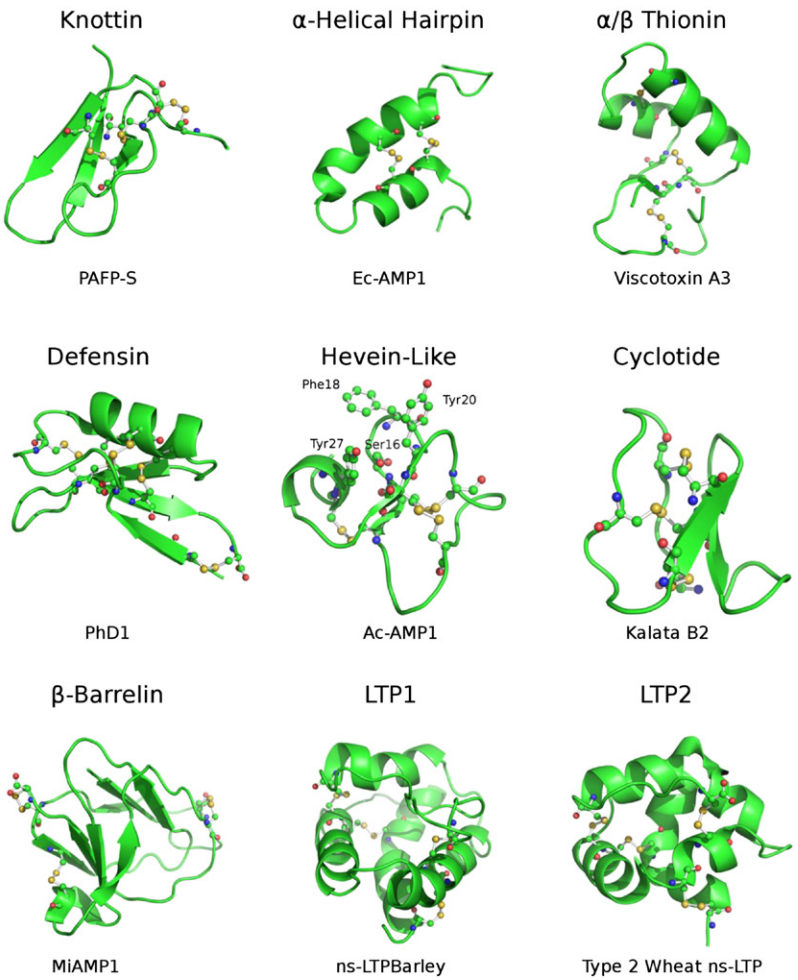

FIGURE 2 Three-dimensional structures of different antifungal plant peptide families. Disulfide bridges are shown as ball and stick. In hevein-like peptides, the active residues are also shown as ball and stick and labeled. See color plate 13.

also proposed. It has been suggested that DNA binding could occur through the structural helix-turn-helix motif, common in prokaryotic gene-regulatory proteins and homeodomain-containing proteins.[23]

Interestingly, the absence of structural information can lead to a wrong classification of peptide classes. Plant defensins are good examples of the first mistaken cataloging. In 1990, when the first plant defensin was described and no structures were available, they were classified as a subclass of thionins, named γ-thionins, because of their cationic and cysteine-rich composition similar to that of thionins. In subsequent years, with the discovery of related sequences in insects and the elucidation of first structures, it was observed that structures of α/β-thionins are different from those of defensins.[23] Although α/β-thionins have a fold that resembles the capital letter L, defensins have a typical cysteine stabilized αβ motif (CSαβ), consisting of an antiparallel β-sheet with three β-strands and one α-helix (Figure 2). This class is probably one of the most ancient antimicrobial peptides, present in the whole Eukaryote Domain and it is found in plants, animals, and fungi, which suggests that defensins have existed for one billion years.[23]

Overall, defensins can have three, four, or five disulfide bonds, but in the Plant Kingdom, they have been found only with four or five disulfide bonds and have several kinds of activities, such as α-amylase and protein synthesis inhibition as well as bactericidal and antifungal activities.[23] In contrast to other antifungal classes, the antifungal activity of plant defensins has not been related only to their amphipathic surface, although most, if not all, of them show this property. Actually, the antifungal activity is related to a structural motif that comprises the region of second and third β-strands. This region that comprises the second and third β-strands came to be called the γ-core by Yount and Yeaman.[35] The dextromeric isoform of the γ-core found in defensins is represented by the pattern [A–Z]{1,3}G[A–Z]C[A–Z]{3,9}C, where "[A–Z]" means any natural amino

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

acid residue; and the numbers inside curly brackets represent the range of amino acid residues. Through this γ-core, the antimicrobial activity of brazzein,[35] a sweet-tasting protein from *Pentadiplandra brazzeana*, could be predicted and its deleterious activity confirmed against *Candida albicans*.

Another class with a well-defined antifungal active site is the hevein-like one. This class has a fold composed of a twisted antiparallel β-sheet with two β-strands, stabilized by three or five disulfide bonds,[8,16,34] and the γ-core also is observed in this class (Figure 2). The first solved structure from this class was Ac-AMP1 isolated from *Amaranthus caudatus*.[16] Ac-AMP1 shows a clear similarity to hevein domains. However, this peptide lacks a C-terminai portion of about 10 residues, including the fourth disulfide bond. The antifungal activity was related to a sugar binding domain composed of residues Ser^{16}, Phe^{18}, Tyr^{20}, and Tyr^{27}. Like Ac-AMP1, EAFP2 from *Eucommia ulmoides*[34] displays a similar sugar binding site of hevein, composed of residues Ser^{18}, Tyr^{20}, Tyr^{22}, and Tyr^{29}, and its structure is stabilized by five disulfide bonds. Nevertheless, EAFP2 also has inhibitory effects on cell wall chitin-free fungi, which may be related to the amphipathic surface of EAFP2. The third structure from this class is WAMP-1a,[8] which also possesses five disulfide bridges but with a different pattern when compared with that of EAFP2 (Figure 2).

Like hevein-like peptides, LTPs also have a well-defined structural scaffold. The overall tertiary structure is composed of a helix bundle with four α-helices, stabilized by four disulfide bonds.[23] There are two subfamilies of LTPs known as LTP1 and LTP2, which differ in mass but show similar disulfide connectivity. LTP1 displays 9 kDa and a disulfide pattern of Cys^{I}–Cys^{VI}, Cys^{II}–Cys^{III}, Cys^{IV}–Cys^{VII}, and Cys^{V}–Cys^{VIII}, LTP2 shows 7 kDa and the disulfide arrangement of Cys^{I}–Cys^{V}, Cys^{II}–Cys^{III}, Cys^{IV}–Cys^{VII}, and Cys^{VI}–Cys^{VIII} (Figure 2). Despite such differences, the two subfamilies exhibit a single hydrophobic cavity responsible for their activity. Molecular dynamics studies show that LTP penetration into the membrane leads to change in membrane conformation. However, the *in vivo* role of LTPs is still unknown.[23]

More recently, a novel structural class of antifungal peptides has been described and characterized as disulfide-stabilized α-helical hairpins[20] (Figure 2). EcAMP1 from *Echinochloa crusgalli* is the first prototype from this class with solved three-dimensional structure. As the name suggests, the fold comprises two antiparallel α-helixes connected by a short loop, resembling a hairpin. This fold is somewhat similar to the α/β-thionin fold, with different disulfide bond patterns (Figure 2). Interestingly, the mechanism of action of this peptide involves no membrane disturbance. It first acts by binding to the membrane and subsequently by internalizing cytoplasm.

Indeed, a better relation between structure and antifungal activity must be established when the majority of structure analogs for classes with few members become available. The amphipathic surface is the broadest explanation of peptide activity; however, it may have a secondary role. Actually, there must be a set of amino acid residues, such as that observed in hevein-like peptides, or a structural motif, such as the γ-core in defensins, which are responsible for the activity.

PROPOSED MECHANISMS OF ACTION OF PLANT ANTIFUNGAL PEPTIDES

The elucidation of mechanisms of action of multiple plant antifungal peptides has been sought in recent years. However, many of these mechanisms are still unknown or at best shadowy. Here, we discuss several possible situations that arise from interaction between plant antifungal peptides and fungal cells. To elucidate how the peptides can inhibit fungal growth, different strategies have been assessed.

Morphological effects of plant antifungal peptides on fungal cells have been commonly demonstrated through microscopic analyses. Investigations such as these have showed, for example, that beyond reducing growth, defensins such as RsAFP2 from *Raphanus sativus* and HsAFP1 from *Heuchera sanguine* may cause alterations in fungal hyphae, like reducing branching and elongation, whereas other defensins, such as $DmAMP_1$ and $DmAMP_2$ from *Dahlia merckii*, $AhAMP_1$ from *Aesculus hippocastanum*, and $CtAMP_1$ from *Clitoria ternatea*, reduce hyphal elongation without leading to drastic morphological distortions. Therefore, based on morphological effects, the first group was named morphogenic defensins, and the second group nonmorphogenic defensins. Interestingly, among many fungi evaluated for these effects, only *Neurospora crassa* was inhibited by two defensin groups, and no morphological alteration was observed, suggesting that peptides could have a different action mode according to fungal species.[5]

Studies have also shown that plant antifungal peptides may have inhibitory activity affected by the presence of monovalent and divalent cations in the culture medium. In summary, it has been suggested that cations could compete with peptides for fungal membrane receptors through electrostatic interactions. This could reduce the interaction between peptides and fungal cells, and consequently lead to a decline in antifungal activity.[4] Because plants and other organisms present intracellular and extracellular ion concentrations, the ability of antifungal peptides to resist ions under physiological levels is extremely important for their activity.

Besides morphological alterations, plant antifungal peptides can also induce several physiological fungal responses such as modification in Ca^{2+} uptake, K^{+} efflux, and pH of mycelial suspension. The defensins RsAFP2 and DmAMP1, for example, can induce a rapid Ca^{2+} uptake, K^{+} efflux and broth alkalinization in *N. crassa*. However, in

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

the incubation medium supplemented with divalent cations, these effects were suppressed.[30]

Further efforts to understand the reason for the responses of fungi to plant antifungal peptides have demonstrated the relevance of interaction of antifungal peptides with receptors in fungal cells for antifungal activity. These targets have been found in the wall, membrane, and nuclei of fungal cells. The cell wall seems to be the goal for the peptide NaD1 (*Nicotiana alata* defensin), which is also able to permeate the plasma membrane and enter the fungal cytoplasm. Removal of components from the fungus cell wall, like β-glucan network or glycosylated proteins, prevents the permeation of NaD1 or hyphal death, thus indicating the importance of the cell wall for antifungal activity of NaD1.[32]

Moreover, sphingolipids present in fungal membranes are considered another target site for antifungal peptide interaction. These compounds act as binding-sites for antifungal peptides. Studies have shown which mutant fungi without genes responsible for biosynthesis of sphingolipids, like mannosyldiinositolphosphoryl-ceramide [M(IP)2C] and glucosylceramides (GlcCer), presented resistance to DmAMP1 and RsAFP2, respectively, when compared with that of wild-type fungi, demonstrating the importance of these sphingolipids to antifungal activity of DmAMP1 or RsAFP2. Interestingly, RsAFP2 can also interact with GlcCer isolated from *Pichia pastoris* but was unable to bind to soybean or human GlCer.[4] Probably, differences in ceramide structures among these three classes of organism (fungal, plant, and mammalian) may confer biding selectivity. It was later shown that RsAFP2 shows nontoxicity for mammalian cells.[31]

The interaction of antifungal peptides with fungal membrane also seems important for the inhibition of biofilm formation. Antifungal peptide TnAFP1 from *Trapa natans* can inhibit the biofilm formation of *Candida tropicalis*. This peptide may also affect the expression of the genes MDR1and ERG11, which are very important for ergosterol biosynthesis. The overexpression of these genes is commonly associated with biofim formation and consequently drug resistance.[14] Because most of the nosocomial infections caused by *Candida* species are associated with the formation of biofilms on medical devices, TnAFP1 is a promising potential candidate for biofilm control.

Proteins present in the nucleus can also interact with defensins and affect fungal development. Lobo et al.[13] reported which PsD1 (a defensin isolated from garden pea, *Pisum sativum*) can interact with several nuclear proteins, including a cyclin-like protein. This work was performed through a yeast two-hybrid screening system, using Psd1 as bait and proteins of *N. crassa* cDNA library as targets. Indeed, fluorescence microscopy analysis reveals colocalization of FITC-conjugated PsD1 and DAPI-stained fungal nuclei. This report also showed, through analysis of DNA content by flow cytometry, that PsD1 interferes in cell cycle progression.[13] In a study by Medeiros et al.,[18] the interaction of PsD1 with membrane was assessed by Nuclear Magnetic Resonance (NMR), showing which conformational selection is a binding mechanism and which regions around loop 1 of the peptide interact with carbohydrate and ceramide parts of GlcCer.[18,33]

Another investigation showed that some amino acid residues in specific positions are important for antifungal activity. Mutational analysis in RsAFP2, through several amino acid substitutions, resulted in a decrease or improvement of antifungal activity.[6] Parallel analysis of the three-dimensional structure of RsAFP2 allows prediction of the sites possibly relevant to antifungal activity. Similar studies were performed with MsDEF1, a morphogenic defensin from *Medicago sativa* and MtDef4, a nonmorphogenic defensin from *Medicago truncatula*.[28] In plant defensins, it has been observed that a γ-core motif is conserved, and as shown above, this site is associated with antifungal activity. Investigations using MsDef1 and MtDef4 have allowed the identification and functional characterization of the γ-core motifs for activity toward *Fusarium graminearum*. Interestingly, a γ-core substitution variant of MsDef1, containing the γ-core motif of MtDef4 (designated MsDef1- γ4) becomes a nonmorphogenic defensin. Moreover, this variant was more potent than MsDef1 and almost as potent as MtDef4. The variant MsDef1- γ4 presented a net charge that was more positive (+7) than MsDef1, net charge (+3). Interesting results were obtained about the activity of this variant toward *F. graminearum* lacking GlCer. First, it is important to know, as shown in a previous report, that *F. graminearum* lacking GlCer becomes resistant to MsDef1, but not to MtDef4.[26] As observed for MtDef4, *F. graminearum* lacking GlCer is highly sensitive to MsDef1- γ4. Based on this, the authors suggested that the γ-core motif of MsDef1 might be responsible for determining its morphogenicity and may possibly interact with GlCer in the fungal membrane.[28]

More recently, fungal growth inhibition by AFPs has been associated with fungal cell oxidative stress by reactive oxygen species (ROS) generation. This molecule can be produced by the activity of the mitochondria's electron transport chain. ROS can damage intracellular DNA, proteins, and lipids, consequently compromising cellular development. ROS have also frequently been associated with apoptosis induction. Defensins like RsAFP2 can induce ROS production in wild-type *C. albicans* and also lead to membrane permeation and fungus death.[1] However, in some *C. albicans* mutants, lacking GlcCe, this effect was not noticed, indicating that interaction between RsAFP2 and GlcCer is required for ROS generation. These studies also showed that ascorbic acid blocks RsAFP2-induced

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

ROS production and also antifungal activity, indicating the existence of intracellular signaling induced by defensins.[1] Further studies showed that RsAFP2 can induce cell death by apoptosis.[3] These investigations involved yeast apoptosis assays, measuring apoptosis markers, including: ROS levels, phosphatidylserine externalization and DNA fragmentation of yeast cultures. Concomitant to apoptosis, RsAFP2 triggered the activation of caspases or caspase-like proteases, which are essential molecules in the apoptotic process.[3]

Although sphingolipids [M(IP)2C] and GlcCer seem to be indispensable for antifungal activity of the defensins RsAFP2 and DmAMP1, this is not a rule for all AFPs. HsAFP1, for example, does not require the presence of the above-mentioned sphingolipids.[2] To understand the action mode of HsAFP1, Aerts et al.[2] screened the *Saccharomyces cerevisiae* deletion mutant library for hypersensitivity and resistance toward HsAFP1. Several genes identified in this study were important for mitochondrial functionality. Based on genetic results, these authors demonstrated by *in vitro* experiment the involvement of mitochondrial function in the antifungal action of HsAFP1. This revealed that the respiration inhibitor sodium azide blocks mitochondrial function by HsFP1 antifungal action antagonization. Further, it was observed that HsAFP1 induces ROS accumulation in *C. albicans* cells. These investigations showed that adequate mitochondrial respiration is essential for antifungal activity of HsAFP1.[2]

Finally, all investigations to understand the antifungal action of peptides isolated from plants have shown the breadth of this process after initial interaction between plant peptides and receptors in the fungal cell[33] (Figure 3), making it impossible to detect a single mechanism of action. Many improvements have already been made to understand the mechanism of antifungal activity of plant peptides. But much remains to be done, because there are hundreds of antifungal peptides described in plants,[11] and few clarifications of the antifungal action mode of a considerable proportion of these plant peptides.

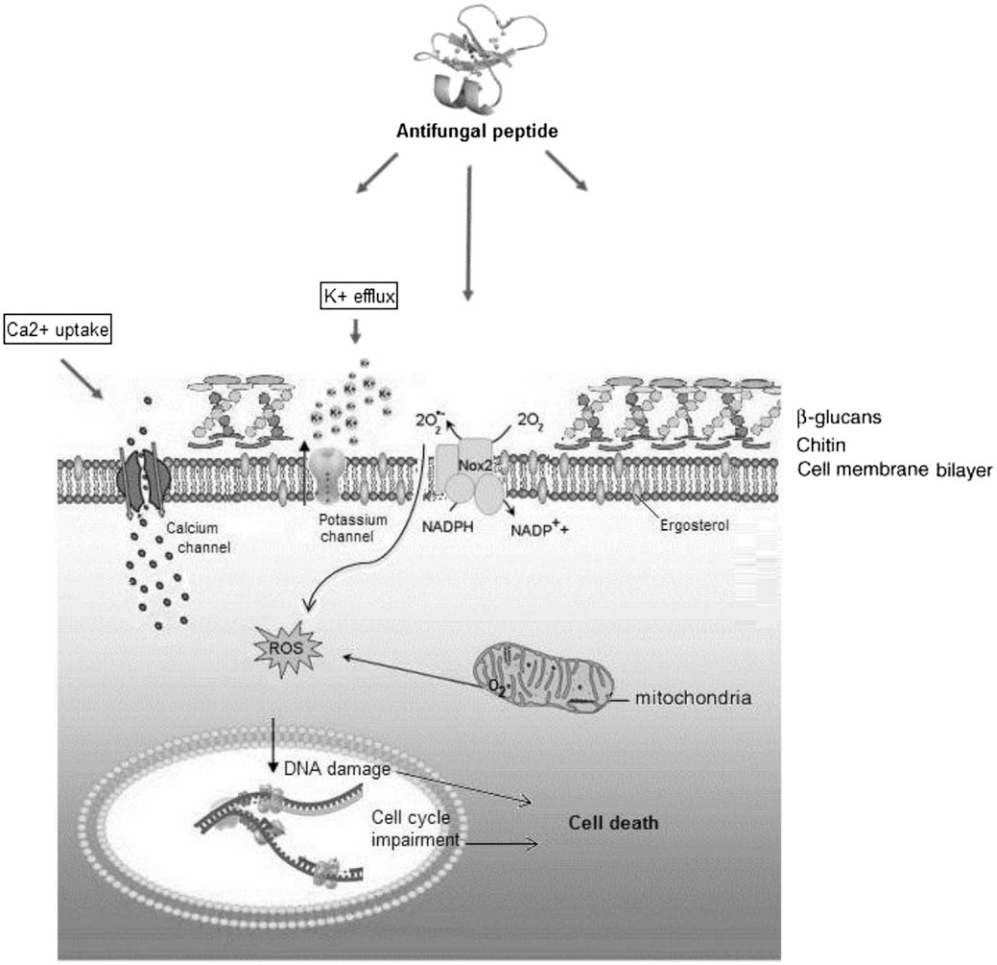

FIGURE 3 Schematic representing the possible action mechanisms of plant antifungal peptides and their biotechnological potential.

TRANSGENIC PLANTS EXPRESSING ANTIFUNGAL PEPTIDES FROM PLANTS

Transgenic plants can be considered an attractive alternative for heterologous protein production due to lower production costs and less investment needed in appropriate infrastructure. The potential of plants to act as an expression vector or in bioindustry has not been much used commercially due to lower protein production levels and the difficulty in extracting and marketing any biopharmaceutical produced in transgenic plants. Nevertheless, tremendous progress has been made in the last decade in this transgenic plant field, reaching expression levels and offering a competitive alternative to the establishment of novel production technologies including bacteria, insects and mammalian cell cultures.[7] AMPs can also be produced in model and crop plants, establishing this as a valuable biotechnological approach. This tactic may offer a solution for yielding crops that are resistant to a wide range of bacterial and fungal pathogens.[22] Antimicrobial peptides from different origins have emerged as an option for improving crop disease resistance because proof of their activities against microbial phytopathogens has been widely provided.[19] Moreover, in the near future, the transgene probably could also be used as a systematic way of improving knowledge about AMPs, including mechanisms of action, cellular targets, and possible effects on the mammalian immune system, thus diversifying the arsenal against plant pathogens.

In plants, AMPs may be expressed in a stable manner and transformed via biolistics, agrobacterium-mediated, or transiently expressed via a plant virus carrying the transgene.[7] To date, several plants have been transformed with plant AMP genes to improve resistance toward various pathogenic fungi (Table 2). The first field trial using AMP genes produced complete protection against *Verticillium dahliae* in potato, with equivalent results to fumigant practices, successfully showing that the single-gene approach may be effective to control pathogen attack.[12] Transgenic model plants such as

tobacco and *Arabidopsis*[19] have also been evaluated against fungi and bacteria due to transformation facilities. Moreover, several other transgenic crops expressing fungal resistance genes, such as rice and barley,[12,19] have been produced. An unusual study with the forestry tree *Picea abies* expressing *Pa18* encoding gene for a putative lipid transfer protein in somatic embryos showed inhibition of agrobacterium growth around the embryogenic callus.[27]

The *Wj-AMP*1 gene, isolated from wasabi leaves (*Wasabia japonica*), is the plant AMP most frequently found in transgenic plant studies so far. *Nicotiana benthamiana* transformed via viral vector expression and further expressing this gene was able to inhibit fungal and bacterial growth. This plant exhibited high resistance to *Magnaporthe grisea* and *Botrytis cinerea* but was weakly active against the phytopathogenic bacterium *Pseudomonas cichorii*. Further, transgenic potato expressing the same gene also showed antifungal activity against *B. cinerea*. Similar results have been obtained when the fungal defensin Wj-AMP1, expressed in the orchid *Phalaenopsis*, exhibited resistance against the phytopathogen *Erwinia carotovora*. Finally, resistant rice overexpressing wasabi defensin showed higher resistance toward the fungus *M. grisea*.[12,21]

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Nevertheless, it is important to remember that the mechanism of expression control by using different promoters seems to be essential for plant resistance improvement. Most transgenic plants carrying AMPs are driven by constitutive promoters such as cauliflower mosaic virus 35S (CaMV 35S) or ubiquitin (UBQ).[7] In both cases, transcripts are produced at high levels in a wide variety of plant tissues. Oard et al.[22] used a light-regulated leaf-specific promoter of chloroplast carbonic anhydrase (CA), which is considered a moderate promoter, to control the AMP β-purothionin fused to an extracellular rice endochitinase signal peptide (RSP). This unusual construction generates higher resistance against *Xanthomonas oryzae*, *Pseudomonas syringae*, and *Rhizoctonia solani*. These data suggest that the use of constitutive promoters is not essential to antimicrobial control. Patkar and Chattoo[24] used phenylalanine ammonia lyase (PAL), wound pathogen promoter and UBQ promoter to control Ace1AMP coding gene in transgenic rice, observing that resistance levels against the fungi *M. grisea* and *R. solani* and bacterium *X. oryzae* increased when a regulated promoter was used.

Moreover, the use of additional proteins or fused AMPs may involve an increase in antimicrobial activities. In Arabidopsis, it was found that the use of the specific CWP2 (chicken-derived specific antibody) for *Fusarium* cell wall protein fused to RsAFP from *R. sativus* enhanced resistance specifically against *Fusarium oxyosporum*.[25] However, constructions containing a polygene coding region for two AMPs, DmAMP1, and RsAFP2, produced a peptide that was cleaved after transduction. These plants exhibited greater resistance to *Fusarium culmorum* compared with that which was expressed with a single gene, demonstrating a synergistic effect.[9] These strategies are extremely valuable for the understanding of synergistic effects toward multiple pathogens.

CONCLUSIONS

In summary, the plant antifungal peptides described here and the novel peptides that certainly will be discovered in future could be used as important molecules in the development of biotechnological products. These peptides could be used as pharmaceuticals or in the production of resistant transgenic plants that could clearly contribute to agribusiness. Although some authors suppose that maintaining the stability of natural peptides outside the original organism may be a potential problem for transgenic plants, due to small size and susceptibility to protease degradation,[15] protein engineering applied to antifungal peptides could help with this issue. Moreover, these authors propose that rational design of peptides, including deletions or insertions into the original gene, could also improve peptide specificity, reducing toxicity to the host organism and finally modulating the spectrum of action. Prospects for using plant antifungal peptides to combat economic and social problems are excellent, despite the many intrinsic problems to be solved; indeed, this is an opportunity to bring together multiple techniques from biochemistry and molecular biology. Discovering novel antifungal peptides by genomic and peptidomic strategies, elucidating peptide structures unsolved until now, finding new promotors and expressing these molecules in different organisms will certainly boost the application of these remarkable compounds.

Chapter 27

Polysaccaride Krestin (PSK) and Polysaccharopeptide PSP

Jennifer Man-Fan Wan

ABSTRACT

Higher basidiomycetes fungi commonly known as mushrooms have been applied as folk medicine for thousands of years particularly in Asia. Today, fungi are becoming one of the important natural resources for the development of pharmaceutical agents, particularly, against cancer and autoimmune diseases. They are known to produce a variety of proteins with interesting biological activities. These include lectins, antifungal proteins, ribonucleases, ubiquitin-like proteins, hemolysis, and peptides. The 1-3-glycopeptides (polysaccharide–peptide complexes) isolated from mushrooms are well known for their immunomodulating and antitumor activities. Polysaccharopeptide (PSP) and Polysaccharide Kurcha (PSK) (commercial name Krestin) derived from *Coriolus vesicular* mycelia are probably the two most notable ones. Both have been discovered with very strong immunological values and are commercially available as biologic response modifiers. Other pharmacological activities of PSP and PSK include antitumor, antiviral, antimicrobial, and anti-inflammatory. This chapter discusses their discovery, structure, and chemical composition as well as their biological activities.

DISCOVERY

Polysaccharide Krestin (PSK) and polysccharopeptide (PSP) are two of the best-known commercial fungal polysaccharide–protein complexes derived from *Coriolus versicolor* mycelia with very important therapeutic values. These mushroom peptides have been used to treat infectious diseases and cancer.[2–6,15,16,23,25] PSK and PSP are derived from the CM-101 and COV-1 strains of the fungus *Coriolus versicolor* by Japanese[7] and Chinese[33] scientists, respectively. According to the *Shennong Emperor's Classic of Materia Medica*, a book published over 3000 years ago, *C. versicolor* (*L. Ex Fr.*) *Quel,* belonging to the higher basidiomycete fungi, was applied as folk medicine for thousands of years particularly in Asia. *C. versicolor* is a wood-decaying mushroom occurring in tropical, subtropical, and temperate zones. Because of its unique appearance, it is called "云芝" (Yun-Zhi) in Chinese, which means "cloud-like mushroom." It has also been named *Polyporous versicolor* (L.) Fr. or *Polysticutus versicolor*, and some taxonomists considered that this fungus belongs to the *Trametes* family.[4,23]

PSK was first isolated in Japan in the late 1960s, and PSP was isolated around 1983 in China.[2,4,23] Each compound was discovered with strong immunological values and has been used as an adjuvant for cancer treatment with no known side effects.[2,6,12,19,21,25] The fermentation for PSK lasts up to 10 days, whereas PSP production involves a 36- to 72-h culture. PSK is recovered from water extracts of the biomass by salting out with ammonium sulfate, whereas PSP is recovered from ethanol precipitation.[2,7,33] Both are dark brown powders, with a light odor and are soluble in hot water with a pH ranging from neutral to slightly acidic. The PSP/PSK polymers are only soluble in hot water and insoluble in methanol, pyridine, chloroform, benzene, and hexane.

STRUCUTRE AND CHEMICAL COMPOSITIONS

The composition and structure of PSK and PSP have been reviewed elsewhere.[2,4,15,23,25] PSK and PSP share very close chemical structures and biological functions. The presence of fucose in PSK and rhamnose and arabinose in PSP distinguishes the two protein-bound polysaccharides, which are otherwise chemically similar. PSK is composed of 34–35% soluble carbohydrate, 28–35% protein, 7% moisture, 6–7% ash, and the remainder is composed of free sugars and amino acids. PSP is made up of 46% soluble carbohydrate, 31% protein, and 15% of incombustible substances. Both have a molar mass of approximately 100 kDa. PSP and PSK contain β-1→3, β -1→6, α-1→4, and α-1→2 glucosidic linkages in their polysaccharide moieties with D-glucose being the major monosaccharide and are covalently linked to several proteins. The amino acid composition is 0.58% glutamine, 0.4% aspartic acid, 0.32% serine, 0.26% alanine, 0.26% glycine, 0.24% leucine, 0.23% lysine, 0.23% threonine,

0.22% Isoleucine, 0.18% arginine, 0.18% valine, 0.17% trpyptophan, 0.15% phenylalanine, 0.15% tyrosine, 0.1% proline, 0.09% cystine, 0.07% histidine, and 0.04% methinione. The polysaccharide component is composed of 74% glucose, 4% xylose, 2.7% glalactose, 2.4% fructose, and 1.5% mannose.

BIOLOGICAL ACITVITIES

Biological Response Modifiers (BRMs) Activity

Both PSK and PSP have been classified as biological response modifiers (BRMs) because they can interact with the immune system and able to upregulate or downregulate specific aspects of the host response. The biological response activities of PSK and PSP include immunopotentiation by inducing production of interleukins (ILs) such as IL-8, IL-6, tumor necrosis factor-alpha (TNF-α), interferons,[13,18,25] macrophages,[11,14,18,20] T-lymphocytes,[12,14,17,18,21] counterimmunosuppressive effects of chemotherapy,[24] radiotherapy,[6] antagonism of immunosuppression induced by tumors, antiviral,[3,26] anti-inflammatory,[1,2] analgesic,[22] antihyperlipemic,[35] antioxidative, production of superoxide dismutase, and glutathione peroxidase.[10] The enhanced anticancer properties of PSK and PSP in combination with radiation, chemotherapy, or immunotherapy are associated with their ability to activate both cellular and humoral components of the host immune system.[2,4,5,12,14,15,24,27,29]

Modulate Both Innate (NonSpecific) and Adaptive (Specific) Immunity

Macrophages are involved in all stages of the immune response. They function in phagocytosis, antigen processing and presentation, secretion of cytokines, and antibody-dependent cell-mediated cytotoxcity. Both PSP and PSK can restore and increase phagocytic function of macrophages.[11,14,18,20] PSK can stimulate production of differentiation-inducing factor from macrophages, and activate the function of polymorphonuclear leukocytes (PMN), promote the phenotype and functional maturation of dendrite cells derived from human $CD4^+$ mononuclear cells, and resolve the immunosuppressive state of a cancer-bearing host.[11] PSK inhibits Epstein–Barr virus induced B-cell proliferation through T cells activated by the monocyte products IL-15 and IL-12.[18]

Natural killer cells (NKs) are a subset of bone marrow-derived lymphocytes that are capable of lysing or killing infected or tumor cells. Cytotoxicity and production of cytokines such as interferon-gamma (IFN-γ), TNF-α, and granulocyte-macrophage-colony stimulating factor (GM-CSF) that can modulate natural and specific immune responses are two relevant functions of NK cells. The ability of PSK to increase the production of human NK cells[21] makes it a unique biological response modifier for the treatment of cancer and viral infection. PSK inhibits human immunodeficiency virus infection *in vitro*.[26] PSP can activate macrophages to release mediators such as nitric oxide (NO) and TNF-α; prostaglandin E_2, IL-1, and IL-6[1,13] in response to bacterial infection.

PSK and PSP act as mitogens, and they play a role in the first step of activation signaling pathways in antigen-presenting cells (APCs). Subsequent to this activation and signaling is humoral- and cell-mediate-immunity induction. The biological abilities of PSP and PSK include stimulation on Th1- and Th2-dependent antibody production, promotion of Th1-dominant state and killer activities, and enhancement of both Th1- and Th-2-dependent cytokines such as IL-10, IL-4, and IL-2.[2,12,17] Both PSP and PSK are able to stimulate or suppress the production of cytokines that mediate innate immunity. These include proinflammatory cytokines (e.g., IL-1, IL-6, TNF-α, and regulatory cytokines such as IL-2 and IL-10).[13,17] In lipopolysaccharide (LPS)-treated mouse peritoneal macrophages, PSP potentiates the release of inflammatory mediator prostaglandin E2 and the proinflammatory cytokines TNF-α, IL-1β, and histamine.[1] Increased production of IL-1 may cause the production of various other cytokines such as TNF-α, which elicits the lysis of malignant cells and bacterial cells.

Maintaining the Correct Balance Between Th1- and Th2-Mediated Immunity

Maintaining the correct balance between cellular (mediated by T-helper 1 cells, Th1) and humoral (mediated by T-helper 2 cells,Th2) immunity, is critical to ensure an effective immune response to infection and human diseases based on the types of cytokines secreted. Uncontrolled Th1- and Th2-mediated responses can lead to autoimmune and inflammatory diseases, respectively. For instance, in cancer, the balance between Th1 and Th2 immune responses is shifted toward Th2 dominance resulting in a poor prognosis. Therefore, identifying agents that modulate the Th1/Th2 cytokines are therefore essential for controlling these diseases. PSK therapy shifts the Th1/Th2 balance toward Th1 dominance in patients with gastric or colorectal cancer.[12]

Our *ex vivo* study of human T lymphocyte proliferation showed that PSP exhibits similar characteristics as cyclosporine A (CsA) does in controlling aberrant T cell proliferation.[17] Differing from that of CsA, PSP reduces Th1 cytokines and CD3+/CD25+ cell expression but not Th2 cytokine expression, which could help the cytokine balance shift toward Th2 dominance. Molecular analysis

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

indicates that the suppression of IL-2 expression by PSP, like that of CsA, was via Janus-kinase-signal transducers and activator of transcription pathways, and subsequently reduces the production of the IL-2 receptor, cytotoxic T cells, natural killer cells, and gamma interferon. The effect of PSP on Th1 cytokine suppression involves the activation of mitogen-activated protein kinase (MAPK) p38 and signal transducers and activators of transcription 5 (STAT5) on T cells. Unlike CsA, PSP does not induce an apoptotic influence on the proliferating T cells.[17]

CsA is also a microbial product, derived from the fungus *Tolypocladium inflatum* and is used as an immunosuppressive drug for the treatment of autoimmune diseases. It is capable of altering the Th1/Th2 cytokine production profiles in the control of autoimmune and inflammatory diseases through the inhibition of IL-2. However, CsA is not specific, and its long-term use is associated with significant side effects and toxicities. Whether PSP can be a more suitable candidate for maintaining the correct balance between Th1- and Th2-mediated immunity than CsA in treatment of autoimmune diseases.

Antitumor Activity

The antitumor activity of PSK and PSP has been extensively described.[2,5,6,15,16,22,23,25,27,29,31,32] Evidence relating to the therapeutic efficacy of PSK and PSP comes from numerous clinical trials conducted on hundreds of cancer patients. Three reviews of human studies with PSK have positive conclusions: The 1998 review by T.B. Ng concluded that PSK helps alleviate symptoms and prevents the decline in the immune-status of patients with esophageal, gastric, and lung cancers treated with radiotherapy and chemotherapy.[23] A review by Parris Kidd summarized the benefits of PSK on the quality-of-life aspects of the patients who underwent chemotherapy and radiation therapy.[15] Fischer and Yang summarized that the greatest amount of clinical evidence for the use of PSK was in the treatment of gastric cancer after curative resection.[5] The immune-protection of PSK has been greatly notified in cancer patients during chemotherapy and radiotherapy.[12–14] Cotreatment of PSK helped to restore the suppressed immune system of the patients caused by anticancer drugs during chemotherapy and radiotherapy. The immune restoration abilities of PSK/PSP include the increase of antibody and cytokine production and improvement of impaired antitumor activity of natural killer cells, T cells, macrophages, and peripheral blood lymphocytes.[2,6,12–14,19–21,24,29] Other antitumor activities include detoxification of carcinogens via increased expression and activity of phase I and phase II enzymatic–oxidative–radical–scavenging effect, induction of differentiation, direct cytotoxicity, angiogenesis, and antiproliferation.[5,9,10,25,32,34] PSP/PSK work in multiple steps of the malignant process by inhibiting adhesion, invasion, motility, and metastatic growth of tumor cells.[2,6]

Mechanistic studies at the cellular level with cancer cell line reveal that PSP and PSK act via the host to boost cellular immunity indirectly on tumor cells and directly on cancer cells. These fungal peptides can activate the cell death program (apoptosis), inhibit DNA synthesis, arrest cell cycle, and inhibit cell division,[5,9,27,28,34] which are all strategies for treatment of human cancer. The induction of apoptosis by PSP involves mitochondrial pathways and an increase of the Bax/BCl_2 ratio.[35] Induction of S-phase cell cycle arrest by PSP is positively associated with the accumulation of the cell cycle phase proteins, cyclin E, and B1.[9,28,35] PSP can synergistically enhance the apoptotic effect of the S-phase targeted drugs doxorubicin (Doxo) and etoposide (VP-16) via enhancing the sensitivity of cancer cells to PSP by creating an S-phase trap.[9,28] Bivariate bromodeoxyuridine (BrdURd)/DNA flow cytometry analysis estimated a longer DNA synthesis time (Ts) for the HL-60 cells cotreated with PSP, confirming that PSP can create an S-phase trap. A negative correlation between the increase in apoptotic cell population (pre-G1 peak) with their S-phase cell population expression ($R2=0.998$) and the expression of cyclin E expression ($R2=0.872$) and caspase 3 activity ($R=0.997$) suggest that PSP enhances the apoptotic machinery of Doxo and VP-16 in a cell cycle-dependent manner and is mediated, at least, in part, by the PSP-mediated modulation of the regulatory checkpoint cyclin E.[9]

OTHER BIOLOGICAL ACTIVITIES

In addition to the antitumor activity, PSP and PSK exhibit antiviral activity[336] and analgesic activity.[1,22] PSK can inhibit HIV infection by modifying the viral receptor or by stopping HIV from binding with lymphocytes.[3] Alpha-glucosidase is a Golgi complex enzyme involved in viral protein processing and HIV-1 gp 120 processing. PSP inhibits the interaction between HIV-1 reverse transcriptase, and inhibits a glycohydrolase enzyme associated with viral glycosylation.[26] PSP shows analgesic action in mice subjected to hot-plate-induced pain stress.[1] Other biological activities of PSK/PSP include strong scavenging effects on superoxide and hydroxyl radicals,[26] expressing the mimetic activity of superoxide dismutase (SOD), promoting oxidative stress relief for cancer-bearing hosts,[10,26] and protecting macrophages from lipoperoxide accumulation and foam cell formation caused by oxidative modified low density lipoprotein.[35] The antimicrobial activity of PSK has been shown in *Escherichia coli*, *Listeria monocytogenes* and *Candida*.[26] Phagocyte activation and reactive nitric oxide production of macrophages are suggested mechanisms contributing to the antimicrobial activity of PSK.[26]

CONCLUSIONS

Polysaccharides-Krestin and polysaccharide peptide are two effective protein complexes derived from *C. versicolor* with very important therapeutic significance. They are considered as biological response modifiers because they can modulate both innate and specific immunity, induce multicytokine production and regulate their function, as well as to correct the balance between Th1 and Th2 immunity. Both PSP and PSK have the ability to modulate inflammation, immunity, and hematopoiesis thereby eliciting various therapeutic effects. Other pharmacological activities of PSP/PSK include analgesic, antimicrobial, antiviral, and antioxidant. They are sold in the form of capsules, ground biomass tablets, syrups, food additives, and teas around the world and are used as adjuvant for cancer therapy and neutraceuticals with no reported side effects.

Chapter 28

AKH/RPCH Peptides

Gerd Gäde and Heather G. Marco

ABSTRACT

Color change in the integument is the obvious action of the red pigment-concentrating hormone (RPCH), which is produced in the neurosecretory cells of the X-organ of crustaceans. Mobilization of various fuels used during energy-demanding processes is the classical regulatory role of the adipokinetic/hypertrehalosemic/hyperprolinemic hormones (AKHs), which are produced in neurosecretory cells of the insect corpus cardiacum. These neuropeptide hormones have common structural features: a chain length of 8–10 amino acids, blocked N- and C-termini, and aromatic amino acids at positions 4 and 8. The precursor is organized as signal peptide, AKH/RPCH peptide, amidation and processing sites, followed by another peptide of unknown function. Only one AKH receptor type is known yet, although certain insect species have up to three mature AKHs. Ligand–receptor interaction, receptor conformational changes necessary for receptor activation, and intracellular signaling pathways have been partly unraveled.

DISCOVERY

Already in the 1920s–1940s it was shown that extracts from certain glands of crustaceans and insects caused a change of integumental color from dark to light when injected into shrimps.[9,23] Complete purification of the active material from the eyestalks of the prawn *Pandalus borealis* (Panbo) was achieved mainly by gel chromatography on Sephadex LH-20 in water/butanol mixtures, and the structure of the active principle was elucidated as a blocked octapeptide by the use of quantitative amino acid analysis, proteolytic cleavage, Edman-dansyl sequencing, and high-resolution mass spectrometry. This resulted, in 1972, in the first complete primary structure of an invertebrate neuropeptide,[3] which was termed red pigment-concentrating hormone (RPCH; today denoted as Panbo-RPCH) (Table 1). In insects, extracts of the corpus cardiacum (CC) from either the American cockroach or the migratory (*Locusta migratoria*; Locmi) and desert locusts were shown, during the 1960s, to have metabolic effects: elevation of the hemolymph sugar trehalose (hypertrehalosemic effect) or of the hemolymph lipids (adipokinetic or hyperlipemic effect). In 1976, the complete primary structure of one of the locust's adipokinetic neuropeptides from the CC, today denoted as Locmi-AKH-I (Table 1), was obtained by enzymatic cleavage and mass spectrometry after purification by size-exclusion gel chromatography on controlled-pore glass and thin-layer chromatography on silica gel.[25] The sequence of the decapeptide Locmi-AKH-I showed close structural similarities with Panbo-RPCH; both peptides are crossreactive in the reciprocal biological system. Today, >50 members of this AKH/RPCH family of peptides are known by primary structure from the two arthropod sister groups, Crustacea and Insecta. Interestingly, individual crustaceans have only one family member, and only two AKH members have been identified to date in Crustacea: the highly conserved Panbo-RPCH in decapod crustaceans and Dappu-RPCH (Table 1) in branchiopod (cladoceran) crustaceans of the genus *Daphnia*.[1] Insecta, on the other hand, contain up to three AKHs in an individual and show a high degree of variability in the sequence. There is, however, group specificity in the insect AKHs and, moreover, insects of some orders synthesize the crustacean form Panbo-RPCH[5,7] (Table 1).

AKH STRUCTURE

Primary Structure

Commonly, AKHs are characterized by a chain length of 8–10 amino acids, a blocked N-terminus (pGlu), a blocked C-terminus (carboxyamide), and aromatic amino acids at position 4 (mostly Phe but sometimes also Tyr) and position 8 (Trp). A few AKHs even have a third aromatic amino acid (at position 2: see Scade-CC-I and -II in Table 1), and some have a negatively charged amino acid (Asp, as in Scade-CC-I and -II, and in Phote-HrTH, Table 1). In addition to the modified termini, other posttranslational modifications encompass an AKH with a phosphorylated Thr residue at

TABLE 1 Primary Structures of Selected Peptides of the AKH/RPCH Family

Peptide code name	Primary structure*	Comments
Panbo-RPCH	pGlu-Leu-Asn-Phe-Ser-Pro-Gly-TrpNH_2	Color change hormone of *Pandalus borealis* and adipokinetic hormone of stink bug *Nezara viridula*
Dappu-RPCH	pGlu-Val-Asn-Phe-Ser-Thr-Ser-TrpNH_2	Peptide found in *Daphnia pulex* that has no color change effect in shrimps but adipokinetic effect in stink bug
Locmi-AKH-I Locmi-AKH-II Locmi-AKH-III	pGlu-Leu-Asn-Phe-Thr-Pro-Asn-Trp-Gly-ThrNH_2 pGlu-Leu-Asn-Phe-Ser-Ala-Gly-TrpNH_2 pGlu-Leu-Asn-Phe-Thr-Pro-Trp-TrpNH_2	Adipokinetic hormones of *Locusta migratoria*, three isoforms known
Emppe-AKH	pGlu-Val-Asn-Phe-Thr-Pro-Asn-TrpNH_2	Adipokinetic peptide of the mantid *Empusa pennata*
Tenmo-HrTH	pGlu-Leu-Asn-Phe-Ser-Pro-Asn-TrpNH_2	Hypertrehalosemic peptide of the beetle *Tenebrio molitor*
Declu-CC	pGlu-Leu-Asn-Phe-Ser-Pro-Asn-Trp-Gly-AsnNH_2	Peptide found in the meloid beetle *Decapotoma lunata*
Scade-CC-I Scade-CC-II	pGlu-Phe-Asn-Tyr-Ser-Pro-Asp-TrpNH_2 pGlu-Phe-Asn-Tyr-Ser-Pro-Val-TrpNH_2	Peptides of the scarabaeid beetle *Scarabaeus deludens*, very likely hyperprolinemic
Phote-HrTH	pGlu-Leu-Thr-Phe-Ser-Pro-Asp-TrpNH_2	Hypertrehalosemic peptide of *Phormia terraenovae* and also *Drosophila melanogaster*

**For sequence references, see Ref. 5.*

position 6 (synthesized in the CC of a cetoniid beetle),[10] an AKH with a hydroxylated Pro residue at position 6 found in the CC of a stink bug[11] and an as yet unknown modification in AKHs of various cicadas.[9] In two stick insect species, the Trp[8] residue is either modified to kynurenine or displays an unusual C-glycosylation.[9,19]

Three-Dimensional Structure

As is obvious from Table 1, the termini and the aromatic amino acids at positions 4 and 8 are conserved, suggesting an important feature for receptor binding. This was confirmed by structure activity studies using analogs (see, e.g., Ref. 8). Studies on the solution conformation of a few selected AKH peptides (mostly Locmi-AKHs, Emppe-AKH, Tenmo-HrTH, and Declu-CC) have been performed using either circular dichroism or nuclear magnetic resonance techniques and applying constrained molecular dynamics. All studies indicate a β-turn between residues 4–8, but they are at variance with each other about the N-terminus where β-sheet, "extended structure" and "extended PII conformation" have been proposed.[21]

AKH/RPCH Distribution

The results from several immunocytochemical and in situ hybridization studies have shown that AKHs are localized and synthesized mainly in the glandular lobe of the insect CC.[9] Interestingly, in the case of the migratory locust, mRNAs encoding the three Locmi-AKHs were shown to colocalize in neurosecretory cells of the locust CC,[9] suggesting that the three AKH peptides are synthesized and released from the same cells. Although some have also reported immunoreactivity in neurons of the brain and other parts of the central nervous system of insects, this nonCC immunoreactivity is often a nonspecific crossreaction to other unidentified peptides.[2] Such crossreactions are clearly abolished by the use of antisera preabsorbed with RPCH, whereas the specific immunoreactions in neurons of the CC remain unaffected by preabsorption.[2] Neuronal projections from AKH-producing cells in the CC onto the crop have been observed in dipterans, and it is postulated that AKH may play a role in such animals by stimulating crop emptying.[15,17]

Immunocytochemistry in crustaceans has identified RPCH in neurons of the X-organ and, to a lesser extent, in the medulla terminalis (in the eyestalks of decapods); RPCH immunoreactivity is also distributed in neurons of abdominal ganglia in a crayfish and in neurons that project to the neuropil of the stomatogastric ganglion of a crab and a spiny lobster.[9] This distribution pattern ties in well with the functional activity of RPCH in crustaceans. In situ hybridization studies have confirmed that RPCH is synthesized in neurons of the eyestalks of crustaceans.[18]

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

AKH/RPCH Precursor Structure and Processing

Direct protein chemical methods and molecular cloning techniques have been used to show in detail the biosynthesis of up to three AKHs in locusts, including the characterization of the precursor.[9] The AKH gene/precursor is also known from all fully sequenced insect genomes, a number of other insects where genomic information is still lacking, such as the tobacco hornworm moth (*Manduca sexta*), and two blaberid cockroaches (*Blaberus discoidalis* and *Blattella germanica*).[14,15] The Panbo-RPCH precursor is known from a number of crab species, and the Dappu-RPCH gene is known from the *Daphnia pulex* genome data. Apparently, a distinct mRNA encodes each AKH or RPCH precursor, which is translated into a preprohormone with the following general organization: signal peptide, followed by the mature AKH or RPCH peptide, a Gly residue for amidation, a dibasic processing site, and C-terminally a so-called "tail" or "precursor-related peptide" of variable length (shorter in insects than in crustaceans).[23] Specific functions have not yet been annotated for these precursor-related peptides.

For the migratory locust, two independently translated monomers of the proLocmi-AKH-I are oxidized to a unique precursor dimer by the formation of a disulfide bond at the "tail peptide." Processing, therefore, results in two monomeric Gly-Lys-Arg-extended Locmi-AKH-I decapeptides in addition to the dimeric molecule of the "tail peptide." First, the two basic amino acids are enzymatically removed by carboxypeptidase, and the resulting Gly-extended Locmi-AKH-I is modified to the amidated form by a peptidylglycine-α-amidating monooxygenase (see Ref. 9 and the Peptide Biosynthesis/Processing section of this book). This processing scheme has not been verified for any RPCH, and it is not even known whether dimers of other AKHs are formed.

AKH/RPCH RECEPTORS AND THEIR SIGNALING

Although the mature peptides (Panbo-RPCH and Locmi-AKH-I) have been known since the 1970s, receptor studies for AKH/RPCH were scarce. The first report on an AKH receptor protein in insects mentioned specific binding studies with tritiated Manse-AKH on membrane fractions purified from the fat body of adult *M. sexta*, and later, the putative AKH receptor was cloned and sequenced.[27] In crustaceans, it has only been shown that unidentified membrane proteins from various neuronal tissues are able to bind Panbo-RPCH.[9] Less than 10 years ago, with the help of molecular biological methods, receptors for AKH peptides of the fruit fly *Drosophila melanogaster* and the silkworm *Bombyx mori* were cloned and characterized.[22,24] Interestingly, the G protein-coupled receptors (GPCRs) with 7 membrane-spanning domains are structurally related to receptors of the vertebrate gonadotropin-releasing hormone. The identification of the *D. melanogaster* AKH receptor and the subsequent sequencing data from the entire genome of several other insects/organisms led to the identification of similar receptor sequences from those genomic databases. Thus, to date, AKH receptors are known from all those insects that have had the entire genome sequenced. However, researchers have constrained themselves to searching only for homologous sequences (using BLAST programs and consensus cloning), and curiously, only one such AKH receptor per species has been found even in those species where >1 AKH ligand is present (e.g. *B. mori* with two AKHs).[24] It is conceivable that where the ligand (AKH gene) has been duplicated, there may also be a duplication (and modification) of the receptor and that this undiscovered second receptor is very different from the known AKH receptors and therefore not amenable to the current search strategies. The AKH receptor is expressed in insect fat body.[12,15,26,27] Receptor specificity and characterization of cloned receptors have all taken place via *in vitro* assays in which the AKH receptor was expressed in a heterologous system, namely, in vertebrate cell lines (e.g. Chinese hamster ovary cells, CHO; human embryonic kidney cells, HEK) or in frog oocytes.

For a number of insect species and AKH peptides, we have a good knowledge of the events after receptor binding, that is, the mode of action pathways.[6] In brief, for the activation of glycogen phosphorylase, which ultimately results in the increase of trehalose in the hemolymph (see below: biological function), a G_q protein is activated, phospholipase is stimulated, the second messenger inositol trisphosphate is produced, Ca^{2+} from internal stores are released but, apparently, entry of extracellular calcium into the cell is also promoted. For the activation of triacylglycerol lipase, which leads to the increase of diacylglycerol in hemolymph, a G_s protein is activated, adenylyle cyclase is stimulated, the second messenger cyclic AMP is increased, and intracellular Ca^{2+} also plays a role.

Later studies on the *B. mori* AKH receptor (Bommo-AKHR) used molecular and cell biology methods to characterize its signaling after stably expressing the receptor in HEK293 cells.[13,26] These experiments confirm that the ligand Manse-AKH binds to a G_s-coupled Bommo-AKHR and dose dependently increases cAMP and intracellular Ca^{2+}, which stimulates phosphorylation of extracellular signal-related kinase 1/2 (ERK 1/2); activation of the ERK 1/2 pathway is mediated via protein kinases A and C. After ligand-binding and activation of Bommo-AKHR, the receptor is rapidly internalized from the cell membrane in clathrin-coated pits and slowly recycled in endosomes after the removal of the ligand; internalization is mediated by GPCR kinase and β-arrestin-2, desensitizing the receptor after ligand-binding; three amino acids (Thr^{356}, Ser^{359}, and Thr^{362}) at the C-terminus of Bommo-AKHR are important for this internalization. In contrast to biochemical studies

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

using fat body tissues of insects to study the signal transduction pathways of AKH/AKHR (see above), the heterologously expressed Bommo-AKHR does not involve a phosholipase. This may be a limitation of the HEK cell machinery versus that of the insect fat body and should serve as a reminder that the Bommo-AKHR studies should be repeated in *B. mori* fat body tissue to confirm that the homologous system does, indeed, operate via the same transduction pathways as seen with the HEK cell line.

Much less is known of the mode of action of Panbo-RPCH in crustaceans, but it seems to be clear that for both the aggregation of the integumentary pigment and the retraction of distal retinal pigment in the compound eye, internal and external Ca^{2+} are necessary and that phospholipase and inositol trisphosphate may be involved in the signaling processes.[9]

G protein–coupled receptors are classified into three classes (A–C) based on their cell signaling and trafficking pathways.[20] According to the current model, the insect AKH receptor belongs to Class A GPCRs along with μ-opioid receptor, endothelin type A and β-2-adrenergic receptor, among others.[13] The crystal structures of the two main subgroups of class A GPCRs are known and by homology modeling, two models were constructed for the three-dimensional structure of the *Anopheles gambiae* AKH receptor (Anoga-AKHR).[20] The β-2-adrenergic–based structure of Anoga-AKHR represents an "open" conformation, that is, the ligand Anoga-AKH has easy access to the hormone binding pocket (typifying the inactive, ligand-free AKHR state), whereas the rhodopsin-based structure is "closed" (inaccessible to the free ligand, equating the active receptor to which the ligand is bound). Ligand-docking calculations show a 30 times higher affinity for the endogenous ligand than for another AKH used in the study.

BIOLOGICAL ACTIONS

In crustaceans, the major biological function of Panbo-RPCH is surely the aggregation of pigment granules in the epithelial chromatophores. Thereby, one or more different types of chromatophore (and, thus, pigment colors) can be affected. Next, the peptide is also responsible for the retraction (aggregation) of the distal retinal pigment in the ommatidia. Extrapigmentary effects of Panbo-RPCH are known as well. For example, it is implicated in the stimulation of the release of methyl farnesoate from mandibular organs; other effects are neuromodulatory, which affect the rhythm of certain parts of the stomatogastric and swimmeret system; moreover, modulation of photoreceptor cells has been reported.[9] There is a claim that Panbo-RPCH increases the glucose level in the isopod crustacean *Porcellio scaber*; however, the article is not clear on the methods and concentrations used, and a number of necessary controls were omitted.[28]

In insects, the basic physiological action of AKH peptides is the increase of those metabolites (regardless of the nature of the metabolites, see below) that are used by the muscles (and other tissues) as a source of energy especially during exercise, such as flight and running. The AKH peptides target the fat body tissue to convert its stored triacylglycerols or glycogen to diacylglycerol or trehalose, respectively, or to synthesize the amino acid proline from alanine and fatty acids. Diacylglycerols, trehalose, or proline are released from the fat body, and their concentrations are consequently elevated in the hemolymph. There is no specific AKH peptide that is responsible for eliciting the increase of diacylglycerols in the hemolymph of locusts, for example, and another one that elevates the concentration of hemolymph trehalose in cockroaches or the level of proline in the tsetse fly. The activation of the respective pathways for lipid-, carbohydrate-, or proline mobilization is inherent in the enzymatic machinery of the fat body of the respective species and correlates with its main fuel for heavy locomotory activities, for example, flight activity.[4] Other actions of AKH peptides are on the hemolymph level to increase the concentration of lipophorins, that is, proteins that elevate the capacity of shuttling more lipids from fat body to muscles, or, on the flight muscle level where AKH peptides, are proposed to stimulate the oxidation of lipids. Other stimulatory actions are the acceleration of the rate of the heart beat, which is interpreted as a mechanism to facilitate faster distribution of metabolites, and the increase in the oxidative capacity of mitochondria. Inhibitory actions of AKH peptides are also known on the biosynthesis of protein, RNA and fatty acids.[4] The effect on fatty acids is logical, because the main effect of AKH is to stimulate lipid degradation, while the former effect is mainly discussed under the physiological aspect of reproduction where AKH peptides and the repression of the synthesis of vitellogenin (the egg yolk precursor protein) have been analyzed. The functional importance of AKHs has been investigated by molecular manipulations *in vivo* in *D. melanogaster* where mutant flies were generated by targeted genetic constructs and specific crossbreeding,[12,17] and in the cockroach *B. germanica* by the use of RNA interference (RNAi) methods.[14] The fruit fly studies confirm that AKH and its receptor play an important role in metabolism, specifically in mobilizing stored metabolites from the fat body. However, the absence of AKH and/or its receptor does not seem to have adverse conditions during larval development, and does not affect the normal reproductive ability of adults, despite the lowered levels of trehalose and lipids in the hemolymph. A possible explanation for these results may be that there is a compensatory mechanism or alternative pathway by which lipids are mobilized in insects. Evidence for such a dual, independent adipokinetic system is seen in *D. melanogaster*, where an adipose triglyceride lipase called Brummer lipase is as important as the AKH/AKHR in fat mobilization: dual loss of Brummer lipase and AKHR results in extreme obesity in flies, the stored lipid could not be mobilized by AKH (although the stored carbohydrates are

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

accessed and depleted), and double mutant flies die quickly after food deprivation – all in contrast to single mutants (i.e. where either Brummer lipase or AKHR was lacking).[12] Inactivation of the AKH/AKHR system results in upregulation (hyperstimulation) of the Brummer lipase gene expression in starving flies. Conversely, overexpression of AKH in fat body suppresses Brummer lipase transcription, thus showing clear compensatory regulation between the two systems. Another triglyceride lipase has been characterized from moth fat body (a homolog is present in *D. melanogaster* too) as an active phospholipase AI.[12]

It seems that AKH peptides are somehow intricately linked with certain actions of Juvenile hormone in its inhibitory effect on vitellogenin production.[4] Blage-HTH is a member of the AKH family that causes hypertrehalosemia in *B. germanica*; adult female cockroaches display a higher concentration of trehalose in the hemolymph than the males, and this fluctuates in a cyclic pattern that correlates with the maturation of oocytes in the reproductive cycle. When the hypertrehalosemic hormone (HrTH) is silenced in female cockroaches via double-stranded RNA, the peak in circulating trehalose, as well as oviposition is significantly delayed in virgin females and in some instances, deformed ootheca were produced.[14]

AKH peptides also have functions that are not directly related to energy metabolism, such as an implied role in the immune response of locusts and activation of antioxidant mechanisms. These studies have been reviewed.[16] In certain insects (firebug, cricket), AKH peptides have an effect on the locomotory activity. Interestingly, AKH-deficient *D. melanogaster* shows normal circadian locomotory activity (peaks at dawn and dusk) but do not display starvation-induced hyperactivity that is observed in normal (wild-type) flies; this implies that AKH regulates "foraging" locomotion.[17]

In summary, although the mobilization of substrates for high-energetic phases is the major and most well-known function of AKH peptides in insects, these peptides are truly multifunctional and exert pleiotropic action as is also known from the majority of other hormones in invertebrates and vertebrates.

Chapter 29

Allatostatins

Stephen S. Tobe and William G. Bendena

ABSTRACT

There are three families of allatostatins (ASTs), peptides discovered on the basis of their ability to inhibit juvenile hormone (JH) production in insects: the cockroach type representing the FGLa family, the cricket type representing the $W(X)_6Wa$ family, and the *Manduca* type representing the PISCF family. Each of these families performs multiple functions, including the modulation of myotropic activity and neurotransmission. These effects are species and order specific, and each family inhibits JH production in only a limited number of related orders, suggesting that their original functions were probably not the inhibition of JH production. This chapter summarizes the expression and distribution of these peptides, their interaction with receptors, and their biological activities.

DISCOVERY

JH, produced by the insect corpora allata (CA), is the regulator of metamorphic and reproductive functions in most insects. The JHs are a family of sesquiterpenoid compounds, the most ubiquitous of which is JH III. The production of JHs and related compounds[1] are regulated by other compounds originating in the central nervous system, principally neuropeptides. Measurement of the production of JH has revealed large changes in the rates of biosynthesis, which are also believed to be reflected in changes in the titers in the hemolymph.[28] ASTs, inhibitors of production of JH, were hypothesized to exist in 1980,[27] after demonstrations by Scharrer and colleagues[24] that presumed that peptidergic factors in the brains of cockroaches modulate the volume of the CA, which in turn was believed to translate into changes in hormone production.

The first ASTs were discovered in the cockroach, *Diploptera punctata*, and are members of the 'FGLa' family (the common C-terminal sequence for all members of the family) (FGLa-related allatostatins—FGLa/ASTs).[5,34] Two years later, the first member of the 'PISCF' family was identified in the moth *Manduca sexta* (PISCF-related allatostatins—PISCF/AST).[5,16] In both instances, the ability of the peptides to inhibit the production of JH was the principal assay used for identification, after HPLC separation of brain extracts. Because the first function ascribed to the families was inhibition of JH production, the name 'allatostatin' was applied to the families. The FGLa/ASTs have numerous other biological actions, including modulation of myotropic activity and gut enzyme activity, and they also can act as neurotransmitters. The FGLa/AST family is now known to consist of >400 different peptides,[11] and members are found in many invertebrate phyla, including most arthropods examined to date, as well as in arachnids and nematodes (Table 1). However, only in cockroaches, crickets, and termites do they function as inhibitors of JH production.[25] DNA sequencing projects have indicated that the PISCF/AST family is also widely distributed, occurring in annelids, arachnids, molluscs, crustaceans, and insects. Evidence that PISCF/ASTs inhibit JH biosynthesis is limited to the dipteran *Aedes aegypti* and Lepidoptera.

A third family of peptides was subsequently discovered in crickets and is characterized by the consensus sequence $W(X)_6Wa$,[20] which is characteristic of the Myoinhibitory peptide (MIP) family of peptides. This family of peptides is widely distributed throughout the protostomes. The ability to inhibit JH production has been shown in *Gryllus* and *Tenebrio molitor*. Although this family does have allatostatic activity in a limited number of species, it is not classified as an allatostatin because of its prior discovery as a member of the MIP family. The peptides of this family are now known as the MIPs.

STRUCTURE OF ALLATOSTATIN PRECURSORS

The first preproallatostatin protein was characterized from a gene sequence obtained from the cockroach, *D. punctata*.[2,6] The *Diploptera* AST precursor has 370 amino acid residues and contains 13 unique ASTs that range from 6 to 18 amino acids and, when processed, share a COOH-terminal core sequence Y/FXFGL/I-amide. Each AST in the precursor is followed by glycine and a dibasic KR or RK endoproteolytic cleavage site. After cleavage, the terminal glycine functions as the substrate for peptidyl-glycine α-amidating monooxygenase. Purified FGLa/ASTs are C-terminally amidated and require amidation for biological activity, confirming

TABLE 1 Sequences of Representative Members of the Three Allatostatin Families

Species	Designation	Sequence
FGLa/AST family		
Diploptera punctata	Dippu-AST 1	LYDFGLa
	Dippu-AST 2	AYSYVSEY**KR**LPVYNFGLa
	Dippu-AST 5	DRLYSFGLa
Drosophila melanogaster	Drome-AST 3	SRPYSFGLa
Bombyx mori	Bommo-AST 5	ARMYSFGLa
C. elegans	*nlp-5**	ALSTFDSLGGMGLa
	*nlp-6**	MAAPKQMVFGFa
		YKPRSFAMGFa
		AAMRSFNMGFa
		LIMGLa
W(X)$_6$Wa/MIP family		
Gryllus bimaculatus	Grybi-AST 1	AWRDLSGGWa
	Grybi-AST 2	AWNNLGSAWa
	Grybi-AST3	GWRDLNGGWa
	Gybi-AST4–6	GWQDLNGGWa
PISCF/AST family		
Manduca sexta	Manse-PISCF AST	pQVRFRQCYFNPISCF-OH
Drosophila melanogaster	Drome-PISCF AST	pQVRYRQCYFNPISCF-OH
Anopheles gambiae	Anoga-PISCF AST	pQIRYRQCYFNPISCF-OH

One dibasic cleavage site in Dippu-AST 2 is shown in bold. Substitutions in the PISCF family are underlined.
*C. elegans *AST-like peptides have no designation but are derived from the* nlp-5 *and* nlp-6 *genes.*

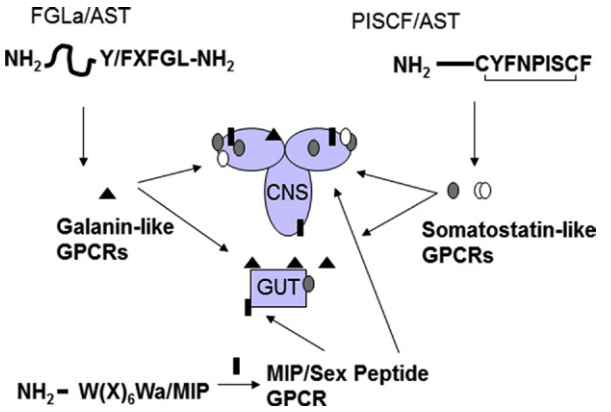

FIGURE 1 The FGLa/ASTs interact with two galanin-like G protein-coupled receptors (GPCRs). One type of receptor may be more prevalent in the CNS and the other more abundant in the gut tissue. PISCF/ASTs with oxidized cysteines C7–C14 binds with two somatostatin-like receptors. In *Drosophila*, these receptors seem to be localized to the pars intercerebralis of the brain and the optic lobe. Somatostatin-like receptors have not been found to be expressed in the gut although PISCF/AST immunoreactivity is present in gut tissues. WX_{6W} ASTs/MIP interact with MIP/sex peptide GPCRs although expression data are not yet available. The MIP/ASTs share sequence similarity with myoinhibitory peptides (MIPs) and galanin. As the N-terminus of galanin is required for receptor binding, MIP/ASTs and myoinhibitory peptides could hypothetically interact with the galanin-like GPCRs.

that these signals are utilized *in vivo*. The FGLa/ASTs are clustered in groups within the precursor, with each group separated by spacer regions containing acidic amino acids which effectively neutralize the basic charge contribution of the FGLa/ASTs and their processing sites (Fig. 1).

The structure and organization of the *Diploptera* precursor serve as a prototype for all FGLa/AST precursors identified to date. There is variation between different orders in the number of FGLa/ASTs present in their respective precursors. For example, Lepidoptera FGLa/AST precursors contain 8–10 peptides, Dipterans, 4–5, and crustacean AST precursors contain up to 50 peptides (see genome databases).

In crickets, the W(X)$_6$Wa/MIP precursor expresses multiple peptides structurally similar to the Dippu FGLa/AST precursor. The preproAST polypeptide sequence for the W(X)$_6$Wa cricket family of ASTs was first identified from cloned DNA in *Drosophila*[32] and the cricket, *Gryllus bimaculatus*.[31] The *Drosophila* W(X)$_6$Wa precursor contains sequences for five unique W(X)$_6$Wamide peptides, which are followed by GKR, indicating COOH-terminal amidation and cleavage. The *Gryllus* precursor contains sequences for six cricket ASTs, four of which are unique in sequence. The spacing between W residues is generally 6 amino acids but has been found to be 7 or 8 in select organisms.[12,29]

The sequence of the preproAST polypeptide of *Manduca* PISCF was deduced from the DNA sequence in the moth, *Pseudaletia unipuncta*[13] and in *Drosophila*.[23,33] A single 15 amino acid AST peptide flanked by dibasic endoproteolytic cleavage sites is released as a nonamidated peptide from the carboxyl terminus of the 125 amino acid precursor. The PISCF/AST differs between *Manduca* and *Drosophila* by one conservative amino acid substitution (Y^4 for F^4) and an additional substitution in *Anopheles*/*Aedes* (I^2 for V^2).[19] A more dramatic alteration occurs in *Acrythosiphon pisum* that differs from *Drosophila* through the loss of pQ^1 and C-terminal amidation.[12] In all PISCF/ASTs, the C residues at –2 and –9 from the C-terminus are maintained (Table 1).

DISTRIBUTION OF mRNA AND PEPTIDES

The distribution and expression of ASTs have been examined with antibodies specific to AST peptides, through tissue in situ hybridization whereby specific nucleic acid probes

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

detect cells expressing AST mRNA and by quantitative PCR of individual tissues.[7,8] The following describes the extensive expression of FGLa/ASTs noted in *D. punctata*. Four medial cells of the pars intercerebralis express FGLa/ASTs and extend axons that arborize and terminate adjacent to 25–30 lateral neurosecretory cell bodies of the protocerebrum. These lateral cells project FGLa/AST-immunoreactive nerve fibers in the nervi corporis cardiaci (NCC) II and arborize within the corpus cardiacum and CA. Extensively arborizing AST-immunoreactive neurons are also detected in the optic, central and antennal brain lobes as well as in the pulsatile organ muscle.[26] Clearly, the brain and associated structures contain large amounts of FGLa/ASTs, but we do not know the relative percentage of this material that projects into the CC and CA, for inhibition of JH biosynthesis. However, these observations do suggest that the FGLa/AST peptides play other major roles in the brain.

FGLa/AST-immunoreactive neurons innervate the rectal dilator muscles, muscles of the rectum, anterior hindgut, midgut,[26] and the lateral and common oviducts. FGLa/AST-immunoreactive cells are also detected in open-type midgut endocrine cells. These cells extend from the basal lamina to the lumen of the midgut and are sites of AST mRNA synthesis. AST expression and production are also found in a population of circulating hemocytes that comprise approximately 5% of the total hemocytes[25] In other insects, such as flies, moths, and earwigs, FGLa/ASTs are detected in the cells of the brain and optic lobe but generally are not detected in nerve fibers extending within the CA. Immunoreactive nerve fibers have been detected in the foregut, midgut, and hindgut of *Locusta* but such localization is rare in other insects. However, expression in endocrine cells of the midgut is common.[2] Immunoreactive midgut cells for each family of AST have been mapped in *Drosophila*.[30]

Little data are available on the expression of the two FGLa/AST receptors in *Drosophila*. However, microarray suggests that one receptor subtype may predominate in brain and the other in the gut.[4]

PEPTIDE PROCESSING

The occurrence of multiple FGLa/ASTs in the preproallatostatins, with associated cleavage and amidation signals, suggests that all of the peptides are probably cleaved and present at the same time in any given tissue. Prohormone convertases are probably responsible for the liberation of the various AST peptides. There is no evidence for selective processing of the precursor or of tissue-specific processing.

Degradation of the FGLa/ASTs to terminate their biological actions occurs in several different ways and is dependent on the precise sequence of the peptides and the tissues in which degradation is studied. For example, endopeptidases as well as amino- and carboxypeptidases are the principal proteolytic enzymes for degradation of the ASTs.[9] In tissues, the FGLa/AST peptides are cleaved by carboxypeptidases to yield the corresponding nonamidated FG-OH peptides (removal of L-amide), resulting in inactive peptides. Hemolymph of *D. punctata* does not contain carboxypeptidases, but rather aminopeptidases, which produce peptides with an intact core sequence, and hence continued but reduced biological activity. Interestingly, changes in the sequence can also alter the half-life of the AST peptides. For example, Dippu-AST 5 has a much longer half-life than other ASTs in hemolymph. To date, the peptidases responsible for the cleavage of the ASTs have not been identified or cloned.

ALLATOSTATIN RECEPTORS

The sequencing of the *Drosophila* genome has led to the identification of at least 32 neuropeptide-encoding genes. These neuropeptides interact with G protein-coupled receptors (GPCRs) which are characterized as seven-transmembrane domain receptors (see Figure 1). *Drosophila* has approximately 160 GPCRs of which 44 have characteristics of receptors for peptide ligands.[10]

The presence of multiple FGLa/AST receptors was first suggested by ligand–membrane binding studies in the cockroach, *D. punctata*.[26] Two *Drosophila* genes encode GPCRs functionally specific for FGLa/AST peptides. Both GPCRs belong to the rhodopsin-like GPCR family and are most closely related to the vertebrate galanin receptors. The first, gene, CG2872, is located at chromosomal locus 3D6-E1 and encodes a GPCR (AlstR, Dar-1) of 394 amino acids that responds to FGLa/ASTs.[3] AlstR/Dar-1 mRNA is not expressed in embryos but appears in larvae, pupae, and adults. Expression is found in both heads and bodies of adults. The second *Drosophila* gene, CG10001 (Dar-2), is located at chromosomal locus 98DE and encodes a GPCR of 357 amino acids.[18] Dar-2 is probably a paralog of AlstR/Dar-1 as Dar-2 shares 47% overall sequence identity and 60% identity in the transmembrane regions. Dar-2 mRNA expression begins in 8- to 16-hour embryos and is found in all later stages of development. In third instar larvae and adults, mRNA expression in the gut/abdomen is greater than that in isolated brain/head. RNAi knockdown of either Dar-1 or Dar-2 does not alter juvenile hormone biosynthesis or release and therefore, they do not seem to be involved in the regulation of JH production in *Drosophila* (Bendena and Tobe, unpublished). AST receptor (Dar-1) orthologs have been sequenced in *D. punctata*, *Periplaneta americana*, and *Bombyx mori*. *Bombyx* fifth instar larvae express GPCR mRNA in the foregut, midgut, hindgut, and brain. Additional AST receptor orthologs have been identified through sequencing projects to include invertebrates such as *Apis mellifera*, *Anopheles gambiae*, and *Caenorhabditis elegans*.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

The *Drosophila* $W(X)_6W$/AST or MIP receptor gene has been identified as the sex peptide receptor (CG16752),[15,22] which corrects the original assignment (CG14484 = CG30106), and which is now known as a CCHamide receptor.

Two *Drosophila* PISCF/AST receptor genes (CG7285 and CG13702) have been identified in two separate functional assays.[17] CG7285 and CG13702 encode GPCRs of 483 amino acids (Drostar1) and 549 amino acids (Drostar2), respectively (Fig. 1). Both receptors share 60% overall identity and 76% identity in the transmembrane regions. These genes are paralogs located at cytological locus 75D1 and 75D2 and are separated by 80 kb. Drostar 1 and 2 are orthologs of the vertebrate somatostatin receptors sharing 42% amino acid identity in the transmembrane region. This identity is concentrated in those parts of the transmembrane regions facing the cytosol where the receptors couple with their heterotrimeric G-protein. In situ hybridization has localized the Drostar genes to cells in the lamina region of the optic lobes and to cells of the pars intercerebralis of the brain of adult flies.[17]

STRUCTURE ACTIVITY AND ACTIVE CONFORMATIONS

Structure–activity studies have shown that the core sequence for biological activity in the FGLa family is the C-terminal pentapeptide Y/FXFGL/I-a although some analogs of FGLa/AST (Y/FX region substituted with an aromatic group) do show activity.[14,35] Amidation is also essential for biological activity. The consensus sequence for the cricket family seems to be $W(X)_6Wa$ and amidation is similarly necessary. The minimal biologically active region for the PISCF family is unknown although the oxidation of the two cysteine residues is critical for receptor binding. Receptor binding activity was not dependent on the presence of a blocked N-terminus.[16]

The core region of the FGLa/AST family seems to possess secondary structural elements, which are probably essential for interaction with the receptors. In particular, this region probably contains a type- II β turn, with the most critical residues being F and L, at least in selected ASTs. Incorporation of moieties promoting a β turn in the core region permitted the synthesis of analogs of these peptides that exhibit high biological activity.[21]

BIOLOGICAL ACTIONS

Based on immunocytochemical distribution, isolation, and sequencing, or mining of genomic databases, it has become clear that the AST families are ubiquitous throughout the Class Insecta and many other invertebrate phyla, and regulate many processes in addition to JH production.[25]

Other actions of ASTs have been largely defined in individual species, and therefore, it is unknown at present if such actions can be inferred across the insects. In the case of the FGLa/AST family, such actions include 1. the inhibition of vitellogenin production by fat body in cockroaches, 2. the inhibition of myotropic activity, particularly in gut tissue of Dictyoptera and Orthoptera, 3. regulation of release of digestive enzymes in the midgut of cockroaches, 4. neurotransmission in crab stomatogastric ganglion, and possibly cockroach CNS. Treatment of cultured mammalian neurons expressing Dar-1 receptor with the FGLa/AST ligand is being used to selectively silence these neurons.[25]

Biological actions of the $W(X)_6Wa$/MIP family include 1. inhibition of ecdysteroid biosynthesis (prothoracicostatic activity) by prothoracic glands in silk moth and ovaries of crickets, 2. inhibition of locust oviduct muscle, and 3. inhibition of spontaneous muscle contraction in foregut of the cockroach.

The PISCF/AST family displays biological effects similar to the other two AST families, dramatically inhibiting contraction in larval *Drosophila* heart muscle for example, (hence, its name *flatline*) and its localization in gut suggests similar functions in this tissue. This peptide family may also play a role in the regulation of migratory flight in Lepidoptera. Although the PISCF/AST family seemed to inhibit JH production only in the members of the Lepidoptera, the discovery of a conservatively modified PISCF peptide in the *A. gambiae* genome database and its apparent ability to inhibit JH production in adults of another mosquito, *A. aegypti*[19] suggests that this peptide family may be important as an allatoregulator in at least some Diptera as well.

The modes of action of these three peptide families remain largely unexplored, although studies with the FGLa/AST family indicate that the second messengers cAMP, cGMP, and calcium are all effectors. With our present knowledge of second messenger cascades and signaling pathways, the time is appropriate for a reexploration of this area.

CONCLUDING REMARKS

As is the case with many invertebrate peptide families, the allatostatin families are multifunctional peptides. The very large number of peptides in the FGLa/AST family, with significant variation in length, but conservation of the core C-terminal pentapeptide, indicates that this family serves important functions across the invertebrates. However, the relatively limited number of orders in which they act as inhibitors of JH biosynthesis[25] also suggests that this function appeared secondarily; thus, the FGLa/AST family was coopted as inhibitors by cockroaches, crickets, and termites early in evolution. In these instances, specificity of function resides with the tissues and the cognate allatostatin receptors. Because the CA of these orders are heavily invested by FGLa-containing nerves, with multiple release sites, the local concentration of the peptides is probably very high.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

It is therefore conceivable that differing concentrations of the peptides or differing receptor affinity could confer multiple functionality. Receptor affinity in both the CA and other target tissues such as gut and oviduct muscle no doubt dictate responsiveness. The occurrence of at least two receptor types in insects and their similarity to the galanin GPCRs suggests an ancient origin. The same ideas can be applied to the evolutionary necessity of varying insects to adopt alternative peptides as ASTs. A clue may come from the cricket MIP/ASTs whereby the most potent molecule resembles the mammalian galanins and hence may interact with the galanin-like receptor as does the FGLa/AST. Subtle changes in the receptor "binding pocket" may have provided the "evolutionary pressure" to solicit other peptide molecules to perform the "allatostatic" function. The PISCF/AST is further removed in sequence yet has the same functional quality as the FGLa/ASTs in that a major role is inhibition of muscle contraction. As muscle contraction is the probable ancestral function, a reasonable hypothesis would be that all ASTs were coopted for allatostatic regulation somewhat later in evolutionary time.

Chapter 30

Allatotropin

Frank M. Horodyski

ABSTRACT

Allatotropin (AT) was first characterized in the lepidopteran insect, *Manduca sexta*, based on its ability to stimulate juvenile hormone biosynthesis by adult female lepidopteran corpora allata *in vitro*. Since that initial discovery, a family of related peptides were isolated or predicted from genomic sequences from a large number of invertebrates. The AT gene is expressed in numerous defined neurons in the central and peripheral nervous systems, and in some insects is expressed in peripheral tissues, notably the gut and Malpighian tubules. Myotropic activity is stimulated in a wide range of invertebrates suggesting that this could be the ancestral role of this peptide. This widespread distribution of AT and its receptor is consistent with the multiple biological activities of AT which include myotropic and cardioacceleratory activities, regulation of fluid secretion, nutrient allocation, and entrainment of the circadian clock.

ISOLATION AND STRUCTURE OF ALLATOTROPIN

The precise regulation of juvenile hormone (JH) levels in the insect hemolymph is fundamental to the control of development, metamorphosis, and reproductive physiology. Among the mechanisms for controlling JH levels is the stimulation or inhibition of its biosynthesis. An *in vitro* radiochemical assay was developed to measure JH biosynthesis by the corpora allata (CA), the source of JH in insects.[25] In this assay, a radioactively labeled precursor to JH, ^{3}H- or ^{14}C-[methyl]-methionine, was incubated with the CA and the incorporation of label into the methyl ester of JH allowed its quantification after the separation of the precursor from the product. With this assay, the neuropeptide allatotropin (AT) was isolated based on its ability to stimulate JH biosynthesis by adult female CA.[13] This C-terminal amidated tridecapeptide is now referred to as Manse-AT (for *Manduca sexta* allatotropin).

Manse-AT is a member of a peptide family whose sequences have been determined by biochemical methods, deduced from gene sequences, or identified in silico from nucleotide sequence databases of insects whose genomes have been sequenced.[7,33] The rate of identification of new AT-related peptides has rapidly increased as new genomic and EST data are being acquired. Thus far, 34 unique sequences have been determined or predicted for this peptide family, and the number will undoubtedly increase as genome sequences from additional species are acquired (Table 1). The peptide sequences have rapidly evolved, but some defining features of the sequences are conserved. A glycine residue followed by phenylalanine and a basic amino acid is often present at or near the N-terminus. At the C-terminus, all peptides contain an aromatic residue followed by the C-terminal amidation, and this is often preceded by a basic amino acid (arginine or histidine). Truncated Manse-AT lacking the N-terminal 5 amino acids retains full biological activity on the CA.[13] However, the truncation of the N-terminal 6 amino acids results in a 10-fold decrease in biological activity. The C-terminal amide is essential for activity. Among the insects, it is noteworthy that a sequence encoding a peptide related to AT is not found in the genomes of the fly *Drosophila melanogaster*, the bee *Apis mellifera*, or the parasitic wasp *Nasonia vitripennis*; indicating that the AT gene was probably lost in these insects.[11] This suggests that either the regulatory functions of AT are performed by other peptides or that the regulatory functions of AT are missing in these insects.[19] Besides the insects, a related peptide was isolated and characterized or predicted in several species of mollusks, annelids, an arachnid, and in a crustacean.[5,7,12,31] Interestingly, several peptides have been isolated from mollusks and annelids based on their myotropic activity.[7,12] No evidence for a peptide structurally related to AT has been found invertebrates, so this peptide family probably exists only in invertebrates.

There are reports of other peptides that are structurally unrelated to Manse-AT, which have allatotropic activity as shown with the *in vitro* radiochemical assay. The 36 amino acid sex peptide from *D. melanogaster* stimulates JH biosynthesis in *D. melanogaster* and *Helicoverpa armigera*.[8] A predicted decapeptide, Spofr-AT 2, possesses allatotropic activity on *Spodoptera frugiperda* CA.[2] The C-terminal 6 amino acids of Spofr-AT 2 are identical to Manse-AS, an allatostatin peptide that inhibits JH biosynthesis. Thus,

multiple unrelated peptides might function in an insect to stimulate JH biosynthesis.

THE ALLATOTROPIN GENE AND ITS EXPRESSION

The AT gene was first characterized in *M. sexta* and the peptide is processed as part of a larger propeptide.[7] In *M. sexta*, the AT gene is transcribed as three mRNAs that differ by alternative splicing. Each mRNA can encode Manse-AT, and the alternative exons contained in the larger mRNAs each encoding an allatotropin-like (ATL) peptide whose sequence is related to Manse-AT. A total of three ATL peptides are predicted from *M. sexta* cDNA sequences. Subsequently, gene sequences were determined or predicted from other insects, and alternative splicing of AT mRNAs with the predicted presence of ATL peptides was found in several lepidopteran insects. Outside the Lepidoptera, the predicted organization of the propeptide is conserved, but the only example of two potential AT-like peptides is in the tick, *Ixodes scapularis*, in which an EST sequence predicts two AT peptides (Accession: EEC06620).

Expression of the AT gene was first described in the lepidopteran insects *M. sexta* and *Pseudeletia unipuncta*, and later in multiple other lepidopterans.[7] In all cases, the gene is expressed in multiple cells throughout the central and enteric nervous systems. There are some differences in cell localization between insect species, but the most predominant expression in larvae is in the frontal ganglion and terminal abdominal ganglion followed by the brain and subesophageal ganglion. Additional cells contain AT mRNA in the adult including neurosecretory cells in each abdominal ganglia and brain, and a cluster of sex-specific cells in the posterior region of the terminal ganglion.[7,29] In *Bombyx mori*, AT mRNA is in the midgut,[23] and in *S. frugiperda*, AT mRNA is in the larval gut, in the adult testes and ovaries, and in the follicle cells between the oocytes.[1] Midgut and ovary expression is also present in *Samia cynthia ricini*.[28] The widespread expression of AT throughout the insect is consistent with multiple biological roles of the peptide throughout development.

The multiple Manse-AT mRNAs derived from alternative splicing are expressed in a stage- and tissue-specific manner.[15] Because each mRNA is predicted to encode AT and a unique set of ATL peptides, the diversity of peptides products from a single gene could vary in a dynamic manner between tissues and during development. Stage- and tissue-specific expression of alternatively spliced AT mRNAs is also documented in other lepidopteran insects.[7]

The localization of an AT-like peptide was characterized in a large number of insects by immunocytochemistry.[7] In general, there is a close correlation between AT-immunoreactive cells and those that contain AT mRNA. Additional information can be obtained with AT antiserum, such as the location of axons and the localization of release points around the adult CA in lepidopteran insects for the allatotropic action of the peptide.[6,29] The distribution of AT-immunoreactive cells can often provide clues for additional roles of the peptide, such as the presence in the *M. sexta* developing antennal lobe suggests a role in the formation of olfactory glomeruli.[30] The presence of AT-like immunoreactivity suggests the widespread presence of AT in insects, but the existence of crossreactive substances cannot always be ruled out.

BIOLOGICAL ACTIVITY OF ALLATOTROPIN

Activity in Lepidopteran Insects

This initial report on the identification of Manse-AT showed a specific stimulation of JH biosynthesis by CA from adult female lepidopteran insects, in which JH biosynthesis was stimulated by about 4-fold.[13] Subsequent studies showed the existence and activity of the peptide to be more widespread. In numerous lepidopteran insects, Manse-AT stimulates JH biosynthesis by the adult female CA. However, in some, but not all lepidopteran species, Manse-AT stimulates JH biosynthesis by larval CA.[3,7] The key to this finding is the observation that endogenous JH esterases in the CA can sometimes prevent the detection of biological activity by the use of ^{3}H-methylmethionine in the *in vitro* radiochemical assay, because the ^{3}H-methyl group is incorporated into the labile methyl ester of JH.[3] When ^{3}H-propionate is used as a precursor, the label is incorporated into the carbon skeleton of JH-I and JH-II, homologs that are synthesized by larval CA. However, the biological activity of Manse-AT is not detected on larval *M. sexta* CA using ^{3}H-propionate, so the activity of Manse-AT on larval CA is not universal in Lepidoptera. Together, these results show that an important function of AT in Lepidoptera is the stimulation of JH biosynthesis by the CA.

Because AT was first isolated based on bioactivity on the CA, there is an inherent bias in thinking of AT as solely an allatotropic peptide. We are limited to the use of established bioassays largely done *in vitro*, so important functions for peptides might be missed until additional assays are used to characterize the peptide. Even still, important roles for peptides might be unknown to this day because of the lack of suitable means to detect their function. Indeed, many neuropeptides possess multiple bioactivities that can differ during different life stages or target tissues. Manse-AT and its homologs stimulate muscle contractions and possess cardioacceleratory functions in multiple insect species.[7] Also, Manse-AT increases oscillations of the ventral diaphragm, which surrounds the nerve cord in the lepidopteran *P. unipuncta*.[14] This activity could enhance the circulation of the peptide in the hemolymph after its secretion.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

With midgut tissue mounted on a modified Ussing Chamber, Manse-AT inhibits active ion transport across the larval midgut epithelium.[17] This activity is only found in feeding *M. sexta*, and the peptide is inactive when tested on molting or wandering *M. sexta*, or on midguts of two other lepidopteran insects. This activity suggests a role for Manse-AT in regulating nutrient absorption from the diet. It is not known whether this bioactivity of AT is shared among other insect orders, because technical considerations prevent the use of the short circuit bioassay in most other insects, because a large tissue size is required to avoid experimental artifacts. AT also stimulate the release of digestive enzymes from the gut of *S. frugiperda*.[18]

Although the Malpighian tubules are not often thought of as a target of AT, Manse-AT inhibits fluid secretion by larval *M. sexta* Malpighian tubules (G.M. Coast, personal communication). The effect of Manse-AT on growth, development, and food consumption was investigated by injection into larval *Lacanobia oleracea*.[4] The lack of an effect in this assay was attributed to the short half-life of the peptide in the hemolymph, that is, <5 min. By contrast, injection of Manse-AT into the last instar *S. frugiperda* reduced weight gain, increased mortality, and reduced oviposition.[22]

The lack of AT in *D. melanogaster* precludes the investigation of AT function using genetic tools available in that insect. The technique of dsRNA-mediated RNA interference has the potential to knock down the expression of any gene in any insect provided the gene sequence is known. The challenges to be overcome include the delivery and uptake of dsRNA to the tissue of interest, the nervous system in the case of neuropeptides. The only study to test the effects of reducing AT expression thus far is the knockdown of Spofr-AT 2 mRNA in *S. frugiperda*.[9] This peptide shares identify with Manse-AS at the C-terminus and is structurally unrelated to Manse-AT. Feeding or injection of Spofr-AT 2 dsRNA to larvae leads to reduced mRNA levels in the brain and gut, and results in an increase in JH levels and a prolongation of the last larval stage, indicating that this peptide acts as an allatostatin in larvae. By contrast, injection of Spofr-AT 2 dsRNA to adults leads to reduced mRNA levels in the brain, and results in decreased JH levels in young adults and a decreased oviposition rate, supporting an allatotropic role in adults.

The Manse-ATL peptides, predicted from the cDNA sequences of alternatively spliced AT mRNAs, were tested for bioactivity using three different assays. Manse-ATL-I (the ATL peptide with the greatest structural identity to Manse-AT) stimulates JH biosynthesis by the adult female *M. sexta* CA at 20 nM.[15] All three Manse-ATL peptides inhibition transport across the midgut epithelium at 100 nM. Also, each Manse-ATL peptide stimulates foregut contractions in *L. oleracea*, with Manse-ATL-I being the most potent, and Manse-ATL-III the least potent (N. Audsley, personal communication). Thus, the expression of the longer alternatively spliced mRNAs would lead to the production of multiple peptides that might provide a more robust biological response.

Changes in Manse-AT mRNA levels can also provide clues to the functions of the peptide. In larval *M. sexta*, starvation, parasitism, or feeding of an ecdysteroid analog correlates with the upregulation of a specific alternatively spliced Manse-AT mRNA, implicating Manse-AT and/or Manse-ATL peptides in the physiological response to nutrient deprivation and increased JH levels that occur during these treatments.[16] In the monarch butterfly, *Danaus plexippus*, summer butterflies contain high JH levels compared with that of migrants which are JH deficient.[35] Summer butterflies also contain higher levels of AT mRNA, which invoke a role for AT as one of the factors that controls JH levels and prevents the triggering of migration.

Activity in Other Insect Orders

In *Aedes aegypti*, larval nutrition influences the activity of the CA at adult emergence, so that a mosquito reared under suboptimal conditions has low JH synthesis.[20] CA activity in the adult is correlated with AT levels in the head measured by ELISA, providing strong evidence for the role of AT in the control of JH levels in the mosquito.[10] Stimulation of JH biosynthetic activity by the CA *in vitro* has also been seen in dipteran, coleopteran, and dermapteran insects by Manse-AT or the endogenous peptide by the *in vitro* radiochemical assay, indicating that this peptide family can regulate JH levels in many insect orders.[7] A myotropic role for AT was found in many insects from the orders Orthoptera, Dictyoptera, Hemiptera, and Coleoptera, indicating that this is a conserved function for this peptide family.[7]

In the kissing bug, *Triatoma infestans*, an AT-like peptide is involved in the elimination of urine after ingestion of a blood meal.[27] The Malpighian tubules secrete an AT-like peptide that stimulates peristaltic contractions of the hindgut. This activity induces diuresis *in vitro* using a Malpighian tubule–hindgut preparation, because secretion can be blocked by an antiserum to *A. aegypti* AT. An effect was also observed *in vivo*, because injection of AT antiserum inhibits urine production in blood-fed insects.

A role for AT in the regulation of the circadian clock is seen in the cockroach, *Leucophaea maderae*.[24] AT-like immunoreactivity is present in the optic lobe, which sends processes into the accessory medulla. Injection of AT into the medulla results in phase shifts in circadian locomotor activity.

Activity in Other Invertebrates

As previously mentioned, peptides similar to Manse-AT have been identified and characterized in annelids and mollusks, phyla, which lack JH. In many cases, these peptides were

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

isolated and characterized based on their myotropic activity. This finding led to the suggestion that the ancestral role of AT is myotropic, and its function to stimulate JH biosynthesis is secondary and was acquired in insects.[7] The function of an allototropin-related peptide (ATRP) is most extensively characterized in *Aplysia californica*.[12] The central actions of ATRP on a defined motoneuron that drive ingestive motor programs, and its peripheral actions on muscle contractions, implicate ATRP in the regulation of feeding.

THE ALLATOTROPIN RECEPTOR

The majority of neuropeptide receptors are members of a large family of structurally related proteins that contain seven hydrophobic membrane-spanning regions, the G protein-coupled receptors (GPCRs). Ligand binding to a GPCR leads to activation of a GTP-binding protein (G protein) that induces alterations in the level of second messengers which exert functional biochemical changes in the target cells and in the organism. The AT receptor (ATR) was first identified in the silkmoth, *B. mori* by a systematic screen to identify all GPCRs expressed in the corpora cardiaca-corpora allata complex, followed by functionally testing the response of GPCR-expressing *Xenopus laevis* oocytes elicited by known neuropeptides.[34] One expressed GPCR (BNGR-A16) specifically responds to AT in a dose-responsive manner. A highly related GPCR (BNGR-A5) shares a high degree of structural identity to BNGR-A16 but has not been tested for a functional response to AT. Thus, it is not yet known whether BNGR-A5 represents a second receptor for AT, or whether it responds to a different peptide. A similar approach was used to identify the ATR from *A. aegypti*, and its functional properties were confirmed in transfected mammalian cells tested with mosquito AT.[21]

PCR and genomics-based approaches were used to identify an ATR from *M. sexta*[11] and *Tribolium castaneum*.[32] In addition, similar sequences were identified in several additional insects by in silico screening of genomic or EST sequences. It is probable that these receptors recognize the endogenous AT, but their functional properties have not yet been tested. Consistent with the lack of AT in *D. melanogaster*, no sequence related to ATR was identified in the genome of that insect; however, a sequence related to ATR was identified in *A. mellifera* and *N. vitripennis*, suggesting that a hymenopteran peptide may have diverged from a Manse-AT-related sequence and might act through the identified GPCR.

The *M. sexta* ATR expressed in three separate transfected mammalian cell lines is specifically activated in a dose-responsive manner by low or sub-nanomolar concentrations of Manse-AT and each Manse-ATL peptide.[11] Interestingly, the Manse-ATL peptides are more potent than Manse-AT in each cell line. The expressed *T. castaneum* ATR is activated by low or sub-nanomolar concentrations of the endogenous Trica-ATL, and is also activated by the heterologous peptides Manse-AT and Locmi-AG-myotropin-I (Locmi-AT), but at a lower potency.[32] For both the Manse-ATR and Trica-ATR expressed in mammalian cells, the receptor is coupled through two second messenger pathways, resulting in increases in cAMP and intracellular calcium.[11,32] Early work showed that Manse-AT stimulates inositol phosphate production in adult female CC-CA, and the elevation of intracellular Ca^{2+} elicits an increase in JH biosynthesis.[26]

The biological actions of neuropeptides require the presence of a receptor in target cells and the availability of peptide to interact with the receptor. In larval *B. mori*, ATR mRNA is present at highest levels in the brain, CC-CA, epidermis, and testes, and the relative mRNA levels in tissues varies depending on the precise developmental stage.[34] In *M. sexta*, ATR mRNA is present at the highest level in larval Malpighian tubule, gut, testes, CA and CC; and is also present in the adult CC-CA complex.[11] In *T. castaneum*, ATR mRNA is present at highest levels in the head, fat body, and reproductive system, with a higher level in males compared with that in females.[32] In *A. aegypti*, ATR mRNA is present in the highest quantities in the CA, nervous system, and reproductive system.[21] The widespread distribution of ATR mRNA in these insects indicates multiple and diverse actions of AT that are elicited throughout the development of the insect. This is consistent with the results of biological assays, in which the target tissues of AT express the receptor. Additionally, novel functions for AT are suggested by the presence of ATR in tissues which are not known targets for AT, such as the reproductive system, and will drive further studies to more completely define the function of AT in insects and other invertebrates.

Chapter 31

B-Type Allatostatins and Sex Peptides

Hans Peter Vandersmissen, Ronald J. Nachman and Jozef Vanden Broeck

ABSTRACT

In many species, mating induces many behavioral changes in the female. For *Drosophila melanogaster*, the sex peptide (SP) has been identified as the main molecular factor behind these responses. Recently, the sex peptide receptor (SPR), a GPCR activated by SP, has also been characterized as responsive to *Drosophila* myoinhibiting peptides, a conserved peptide family that is also known as B-type allatostatins. These peptides bear the C-terminal hallmark of –WX_6Wamide. Given this unexpected link between these peptides, they will be covered together in the following chapter.

DISCOVERY

Sex Peptides

Sex peptide (SP, also known as Accessory gland peptide 70A), was characterized in 1988 as a factor synthesized in the *Drosophila* male accessory glands and transferred to the female on copulation. The observed effects were an increase in egg laying and a loss of receptivity of the female toward new mating partners. The sequencing of the peptide and cDNA revealed a 36-aa long peptide, preceded in its precursor by a 19-aa hydrophobic signal sequence.[15]

The second of the sex peptides, ductus ejaculatorius peptide 99B (DUP99B), was not characterized until 2002. As its name implies, DUP99B is produced in the ejaculatory duct from a precursor that gives rise to a 31-aa mature peptide. The sequence of the peptide is almost identical to that of SP with regard to its C-terminal region. DUP99B was shown to elicit the same postmating responses as SP when injected into a female fly's hemolymph.[23]

Although both peptides have only been identified in *Drosophila* species, they also elicit physiological responses (see Biological Action) in the lepidopteran, *Helicoverpa armigera*. Therefore, it has been suggested that a similar sex peptide could be also be present in this species.[7,15] Because these sex peptides have only been characterized in various species of fruit flies, the following chapter on the sex peptides will be largely focused on these dipterans.

B-type Allatostatins

The B-type—or cricket type—allostatin family is characterized by a C-terminal WX_6Wamide sequence. The first identified B-type allatostatin was the myoinhibiting peptide from *Locusta migratoria.*[24] *Lom*-MIP was purified from an extract of brains, corpora cardiaca, corpora allata, and subesophageal ganglia. It was determined to repress spontaneous contractions of the hindgut and the oviduct in *L. migratoria*, as well as the hindgut of *Leucophaea maderae*. In the locust, however, the peptide does not display an inhibitory effect on juvenile hormone (JH) synthesis by the corpora allata. It was not until the discovery of the four peptide family members (*Grb*-AST1-4) from the cricket, *Gryllus bimaculatus*, that they were characterized as allatostatins.[16,17] The names "B-type allatostatin" and "myoinhibiting peptide" are synonymous to each other.

Although most results on this peptide family have been generated in insects, members of this peptide family have also been identified in a number of crustacean species. Most of these were discovered in decapod species, but a B-type allatostatin was also found in *Daphnia pulex.*[3,5]

STRUCTURE OF THE mRNA/GENE

Sex Peptides

Both genes encoding SP and DUP99B have been cloned and sequenced in *Drosophila melanogaster*, and both display an intron insertion at the same site. The highly similar C-terminal parts of the peptides are encoded by the second exon, whereas the first encodes the signal sequence and the N-terminal part of the peptide. It has been proposed that both genes have arisen by gene duplication. This is supported by the aa sequence similarities in not only the C-terminal regions of the peptides but also in the signal sequences.[15,23]

B-type Allatostatins

Knowledge of the gene structure for the B-type allatostatins was not generated until the publication of the *Drosophila* genome. The fruit fly *myoinhibitory peptide* (*mip*) gene encodes a precursor in two exons, spaced by an intron. This preprohormone gives rise to five MIPs.[31] In *Rodnius prolixus*, the *Ast-B* gene shows more complexity, having four exons.[18] With five exons, the *AstB* gene features more complexity in *D. pulex*.[5]

PROCESSING OF THE PRECURSOR

Sex Peptides

SP synthesis occurs via a precursor, 55 aa in length, from which a 19-aa signal peptide is released. Amino acid sequence analysis of the SP from various *Drosophila* species has revealed two regions of high similarity. The five most N-terminal aa (WEWPW) are identical and the C-terminal region, encoded by the second exon, shows strong conservation.[15]

Like SP, DUP99B is synthesized from a precursor of 54 aa, from which 21 are cleaved off N-terminally as well as the two C-terminal aa (RK). The peptide displays a pyroglutamic acid modification in the N-terminus. Further, the N-terminal region was shown to undergo glycosylation, consisting of a difucosylated oligosaccharide structure. This latter modification decreases the amount of peptide required to induce ovulation, although this effect has not been observed in receptivity assays.[23]

The processed SP and DUP99B peptides are, respectively, 36 and 31 aa long and display a linear N-terminal region and a circular C-terminal part, resulting from a disulfide bridge formation. In between the two bridge-forming Cys residues, 9 out of the 11 aa are identical.

B-type Allatostatins

In *Drosophila*, the B-type allatostatin gene encodes a precursor of 211 aa that starts with a signal sequence and harbors five WX_6Wa peptides, all of which are flanked by dibasic or tribasic cleavage sites.[31] Results from *Rhodnius* indicate the presence of an *AST-B* gene encoding at least nine peptides.[18] For *Bombyx mori*, the precursor gives rise to eight peptides.[32] In the tick, *Ixodes scapularis*, the 132 aa MIP precursor likely gives rise to three peptides, of which two show the hallmarks for C-terminal amidation.[26]

DISTRIBUTION OF THE mRNAs AND PEPTIDES

Sex Peptides

The results generated in *D. melanogaster* reveal very similar temporal expression profiles for both the *sp* and the *dup99B* gene. Little to no transcript can be detected during development until the late pupal stages. Not surprisingly, expression levels are by far the highest in male adults. By contrast, female adults show no expression of *sp* or *dup99B*.[20]

The spatial expression patterns of *sp* and *dup99B* are equally constricted but notably different. Although *sp* transcripts are only found in the male accessory gland, the expression of *dup99B* is limited to the upper ductus ejaculatorius.[15,20,23] In addition, *dup99B* is also expressed in the cardia of both male and female flies.[15]

B-type Allatostatins

In contrast to the strictly limited expression profile of the sex peptides, the transcript for the B-type allatostatin is much more widely distributed. In *D. melanogaster*, the expression of the precursor has been found throughout all developmental stages.[20] The expression of *mip* is by far the greatest in the central nervous system (CNS). These results correspond with those obtained from immunohistochemical analyses, which point out the presence of MIP in the CNS of *Drosophila* and *Aedes aegypti*.[11]

Detailed immunohistological studies on *D. melanogaster* have revealed additional sites of strong MIP immunoreactivity in the larval midgut in the region before the copper cells and much weaker signals from between the copper cells. Also, a group of cells in the posterior part of the larval midgut is weakly MIP immunoreactive, and these decrease in density toward the middle of the posterior midgut. By contrast, MIP immunoreactivity is hard to pinpoint on the adult fly's midgut.[29] Immunohistochemistry in combination with Gal4 enhancers has allowed for the identification of MIP expression sites in the central complex of the *Drosophila* brain. Immunoreactivity appears in the ventral, central, and dorsal layers, with the latter showing strong labeling.[10]

Using in situ hybridization, the transcript for the *B. mori* prothoracicostatic peptides (PTSP) has been mapped to the CNS with the most intense signals in a pair of brain medial neurosecretory cells and also strong signals from the interneuron 704 and epiproctodeal glands. In the brain, the expression is detected during the feeding period but decreases before the time of each ecdysis. Transcript levels in the terminal ganglia, however, remained constant during the fourth and fifth instar stages. In the epiproctodeal glands, the expression is strong in pharate fifth instar larvae and just after ecdysis. It is at a low level during the first 5 days of the fifth instar stage, then rises. Immunohistological results are also available from *B. mori* and concur with the findings from the expression results.[32] These results generally correspond with what is known from *Manduca sexta*.[4]

Further, in *L. migratoria*, the presence of the peptide has been traced to approximately 12 neurons, including those innervating the glandular cells of the corpora cardiaca and the corpora allata.[24]

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Detection of the myoinhibiting peptide resulted in very similar patterns for the tick species *I. scapularis* and *Rhipicephalus appendiculatus*. In the synganglion, immunoreactivity could be detected in the neurons of the protocerebrum, palpal lobe, cheliceral lobe and the pedal lobes 2 and 3 (and 4 in the case of *I. scapularis*) and on the ventral side, the opistosomal lobe and a number of small neurons that were not detected in *R. appendiculatus*. Further, it was shown that the salivary gland in the tick is innervated by MIP-positive axonal projections.[25]

In decapods, the B-type allatostatins are widely distributed in the CNS as indicated by mass spectrometry analyses. In these animals, they are likely to serve as both autocrine or paracrine factors and as circulating hormones.[3] Using an antibody raised against *Cancer borealis* AST-B1, immunostaining reveals the distribution of this peptide throughout the stomatogastric nervous system of the Jonah crab. Immunoreactivity is detected in neurons and neuropil in the commissural ganglia, in somata in the esophageal ganglion, in fibers in the stomatogastric nerve and in neuropilar processes in the stomatogastric ganglion.[27]

RECEPTORS AND SIGNALING CASCADES

Studies in *Drosophila* show that SP activates the G-protein-coupled receptor encoded by CG16752, the sex peptide receptor, of which putative homologs have also been identified in various other insect species.[11,20,34] Transcript and protein presence of this receptor has been shown in the female reproductive organs, especially in the spermatheca, and in the CNS of both females and males in very similar patterns.[20,34] An in-depth study focusing on the neurons in which *spr* is expressed reveals that the presence of SPR in neurons expressing both *fruitless (fru)* and *pickpocket (ppk)* is necessary and sufficient for the mating-induced behavioral changes. This conclusion is warranted as *spr* knockdown in *ppk*$^+$ or *fru*$^+$ neurons is enough to eliminate postmating responses. In addition, specifically expressing *spr* in either of these neuron populations rescues the phenotype of *spr* null mutants in assays of egg laying, virgin receptivity, and remating frequency. Further, silencing the *ppk*$^+$ neuron signaling by means of specifically blocking the synaptic transmission of these neurons reveals a significant decrease in virgin receptivity and an increase in virgin egg laying. The sensory neurons innervating the uterus are thus far the only ones identified as expressing both *ppk* and *fru*.[8] Independently, other data support the importance of these neurons in SP signaling. Inhibition of PKA in these neurons raises the rate of egg laying by virgins and reduces the virgin's receptivity. Therefore, signaling through Gαi followed by PKA inhibition has been proposed as the *in vivo* path of action.[33]

Most interestingly, SPR from *Drosophila* has also been identified as the cognate receptor for MIPs, with MIP4 showing a lower EC50 value than SP (Fig. 1). As the C-terminal sequence similarity between MIPs and SP is limited to the $-WX_6W$ motif in MIPs compared with that of $-WX_8W$ in SP, it was hypothesized that the Trp residues present in these peptides might be essential for receptor activation. Indeed, truncated and Ala-substituted analogs of the peptides in which the Trp residues were eliminated show a strong loss of agonist activity.[11,20] Given the conserved nature of the receptor, in contrast to the limited number of species in which SP has been identified, it is sensible

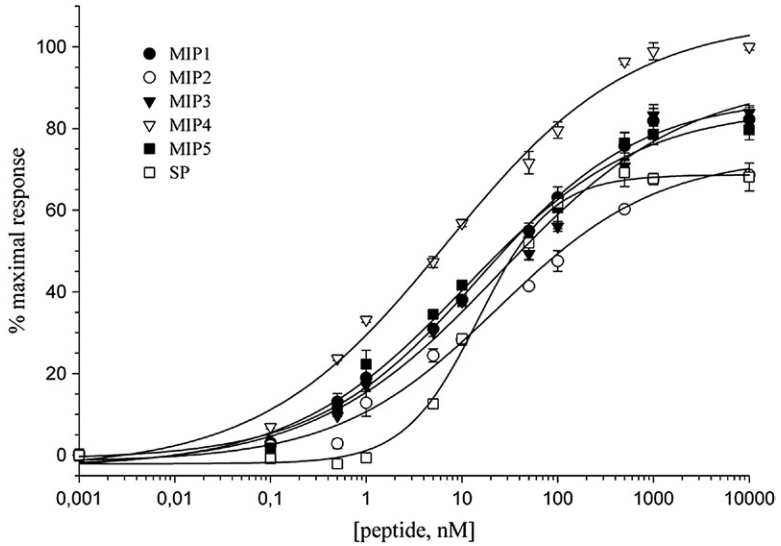

FIGURE 1 *Drosophila* SPR is a receptor for both SP and MIPs. CHO cells coexpressing aequorin, Gα16, and *Drosophila* SPR dose dependently increase intracellular Ca^{2+}-concentration when challenged with *Drosophila* SP and MIPs 1–5. Data points represent mean ± SD of three independent measurements performed in triplicate and are given as a percentage of the maximal response. The zero response level corresponds to the treatment with buffer only. (Figure reproduced from Ref. 20 with the publisher's permission.)

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

to put forward the MIP family as the ancestral ligands for SPR. Further evidence from *B. mori* supports this theory. In this organism too, the SPR homolog has been identified as a cognate receptor for the *Bom*PTSPs (B-type allatostatins).[32]

BIOLOGICAL ACTIONS

Sex Peptides

The biological effects initially attributed to SP have been witnessed in both mated female flies and virgin females that were injected with SP. First, there is dramatic loss of receptivity of mated females compared with virgins. Once fruit fly females have copulated, they will actively reject new males that present themselves as additional mating partners. Second, after mating, the *Drosophila* female will display a strong increase in egg laying.

Further, it has been shown that SP induces the progression of oocytes to stage 10. This effect is likely mediated by juvenile hormone (JH) as SP is known to have allatotropic effects and because the oocyte progression can also be stimulated by methoprene, a JH mimic. Like SP, methoprene also induces the uptake of yolk protein (YP) into the ovary, in addition to strong increase of *yp* transcription in the ovary. However, the stimulation of egg laying and loss of receptivity cannot be mimicked by methoprene treatment.[15]

Further, female flies, having mated, significantly increase their food uptake. This effect has also been attributed to SP-transfer during copulation, without substantial involvement of sperm or the act of copulation.[2] A closer look at this aspect has made clear that this effect is probably an indirect consequence of the increased egg laying mentioned above. This is supported by the lack of feeding increase in sterile ovo^{D1} mutant females and the triggering of the effect in virgin females by silencing *fru* neurons rather than exposing them to SP.[1]

The observation that mated female's life spans are significantly shorter in comparison with their virgin counterparts raises the question as to whether this could result from adverse effects coupled with an increase in feeding. This has been refuted based on sterile ovo^{D1} mutant females displaying the same survival cost linked with mating, despite the observation that their food intake is not elevated.[1]

Results on feeding in *Drosophila* indicate that not only the quantity of the female's food intake will differ after copulation, but also its preference. In contrast to virgin females, mated females that have been deprived of a protein rich food source (i.e. yeast) for 3 days will show a strong preference for food containing yeast. SPR activity in the *ppk+* neurons is essential for this effect because expression of SPR in these neurons in an *SPR* mutant background largely restores the wildtype phenotype. Further, evidence suggests the involvement of TOR/S6K signaling and serotonin in the modulation of food preference.[22,28]

The presence of an intact C-terminal region of SP, including its disulfide bridge, is key to the biological activity of the peptide in receptivity and oviposition assays but it is not sufficient. In contrast, deletion of the 10 most N-terminal aa residues does not affect the peptide's activity in these assays.[15] However, the N-terminal part of the peptide has been shown to induce JH biosynthesis in the corpora allata of both *Drosophila melanogaster* and the moth, *H. armigera*. In concurrence with these results, DUP99B, which does not show strong similarity with SP in the N-terminal region, is not capable of eliciting allatal stimulation. For *Helicoverpa*, the C-terminal region of SP can reduce PBAN-induced pheromone production, which has been interpreted as a mechanism to lower the chance of a female participating in multiple copulations, thus increasing a male's chance for successful reproduction.[7,15]

Based on female postmating responses after mating with males that either produce no sperm-bound SP or SP that lacks the dibasic cleavage site at its N-terminal region, for the postmating responses to linger longer than 1 day (short-term postmating response), sperm-bound SP needs to be present and the long term postmating response requires the possibility of SP being cleaved from the sperm at the aforementioned dibasic cleavage site. The short-term postmating response, however, does not require this and is most likely primarily the result of unbound SP present in the seminal fluid.[19]

Although SP alone is capable of inducing a transient increase in egg production and laying, the presence of many conserved classes of seminal proteins is also required to reach the witnessed long term postmating effects.[15] A cascade unfolds in which the protease CG9997 is necessary for the transfer of lectins CG1652 and CG1656 to the female on mating. These lectins also require the presence of cysteine-rich secretory protein CG17575 to efficiently accumulate in the seminal receptacle. A lack of any of these factors will lead to a quick deficiency of SP in the female seminal receptacle.[21]

In addition to the postmating effects described above, copulation induces a number of other responses that have been attributed to the action of SP. Mating induces the expression of an array of antimicrobial peptide genes. Using SP^0 males and males lacking germline, it has been demonstrated that SP is the principal factor underlying this response. SP^0 males fail to induce transcription of the antimicrobial peptide genes *Metchnikowin*, *Drosomycin*, and *Diptericin.* However, the effect on the last two is weaker in comparison with the first. Further, continuous expression of SP in the fat body elevates the transcript levels of these genes above the level of mating-induced expression. SP is therefore believed to regulate the transcription of antimicrobial peptide genes in a dose-dependent manner.[19] Looking further into this aspect of SP functionality, it was discovered that the hydroxyproline-rich region in the middle of the peptide is the eliciting factor of the immune response. Given the particular pattern formed by the five hydroxyprolines,

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

the hypothesis was raised that these motifs' actions result from its mimicking, on a molecular level, of sugar components within the microbial cell wall. In this case, pattern recognition receptors would be responsible for the elevated immune response on challenging by SP.[6]

A sexual dimorphism exists in *Drosophila* in relation to sleep–wake behavior. Male flies show an increased activity concentrated around the period of lights-on or lights-off, interspaced with periods of quiescence. A similar pattern is seen in virgin females. In contrast, females that have copulated only display a period of quiescence during the nighttime. These females are significantly more active during the daytime than males or virgin females. This effect is not sperm dependent, as mating of wildtype females with males lacking sperm does not abolish it. It is, however, also an effect of SP as this behavioral change is not found in females that are mated to SP^0 males. This loss of daytime rest has been proposed as one of the factors contributing to the decrease of lifespan observed in mated females.[9]

The link between *Drosophila* male reproductive success and SP has been studied in more detail, resulting in the notion that more SP is transferred to the female during mating in the presence of a competitor male. Additionally, males that have larger accessory glands, and therefore produce more SP, will have a greater reproductive success.[30]

B-type Allatostatins

The first characterized biological function of these peptides is the ability of *L. migratoria* MIP to inhibit spontaneous muscle contractions in the hindgut and ovaries of the locust.[24] Further, juvenile hormone biosynthesis in the cricket *G. bimaculatus* is inhibited by *Grb*-ASTs and, to a lesser extent, by *Lom*-MIP.[16]

In both *D. melanogaster* and *M. sexta*, the CCAP/MIP neurons have been determined as responsible for the initiation and/or execution of the ecdysis behavior. Specifically, MIP was proposed to silence neurons that are not required during the ecdysis program.[12,13]

In *Drosophila*, a novel type of MIP-producing neuron was identified, which has cell bodies anterior to the base of the optic lobe medulla. Because branches of these neurons are closely associated with branches of clock neurons a putative link between the circadian clock and MIP has been proposed.[14]

In vitro evidence from *B. mori* indicates that expression of the receptor is strongly upregulated after a sudden decline of the 20-hydroxyecdysone titer. Considering the observation of sudden PTSP release coinciding with a drop of the 20E titer, it has been proposed that PTSP/PTSPR signaling is involved in the fine-tuning of ecdysteroid titers by suppressing prothoracic gland activity.[32]

Little is known about the physiological effects of the B-type allatostatins in Crustacea. For *C. borealis*, three out of the ten *Cb*-AST-B peptides identified by mass spectrometric analysis affect the pyloric rhythm in a state-dependent manner.[27]

Chapter 32

Crustacean Bioactive Peptides

H. Dircksen

ABSTRACT

Research on crustacean peptides has concentrated mainly on decapods and isopods, and a growing number of >200 peptides have been sequenced from these two groups, the majority from decapods, but recently, the annotation of the *Daphnia pulex* genome has contributed many more novel peptides many of which were also sequenced *de novo*. Identified and bioactive crustacean peptides — the only ones reported here — regulate a large range of physiological functions, including color change, activities of heart, exoskeletal and visceral muscles, metabolic function, development, metamorphosis, and reproduction.

INTRODUCTION

Crustaceans are classical model animals for endocrinological research from the beginning of the discovery of neurosecretion in vertebrates and invertebrates in the 1920s. Crustacean peptides particularly from commercially valuable species have gained interest because many of them are involved in the control of growth by molting, of many metabolic processes and reproduction. Genomic, transcriptomic (e.g. via expressed sequence tags, ESTs) and proteomic approaches especially with the aid of sensitive mass spectrometric techniques have led to a rapid increase in the number of precursors and derived identified peptides in crustacean species preferably from Decapoda, Isopoda, and more recently Branchiopoda, because *Daphnia pulex* became the first crustacean model organism with a fully annotated genome. This gave another boost of peptide discovery with especially notable similarity to insect peptides and protein hormones (see for further references (sffr)[9]). Although functional studies on identified peptides are mainly available from the first two groups, this may soon change rapidly. Unfortunately, physiological investigations of their bioactivity have not kept pace with the speed in the discovery of crustacean peptides, hence their names are often just inferred from homology to insect peptides, and, thus, only suggestive of similar function.

Chromatophorotropic hormones were the first sequenced invertebrate neuropeptides in the 1970s, the antagonistic red pigment concentrating hormone (RPCH) and pigment dispersing hormone (PDH), but about 30 years later, crustacean cardioactive peptide (CCAP) and corazonin had to be added to this functionality. The first two peptide families, along with the crustacean hyperglycemic hormone superfamily,[33] have been studied extensively in several crustacean model systems. Most of the peptides were discovered from the extracts of major crustacean neuroendocrine organs such as the X-organ-sinus gland system (XO-SG) in the decapod eyestalk or the isopod brain and the pericardial organs (POs), large neurohemal release sites of neurosecretory neurons in the ventral nerve cord (VNC).[33] Apart from suitable crustacean muscle systems such as the easily accessible heart, some exoskeletal muscles and the hindgut, well-established simple systems for electrophysiological studies of neuronal networks such as the stomatogastric and cardiac ganglia (STG, CG) controlling the foregut and the neurogenic heart served as bioassay systems.

This review considers in alphabetical order biochemically fully identified crustacean peptides for which bioactivity has been established even if only seen in heterologous bioassays. Where known, the few crustacean neuropeptide receptors are commented on. Further, with possible exceptions in cases of CHH-superfamily peptides, chromatophore activators, and some myotropic peptides (e.g. proctolin, FMRFamide-related peptides (FaRPs)), work has often just begun to unravel involvement of cyclic nucleotide, Ca^{2+}/calmodulin or Ca^{2+}/inositol-triphosphate (IP_3)-dependent mechanisms of intracellular signaling.

ANDROGENIC GLAND HORMONE (AGH)/ INSULIN-RELATED PEPTIDES

Discovery

The androgenic gland hormone (AGH) regulating male sexual differentiation in isopod and decapod crustaceans

Handbook of Biologically Active Peptides. http://dx.doi.org/10.1016/B978-0-12-385095-9.00032-4

was originally identified from the pill bug *Armadillidium vulgare* as an insulin-like peptide typically composed of A and B chains. Its A-chain is glycosylated, contains an unusual intrachain cystine-bridge, but is connected to the B-chain via two cystine-bridges. Later on similar insulin-like AG (IAG) peptides have been identified from other isopods and more recently from crayfish, shrimps, and a crab.[32] In *D. pulex*, a single nonglycosylated brain insulin-related peptide (DIRP) has been identified, and three putative insulin-like growth factors (DIGFs) were predicted.[9]

Structure of the mRNA/Gene and Processing of the Precursor

All precursors of AGHs/IAGs and DIGFs contain the B-C-A chain configuration typical of insulins after the signal peptide (SP), whereas in the DIRP precursor, as derived from a complex 5-exon *irp*-gene, two additional identified peptides precede the B-C-A chains. From AGHs/IAGs and DIRP, B- and A-chains are cleaved from the C-peptides at dibasic and/or RxxR cleavage sites; however, there are no such sites in DIGFs (sffr and detailed comparisons[9]).

Distribution of the mRNA/Peptide

Although AGHs/IAGs are restricted to decapod AGs (sffr[32]), DIRP occurs in distinct brain neurons (Ref. 9; J. Strauß and H. Dircksen, unpublished).

Biological Actions

The AG regulates male sex differentiation, that is, development of testis and secondary external sex characters in males, and implantation of AGs into females can induce sex shifts and changes toward male-like behaviors (sffr[32]).

ALLATOSTATINS (SEE CHAPTER 29)

Allatostatin (AST) denominates a peptide with inhibitory activity on juvenile hormone production or release from insect corpora allata (CA). AST-like peptides are ubiquitous in arthropods and can be divided into three types A, B, C. Neither has any crustacean AST hitherto been tested in heterologous assays using CA, nor has any authentic AST an effect on the mandibular organs, the crustacean CA-homologs producing the juvenile hormone-precursor methyl farnesoate, and its precursor, farnesoic acid (sffr[15]). Nevertheless, these ASTs share the names because of sequence similarities. Of note, in many insects also, CA-stimulatory allatotropins exist; but a brain peptide slightly different from insect allatotropins has only recently been identified as GFKTVGLATARGFamide in *D. pulex* only,[9] while seemingly being absent from decapods.

Allatostatin-Like Peptides of Type A (ASTAs)

Discovery

A very large number of ASTAs sharing the Y/F-X-FGLamide motif have been identified in several crustacean species: first, 20 from the crab *Carcinus maenas*, 3 from the crayfish *Orconectes limosus*, 40 from the shrimp *Penaeus monodon* and a growing number from other crabs, lobsters, and even a copepod and *D. pulex*.[2,9]

Structure of the mRNA/Gene and Processing of the Precursor

A precursor mRNA from the crayfish *Procambarus clarkii* encodes, immediately after the SP, 27 ASTAs (thereof 22 different) all separated by dibasic cleavage sites and some intercalating precursor-related peptides (PRPs), two ASTAs among them occurring in multiple copies. In the branchiopod precursor as derived from a 3-exon gene, only single copies of six ASTAs occur, whereas the copepod precursor shows three (one in three copies) ASTA-like peptides with noncanonical Y/F-X-FGI/Vamide C-termini.

Distribution of the mRNA/Peptide

ASTA-immunoreactive peptides seem to occur throughout the entire CNS and peripheral nervous systems such as the STG and seem to be released from classical neurohemal organs such as SGs and POs (sffr[2,10]).

Biological Actions

Although most earlier studies only used heterologous cockroach ASTAs, biological activities of three authentic ASTAs have only been tested in the crayfish *O. limosus* in which they are the first identified inhibitory peptides of crustaceans, inhibiting frequency and amplitude of contractions of semiisolated hindguts (Carcinustatin-8, Orcostatins I, II) and STG neuronal activities (Carcinustatin-8).[10] Similar inhibitory effects on motor output of *Cancer borealis* STG and cardiac ganglion have been found but merely by testing insect ASTAs (sffr[2]).

Allatostatin-Like Peptides of Type B (ASTBs, = Myoinhibitory Peptides)

Discovery

Originally described in crickets, ASTBs share WX_6Wamide C-termini (X variable amino acids (aas)). After the first ASTB, VPNDWAHFRGSWamide (CbAST-B1), was

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

identified from POs of two *Cancer* species, up to ten different ASTBs were identified in a single species of crabs, shrimp and lobsters (sffr[2]).

Structure of the mRNA/Gene and Processing of the Precursor

The structures of a complex 5-exon gene and the precursor containing 8 different ASTBs (5 of which fully identified) are only available from *D. pulex*. The peptides are flanked by double-basic cleavage sites interspersed between six varied PRPs.[9]

Biological Actions

In the STG of *C. borealis*, CbAST-B1 decreases the frequency of the pyloric motor output depending on the crab's physiological state (sffr[2]).

Allatostatin-Like Peptides of Type C (ASTCs)

Discovery

A 15-mer peptide containing the C-terminal nonamidated PISCF motif was first described in *Manduca sexta*. ASTCs are further characterized by a cystine bridge spanning 6 aas N-terminally from this motif. The pentadecapeptide pQIRYHQCYFNPISCF (CbAST-C1) apparently is the most common ASTC in 29 species of decapod crustaceans, but others have been found in *C. borealis* (e.g. CbAST-C2: SYWKQCAFNAVSCFamide; sffr[2]). In *D. pulex* three genes with distinctly different ASTC1-C3 were found,[9] only DappuASTC1 being identical to CbAST-C2.

Structure of the mRNA/Gene and Processing of the Precursor

EST-deduced precursors from shrimp, crab and lobster encode single copies of either CbAST-C1 or CbAST-C2 at the end between a dibasic (KR) and/or tribasic (RRK, RKR, KRK) cleavage sites.[2] Two of the three *astC1-C3*-genes in *D. pulex* occur clustered in head-to-tail tandem arrangement on the same scaffold, whereas the third one is separate. In all three precursors, single ASTCs occur close to or at the end and are flanked on one side of the peptides by a monobasic (R) and on the other side by a dibasic cleavage site.[9]

Distribution of the mRNA/Peptide

MALDI-based surveys of lobster tissues show that CbAST-C1 occurs in *C. borealis* POs. However, CbAST-C2 was found widely distributed in the central nervous system (eyestalk ganglia, brain, commissural ganglia) and occurs also in the posterior midgut caecum but has not been found in SGs and was hardly detectable in POs (sffr[2]).

Biological Actions

Both CbAST-C1 and CbAST-C2 inhibit dose dependently the cycle frequency of the pyloric motor output from the STG ($EC_{50} \sim 10^{-8}$ M) and seem to modulate heart rate in crabs and lobsters (sffr[2]).

CHH-SUPERFAMILY

Discovery

The crustacean hyperglycemic hormone (CHH) superfamily can be divided into type-I and type-II subgroups, that is, the CHH subfamily sensu stricto, which contains 72 aa with often N-terminal pyroglutamate and always C-terminal amidation, and the molt-inhibiting hormone (MIH)/gonad-inhibiting hormone (GIH)/vitellogenesis-inhibiting hormone (VIH)/mandibular organ-inhibiting hormone (MOIH) subfamily (MIH subfamily), nonprotected 77–83 aa (usually 78), respectively, based on their structures and bioactivities. The first CHH was identified from the SG of *C. maenas* and soon after an MIH of similar structure but no hyperglycemic activity from the same source. Further type-II GIHs, VIHs and MOIHs were later identified. Altogether, the CHH-superfamily now comprises >80 family members from about 40 crustacean species (sffr[33]).

Structure of the mRNA/Gene and Processing of the Precursor

Characteristically, several *chh*-genes often occur in multiple isoforms of 3-exon or 4-exon genes in decapods and *D. pulex* (except a 2-exon *chh*-gene for *P. monodon*), and *mih*- and *moih*-genes are only found as 3-exon genes in shrimps, giant tiger prawns and crabs. However, no specific *vih/gih*-genes have hitherto been described. Although multiple *chh*-genes occur in clusters of up to nine *chhA*- or *chhB*-genes in tandem in penaeid shrimps, in other species, several copies of slightly differing *chh*-genes have been found. The 4-exon *chh*-genes usually give rise to products of alternative splicing, that is, precursors encoding the long nonamidated or the short amidated isoforms, the latter being devoid of the message from the third exon. Two single *mih*-genes only have been found for several species, and slightly different *mih*- and *moih*-genes occur distinctly clustered (apparently only) in cancrid crabs. A clear-cut difference between of type-I and type-II subfamily precursors is the occurrence of PRPs restricted to CHH-subfamily precursors (sffr[33]).

Distribution of the mRNA/Peptide

CHH superfamily mRNAs and peptides are produced by neurosecretory cells in the classical XO-SG system and intrinsic cells of pericardial organs or astacuran thoracic

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

roots, but they occur also as paraneurons in nonneural tissues, especially in the foregut and hindgut epithelium of crabs (sffr[33]).

Receptors and Signaling Cascades

Receptor-binding studies have clearly identified distinct receptors for CHHs and MIHs in crabs and lobster although their primary structures remain to be elucidated. Although both cAMP and cGMP have distinct but overlapping functions in the inhibition of Y-organ ecdysteroidogenesis by MIH and CHH, respectively, apparently cGMP acts as a major second messenger mediating diverse CHH actions.[33]

Biological Actions

Classically, the name-giving bioactivities characterized the diverse CHH-superfamily members, although type-II peptides have only restricted actions (hence their names) compared to those of the rather pleiotropic type-I peptides. CHHs exhibit at least eight different functions, that is, apart from upregulating hemolymph (1) glucose and (2) lipid levels, they stimulate (3) hepatopancreatic amylase secretion and (4) ion transport in gills and, transiently during premolt and ecdysis, (5) water uptake as necessary for successful molting, inhibit (6) ecdysteroidogenesis in Y-organs, (7) MF-synthesis in mandibular organs, and (8) AGH and protein synthesis in the androgenic glands (sffr[33]).

CORAZONIN

Discovery

The N- and C-terminally blocked undecapeptide Arg^7-corazonin (pQTFQYSRGWTNamide, CRZ) was first identified as a cardioactive factor in the American cockroach. In crustaceans, the highly conserved Arg^7-CRZ was much later identified in POs of the crab *C. borealis*, several other decapods (sffr[2]) and recently also in *D. pulex* brains.[9] It is to date the only known isoform in crustaceans.

Structure of the mRNA/Gene and Processing of the Precursor

Precursors have been predicted for the shrimp *Litopenaeus vannamei* and the water flea *Daphnia carinata* (sffr[2]). The only crustacean identified *crz*-gene (with three exons), its derived mRNA and precursor are presently known from *D. pulex*. Similar to RPCH/AKH precursors (see below), the peptide always follows immediately after the SPs and is separated by a double-basic cleavage site from a long PRP containing up to two cysteines. Apart from the CRZ region, however, insect, decapod and *D. pulex* precursors have only little in common.[9]

Distribution of the mRNA/Peptide

CRZ was sequenced from POs, brain and VNC tissues (sffr[2,9]), but there are currently no data about CRZ-expressing cells in crustaceans.

Biological Actions

CRZ leads to retraction of erythrophore pigment granules and dispersion of leucophore pigment granules in crayfish, and inhibits spermatogenesis in freshwater prawns, though at relatively high concentrations (sffr[23]).

CRUSTACEAN CARDIOACTIVE PEPTIDE (CCAP)

Discovery

Crustacean cardioactive peptide (CCAP; PFCNAFTG-Camide), a cyclic amidated nonapeptide hormone containing a cystine bridge between Cys^3 and Cys^9, was isolated via heart bioassays from *C. maenas*.[26] In crustaceans, this isoform only has now been identified in many decapods but an exceptional isoform (Ala^7-CCAP) has been predicted from *D. carinata* ESTs and the *D. pulex* genome (sffr[9]).

Structure of the mRNA/Gene and Processing of the Precursor

Precursor mRNAs have been cloned from several decapods[5] and recently been predicted from *D. carinata* ESTs and the *D. pulex* genome (sffr[9]). In the highly similar precursor, the peptide is flanked by two pairs of PRPs all separated by dibasic to tetrabasic cleavage sites.[5] The peptide message in the 3-exon *Ala^7-ccap*-gene of *D. pulex* is characteristically split by an intron as in insects.[9]

Distribution of the mRNA/Peptide

In crustaceans, CCAP-expressing serially homologous neurons usually occurring in almost every VNC segment as pairs of an interneuron and a neurosecretory neuron with peripheral release sites (e.g. crustacean POs). These cell types are highly conserved neurons in arthropods. In crabs, these cells start CCAP-expression already by 50% embryogenesis.[5] In crab and lobster, as in insects, the peptide occurs together with the dimeric bursicon homolog of the insect cuticle tanning and sclerotizing hormone (sffr[25]).

Biological Actions

Originally named for its excitatory activity on the shore crab heart, CCAP is excitatory on other invertebrate muscles and an established neuromodulator of STG and CG

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

(sffr[2]). Chronotropic and inotropic effects on blue crab heart likely are brought about by four stimulatory actions on both the heart muscle and the CG, that is, contraction amplitude, motor neuron burst and contraction frequency, burst duration, and number of spikes per motor neuron burst (sffr[2]). Its dramatic release into the hemolymph during ecdysis indicates its involvement in coordinating physiological and behavioral processes, in particular increased hemolymph pressure and flow, and the potentiation of muscular force during this stage.[22] Although not clear at present, the role of bursicon in these crustacean CCAP neurons may be similar to that in insects (sffr[25]). In a freshwater shrimp, CCAP can even act as a chromatophorotropin inducing pigment dispersion and reducing RPCH-induced pigment aggregation albeit at relatively high effective concentrations.[19]

DIURETIC HORMONE 31

Discovery

A precursor of a typically 31aa calcitonin-like diuretic hormone (CLDH or DH31), well conserved in insects and identical in structure to CLDH of *Tribolium castaneum* (GLDLGLGRGFSGSQAAKHLMGLAAANFAGGPamide), has first been predicted and full-length cloned from an EST library of *Homarus americanus*, and the derived HomamDH31 has been tested for cardioactivity.[3] A very similar DappuDH31 (5 aa-exchanges only) was fully sequenced by mass spectrometry from *D. pulex* brains.[9]

Structure of the mRNA/Gene and Processing of the Precursor

The precursor structures of lobster and water flea precursors are very similar with regard to the DH31s even when compared with insect DH31 precursors typically encoding DH31 in the second last position flanked by dibasic (KR) and tetrabasic (RRRR, RKRR) cleavage sites, among 4 PRPs not related to any other arthropod peptide. The 3-exon *dh31*-gene in *D. pulex* contributes with all exons to the DappuDH31-precursor.[3,9]

Distribution of the mRNA/Peptide

RTPCR shows amplicons in the brain, eyestalk ganglia, commissural ganglia, and in motoneurons but not pacemaker neurons of the cardiac ganglion of the lobster,[3] and in the brain of *D. pulex*.[9]

Biological Actions

A synthetic lobster peptide shows profound stimulatory effects on the lobster heart at low threshold concentrations of 10^{-11}–10^{-10} M as probably brought about by HomamDH31-containing CG motoneurons and/or by direct peptide actions on the heart muscle. Perfusion of semiisolated hearts leads to increased frequency and amplitude but a decreased duration of contractions.[3]

ENKEPHALINS (SEE CHAPTER 219)

Discovery

Early evidence from immunocytochemistry and combined HPLC/radioimmunoassay studies strongly suggested Leu-enkephalin/Met-enkephalin (YGGFL/M) in eyestalk ganglia neurons of spiny lobster and shore crab. Both peptides were later Edman-sequenced from extracts of SGs and thoracic ganglia of *C. maenas* (sffr[16]).

Distribution of the mRNA/Peptide

Enkephalins occur throughout the medullae of the eyestalk ganglia and in the SG (in *C. maenas* even colocalized with MIH). Fibers in the medulla terminalis presumably interacting with dendrites of XO-SG neurons probably originate also in the brain and/or thoracic ganglia of *Panulirus interruptus* and *C. maenas* (sffr[16,33]).

Receptors

Three receptor types resembling the vertebrate δ- and κ-type opioid receptors have been characterized pharmacologically in nervous tissues (e.g. K_i = 18.9 nM for Leu-enkephalin) and localized by autoradiography at CHH terminals in the SG of *C. maenas*. Moreover, displacement studies using several opioids and antagonists have shown that these receptors competitively bind both Leu- and Met-enkephalins (sffr[2]).

Biological Actions

Enkephalins in crustaceans have been implicated in the regulation of stimulated release of chromatophorotropins (RPCH, PDH), inhibition of ovarian maturation, and in the control of carbohydrate metabolism and locomotory activity. The Effects of injected enkephalins, usually substantiated by the use of opioid receptor antagonists such as naloxone, on hemolymph glucose concentrations seem to be species specific, as either hypoglycemia (e.g. in *Uca pugilator*, *P. clarkii*, *O. limosus*) or hyperglycemia (e.g. in *Oziotelphusa senex senex*, *Penaeus indicus*, *Metapenaeus monocerus*) are reported. These effects are apparently caused by stimulation or inhibition of CHH release from XO-SG neurons via synaptic contacts on their dendrites in the medulla terminalis, explaining the often high threshold concentrations around 10^{-7} M used (sffr[2]).

FMRFAMIDE-RELATED PEPTIDES (FARPS) (SEE CHAPTER 35)

Even though the family founder tetrapeptide, the molluscan cardioactive FMRFamide, does not occur in crustaceans, several distinct groups of peptides with members exhibiting RFamide or LRFamide C-termini and extended N-termini are known, but only a few are established bioactive. Five heart bioactive extended FaRPs from POs and STGs were the first to be identified in lobster, crayfish, and crab followed later by several other decapod isoforms from eyestalk shrimp ganglia and CNS of several crustaceans, which but await being tested for bioactivity (sffr[2,17]). In *D. pulex* only two variants extended FaRPs exceptionally exhibiting an antepenultimate Leu to Ile exchange, that is, an -FIRFamide motif, have been identified.[9] Other bioactive FaRPs such as sulfakinins and myosuppressins were identified much later as was the unique peptide GAHKNYLRFamide.[6] Although yet to be identified biochemically, synthetic lobster neuropeptide F-related peptides as predicted from cloned cDNAs are orexigenic (see below).

Extended FaRPs

Discovery

Heart bioactive extended FaRPs, that is, N-terminally extended FLRFamides such as TNRNFLRFamide (F1) and SDRNFLRFamide (F2) were first identified from lobster POs, followed by the closely related NRNFLRFamide (NF1) and DRNFLRFamide (DF2) from crayfish POs, and GYNRSFLRFamide from crab POs. Shortly after F1 and F2 were identified also neuromodulatory substances from crab STGs (sffr[2,17]).

Structure of the mRNA/Gene and Processing of the Precursor

The only known two extremely similar decapod precursor mRNAs from crayfish *P. clarkii* brain encode five single copies and one double copy of different decapeptide, nonapeptide, or heptapeptide RNFLRFamides, among which also the heptapeptides F1 and F2 occur and the first decapeptide is encoded as two variants AYSDRN(F/Y)LRFamide. The peptides are flanked by dibasic (KR) and monobasic (R) cleavage sites (except for the last one) and several spacer peptides of variable length with no similarity to any other known arthropod peptides.[35]

Distribution of the mRNA/Peptide

Although several immunocytochemical analyses usually detected crossreactive RFamides throughout the CNS of nearly all crustaceans, more specific ISH analyses of crayfish extended FaRPs mRNAs detected numerous distinct brain neurons (mainly cluster 9, a few in cluster 11) that were partially ISH reactive for mRNAs of ASTAs, orcokinins and tachykinin-related peptide precursors.[35] Similar extended FaRPs were identified, although with less spatial resolution, from crab STGs and brain sections by mass spectrometry. Several extended FaRPs have been identified from decapod POs suggesting hormonal release (sffr[2]).

Receptors and Signaling Cascades

Four enzymes such as calcium/calmodulin- dependent protein kinase, protein kinase C, cAMP- and cGMP-dependent protein kinases are involved in the complex differential effects of F1, F2, NF1, and DF2 on tonic and phasic lobster and/or crayfish muscles as measured *in vitro* via excitatory and inhibitory junction potentials (EJPs, IJPs; sffr[17]).

Biological Actions

Among the most extensively studied extended FaRPs F1, F2, NF1, DF2, and GYNRSFLRFamide, the first four affect various aspects of (1) circulation by altering the cardiac output and arterial valve performance thereby redirecting the organ distribution of hemolymph, stimulate (2) parts of the digestive system (gastric mill and pyloric activity via the STG motoneurons; circular and longitudinal hindgut muscles via terminal ganglion neurons), (3) temperature-compensated synaptic transmission, and (4) contraction amplitudes of exoskeletal muscles (dactyl opener, abdominal extensors, respectively) in lobster and crayfish. These effects usually occur at threshold concentrations of 10^{-10}–10^{-9} M that are in the range of hemolymph contents as measured in lobster and apparently require a C-terminal -RNFLRFamide motif. GYNRSFLRFamide is a powerful modulator of the blue crab heart at threshold concentrations of about 10^{-8} M, which required at least a heptapeptide sequence XXZFLRFamide for full potency (sffr[17]). Similar chronotropic and inotropic effects on crab heart by F1, F2, and GYNRSFLRFamide probably occur by dual actions on both the heart muscle and the CG. Further, SDRNFLRFamide increases intracellular Ca^{2+} via voltage-dependent Ca^{2+}-induced release from sarcoplasmic reticulum or through the sacrolemma (sffr[12]). In *C. borealis* STGs, stimulatory activities by TNRNFLRFamide elicited via distinct ion currents converge together with other peptides such as CCAP, proctolin, RPCH, Cab-TRP-Ia on specific neurons in the pyloric circuitry (sffr[30]).

GAHKNYLRFAMIDE

Discovery

Among the three identified decapod peptides sharing a -YLRFamide C-terminus in shrimps and several *Cancer* crabs, the last discovered but the only one extensively studied was the nonapeptide GAHKNYLRFamide (sffr[6]).

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Distribution of the mRNA/Peptide

GAHKNYLRFamide has been identified from brain, STGs, and POs of crabs and shrimps by mass spectrometry (sffr[2]), but no cell type-specific associations have hitherto been worked out.

Biological Actions

Similar to the identified crab FaRPs F1 and F2, GAHKNYLRFamide stimulates neurons in both *C. borealis* CGs and STGs inducing a concentration-dependent increase in burst frequency and duty cycle (burst duration/period) of large CG neurons at an EC_{50} around 10^{-8} M. Although GAHKNYLRFamide stimulates specific neurons in both pyloric and gastric mill circuits of the crab STG, responses of the gastric mill circuitry (alternating dorsal gastric, lateral gastric, and gastric mill neurons) are much more pronounced. However, in silent pyloric or isolated STGs, GAHKNYLRFamide can actually reinitiate a triphasic pyloric rhythm.[6]

KININS (SEE THE KININ CHAPTERS IN THIS AND OTHER SECTIONS OF THE BOOK)

Discovery

Kinin-family peptides in insects and crustaceans are characterized by an $FX_1X_2WGamide$ motif (X, variable aas). The first crustacean kinins were identified from the shrimp *Litopenaeus* (=*Penaeus*) *vannamei* that contains six Pev-kinins 1–6, among which three even have a C-terminal Ala-amide instead of a Gly-amide. Several kinins have later been found in the crab *C. borealis* (sffr[2]).

Distribution of the mRNA/Peptide

Kinin-immunoreactive fibers and terminals of unknown origin have been detected in *C. borealis* POs (sffr[2]).

Biological Actions

Apart from being myoactive in the heterologous cockroach hindgut bioassay, which led to their discovery, Pev-kinin 1, 3, and 4 have also stimulatory effect on the pyloric rhythm of the STG of C. borealis. Pev-kinins stimulate fluid secretion and muscle contraction in insect tissues, but have only an effect on crustacean hindgut muscle at micromolar concentration (sffr[2]).

MYOSUPPRESSIN

Discovery

A first incompletely sequenced crayfish decapeptide possessed the C-terminal consensus motif -HVFLRFa, a characteristic structure for all arthropod myosuppressins (MS) a subfamily of the FaRPs (sffr[17]). Only a single peptide with this C-terminus has thus far been fully identified as pQDLDHVFLRFamide in decapods, among which it seems to be widely conserved.[27] However, in *D. pulex*, an MS identical to cockroach leucomyosuppressin pQDVDHVFLRFamide has been identified.[9]

Structure of the mRNA/Gene and Processing of the Precursor

A first precursor was sequenced from *H. americanus* EST library clones, and later a similar RTPCR-amplified precursor derived from the 2-exon Dappu *ms*-gene in *D. pulex* (sffr[2,9]). In both precursors, the different decapod MS and DappuMS occur at the end of the ORF and were flanked by dibasic/monobasic (KR, R) or dibasic (KR, RR) cleavage sites, respectively.

Distribution of the mRNA/Peptide

Mass spectrometric analyses only suggest pQDLDHVFLRFamide to be widely distributed within decapod nervous systems and the midgut, where they probably serve both as a locally acting or circulating hormone (sffr[2]).

Biological Actions

The semiisolated lobster heart and its cardiac ganglion (CG) are strongly modulated by MS, that is, *in vitro* decreasing the frequency but increasing the amplitude of heart contractions likely brought about by a decrease in CG cycle frequency via hyperpolarization and direct actions on muscle tissue at threshold concentrations of 10^{-8}–10^{-7} M (sffr[2]).

NEUROPEPTIDE F-RELATED PEPTIDES

Discovery

Two precursors and likely splice variants encoding the so-called long neuropeptide F-related peptides KPDPSQLANMAEALKYLQELDKYYSQVSRPRFamide (LitvaNPF-I) and KPDPSQLANMAEALKYLQELDKYYSQVSRPSPRSAPGPASQIQALENTLKFLQLQELGKLYSLRARPRFamide (LitvaNPF-II) have been cloned for two penaeid species *L. vannamei* and *Melicertus marginatus* based on predicted sequences from an EST another penaeid *Marsupenaeus japonicus.*[1] The shorter isoform is identical in all three penaeids and the longer isoform is identical only in the former two penaeids. Two similar splice forms arise from alternative splicing of the Dappu *npf*-gene, as confirmed by RTPCR and mass spectrometric sequencing of the shorter isoform DappuNPF1.[9]

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Structure of the mRNA/Gene and Processing of the Precursor

As predicted for penaeid NPF precursors and identified for the DappuNPF1 precursor, the peptide sequences start directly after the signal peptide and are cleaved via a dibasic cleavage site KR from a single following carboxy-terminal PRP. Assuming that the penaeid NPF isoforms likely also arise from alternative splicing as in *D. pulex*, then the longer second NPF-II as DappuNPF2 represent isoform peptides containing the unspliced message "insert" (37 aas in penaeids and 27 aas in DappuNPF2) from a second exon.[1,9]

Distribution of the mRNA/Peptide

RTPCR-profiling has much stronger NPF-I- than NPF-II-specific signals in the penaeid eyestalk ganglia, brain, thoracic, and abdominal ganglia and even in the midgut, although the latter seemed to lack NPF-II amplicons.[1] DappuNPF1 was only sequenced from brain tissue.[9]

Biological Actions

Surprisingly, synthetic penaeid NPF-I can simply be fed to the animals as a diet supplement, which leads to a significant increase in food intake and faster growth relative to controls.[1]

ORCOKININ AND ORCOMYOTROPIN

Discovery

The orcokinin peptide family is established in crustaceans and insects, and predicted also for chelicerates and *Caenorhabditis elegans*. The first tridecapeptide orcokinin NFDEIDRSGFGFN (Asn^{13}-OK) was identified as a hindgut-myoactive peptide in 1992 from VNC of the crayfish, *O. limosus*, followed by homologs from *O. limosus* hindguts and from other decapods (*C. maenas*, *Cherax destructor*, *P. clarkii*, *C. borealis*, and *H. americanus*) (sffr[2,9]). Another even more potent hindgut-myoactive peptide orcomyotropin FDAFTTGFamide (OMT) was discovered in the hindgut extracts from *O. limosus*.[8] The first two precursors of the crayfish *P clarkii* contained different orcokinin isoforms, and one copy of an OMT-like undecapeptide FDAFTTGFGHS (OMTL). OMTs and OMTLs have been identified from several decapods and up to three OMTL/OK-precursors in *H. americanus* (sffr[2,27]), but a separate OMT-precursor is not known. In *D. pulex* only two different genes encode only two out of three identified OKs NLDEIDRSNFGTFA, NLDEIDRSDFGRFV, NLDEIDRSDFSRFV, and one out of two different OMTL-related peptides. Of note, DappuOKs are tetradecapeptides as are all insect OKs.[9]

Structure of the mRNA/Gene and Processing of the Precursor

The similar crayfish pre-pro-orcokinins A and B contain one copy of Ser^{11}-OMT followed by 10 and 11 copies of four distinct OKs (NFDEIDRSGFGFX with X = Asn, Val, or Ala; and $Thr^{8}His^{13}$-OK or Ser^{9}-OK). In the three closely related lobster precursors, one copy of Asn^{11}-OMTL followed similarly by the four OKs and further OK isoforms such as His^{13}-OK and SSEDMDRLGFGFN have been found (sffr[2]). Apart from some other unrelated PRPs, all OMTs and OKs are flanked by canonical dibasic KR cleavage sites (in *D. pulex* one additional KK site).[9]

Distribution of the mRNA/Peptide

In several crustaceans, OK immunoreactivity has been localized in the CNS, STNS, neurohemal structures, and in the hemolymph, suggesting both neural and hormonal roles.[2]

Biological Actions

Asn^{13}-OK, Val^{13}-OK, or Ala^{13}-OK exhibit similar myotropic effects most pronounced on crayfish hindguts (chronotropic and inotropic; sffr[8]), although Asn^{13}-OK was inactive on lobster hindgut. OMT is more potent than OKs in *O. limosus* hindgut assay, whereas OMTLs do not seem to be bioactive (e.g. on STG[7]). Exogenous application of OKs to the STG affects the pyloric rhythm in crabs and *H. americanus* (sffr[2]).

PIGMENT-DISPERSING HORMONE (PDH)

Discovery

Discovered as a light-adapting hormone in caridean shrimp (NSGMINSILGIPRVMTEA-amide; alpha-PDH) and later as a pigment-dispersing hormone in many other crustaceans (NSELINSILGLPKVMNDA-amide, beta-PDH), the 18mer peptides can occur in up to three different isoforms. A structurally quite deviating variant has been sequenced recently from *Daphnia magna* and *D. pulex* (sffr[29]).

Structure of the mRNA/Gene and Precursor Processing

Precursors derived from sequenced mRNAs are known from decapod and branchiopod crustaceans contain the PDH at the end separated by a dibasic cleavage site from a long PRP.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

In the 2- or 3-exon PDH genes, the PRP-encoding region is interrupted by the first and/or the only one intron, whereas the second intron splits the 3′ UTR-message (sffr[9,29]).

Distribution of the mRNA/Peptide

A first immunolocalization was described in crabs and crayfish, but it turned out recently that separate PDH-precursor mRNAs and derived slightly different PDHs are differentially distributed in eyestalks of *Cancer productus* (sffr[2,29]).

Receptors and Signaling Cascades

The first putative G protein-coupled receptors for PDH were cloned from the Kuruma prawn *Marsupenaeus japonicus* (MjPDHR, AB478163.1, 2009) and predicted for *D. pulex*.[31] Evidence from erythrophores of freshwater shrimp *Macrobrachium potiuna* suggests that alpha-PDH elicits pigment dispersion via G protein-coupled receptor-mediated increases in cAMP activating a cAMP-dependent protein kinase A. This phosphorylates a granule-bound 53- to 57-kDa protein, which then allows for kinesin-driven dispersion of granules (sffr[18]).

Biological Actions

PDH is a classical antagonist to RPCH in controlling chromatophore pigment dispersion in many crustaceans (sffr[28]) but seems to have no neuromodulatory roles in the STG.[2] As the insect homolog pigment-dispersing factor (PDF) is an established circadian clock output factor, evidence for similar roles of PDHs in controlling circadian rhythmicity in decapod, isopod, and branchiopod crustaceans is now emerging. Methyl farnesoate synthetic activity of crayfish mandibular organs is apparently inhibited by PDH *in vitro* (sffr[28,29,34]).

PROCTOLIN

Discovery

Identified as the first peptide in insects, but later also from lobster and crab pericardial organs (POs), proctolin (RYLPT), is one of the most conserved peptides in arthropods (sffr[2]). However, in *D. pulex*, authentic proctolin has recently been sequenced together with a novel isoform Met[4]-proctolin.[9]

Structure of the mRNA/Gene and Processing of the Precursor

In crustaceans, genes, mRNAs and derived precursors for the two identified proctolin isoforms have only recently been deduced from the *D. pulex* genome and are in both cases similar to the structures known from insect proctolin genes. The proctolins are immediately following the SPs but are separated from long PRPs only by a monobasic (R) cleavage site.[9]

Distribution of the mRNA/Peptide

In decapods, isopods, and branchiopods, proctolin-immunoreactive neurons occur almost throughout the entire CNS, among them also motoneurons coexpressing classical transmitters and in classical neurohemal organs such as the SG in the eyestalk ganglia and in projection neurons innervating the STG from commissural and the POs from thoracic ganglia (sffr[2]).

Receptors and Signaling Cascades

Proctolin enhances force of contractions as a cotransmitter via potentiation of Ca^{2+}-channel activity in postural motoneurons of decapods. However, in isopod skeletal muscles, proctolin apparently does not act via cAMP-dependent protein kinase A-mediated phosphorylation inhibiting non-voltage-dependent K^+-channels as initially shown, but via an activation of protein kinase C reducing cGMP contents by phosphorylating a cytoplasmic guanylyl cyclase (sffr and discussion[21]).

Biological Actions

Proctolin has myotropic effects not only on the hindgut (especially on ring muscles of the proctodeum, hence its name) but also on cardiac, skeletal, and visceral muscles also in isopods and barnacles. Cardioactivity in crustaceans is likely brought about by its neuromodulatory effects on CG neurons, but such effects are also well established for the STG, as brought about by at least three identified proctolinergic projection neurons from crab commissural ganglia (sffr[2,17]).

PYROKININ

Originally isolated as a N-terminally pyroglutamic acid (pQ)-bearing Leucopyrokinin pQTSFTPRLamide, many insect and fewer crustacean pyrokinins (PKs) without a pQ group became known as bearing the C-terminal motif FXPRLamide (with X being Gly, Ser, Thr or Val). In crustaceans, 5–10 aas long pyrokinins were first identified in as Pev-PK1 DFAFSPRLamide and Pev-PK2 ADFAFNPRLamide in shrimps *Litopenaeus (=Penaeus) vannamei*, later others also in crab and lobster (sffr[2]).

Distribution of the mRNA/peptide

Identified crab pyrokinins have hitherto only been localized to the commissural ganglia and STG of *C. borealis*,[24] but

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

mass spectrometric mapping suggests a much wider distribution in the CNS of several crustaceans (sffr[2]).

Biological Actions

Both shrimp Pev-PKs stimulate hindgut contractions in cockroach and crayfish *in vitro*, and authentic crab PKs excite gastric mill rather than pyloric rhythms in *C. borealis* (sffr[24]).

RED PIGMENT CONCENTRATING HORMONE (RPCH)

Discovery

The first invertebrate peptide to be sequenced[11] and being extremely conserved in decapods and an isopod *Porcellio scaber* is the octapeptide pQLNFSPGWamide that shares considerable identities with many adipokinetic hormones (AKHs) from insects.[2,13] The recently discovered homolog pQVNFSTSWamide from *D. magna* and *D. pulex* is, however, much closer in structure to the insect AKHs.[9]

Structure of the Gene/mRNA and Processing of the Precursor

The decapod (crab *Callinectes sapidus*) and branchiopod (*D. pulex*) 2-exon RPCH/AKH genes contain the SP followed by the octapeptide separated by a dibasic (KR) processing site from a long PRP, which is interrupted by the intron (sffr[9]).

Distribution of the Peptide

In decapods and isopods, the RPCH-immunoreactive cells are mainly distributed in the eyestalk ganglia, especially prominent in the X-organ sinus gland (XOSG) system (sffr[2,20]). In crab embryos, another pathway leads from brain cells to possible postcomissural neurohemal organ structures of the VNC (sffr[4]).

Receptors and Signaling Cascades

To date, crustacean receptors for RPCH/AKH-like peptides are unknown, but the RPCH action on chromatophores is likely mediated by a complex interplay of decreased cAMP contents and increased Ca^{2+}-levels. In freshwater shrimp *M. potiuna*, a G-protein-coupled receptor is signaling through phospholipase C-driven inositol-triphosphate production, which elevates Ca^{2+} that in turn via a Ca^{2+}/Calmodulin-activated protein kinase C phosphorylates and activates a serine/threonine phosphatase. This then leads to dephosphorylation of granule-bound proteins followed by pigment aggregation (sffr[18]).

Biological Actions

Decapod RPCH is a chromatophorotropin leading to the concentration of pigment granules in red and other chromatophores of several shrimps and in crayfish distal retinal pigment cells.[13] The *Daphnia* homolog is apparently inactive in this regard but can mobilize lipids in an insect (sffr[9]). RPCH has profound effects in changing coupling of neuronal oscillators in crab STG and can stimulate release of methyl farnesoate from mandibular organs *in vitro*. Furthermore, it modulates the sensitivity of photoreceptor cells and retraction of distal retinal pigment (sffr[28]).

SIFAMIDE

Discovery

The first SIFamide in crustaceans was identified as FMRFamide-like peptide Pem-FLP7 (GYRKPPFNG-SIFamide) from *P. monodon*, a member of a peptide family whose first member was Neb-LFamide from the flesh fly *Neobellieria bullata*. Among crustaceans, Gly^1-SIFamide is the most common, whereas Val^1-SIFamide is found in two *Homarus* species, and both isoforms occur in *C. maenas* (sffr[2,27]). However, a very different and 1aa shorter TRKLPFNGSIFamide identified in *D. pulex* lacks the usual Tyr^2 and contains Leu^4-Pro^5 instead of the usual Pro-Pro motif in SIFamides of most insects and decapods.[9]

Structure of the mRNA/Gene and Processing of the Precursor

In all arthropod SIFamide mRNAs, the peptide is encoded directly after the SP and is followed by a conserved dibasic (KR) cleavage site separating SIFamide from a PRP containing two cysteines. The 2-exon *sifa*-gene in *D. pulex* encodes a 73 aas precursor (sffr[9]).

Distribution of the mRNA/Peptide

In crayfish *P. clarkii*, SIFamide mRNA or peptides are expressed in all nervous tissues, especially in brain projection neurons (cluster 10), but absent from the heart, hepatopancreas, and skeletal muscle but in *H. americanus* also in the midgut (sffr[2]).

Biological Actions

Val^1-SIFamide modulates the lobster pyloric neural network, and Gly^1-SIFamide controls male aggressive behavior in *Macrobrachium rosenbergii*.[2]

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

SULFAKININS

Discovery

Sulfakinins (SKs), first identified in cockroaches, share a heptapeptide structure containing a sulfated tyrosine $XY_{(SO3H)}$GH**M/L**RFamide (X = D or E) in several arthropod groups. In decapod crustaceans, the first peptides pQFDEY$_{(SO3H)}$GHMRFamide (SKI) and AGGSGGVGGEY$_{(SO3H)}$DDY(SO3H)GHLRFamide (SKII) were identified from CNSs of shrimps *P. monodon* and *L. vannamei*, and later a shorter non-sulfated SKII isoform from lobster. Interestingly, in *D. pulex*, two unique SKI (containing a Tyr-amide C-terminus) and SKII were identified which, however, were not Tyr-sulfated (sffr[9]).

Structure of the mRNA/Gene and Processing of the Precursor

Lobster and *D. pulex* sulfakinin-mRNA precursors contain single copies of SKI and SKII in tandem close to or at the end of the ORFs, respectively. The *D. pulex sk*-gene is a 4-exon gene encoding a 207-bp long precursor carrying the SK1-SK2 tandem separated by dibasic (KR, RR) processing sites (sffr[9]).

Distribution of the mRNA/Peptide

Up to ten SK-specific neurons only in total are found in the brain and VNC of shrimp *P. monodon* (sffr[2]).

Biological Actions

Synthetically sulfated isoforms of SKs are cardioactive in the lobster *H. americanus*, increasing both frequency and amplitude of the heartbeat (sffr[2]).

TACHYKININ-RELATED PEPTIDES

Discovery

Tachykinin-related peptides (TRPs) form a large group of invertebrate peptides exhibiting a C-terminal -FX$_1$GX$_2$Ramide motif (X_1, X_2 variable) with slight resemblance to vertebrate tachykinins and neurokinins. Two TRPs have first been identified from *C. borealis*, the *nona*peptide CabTRP-Ia APSGFLGMRamide and a truncated isoform CabTRP-Ib SGFLGMRamide, the former being identified later in many other decapods. A third decapod *nona*peptide TRP, TPSGFLGMRamide, was later identified from *Cancer* crabs, followed by three further *nona*peptide TRPs identified from *L. vannamei* showing slightly different N-terminal sequences (APAGFLGMRamide, APSGFNGMRamide and APSFGLDMRamide; sffr[2]). Interestingly, merely three *deca*peptide TRPs have been identified from *D. pulex*.[9]

Structure of the mRNA/Gene and Processing of the Precursor

The first TRP precursors cloned from cDNA libraries of *P. clarkii* and *P. interruptus* are highly conserved, containing seven copies each of CabTRP-Ia. However, a very similar EST-deduced and full-length cloned precursor of *H. americanus* contained six copies of CabTRP-Ia and one copy of TPSGFLGMRamide at the end. The three quite unrelated decapeptide DappuTRPs (except perhaps for DappuTRP2 TP*N*S*RA*FLGMRa and TPS*G*FLGMRamide) as derived from exon 2 of the 3-exon Dappu *tkrp*-gene are somewhat closer related to insect TPRs than to those of decapods. Within the precursors, all TRPs are flanked by dibasic (KK, KR, RR) cleavage sites and spacer PRPs showing no sequence similarity among the species or resemblance to any other arthropod peptide (see Ref. 9 for more detailed comparisons).

Distribution of the mRNA/Peptide

TRPs are present within several neurons of the CNS partly entering the STG and in the midgut endocrine paraneurons of several crustaceans. In *P. clarkii*, eyestalk ganglia and CNS, especially brain neurons of clusters 9 and 11 and among posterior lateral cells are ISH reactive for TRP-mRNA, which was absent from midgut and hindgut tissue.[35] In the crayfish *Pacifastacus leniusculus*, TRPs occur in many neurons of the brain and the eyestalk ganglia, particularly associated with identified amacrine cells of the lamina, and in fibers terminating in the STG (sffr[14]). CabTRP-Ia is also found in likely open-type midgut endocrine cells of *Cancer* crabs (sffr[2]).

Signaling Cascades

Stimulatory activities of CabTRP-1a on pyloric circuitry in the STG of *C. borealis* are partly mediated via calmodulin-dependent enzyme cascades leading to alterations of voltage-dependent currents (sffr[30]).

Biological Actions

CabTRP-Ia and TPSGFLGMRamide activate pyloric (preferably) and gastric mill circuitries of decapod STGs together with other peptide modulators such as proctolin. When tested at 10^{-6} M, both the peptides equally lead to significant increases in frequency and amplitude of heart contractions (sffr[2,30]). Cockroach *Leucophaea maderae* TRP-4 (=Met^6-CabTRP-Ia) modulates photoreceptor sensitivity in combination with GABA by presynaptic inhibition from amacrine

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

cells of the crayfish lamina.[14] CabTRP-Ia release from midgut endocrine cells seems to elevate circulating levels of the peptide in starved animals, and may lead to its myotropic action on the musculature of the foregut (sffr[2]).

CONCLUSIONS AND PERSPECTIVES

This brief survey of identified bioactive neuropeptides in crustaceans has omitted many novel crustacean neuropeptides for which hitherto no bioactivity profile has been available. In decapods, there are now altogether >200 different peptides including bioactive truncated versions known,[2] and the *D. pulex* genome contains at least 43 identified peptide and protein hormone genes encoding more than 70 different peptides, already half of which have now been sequenced.[9] Furthermore, exploration of other peptide sources such as the gut probably containing so-called "brain–gut peptides" (e.g. as CabTRP-Ia) has just begun. Thus, it is certain that other as yet unidentified neuropeptides, for example, also antimicrobial peptides, and neuropeptide families will soon be added to the list of bioactive crustacean neuropeptides.

Chapter 33

Developmental Peptides: ETH, Corazonin, and PTTH

Michael E. Adams, Young-Joon Kim, Yoonseong Park and Dusan Zitnan

ABSTRACT

Ecdysis-triggering hormones (ETHs) are small, linear, C-terminally amidated peptides produced and released by endocrine Inka cells under the control of ecdysteroids and other peptides. Released into the blood at the end of each molt, they activate peptidergic central neuron ensembles to trigger a sequence of physiological and behavioral events culminating in ecdysis or shedding of the old cuticle. Corazonin is an N- and C-terminally blocked neuropeptide produced by neurosecretory cells in the brain and ventral nerve cord. It has many physiological actions that, depending on the insect, include cardioacceleration, melanization, and ecdysis initiation. PTTH is a large (22-kDa) homodimeric peptide hormone produced by two pairs of lateral neurosecretory cells in the brain. It acts on the prothoracic glands to promote synthesis and release of ecdysteroids. Precursors of all these peptide hormones contain associated peptides of unknown function.

ECDYSIS-TRIGGERING HORMONES

Discovery

Ecdysis-triggering hormones (ETHs) were first isolated and sequenced from epitracheal glands of the tobacco hawkmoth, *Manduca sexta*, and the silkmoth, *Bombyx mori*, and shortly thereafter were identified in *Drosophila*.[29,30] Epitracheal glands consist of a large, peptidergic Inka cell, a smaller putative endocrine cell, an exocrine cell, and a canal cell. Zitnan initially observed strong immunoreactivity with antiserum to the neuropeptide FMRFamide in Inka cells on the surface of tracheal tubes immediately adjacent to each spiracle in the waxmoth *Galleria mellonella*, and noticed that they lost staining after ecdysis. Epitracheal gland extracts trigger premature ecdysis when injected into pharate *M. sexta* larvae. The first isolation of an ETH was accomplished by reversed-phase HPLC using an extract of approximately 40 *M. sexta* epitracheal glands.[31] The peptide was pure after a 2-step purification guided by the ability of fractions to trigger premature ecdysis behavior in pharate *M. sexta* larvae on injection into the hemocoel. ETHs of *M. sexta* (MasETH) and *B. mori* are linear peptides with a conserved C-terminal sequence motif of –NIPRMamide (Fig. 1).[17] Preecdysis-triggering hormone (PETH), discovered through precursor analysis (see below), is identical in the two moth species.[32] The *Drosophila* peptides DrmETH1 and DrmETH2 were deduced using BLAST analysis of the fly genome database using the moth precursor sequences and confirmed by RT-PCR.[12] Subsequently, ETH-related peptides have been identified in a wide variety of insect orders through direct isolation of peptides, PCR, or *in silico* screening.[17] These include Orthoptera (cockroaches, crickets, grasshoppers), Hemiptera (aphids), Homoptera (planthoppers), Phthiraptera (lice), Coleoptera (beetles), Diptera (flies, mosquitoes), Lepidoptera (moths), and Hymenoptera (wasps, honeybee). In the honeybee *Apis*, only one ETH ligand is evident in the precursor. ETH-like peptides also occur in the related arthropod classes Crustacea (water flea, *Daphnia*) and Arachnida (tick, *Ixodes*).

Inka cells and associated ETH-like immunoreactivity occur in all insect Orders thus far examined, including Thysanura (silverfish), Orthoptera (crickets, grasshoppers, cockroaches, walking sticks), Plecoptera (stoneflies), Hemiptera and Homoptera (bugs), Megaloptera (alderflies), Neuroptera (antlions), Coleoptera (beetles), Lepidoptera (moths), Diptera (flies, mosquitos, crane flies), and Hymenoptera (bees, wasps, ants). Extracts of epitracheal glands or trachea containing Inka cells from many of these species induce ecdysis behavior in *B. mori*,[34] verifying that the ETH signaling system is widespread, functional, and conserved in insects.

Structure of the Precursor mRNA/gene and Peptide Processing

Manduca sexta *and* Bombyx mori

The MasETH and BomETH precursors contain a 23-amino-acid signal sequence and one copy each of PETH, ETH,

and ETH-AP.[30] Dibasic proteolytic cleavage sites are depicted in Fig. 2. Direct isolation of peptides from *M. sexta* epitracheal glands yields, in addition to PETH, ETH, and ETH-AP, significant amounts of precursor peptides. These include the unprocessed precursor minus the signal sequence PETH-ETH-ETH-AP (PEA), PETH-ETH (PE), and ETH-ETH-AP (EA). Analysis of peptide content in Inka cells and circulating peptides in the hemolymph during ecdysis behavior reveal a 30% excess of PETH over ETH, despite the 1:1 stoichiometry of these peptides in the precursor. The relatively lower level of circulating ETH results from incomplete processing of the EA precursor, levels of which increase in the hemolymph during the ecdysis sequence.[32]

Ecdysteroid pulses that initiate the molt induce increased synthesis of ETH peptides in Inka cells. This is especially evident during the fifth (last) larval instar of *M. sexta*, where the pupal steroid commitment pulse is followed by a much larger second pulse that programs the pupal stage. Levels of ETHs and precursors increase in synchrony with the leading edges of each of these two steroid peaks,[35] indicating that expression of the ETH gene and precursor processing are steroid regulated.

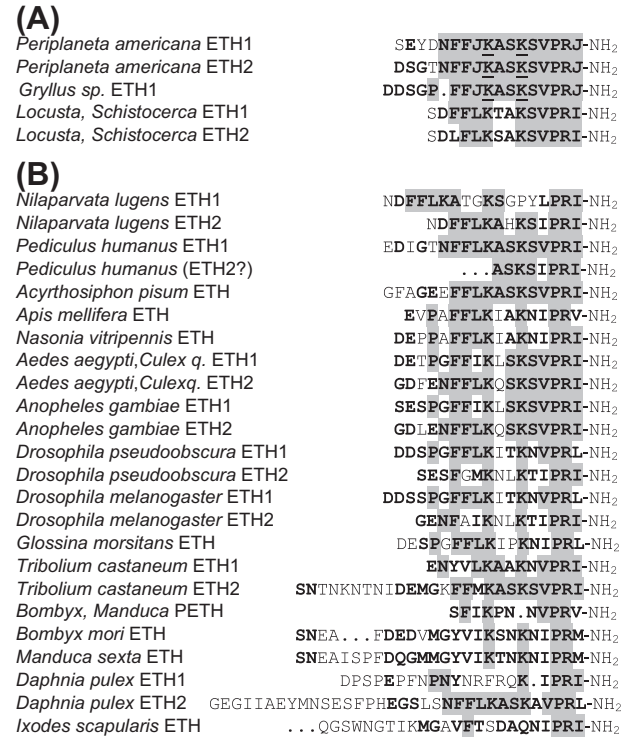

FIGURE 1 Amino acid sequence alignments of ecdysis-triggering hormones.

Drosophila melanogaster *and* Anopheles gambaie

The ETH precursor in *Drosophila* is encoded by the gene CG18105, which occurs on the right arm of the second chromosome at position 60E1–2. The preprohormone consists of a 21-amino-acid signal sequence and one copy each of DrmETH1 and DrmETH2, both of which have ecdysis-triggering biological activity.[12] Assignment of the ETH1 N-terminus is not obvious from inspection of the precursor sequence. However, synthesis and bioassay of the two most probable peptides (N-terminus beginning with either AIS– or DDS–) reveals that the DDS– sequence is significantly more bioactive in inducing adult ecdysis.[12] Three additional putative peptides occurring downstream of ETH2 have not been tested for biological activity. These include a 21-amino-acid peptide unblocked at the C-terminus (DrmETH-AP1), a 63-amino-acid peptide with a blocked C-terminus (DrmETH-AP2), and a 54-amino-acid peptide unblocked at the C-terminus.[12] Processing sites for the precursor are depicted in Figure 2.

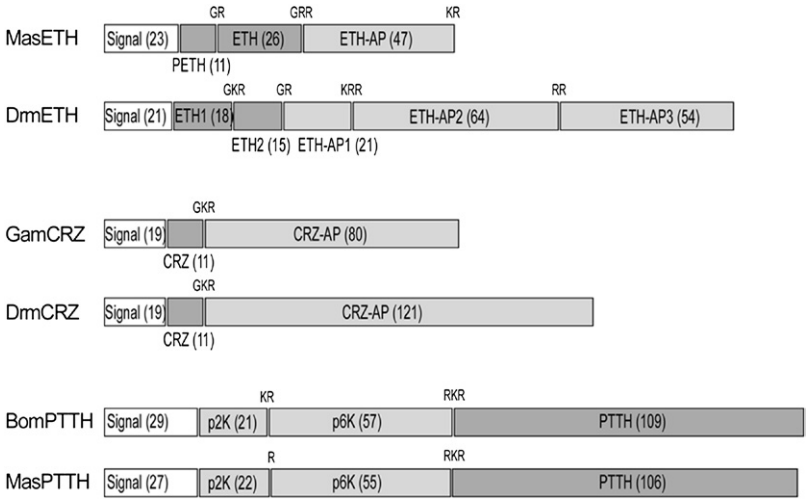

FIGURE 2 Schematic diagrams of precursors and processing sites for ETHs,[12,32] corazonins,[1] and PTTHs.[7]

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

An ETH precursor has been deduced from the mosquito *A. gambiae* genome database.[34] Peptides closely related to DrmETH1 and DrmETH2 are evident in the mosquito precursor and associated peptides downstream of ETH2 (Fig. 2). Related peptides from *Aedes aegypti* (AeaETH1, AeaETH2) have been isolated and sequenced by mass spectrometry. These results verify the sequences inferred from genome analysis.[3]

Distribution of the mRNA and Peptides

The ETH gene and mRNA are detected only in Inka cells. Northern blots were used to detect ETH-encoding mRNA in *M. sexta* epitracheal glands; the signal is absent in the CNS, epidermis, muscle, and trachea.[8] Inka-cell-specific expression of ETH was shown using the ETH promoter to drive expression of EGFP in transgenic flies. A nucleotide sequence encoding the following fusion protein was constructed: the ETH gene upstream promoter region (~300 bp), the ETH gene, and a nucleotide sequence encoding EGFP. Transformed fly lines showed EGFP-associated fluorescence only in Inka cells.[10] The baculovirus expression system (Bac-to-Bac) was used to identify the ETH promoter in *B. mori*. The upstream promoter region (600 bp) with EGFP was subcloned into the bacmid DNA and the recombinant baculovirus was injected into larvae and pupae of *B. mori*. Strong and specific EGFP expression was detected only in Inka cells.[4]

Receptors

ETH receptors identified in *D. melanogaster* are G-protein-coupled receptors.[29,30] A single gene (CG5911) containing 5 exons encodes two ETH receptor subtypes through alternative splicing of two 3′ exons to generate CG5911a and CG5911b. Phylogenetic analysis shows that CG5911 is most closely related to vertebrate thyrotropin releasing hormone and neuromedin receptors, as well as to *Drosophila* receptors for PBAN-like pyrokinin receptors.

ETH receptors are coupled to Gαq, which mobilizes calcium from intracellular stores via the phosphoinositide turnover pathway. Pharmacological profiles of ETH receptors were determined by heterologous expression in mammalian CHO cells using aequorin as an intracellular calcium reporter. ETH receptors in *Drosophila* show high sensitivity and selectivity to fly and moth ETHs. Remarkably, CG5911b shows a considerably higher sensitivity to ETH1 and ETH2 as compared with CG5911a. Both DrmETH1 and DrmETH2 activate CG5911b with EC_{50} values of approximately 1 nM. By contrast, ETH1 and ETH2 activate CG5911a with EC_{50} values of approximately 400 nM and approximately 4 μM, respectively.[11] Thus, although CG5911b is more sensitive to the cognate ETH ligands than CG5911a, the latter is more discriminating between ETH1 and ETH2.

ETH receptors were subsequently sequenced and pharmacologically characterized in the moth, *M. sexta*.[9] As in *Drosophila*, two receptor subtypes (ETHR-A, ETHR-B) are produced through alternative splicing of 3′ exons. Both receptor subtypes are specific for ETH peptides; PETH and ETH show EC_{50} values for ETHR-A of 33 and 17 nM. For ETHR-B, PETH and ETH show EC_{50} values of 10 and 30 nM, respectively. Thus, unlike their *Drosophila* orthologs, *Manduca* ETH receptors have similar sensitivity to ETH ligands.

ETH receptors have been cloned and expressed in the yellow fever mosquito, *A. aegypti*.[3] As previously reported for *Drosophila* and *Manduca*, *Aedes* receptors occur as two subtypes (AeaETHR-A and AeaETHR-B) by alternative splicing of 3′ exons. Pharmacological profiling of the mosquito receptors revealed that, like the *Manduca* receptors, both receptor subtypes have comparable sensitivities to ETH ligands.

Expression of ETH receptors in *Manduca* and *Aedes* coincides with the surge of ecdysteroids that initiates molting. This association supports previous evidence for a causal relationship between ecdysteroid elevation and onset of sensitivity of the CNS to ETH in *Manduca*.[35]

ETHR-A receptors are expressed in discrete sets of central neurons in moths and flies. The majority of these are "peptidergic ensembles" that release peptides involved in scheduling of successive steps of the ecdysis behavioral sequence (see below). For example, subsets of ETH receptor neurons in *Drosophila* release FMRFamide, kinin, or eclosion hormone. Other ensembles co-release myoinhibitory peptides (MIPs), CCAP, and bursicon. In *Manduca*, one ensemble co-releases kinin and CRF-like diuretic hormone, whereas another releases CCAP, MIPs, sNPF and MIPs, or calcitonin-like DH31 and MIPs.

ETH receptors have been found widely in the Insecta using *in silico* screening[17] (see the chapter in the Peptide Biosynthesis/Processing section of the book). This approach also has led to their discovery in representative species from the Crustacea (Daphnia) and Arachnida (*Ixodes*). Interestingly, ETH receptor subtypes in *Ixodes* are predicted to arise through the expression of two distinct genes. This differs from all other species examined, where subtype diversity occurs through alternative splicing of pre-RNAs.

Biological Actions

ETHs released into the hemocoel by Inka cells act directly on the CNS to trigger a behavioral sequence culminating in ecdysis of the old cuticle. It is remarkable that ETH signaling mediates ecdysis in insects with widely divergent body plans. Even though the specific motor patterns may be different as

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

a result, the signaling system and the behaviors seem to be conserved over millions of years.

Injection of MasETH into pharate *M. sexta* larvae initiates preecdysis contractions within minutes. The animal switches to ecdysis contractions after about one hour.[32] The peptide also elicits patterned motor output from the isolated CNS, the parameters of which (e.g., burst frequency, burst duration) correspond precisely to those governing contractions in the whole animal. This is known as "fictive" behavior, because although the pattern of motor output corresponds to the behavior, muscles have been removed and one can record only a "fictional" behavior. These observations indicate that the peptide acts directly on the CNS to elicit centrally patterned preecdysis and ecdysis behaviors. By contrast, injection of PETH into pharate *Manduca* larvae elicits preecdysis only. Indeed, the action of PETH helped to define two preecdysis behaviors: preecdysis I and preecdysis II.[32] Injection of PETH alone triggers preecdysis I only; thereafter, the animal ceases all contractions. Subsequent injection of ETH triggers preecdysis II followed by ecdysis behavior. Injection of a naive pharate larva with MasETH triggers simultaneously both preecdysis I and preecdysis II, followed by ecdysis behavior. Observations of natural behavior reveal that the animal begins the behavioral sequence with preecdysis, and 20 min later begins preecdysis II contractions. Both behaviors continue in parallel for the next 40 min, after which a transition to ecdysis behavior occurs. Therefore, it seems that the action of PETH dominates during the first 20 min of the ecdysis behavioral sequence. This may be explained by the observation that the concentration of PETH in the hemolymph is somewhat higher than that of ETH during early preecdysis.[32]

Injection of DrmETH1 into *Drosophila* larvae elicits the entire ecdysis behavioral sequence.[2,10] These steps include tracheal collapse and inflation, preecdysis behaviors consisting of anterior–posterior contractions and squeezing waves, and peristaltic ecdysis contractions. In contrast, ETH2 injection triggers tracheal collapse and inflation and ecdysis, but fails to elicit preecdysis behaviors. Deletion of the gene encoding *Drosophila* ETHs causes failure of successful ecdysis and lethality.[10] However, null mutants can be rescued by injection of either ETH1 or ETH2. In pharate adults, injection of ETH1 (>1 fmol) or ETH2 (>10 fmol) triggers the entire eclosion behavioral sequence, although ETH2 is less potent than ETH1. Steps in adult eclosion include head inflation (preeclosion), forward head thrusts (onset of ecdysis), bilateral, alternating contractions of the thorax, and strong peristaltic abdominal contractions pushing the body forward.

ETH controls similar behaviors associated with ecdysis or eclosion in *B. mori*, beetles, honeybee, and mosquito; this material is summarized in a recent review.[29]

CORAZONIN

Discovery

Corazonin, an undecapeptide blocked at both N- and C-termini, was first isolated from corpora cardiaca of the cockroach, *Periplaneta americana*.[24] The peptide is named after the Spanish word "corazon" or "heart," because of its signature cardioacceleratory activity in the cockroach. The identical peptide subsequently was identified in other cockroaches, crickets, and moths. A variant of corazonin, His(7)-corazonin, was isolated from the grasshopper *Schistocerca americana*, and subsequently from many other orthopterans, including *Schistocerca gregaria*, *Locusta migratoria*, and the stick insect, *Carousius morosus*. Additional isoforms have been identified in honeybees (Thr^4, His^7-corazonin), crane flies (Gln^{10}-corazonin), bumblebees (Tyr^3, Gln^7, Gln^{10}-corazonin), and in the new insect order Mantophasmatodea (His^4, Gln^7-corazonin).[13] The amino acid sequence of corazonin is somewhat related to adipokinetic hormone and red pigment concentrating hormone of crustaceans, suggesting a common ancestry.

Structure of the Precursor mRNA/Gene and Peptide Processing

The corazonin gene has been characterized in *D. melanogaster* (CG3302) and other *Drosophila* species, including *Drosophila virilis*, *Drosophila simulans*, *and Drosophila erecta*.[1] The cDNA encoding the precursor also has been characterized in the waxmoth, *G. mellonella* and in *B. mori*.[16] The precursor consists of a signal sequence, a single copy of the 11-mer corazonin peptide, and a corazonin-associated polypeptide (CRZ-AP or CAP) of approximately 120 amino acids in flies and a peptide of 80 amino acids in the waxmoth (Fig. 2). The genomic sequence indicates the presence of an intron in the region corresponding to the *D. melanogaster* CAP coding region. A second intron occurs in the 5′ UTR region of *D. virilis*. Although the CRZ sequence is highly conserved in all species examined, the CAP sequence is highly variable and hence seems to be rapidly evolving.

Distribution of the mRNA and Peptides

Corazonin mRNA and the peptide itself are confined to the central nervous system in all insects examined. The pattern of cellular expression depends on the particular insect and is stage dependent. In the cockroach *P. americana*, corazonin-like immunoreactivity (CRZ-IR) is found in 10 lateral neurosecretory cells of the brain, which project to release sites in the ipsilateral lobe of the corpus cardiacum. Bilaterally paired CRZ-IR neurons occur in all neuromeres of the ventral ganglia, in a DUM cell of the subesophageal ganglion,

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

an interneuron in the optic lobes, and additional cells at the base of optic lobes, as well as in the tritocerebrum and deutocerebrum.[27] In the last larval instar of the waxmoth, *G. mellonella*, *in situ* hybridization detected mRNA in four pairs of brain lateral neurosecretory neurons. These same cells showed CRZ-IR, verifying the presence of both mRNA and peptide in the same cells. No other cells in the CNS were observed. Roller et al.[15] surveyed 6 orders of insects for CRZ-IR, and found central neurons, in both the brain and ventral nerve cord of most insects, except for Coleoptera and the albino strain of the grasshopper, *L. migratoria*. Extracts of ganglia displaying CRZ-IR induced melanization in the albino grasshopper, providing further evidence for the widespread presence of the peptide in the CNS.

In *Drosophila*, *in situ* hybridization showed a pattern of corazonin expression in central neurons that changes during the life history of the animal. During larval life, mRNA is present in 1 pair of brain dorsomedial neurons and 3 pairs of dorsolateral neurons. In addition, 8 bilateral pairs are observed in the ventral nerve cord.[1] In the adult, hybridization signals occurred in 6–8 pairs of brain dorsolateral neurons and widely on anterior surface in the optic lobe medulla, but none in the dorsomedial region or in the ventral nerve cord corresponding to cells previously observed in larvae. Despite the presence of mRNA in optic lobe neurons, CRZ-IR is absent. It has been suggested that the absence of immunoreactivity may result from either too rapid turnover of peptides or translational silencing.[1]

Receptors

The corazonin receptor (CRZR) in *D. melanogaster* is a GPCR encoded by the gene CG10698.[30] Phylogenetic analysis groups this receptor with adipokinetic hormone (AKH) and vasopressin receptors. Expressed either in *Xenopus* oocytes or mammalian CHO cells, CG10698 is highly selective for corazonin, whose EC_{50} is in the low nanomolar range. Other ligands tested at up to 10 μM concentration (including AKH) were inactive.

Corazonin receptors (CRZRs) in *M. sexta*[8] and *B. mori* are involved in initiation of ecdysis. Northern blots show CRZR expression in the CNS and epitracheal glands, but not in muscle, epidermis, or trachea. *In situ* hybridization revealed very strong and specific expression of CRZR that is restricted to Inka cells only 3–4 h before ecdysis in *B. mori*.[29] The *M. sexta* receptor is highly sensitive and selective for corazonin when expressed in *Xenopus* oocytes (EC_{50} = 200 pM) or CHO cells (EC_{50} = 75 pM). Inka cells respond to corazonin (≥10 pM) by releasing low levels of ETH. Interestingly, elevated concentrations of corazonin (>1 nM) suppress ETH release from Inka cells, indicating the likelihood that receptor desensitization plays a role in cellular responses. Such densensitization may place limits on the amount of ETH release, ensuring that only low levels are released in the initial stages of the ecdysis behavioral sequence.

Biological Actions

Corazonin is a potent cardioaccelerator in *P. americana* and in a small number of related cockroach species, but not in other insects. His^7-corazonin of locusts triggers melanization, and hence is also known as a "pigmentotropin."[23,25] The melanization activity of His^7-corazonin is confined to locusts. Corazonin signaling may be involved in responses to nutritional stress.[26]

Corazonin is involved in developmental events related to molting, ecdysis, and metamorphosis. For example, the peptide prolongs spinning behavior in fifth instar *B. mori* larvae, and delays adult development during the pupal stage in the same species.[22] As mentioned above, corazonin injection into moth larvae elicits ecdysis behaviors. Injection of corazonin (10 pmol) into pharate fifth instar larval *Manduca* induces preecdysis behavior within approximately 40 min through release of PETH and ETH. Subsequent release of eclosion hormone leads to depletion of PETH and ETH from Inka cells and ecdysis onset. Before natural ecdysis, the peptide was detected in the hemolymph of *Manduca* larvae just before onset of preecdysis behavior. Exposure of isolated Inka cells to corazonin leads to low level release of ETHs. It thus seems probable that, in *Manduca*, corazonin is involved in initiating the early stages of the ecdysis behavioral sequence by causing ETH release from Inka cells.[8]

Finally, corazonin is implicated in circadian rhythms and diapause. The peptide is colocalized with the PER gene product in lateral neurosecretory 1a cells of *Manduca*,[28] and these cells are implicated in regulation of circadian rhythms.[19] Ablation of these cells in *Manduca* suppresses diapause during short days, indicating their possible role in measuring day length.[20]

PROTHORACICOTROPIC HORMONE (PTTH)

Discovery

Stefan Kopec's demonstration of a brain hormone that initiates molting in insects was a propitious event that launched the field of insect endocrinology.[29] The brain hormone constituted the first definitive example of hormonal signaling in insects, yet it took >65 years for its molecular structure to be defined as PTTH. The hormone's molecular size was estimated initially to be approximately 25 kDa, and PTTH-like bioactivity was located in two pairs of lateral protocerebral neurosecretory cells projecting to release sites in the

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

corpora allata.[21] Ultimate determination of molecular identity came through a combination of direct peptide sequencing and cDNA precursor analysis. Sequencing of the peptide was made possible by tissue preparation on a heroic scale. Initially, 500,000 silkmoth heads were processed to obtain the N-terminal 13 amino acids; subsequent processing of 1.8 million *Bombyx* heads yielded virtually the entire peptide sequence and the realization that the hormone is a dimer.[5,6] For elucidation of the precursor sequence, polyclonal antisera directed against the N-terminus were used to screen a cDNA expression library. The amino acid sequence of the predicted precursor was in complete agreement with that obtained by Kataoka et al.[7] (Genbank accession number D90082). *Bombyx* PTTH was thus defined as a homodimer consisting of identical 109 amino acid subunits. Nucleotide probes based on the *Bombyx* sequence were used to determine the primary structures of PTTH in many other lepidopteran species, including *Samia cynthia*, *Antheraea pernyi*, *Hyalophora cecropia*, and *Spodoptera exigua*. cDNAs encoding related peptide sequences have been determined in *Drosophila*, *Anopheles*, and *Tribolium*.[21] In *Drosophila*, PTTH and the protein encoded by *trunk* share structural similarities and a common receptor (see the section on Receptors below).

Structure of the Precursor mRNA/gene and Peptide Processing

The PTTH gene of *B. mori* consists of 5 exons that encode a 224-amino-acid precursor protein with three proteolytic cleavage sites (Fig. 2). Functions for the N-terminal peptides inferred from the precursor (p2K, p6K) have not been established. The C-terminal 109-amino-acid fragment of the precursor is processed to form the biologically relevant monomeric subunit, which contains seven cysteines (Fig. 2). Homodimerization of these subunits via a single disulfide bond formed between Cys15 of each monomer yields the active hormone. Disulfide bonds within each monomer are formed according to the following pattern: Cys17–Cys54, Cys40–Cys96, and Cys48–Cys98. Interestingly, the 109-amino-acid monomer is about 50% as active as the native dimeric hormone. Glycosylation accounts for the disparity between the predicted (13 kDa) and observed (17 kDa) molecular weights of the monomer, and also contributes to full activity of the native hormone, because the expression product from bacteria without glycosylation has lower biological activity than that of the native hormone. Two putative peptides of 2 and 6 kDa predicted from sequences upstream of the 109-mer fragment are flanked by canonical proteolytic cleavage sites. There is no evidence yet regarding possible functions for these peptides. PTTHs cloned and characterized from other moth species (*Samia*, *Hyalophora*, *Antheraea*, *Manduca*) and nonlepidopteran species (*Drosophila*, *Anopheles*) are summarized elsewhere.[18,21]

Distribution of the mRNA and Peptides

Expression and synthesis of PTTH are confined to two pairs of lateral neurosecretory cells in the brain. This was originally shown in *M. sexta* by single cell dissection and bioassay[21] and was substantiated in many species of moth (*B. mori*, *Antheraea polyphemus*, *M. sexta*) by *in situ* hybridization and immunohistochemical staining. Possibly homologous cells were shown in the *Drosophila* brain[33] and in the subesophageal and ventral ganglia of *Drosophila*, but these have not been confirmed by *in situ* hybridization or bioassay.

Receptors

The PTTH receptor of *Drosophila* is a tyrosine kinase encoded by the gene "torso."[14] This multifunctional receptor functions during early embryogenesis to specify correct patterning of anterior and posterior structures. During this period of development, the presumed ligand for *torso* is Trunk (trk), a dimeric protein that is structurally related to PTTH. After embryogenesis, trk disappears and PTTH functions as the ligand of *torso* to regulate ecdysone synthesis. RNA silencing of *torso* phenocopies ablation of PTTH neurons, that is, both manipulations lead to a prolonged third larval instar and increased pupal size.

Expression of *torso* is confined to the prothoracic gland during larval stages. Activation of *torso* leads to phosphorylation of extracellular signal-regulated kinase (ERK) via the MAPK pathway. ERK knockouts also phenocopy loss of PTTH.[14]

Biological Actions

The sole tissue target of PTTH is the prothoracic gland, which responds to the hormone at low to subnanomolar concentrations by elevating synthesis of ecdysteroid. Consistent with this function, hemolymph levels of PTTH increase immediately before ecdysteroid pulses, which initiate molting at each stage of development.[18]

Chapter 34

Diuretic/Antidiuretic

Geoffrey M. Coast and David A. Schooley

ABSTRACT

A diverse group of peptides are implicated in the control of Malpighian tubule and hindgut function in insects. They are the products of neurosecretory cells in the brain and ventral nerve cord ganglia and are present in identified neurohemal structures from which they can be released into the circulation to function as diuretic and/or antidiuretic hormones. Receptors are known for most of them, and they couple to cAMP, cGMP, or Ca^{2+}-signaling pathways to regulate a variety of transport processes.

DISCOVERY

In the excretory process of insects, Malpighian (renal) tubules (MT) generate a flow of primary urine that is subsequently modified by reabsorptive and secretory processes in the hindgut (ileum and rectum). Diuretic hormones (DHs) accelerate primary urine production, whereas antidiuretic hormones either stimulate fluid reabsorption in the hindgut or reduce MT secretion; these are comprehensively reviewed elsewhere.[6,32]

Corticotropin-releasing Factor (CRF)-Like Peptides

To date, 34 CRF-related DHs are known from 26 species of insects representing 8 orders, plus two acarines and one crustacean. They comprise paralogous subfamilies of 'long' and 'short' peptides as exemplified by two of the CRF-related DHs from the tobacco hornworm *Manduca sexta*, Manse-DH_{41}[20] and Manse-DH_{30}[4] (Fig. 1), both of which act *via* cAMP to increase MT secretion. Manse-DH_{41} has 41% sequence identity with sauvagine, but somewhat less with CRF, and has only 9 residues identical to Manse-DH_{30}. *Bombyx mori* contains three paralogs, versus four paralogs in the vertebrate CRF superfamily.[32] "Short" paralogs are present only in lepidopteran, coleopteran, and dipteran (D.A. Schooley and D.A. Jensen, unpublished) insects. The CRF-related DH from beetles are mostly nonamidated (*Tenebrio molitor*-DH_{47} and Tenmo-DH_{37})[32] and Trica-DH_{37} (*Tribolium castaneum*), whereas Trica-DH_{47} is amidated.[32]

Calcitonin (CT)-Like Peptides

The first CT-like DH was identified in the Pacific beetle cockroach, *Diploptera punctata*.[13] Dippu-DH_{31} (Fig. 1) has low sequence identity to vertebrate CT, but it shares the unusual C-terminal Pro-Gly-NH_2. The 19 CT-like DHs that have been identified comprise a highly conserved family present in 15 species of insects, 3 crustaceans, and 2 acarines.[32]

Kinins

Fifty kinins are known from 18 species of insect and one acarine, and frequently (but not always) multiple isoforms are present. The first (Leuma-Ks; Fig. 1) were identified from the Madeira cockroach (*Leucophaea maderae*) by their myostimulatory action on the hindgut,[15] but were later shown to be potent diuretics. There are no kinins encoded by the genome of *T. castaneum*,[32] or hymenopteran insects (D.A. Schooley and Y. Park, unpublished).

CAP_{2b}

Manse-CAP_{2b} (Fig. 1) was first identified as a cardioacceleratory peptide (CAP)[16] but was later shown to stimulate secretion by MT from the fruit fly *Drosophila melanogaster*. Other CAP_{2b} peptides have been identified by mass spectral analysis of tissue extracts and by mining genomic databases. In the blood sucking bug *Rhodnius prolixus*, the yellow fever mosquito *Aedes aegypti*, and in the xeric insect *T. molitor*, CAP_{2b} has antidiuretic activity.[32]

Arginine Vasopressin (AVP)-like DH

An AVP-like peptide (Fig. 1) was first identified in the migratory locust (*Locusta migratoria*)[30] and the antiparallel homodimer (F2; Locmi-AVP-like DH; AVPL-DH) stimulates secretion by a semiisolated MT preparation that includes the ampullae attached to a short segment of

gut.[32] A peptide with a sequence identical to the Locmi-AVPL monomer (F1) is encoded in the genome of the red flour beetle (*Tribolium castaneum*), but homologous sequences are absent from the published genomes of dipteran and lepidopteran insects, and the honeybee (*Apis mellifera*), although an AVPL sequence is present in the genome of the jewel wasp (*Nasonia vitripennis*).[1]

Antidiuretic Factors (ADFs)

Tenmo-ADFa and Tenmo-ADFb (Fig. 1) were identified from head extracts of *T. molitor* pupae on the basis of their ability to increase cGMP production by MT from adult beetles.[11,12] Both are extremely potent in reducing secretion by the free portion of larval MT with an EC_{50} value of 10 fM for Tenmo-ADFa. To date, they have not been identified from any other insect, but Tenmo-ADFa is also a potent antidiuretic in *A. aegypti*.[23] Interestingly, Tenmo-ADFb has diuretic activity in the house cricket, *Acheta domesticus*.[32]

Ion Transport Peptide (ITP)

Schgr-ITP (Fig. 1) is the only identified ADH that stimulates fluid reabsorption from the insect hindgut and was isolated from the locust, *Schistocerca gregaria*, on the basis of its ability to increase electrogenic Cl^- transport across the ileum.[2] A cDNA encoding the prepropeptide was cloned and the C-terminal amidated peptide has 39–42% sequence similarity to crustacean hyperglycemic hormone (CHH) from the shore crab, *Carcinus maenas*.[24] A splice variant of Schgr-ITP encodes an Schgr-ITP-like peptide (ITP-L) with a nonamidated C-terminus (Fig. 1), which has no currently known biological function. cDNAs encoding ITP and ITP-L have been cloned from *M. sexta*, *B. mori*, and *A. aegypti*.[8] Similarly, in *Drosophila melanogaster* and *Tribolium castaneum*, ITP and two distinct ITP-L peptides have been identified.[32] Only the *T. castaneum* ITP is not amidated at the C-terminus.

STRUCTURE OF PRECURSOR mRNAs AND GENES

CRF-Related DH

The CRF-DH gene (*Dh*) of *D. melanogaster* (CG8348) is located in region 85E on chromosome 3R. It comprises four exons, with the prepropeptide (Fig. 2) encoded by exons 2, 3, and 4.[5] The sequence N– and C-terminal to the cleavage signals of Drome-DH_{44} resemble no known

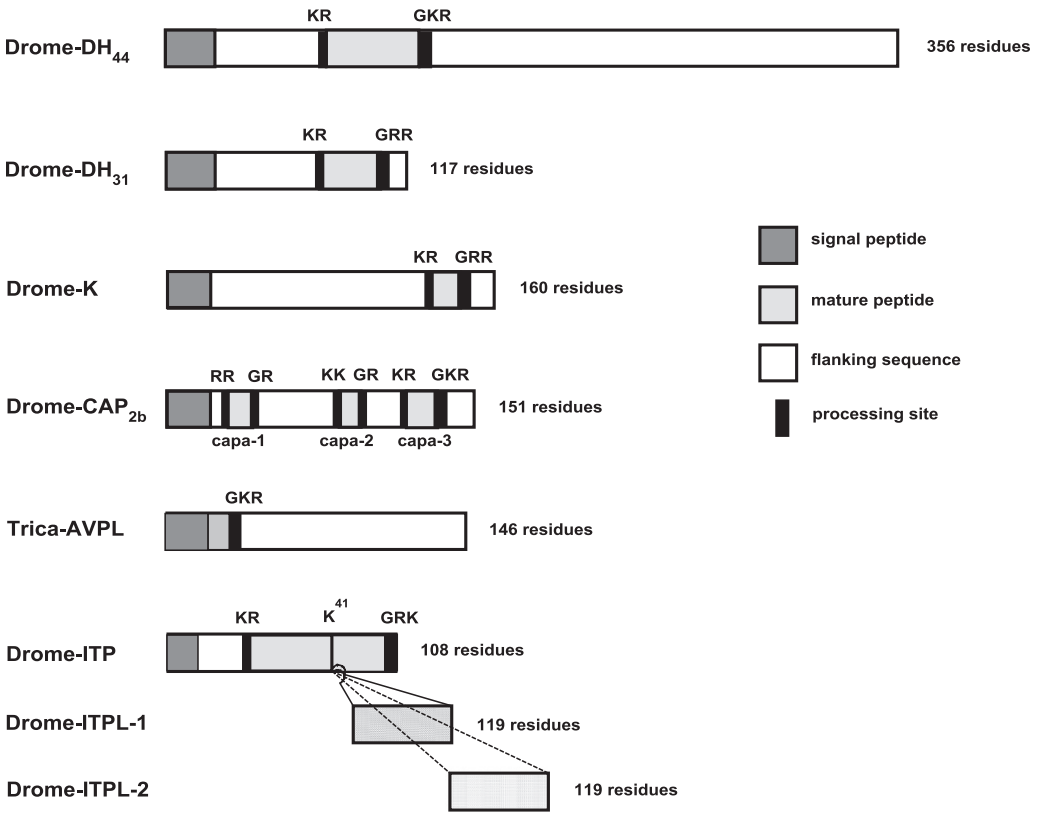

FIGURE 2 Schematic representations (approximately to scale) of precursor structures and processing sites for diuretic and antidiuretic peptides that are encoded by either the *D. melanogaster* genome or, for AVPL, the *T. castaneum* genome. The alternative C-termini of the precursors for Drome-ITP, ITPL1, and ITPL2 are shown as hatched and stippled boxes, respectively.

peptide. In *B. mori*, a single gene encodes three different peptides having 34, 41, and 45 residues; the latter is a paralog of Drome-DH_{44}, whereas the former are paralogs of Manse-DH_{30} and Manse-DH_{41}.[32] All three *B. mori* precursor peptides have 70 identical residues at the N-terminus.

CT-Like DH

The CT-like DH gene (*Dh31*) of *D. melanogaster* (CG13094) is located in region 29D2–3 on chromosome 2L and comprises five exons. The prepropeptide (Fig. 2) is encoded by exons 3, 4, and 5. The flanking sequences have no similarity to other known peptides.

Kinins

The kinin gene (*pp*; *leucokinin*) of *D. melanogaster* (CG13480) is located in region 70E2 of chromosome 3L. The prepropeptide (Fig. 2) is encoded by a single exon and contains one copy of Drome-K. By contrast, three kinins (Aedae-K-1, Aedae-K-2, and Aedae-K-3) are encoded on the corresponding gene of *A. aegypti*,[32] and six in *R. prolixus*.[33]

CAP_{2b}

The *capability* (*capa*) gene of *D. melanogaster* (CG15520) is located in region 99C6 of chromosome 3R. The prepropeptide (Fig. 2) is encoded by three exons, with exon 2 encoding two CAP_{2b} peptides (capa-1 and capa-2), and exon 3 encoding a peptide of the pyrokinin family.

AVP-Like DH

An arginine vasopressin-like (*avpl*) peptide gene is present in linkage group 8 of the *T. castaneum* genome. It comprises three exons and two small introns[1] and encodes a peptide that is identical to the Locmi-AVP-like peptide. Downstream of AVPL is a sequence that closely resembles mammalian neurophysin, which is required for the proper processing of AVP in mammals.[1] There is no gene homologous to *T. castaneum avpl* in the genome of *D. melanogaster*.

ADFs

The genome of *T. castaneum* contains five genes encoding Tenmo-ADFb and four closely related peptides, but none encoding Tenmo-ADFa.[32]

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

ITP

The *ion transport peptide* (*itp*) gene of *D. melanogaster* (CG13586) encodes three different transcripts giving rise to Drome-ITP, Drome-ITPL1 and ITPL2 *via* alternative splicing of five exons.[9] Exons one and two are common to all three mRNAs and encode an unusually short (15 residues) signal peptide, a flanking sequence followed by a processing site (KR), and the first 41 residues of ITP, ITPL1, and ITPL2. The 46 residue nonamidated C-termini of ITPL1 and ITPL2 are encoded by exons 3 and 4, respectively, whereas the 32-residue C-terminus of ITP followed by an amidation processing site (GRK) is encoded by exon 5. The ITP genes in *M. sexta*, *B. mori*, and *A. aegypti* also involve three exons, but they differ in organization from that of *D. melanogaster*.[8]

DISTRIBUTION OF mRNA AND PEPTIDES

CRF-Related Peptides

In *D. melanogaster*, the *Dh* transcript is found exclusively in three bilateral pairs of cells in the *pars intercerebralis* (PI) of the larval and adult brain.[5] Drome-DH_{44} immunoreactivity (IR) is present in the cells and in their axons projecting to the retrocerebral complex. In other insects, CRF-DH-IR material is present in median neurosecretory cells (MNCs) of the brain, in posterior-lateral neurosecretory cells (NSCs) of the abdominal ganglia, and in associated neurohemal organs, corpora cardiaca (CC), perivisceral organs (PVO), and abdominal nerves.[6] CRF-DH-IR material is also present in the endocrine cells of the midgut and MT ampullae.

CT-Like Peptides

CT-like-IR material is present in lateral NSCs of the brain in *R. prolixus* and in axons projecting to the CC and dorsal vessel (heart).[34] In the mesothoracic ganglionic mass, CT-like-IR is present in bilaterally paired NSCs and in five dorsal unpaired medial (DUM) neurons, which also contain serotonin, an identified DH. Axons from CT-like-IR cells extend into abdominal and trunk nerves that form neurohemal release sites.

Kinins

Kinin-like-IR material is widely distributed in the CNS in both interneurons and NSCs. Kinin-IR is present in MNCs of the PI in *L. maderae*, and in axons to the CC,[27] but not in MNCs of locusts, houseflies, and honeybees. Kinin-IR is, however, consistently present in posterior-lateral NSCs of abdominal ganglia 1–7 and associated neurohemal areas.[6] These NSCs colocalize CRF-DH-IR.

CAP_{2b}

The *D. melanogaster* CAP_{2b} prepropeptide is present in three pairs of ventral NSCs in abdominal neuromeres, with neurohemal release sites on abdominal median nerves of larvae and on the dorsal surface of the thoracico-abdominal ganglion of adults.[21] It is also present in a pair of NSCs in the labial neuromere with axons projecting to the brain and retrocerebral complex.

AVP-Like DH

Locmi-AVPL-IR material is present in a pair of NSCs in the subesophageal ganglion (SEG) of *L. migratoria*.[6] Each NSC has a bifurcating axon with the anterior-directed branch extending into the brain and optic lobes, while the posterior-directed branch gives rise to arborizations in each VNC ganglion and to plexuses in peripheral nerves arising from the VNC. Blebbed processes in the proximal part of these nerves might form neurohemal release sites, although they are not closely associated with the nerve sheath in *L. migratoria*.[6] A similar pair of NSCs is present in the SEG of *T. castaneum* and the presence of AVPL has been confirmed by *in situ* hybridization.[1]

ADFs

Nothing is known of the distribution of Tenmo-ADFa, but Tenmo-ADFb-IR is present in two pairs of lateral NSCs in the protocerebrum and in another pair located anterior and lateral to these. Axons from these cells project to ADFb-ir varicosities that might form neurohemal release sites.[12]

ITP

Schgr-ITP mRNA is expressed in the brain and CC of adult locusts,[24] and ITP-like-IR material is present in the PI and CC of *S. gregaria*.[32] There are also ITP-IR NSCs in each thoracic and abdominal PVO. Many cells in the brain and ganglia of *M. sexta* and *B. mori* express both ITP and ITP-L in all life stages examined.[8]

PEPTIDE PROCESSING

The prepropeptides of identified DHs and of ITP contain an N-terminal signal sequence of about 20 amino acid residues (only 15 residues for ITP) followed by active and inactive peptide sequences separated by some combination of two basic amino acids (Fig. 2). However, to obtain Aedae-K-2 and Drome-CAP_{2b} peptides, the propeptide must be cleaved at single Arg residues by a mono-arginyl convertase. In vertebrates, PC1/PC3 convertase, which normally cleaves at Lys-Arg, can in an appropriate context cleave at single Arg residues (see the Peptide Biosynthesis/Processing section of

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

this book). With the exception of three coleopteran CRF-like DH, coleopteran ITP, and ADFs, the mature peptides are amidated and the C-terminal of the propeptide ends with a cleavage and amidation signal –Gly–Xxx–Xxx (Xxx represents Arg or Lys) or –Gly–Arg for Drome-CAP_{2b} peptides (Fig. 2).

RECEPTORS

CRF-Related Peptides

Receptors for CRF-related DH belong to the secretin-like (Family B) family of G-protein-coupled receptors (GPCRs). Two orthologs are present in *D. melanogaster* (CG8422 and CG12370), and CG8422 encodes a functional receptor (Drome-DH_{44}-R1) for Drome-DH_{44}.[18] However, Drome-DH_{44}-R1-IR material is not present in MT principal cells, which suggests CG12370 encodes a receptor (Drome-DH_{44}-R2) that mediates the diuretic activity of Drome-DH_{44}.[19] Indeed, only the CG12370 transcript is enriched in MT compared with that of whole bodies.[35] The EC_{50} for Drome-DH_{44} is >100-fold higher than that for CG8422, consistent with a currently unknown CRF-like DH serving as the CG12370 ligand.[32] A separate receptor probably exists for the short paralogs in other species, but there are no data on this. Interestingly, a CRF-binding protein is also present in insects, providing further evidence for the long evolutionary history of the CRF system.[17]

CT-Like Peptides

The *D. melanogaster* genome encodes a Family B GPCR (CG17415) related to the calcitonin receptor-like receptor (CLR) family.[19] CG17415 signals in response to Drome-DH_{31}; in common with other CLR coexpression with accessory proteins, either mammalian or *D. melanogaster* receptor component protein or with mammalian receptor activity modifying proteins, enhances the potency of signaling. In MT, Drome-DH_{31}-R is present only in principal cells, and the gene transcript is enriched 17-fold compared with that of whole bodies.[35] Drome-DH_{31}-R is present also in corazonin-expressing neurons within the CNS, which also express Drome-DH_{44}-R1.[22] Drome-DH_{31} and Drome-DH_{44} may therefore control corazonin release, possibly at the time of ecdysis.

Kinins

The kinin receptors of *D. melanogaster*[14] and *A. aegypti*[32] belong to Group III-B of Family A GPCRs, and seem to be paralogs of the true neurokinin receptors. Drome-K–R is present only in stellate cells of MT, and the gene (*lkr*) transcript is enriched 3-fold compared with that of whole bodies.[35] The receptor is present throughout the larval and adult CNS, most notably on MNCs of the PI that express Drome-DH_{44} and on their neurohemal axons and terminals in the CC. Outside the CNS, the receptor is present in testes and ovary, and these tissues respond to Drome-K with an increase in intracellular Ca^{2+}.

CAP_{2b}

CAP_{2b} peptides have a C-terminal motif (PRX-NH_2) similar to that of neuromedin U (NMU) and arginine vasopressin (AVP), and receptors related to those for NMU and AVP are encoded in the *D. melanogaster* genome. One of these (CG14575; *capaR*) responds functionally to Drome-CAP_{2b} peptides ending with PRV-NH_2, but not to other PRX-NH_2 peptides.[28] This receptor probably mediates the diuretic activity of CAP_{2b}, and the gene transcript is enriched 11-fold in MT compared with that of whole bodies.[35]

AVP-Like DH

Analysis of the *T. castaneum* genome identified a gene (*avplr*) encoding putative AVP-like peptide receptor that is related to other members of the AVP receptor group of Family A GPCRs.[1] The expressed receptor is activated by low nanomolar concentrations of F1, the monomeric AVPL, and by the antiparallel (F2) and parallel (D2) dimers, although they are 7–12 and 60–80 times less potent than F1, respectively. The expression of *avplr* mRNA is mainly confined to the CNS and, significantly, is not detectable in the MT and hindgut.

Nothing is known of the receptors for ADFs or for ITP.

STRUCTURE–ACTIVITY AND ACTIVE CONFORMATION

CRF-Related Peptides

The N-terminus is required for receptor activation, while the C-terminal two-thirds of the peptide is needed for receptor binding.[32] The C-terminal amide is also important for high affinity binding, although the nonamidated Tenmo-DH_{37} is a potent stimulant of *T. molitor* MT.[12] Manse-DH_{41} and Manse-DH_{30} may adopt a folded helix-loop-helix conformation, bringing the C-terminal amide close to the N-terminus, and the constrained analog [$Cys^{3,40}$]Manse-DH has similar efficacy and potency to Manse-DH.[32]

Kinins

The C-terminal pentapeptide is highly conserved and is the minimum sequence required for activity, but residues outside of this 'active core' may be required for high affinity binding.[32] Within the active core, Phe^1 and Trp^4 are invariant and essential for activity. The active core adopts a *cis*

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Pro type VI β-turn when bound to receptors,[26] bringing the side chains of Phe[1] and Trp[4] together on one face of the molecule where they can interact with the receptor.

CAP_{2b}

The minimum sequence for full activity in *Musca domestica* MT is the C-terminal hexapeptide (YAFPRV-NH_2), within which the critical residues appear to be Arg and Val.[25]

AVP-Like DH

There are three isoforms of the AVP-like peptide; the monomeric F1 with an intramolecular disulfide bridge, and the parallel (D2) and antiparallel (F2) dimeric forms with intermolecular disulfide bridges. In the *L. migratoria* assay using semiisolated MT, only F2 was active and was therefore called the Locmi-AVP-like DH,[30] although it does not stimulate secretion by fully isolated MT.[6] All three isoforms activate the expressed AVP-like peptide receptor, with F1 being most potent, but F1 was the only isoform with diuretic activity in an *in vivo* bioassay using adult *T. castaneum*.[1]

ITP

At the N-terminus of Schgr-ITP, Ala substitutions at positions 1, 4, 5, and 6 have no effect on activity, but Phe[2] and Phe[3] are essential for receptor activation.[29] The C-terminal Leu-NH_2 is also essential as are the six Cys residues, and disulfide bridges probably fix the distance between essential sites at the N- and C- termini.[6]

There have been no structure/activity studies with ADFs.

BIOLOGICAL ACTIONS

MT fluid secretion is coupled to ion transport, and DHs stimulate KCl/NaCl secretion into the lumen. This is driven by active proton transport across the principal cell apical membrane by a V-type ATPase, with secreted protons returning to the cell *via* cation/H^+ antiporters. Drome-DH_{44} and Drome-DH_{31} act *via* cAMP to stimulate V-ATPase activity, possibly by increasing recruitment of the V-ATPase to the apical membrane or by promoting association of the catalytic (V_1) and proton-translocating (V_0) domains. The Na^+:K^+ concentration ratio of the secreted urine is probably determined by their uptake across the basolateral membrane, and the natriuretic response of mosquito MT to Anoga-DH_{31} (the Mosquito Natriuretic Peptide) seems to result from the opening of a cAMP-dependent Na^+ channel and stimulation of Na^+–K^+–$2Cl^-$ cotransport.[3,7]

Kinins open a Cl^--selective conductance pathway making more Cl^- available for KCl/NaCl secretion into the MT lumen.[3] The binding of Drome-K to Drome-K–R on stellate cells activates phospholipase Cβ, promoting the inositol trisphosphate (IP_3)-mediated release of Ca^{2+} from intracellular stores.[10] Secretion is stimulated by the opening of Ca^{2+}-activated 'maxi' Cl^- channels in the stellate cell apical membrane. By contrast, kinins seem to open a paracellular Cl^- conductance in *A. aegypti*.[3] A cocktail of *M. sexta* kinins and both CRF-like DH have been shown to activate pre-ecdysis behavior in this species; moreover, the ecdysis triggering hormone receptor A is expressed in neurons in abdominal ganglia 3–7 which coexpress kinins and CRF-like DH.[22]

Drome-CAP_{2b} also uses IP_3 as a second messenger but acts on principal cells and not on stellate cells.[10] The emptying of IP_3-sensitive Ca^{2+} stores opens store-operated channels and the resultant influx of extracellular Ca^{2+} activates a Ca^{2+}/calmodulin-sensitive nitric oxide (NO) synthase expressed only in principal cells.[10] The NO that is generated activates a soluble guanylate cyclase to elevate the levels of cGMP, which increase V-ATPase activity. At the same time, elevated levels of intracellular Ca^{2+} activate mitochondria in the apical region of the cell and hence increase the availability of ATP to the V-ATPase. However, CAP_{2b} activity in housefly MT is independent of NO and cGMP, and it leads to the opening of a Cl^- conductance pathway.[32]

CAP_{2b} acts *via* cGMP to reduce secretion by MT from *R. prolixus* and *T. molitor* larvae. It antagonizes the diuretic activity of serotonin (*R. prolixus*)[29] and Tenmo-DH_{37} (*T. molitor*),[34] which act *via* cAMP-dependent mechanisms. CAP_{2b} may therefore activate a cGMP-dependent cAMP phosphodiesterase, which will lower the levels of the diuretic cyclic nucleotide.[31] There is no evidence of NO involvement and CAP_{2b} may activate a membrane-bound guanylate cyclase.

Locmi-AVPL-DH (F2) stimulates cAMP production and fluid secretion by a semiisolated MT preparation that includes the ampullae and a short segment of the gut, but it has no effect on fully isolated MT, suggesting it may act as a releasing factor for Locmi-CRF-DH, which is present in ampullary endocrine cells.[6] Similarly, neither F1 nor F2 stimulates secretion by MT of *T. molitor* (used in place of *T. castaneum* because of its larger size) but, importantly, F1 (*not* F2) stimulates secretion when added to MT in the presence of intact CNS, although only when the CC and CA are attached.[1] This is consistent with the diuretic activity of F1 being indirect, acting as a releasing factor for a DH (possibly a CRF-related DH) in the CC/CA complex.

Tenmo-ADFa and Tenmo-ADFb act *via* cGMP to reduce secretion by *T. molitor* MT, and probably activate a cAMP-specific phosphodiesterase because ADFa antagonizes the actions of Tenmo-DH_{37}.[32] Tenmo-ADFa also reduces secretion by *A. aegypti* MT, but it has no effect on tubule electrophysiology or on the concentrations Na^+, K^+, and Cl^- in the secreted urine.[23] This is consistent with the reduced levels

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

of cAMP and the down-regulation of a cAMP-dependent electroneutral transporter.

Different DHs can act synergistically (or cooperatively) with one another to control MT secretion. Thus the dose–response curve of Locmi-DH, a CRF-related peptide, becomes steeper and is displaced to the left when it is tested together with a low concentration (0.05 nM) of the native kinin (Locmi-K) in a diuretic assay using *L. migratoria* MT.[6] A major advantage of such synergism is that small changes in DH titer have a large impact on fluid secretion, thereby permitting more precise control of MT function. Synergism has also been reported between CRF-related (Dippu-DH_{46}) and CT-like (Dippu-DH_{31}) DH,[13] and between a CRF-related DH (Rhopr-DH_{49}) and serotonin.[32]

Fluid uptake from the locust ileum is coupled to active salt (NaCl/KCl) transport. Schgr-ITP increases transepithelial NaCl/KCl transport by stimulating an apical membrane electrogenic Cl^- pump.[29] Na^+ and K^+ cross the apical membrane through separate channels both of which are activated by cAMP. Although Schgr-ITP acts *via* cAMP, it inhibits active proton secretion into the lumen, whereas cAMP increases proton secretion into the medium.[29] The crustacean homologs of ITP, CHH, and MIH are known to act *via* cGMP.[32]

CONCLUDING REMARKS

Insect DH and ADH constitute a diverse group of peptides that have in common their role in controlling fluid and ion loss *via* the excretory system. Their effects on epithelial transport processes in MT and hindgut are reasonably well understood, but there is still much to be learned about the contribution these peptides make singly and collectively to the control of ion and fluid homeostasis *in vivo*. It is also clear that they may have additional roles within the CNS, as is evident from the presence of kinin receptors on NSCs expressing CRF-related DH, and of receptors for CRF-related and CT-like DH on corazonin-containing neurons.

Chapter 35

FMRFamide-Like Peptides (FLPs)

Ian Orchard and Angela B. Lange

ABSTRACT

Since the discovery of the molluscan cardioacceleratory peptide FMRFamide, a variety of neuropeptides that share the C-terminal RFamide have been characterized from cnidarians through to vertebrates. A particularly diverse array of families occurs in insects, including *N*-terminally extended FMRFamides and extended FL/IRFamides, myosuppressins, neuropeptide Fs, and short neuropeptide Fs. These peptide families are distinct and not related to one another and are now collectively referred to as FMRFamide-like peptides (FLPs). The FLPs are found throughout the central nervous system in a variety of neuronal types, in neurohemal organs, in the stomatogastric nervous system, and within endocrine cells of the midgut (at least in insects). The genes for the peptides and their receptors have been cloned and structure–activity relationships established in some cases. Many biological processes seem to be influenced by these peptides, but these peptides seem to be particularly involved in aspects of feeding, digestion, and food transport.

DISCOVERY

Since the discovery of the molluscan cardioacceleratory tetrapeptide FMRFamide,[24] vast arrays of neuropeptides that share the C-terminal RFamide have been characterized from cnidarians through to vertebrates. These FMRFamide-like peptides (FLPs) fall into several families of peptides (Tables 1 and 2) that are now considered unrelated and so the earlier collective term, FMRFamide-related peptides (FaRPs), is inappropriate. A particularly diverse array of FLPs occurs within insects, where there are *N*-terminally extended FMRFamides and extended FL/IRFamides, myosuppressins, neuropeptide Fs (NPFs), short neuropeptide Fs (sNPFs), and sulfakinins (discussed in the chapter on sulfakinins in this section of the book). Excellent reviews of FLPs have been published.[1,13,16,17,31]

Extended FMRFamides and Extended FL/IRFamides

The first FLP to be identified was the tetrapeptide FMRFamide, a cardioexcitatory peptide isolated from the nervous system of the clam, *Macrocallista nimbosa*.[24] Interestingly, authentic FMRFamide is only found in two phyla, the molluscs and annelids, and in these and other phyla, there are many more peptides that are *N*-terminally extended FMRFamides, FLRFamides, FIRFamides, or LRFamides.[31] Echinoderms do not have extended RFamide peptides but instead have peptides that terminate in Famide and Yamide. In insects, extended FMRFamides have only been identified in the dipterans and recently in the hemipteran *Rhodnius prolixus*,[20,21] by the sequencing or prediction from the gene. Other insects contain extended FLRFamides. In *Drosophila* species, single genes encoding 13 extended FMRFamides have been characterized and a number of the predicted peptides sequenced. Similarly, 13 extended FMRFamides have been sequenced from thoracic ganglia of the blowfly, *Calliphora vomitoria*, and are located on a single gene. The dipteran genes also code for some extended FIRFamides. *N*-terminally extended FM/L/IRFamides have been sequenced in many invertebrates (see Tables 1 and 2 for examples), and a comprehensive listing can be found in Walker et al.[31]

Myosuppressins

The first *N*-terminally extended RFamide to be sequenced in insects was leucomyosuppressin (LMS; pQDVDHVFLRFamide), which inhibits spontaneous contractions of *Leucophaea maderae* hindgut.[21] Other members of this so-called "myosuppressin" family have been sequenced,[21,22,31] some of which are shown in Tables 1 and 2. The myosuppressin family seems to be restricted to insects and crustaceans.[15,21,31] In insects, these peptides share the sequence $X^1DVX^4HX^6FLRFamide$ (where X^1 is pQ, Q, P, T, or A; X^4 is D, G, or V; and X^6 is V or S). In *R. prolixus*,[20] there is a variation wherein X^8 is M, resulting in the only FMRFamide to be found outside of the dipterans, and the only myosuppressin to not have the FLRFamide motif. In crustaceans,[31] the myosuppressins share the sequence $X^1X^2LDHVFLRFamide$ (where X^1 is pQ, Q, or P; and X^2 is D or E).

Neuropeptide Fs

The first member of the invertebrate neuropeptide F (NPF) family was identified in the tape worm *Monieza expansa* and shown to be related to the neuropeptide Y (NPY) family of vertebrate peptides (with a *C*-terminal F instead of a Y). Subsequently, NPFs were identified in molluscs.[13,31] These peptides have 32–36 amino acid residues and have a common *C*-terminal GRPRFamide. They are sometimes referred to as long NPFs. In insects,[3,31] many sequenced peptides have been referred to as NPF/NPY-like peptides. Some of these are now known to be members of a different family (short NPFs, see later) causing some confusion in the literature, which has recently been clarified.[16] "True" NPFs (Tables 1 and 2) are 28–45 amino acid residues with a consensus *C*-terminal RXRFamide (where X is commonly P or V). Shorter forms are known to exist but might represent degradation products. NPFs have been described in most invertebrate phyla, except for cnidarians and nematodes.[31] Examples of extended RYamides are known in a few species.

Short NPFs (sNPFs)

Short NPFs, also referred to as head peptides, were isolated (often from the head) by the use of an RIA with an antiserum

For details see Refs. 16,21,31.

against the tape worm NPF or FMRFamide. Short NPFs are not related to NPFs and hence the confusion in the literature.[16] They have only been described in insects and crustaceans and no other invertebrates.[16,22,31] They typically consist of 8–10 amino acid residues with the consensus sequence XPXLRLRFamide.

STRUCTURE OF THE mRNA/GENE

Extended FMRFamides and Extended FL/IRFamides

Genes for this family were first identified in molluscs. In pulmonates, there is a single gene, whereas other molluscs have

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

two genes. Typical of molluscs is the presence of multiple copies of peptides on the same gene. The FMRFamide precursor gene of *Aplysia californica* was the first sequence[31] and found to consist of repeated stretches of 15 or 16 amino acids, each segment containing one FMRFamide, its associated processing signals, and an acidic sequence, which may only be a spacer. All together, the gene encodes 28 copies of FMRFamide, one copy of FLRFamide, and one copy of an apparently related peptide ending in –YLRFamide. In *Lymnaea stagnalis*, the peptides are encoded by a multiexon gene that undergoes alternative mRNA splicing to generate two mRNAs. Exon I is shared by both mRNAs, along with exon II for type 1 mRNA, and exons III–V for type 2 mRNA. Type 1 mRNA codes for tetrapeptides, whereas type 2 mRNA codes for heptapeptides and hexapeptides. In *Helix aspersa*, there are also alternatively spliced mRNAs. The cDNA has also been isolated from the cuttlefish, *Sepia officinalis*, which has a precursor protein encoding 14 peptides, 11 of which are FMRFamide.

In insects, the *D. melanogaster* FMRFamide gene was identified through oligonucleotide isolated DNA clones, using the sequence DPKQDFMRFamide.[18] The gene contains 2 exons and 1 intron. The precursor is 347 amino acids in length and contains a predicted signal sequence of 20 residues. This is a single copy gene that encodes 5 copies of DPKQDFMRFamide, 2 of TPAEDFMRFamide, and 1 each of SDNFMRFamide, SPKQDFMRFamide, and PDNFMRFamide, all bounded by conventional proteolytic sites. Precursors containing *N*-terminally extended FMRFamides have been identified in the dipterans *D. melanogaster*, *Drosophila virilis*, *C. vomitoria*, and *Lucillia cuprina*.[21,31] Precursors in *C. vomitoria* and *L. cuprina* specify 16 potential extended FMRFamides and 2 potential extended FIRFamides. There is no evidence for alternative splicing of the mRNA transcript; however, expression data indicate that the intron of *D. melanogaster* may contain regulatory enhancer sequences. By tandem mass spectrometry, extended RFamides have been structurally elucidated in *Periplaneta americana* and sequence information used for subsequent cloning of the gene.[23] This precursor gene encodes for 24 putative peptides, 23 of which were detected by mass spectrometric methods. Many of these are *N*-terminally extended FIRFamides, although the gene is referred to as the cockroach FMRFamide gene. The cDNA encodes for a protein of 505 amino acids that has several features typical of the *D. melanogaster* FMRFamide cDNA, including a 22 amino acid signal peptide, N- and C-terminal sequences not coding for FMRFamides, and a central region with 24 putative peptide sequences. Although clearly similar in sequence to the extended dipteran FMRFamides, none of the encoded peptides contains the C-terminal FMRFamide. Instead, 10 FIRFamides, 3 FIRLamides, 2 FVRFamides, and peptides with an individual C-terminus of FVRLamide, LVRIamide, TLRVamide, SVRLamide, and LMRFamide are found. The remaining 4 putative peptides are nonamidated peptides. The genes have now also been identified in the genomes of other nondipteran insects such as *Tribolium castaneum*, *Acyrthosiphon. pisum*, *Apis mellifera*, and *R. prolixus*.[7,8,12,20]

cDNAs (AB158642, AB158643) have been cloned in the crayfish *Procambarus clarkii*.[34] The two prepropeptide sequences each consist of 323 residues, encoding 7 copies of extended LRFamide peptides, representing 6 different sequences.

Myosuppressins

The myosuppressin precursor has been determined through cloned DNA or predicted from the genomes in a wide range of insects, including *Diploptera punctata*, *Blattella germanica*, *Pseudaletia unipuncta*, and *Manduca sexta*, *D. melanogaster*, *T. castaneum Bombyx mori*, *R. prolixus*, and *Anopheles gambiae*.[3,12,20,21,30] In all species studied, only a single decapeptide myosuppressin is released from the C-terminus of the precursor upon cleavage at dibasic and tribasic endoproteolytic processing sites and amidation. In *D. punctata*, the myosuppessin gene has 3 exons. There is no evidence to suggest alternative splicing in the expression of the myosuppressin gene, although there may be unusual processing in the midgut of parasitized *M. sexta* larvae.[21] The organization of the *D. melanogaster* myosuppressin gene is similar to the myosuppressin genes in other insect species. Analysis of the nucleotide sequence shows that a 100 amino acid translation product contains a signal peptide of 24 amino acid residues. A phylogenetic analysis has been described.[30] An EST (FE188748) in the Pacific white shrimp *Litopenaeus vannamei* has been identified as encoding a putative precursor for a myosuppressin.[14]

Neuropeptide Fs

Typically, there are either one or two genes encoding NPFs in invertebrates, although there are examples of multiple genes.[3,16,19,28,31] These NPF genes contain only one copy of the mature NPF, although in species with two genes one of these NPFs ends with RGRYamide. The prepropeptide encoded by the *D. melanogaster* NPF gene has 96 amino acids of which the first 26 constitute a putative signal peptide.[3,16] Removal of the signal peptide, posttranslational processing and amidation produces the 36 amino acid *D. melanogaster* NPF. This peptide shares sequence similarity with mammalian NPY and related peptides, although it is more closely related to invertebrate NPFs. The *D. melanogaster* NPF gene is present as a single copy in the genome. Similarly, the genomes of a variety of species of annelids and insects contain sequences encoding an NPF each.[16,31] No NPF gene has been identified in the genome of *T. castaneum*.[1]

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Short Neuropeptide Fs

The gene for *Aedes aegypti* head peptides encodes a protein containing 3 copies of bioactive peptides, whereas the sNPF genes of *A. gambiae* and *D. melanogaster* encode 5 and 4 peptides, respectively, with differing but related sequences.[3,16] Multiple sNPF copies are a common, but not universal, feature. One sNPF is encoded on the prepropeptide in ticks, spiders, and crustaceans, two sNPFs are encoded in many lepidopterans, with other lepidopterans, dipterans, and coleopterans having multiple copies.[16,31] The sNPF gene (CG13968) in *D. melanogaster*[11,16] has 4 exons in the coding region of its transcript. The cDNA encodes a 281 amino acid protein that contains a 30 amino acid signal peptide and 2 putative extended RLRF peptides and two extended RLRWamides, flanked by pairs of basic residues. However, mass spectrometry has revealed that most of the peptides are not processed in the predicted way and that possibly only the first sNPF actually occurs as predicted.[16] The amino acid sequences of the sNPFs are quite different from vertebrate NPY, in contrast to NPF that has 31% homology with NPY. Thus, the NPFs (not the sNPFs) are considered as homologs of the vertebrate NPY.[16]

PROCESSING OF THE PRECURSOR

The genes for enzymes that process or degrade regulatory peptides have been identified in *D. melanogaster* and *A. gambiae*.[25,29] Peptides are synthesized as a larger precursor that is subsequently processed into the active substances. After cleavage of the signal peptide, further proteolytic processing occurs predominantly at basic amino acid residues. Some rules have been proposed that allow a prediction of which putative proteolytic sites are actually used in insects.[29] The great majority of known or predicted insect peptides, including the extended RFamides, are α-amidated, and so the significance of amidating mechanisms for peptide sequencing is great. Peptide signaling is terminated by a combination of mechanisms that include receptor desensitization or internalization, peptide diffusion, and enzymatic degradation.[29] A number of peptidases responsible for neuropeptide inactivation have been identified in insects,[25] but little work has examined FLPs.

Extended FMRFamides and Extended FL/IRFamides

In molluscs, the FMRFamide gene can undergo alternative mRNA splicing to generate two mRNAs, as mentioned earlier. Interestingly, in *Lymnaea stagnalis*, it has been shown that the gene can be differentially spliced in neurons, such that type 1 mRNA is found in neurons within all ganglia, whereas type 2 mRNA is only found in neurons in the visceral and right parietal ganglia. In *Helix aspersa*, there are also alternatively spliced mRNAs that can be expressed in different neurons. Thus, neurons can express different complements of FMRFamide peptides.[13,31]

There is considerable conservation of gene organization for the extended FMRFamides in dipterans. The single copy gene encodes a precursor containing multiple copies of *N*-terminally extended FMRFamides liberated by endoproteolytic and amidation enzymes. In *D. melanogaster*, there is 1 monofunctional peptidylglycine-α-hydroxylating monooxygenase gene and 2 monofunctional peptidyl-α-hydroxyglycine α-amidating lyase genes, which are required to produce α-amidated bioactive products.[5] The DNA regulatory sequences controlling *D. melanogaster* FMRFamide neuropeptide gene expression are a model for insect neuropeptide gene expression.[21] There is some debate over cell-specific processing of the *D. melanogaster* FMRFamide gene. Immunohistochemistry with antisera generated against 3 of the *D. melanogaster* FMRFamides shows a unique, nonoverlapping cellular expression pattern indicative of differential processing of the precursor. By contrast, others have concluded that there is a single predominant pattern of expression, and it is unlikely that there are widespread cell-specific differences in precursor processing.[18,21] The *P. americana* FMRFamide gene[23] liberates 24 putative peptides with appropriate endoproteolytic and amidation processing.

Myosuppressins

Endoproteolytic and amidation enzymes liberate a single myosuppressin neuropeptide from the precursor protein. Alternative processing might exist in parasitized *M. sexta* larvae because 2 extended myosuppressins have been identified in the midgut.[5]

Neuropeptide Fs

The long NPFs are encoded on single genes that contain one copy of the neuropeptide following endoproteolytic and amidation enzyme processing.[16]

Short Neuropeptide Fs

The sNPF genes contain multiple copies of sNPFs that are predicted to be liberated by endoproteolytic and amidation enzymes.[16]

DISTRIBUTION OF mRNA/PEPTIDE

Immunohistochemical studies have indicated the presence of FMRFamide-like immunoreactivity distributed throughout the central nervous system (CNS) and peripheral nervous system (PNS) of invertebrates, and within endocrine cells of

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

the insect midgut. Most of these studies used antisera raised against the C-terminal RFamide and potentially indicate the distribution of multiple members of the extended RFamide families. The specific localization of mRNA by Northern blot and/or in situ hybridization is described here.

Extended FMRFamides and Extended FL/IRFamides

Identifiable neurons express the FMRFamide precursor in molluscs. For example, in *L. stagnalis*, these include heart excitatory motor neurons, visceral white interneurons, and a pleural interneuron. With alternative slicing, 280 neurons distributed among all the ganglia, express the tetrapeptides, while the heptapeptides are found in about 57 neurons in the visceral and parietal ganglia.[13,31]

In situ hybridization reveals that the *D. melanogaster* FMRFamide gene is expressed in approximately 44 neurons of the 10,000 in the larval CNS.[21] In *P. americana*, a nested reverse-transcription PCR analysis for the extended FIRFamides shows expression in the brain, and in thoracic and abdominal ganglia.[23] In the crayfish, *P .clarkii*, the gene is expressed in brain neurons associated with the olfactory system.[15,34]

Myosuppressins

In situ hybridization[21] shows that expression of the *D. punctata* myosuppressin gene is most abundant in the brain and optic lobes and in the frontal and subesophageal ganglia. In the brain, expression is found in cells of the pars intercerebralis, a region known to contain the medial neurosecretory cells. In *P. unipuncta*, 57% of the cells producing the myosuppressin gene transcript are found in the optic lobe. Within the digestive tract, *D. punctata* myosuppressin mRNA-positive endocrine cells are found in the anterior portion of the midgut, as they are in *P. unipunta*. In situ hybridization also reveals a variety of cell types within the CNS, a peripheral neurosecretory cell, and midgut endocrine cells in *M. sexta* that express the myosuppressin gene.

Neuropeptide Fs

In situ hybridization indicates that the NPF gene is widely expressed in the CNS of molluscs.[13,31] In *H. aspersa*, the NPF transcript is found in neurons in most ganglia of the circumesophageal ring, and in all CNS ganglia except the buccal ganglia in *L. stagnalis*. Most of these neurons are found in the cerebral and pedal ganglia, and their distribution suggests a role in reproduction and possibly growth and development. NPF is found in many neurons in the CNS of *A. californica* and also in the abdominal bag cells. Their location in the buccal and cerebral ganglia suggests a role in feeding, and their association with bag cells suggests a role in reproduction.

In situ hybridization for *D. melanogaster* NPFs reveals medial and lateral cell pairs in the larval and adult brains, although the lateral cells are only weakly stained in the adult.[3,16] All of these are interneurons. No NPF neurons were observed in the ventral nerve cord (VNC). There are about 15 endocrine cells in larval midgut and 75–150 endocrine cells in the adult midgut. The transcript expression of *A. gambiae* NPF shows that the PCR product is present in eggs and in head, thorax, and abdomen of 4th instar larvae, and in pupae. It is present in the head and abdomen of adult males and females. Northern blot analysis has also revealed the presence of *A. gambiae* NPF transcript in the brain and midgut of adult female mosquitoes. The *A. aegypti* cDNA is expressed in the brain and midgut,[3] and in the foregut, midgut, and all ganglia of the CNS in *Reticulitermes flavipes*.[19]

Short Neuropeptide Fs

Expression of sNPF has essentially only been reported in *D. melanogaster*. Here, sNPF mRNA has been studied by Northern blot analysis and in situ hybridization. Similar amounts of the transcript are expressed throughout all developmental stages of embryos and larvae. In situ hybridization reveals expression of the sNPF transcript in the nervous system from stage 14 embryos onward and its presence in neurons of the brain and ventral ganglia. No expression is apparent in the midgut. A large number of neurons express sNPF in the larval and adult CNS, in addition to over 1000 mushroom body Kenyan cells. Most of these are unidentified small interneurons, but others are identified, including olfactory sensory neurons, lateral clock neurons, and lateral neurosecretory cells. The *A. aegypti* head peptide gene is expressed predominantly in the brain, terminal ganglion, and midgut.[11,16]

RECEPTORS AND SIGNALING CASCADE

There is little molecular information on these receptors for invertebrates, other than insects. Studies in these other invertebrates have concentrated on the mode of action of the peptide and receptor cascade. Publication of the genomes for a variety of insect species has enabled analysis of putative G-protein-coupled receptors (GPCRs) with "reverse pharmacology" identifying the natural ligand of functionally expressed orphan receptors.

Extended FMRFamides and Extended FL/IRFamides

Molluscs seem to use both GPCRs and gated ion channel receptors to mediate the biological effects of FMRFamide

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

and related peptides.[13,31] A radioligand-binding assay identified an FMRFamide receptor in the brain and heart of *H. aspersa* that was most sensitive to YGGFMRFamide. The cDNA of the FMRFamide-gated receptor/channel protein from *H. aspersa* has been cloned and sequenced and shares 93% sequence identity with the FMRFamide-gated sodium channel in *L. stagnalis*. Structure/activity properties have recently been reviewed.[31] This family of peptides has been shown to directly gate amiloride-sensitive sodium channels in C2 neurons in *H. aspersa*, resulting in excitation, while inhibiting others through increasing permeability to potassium. FMRFamides have also been implicated in transmitter mobilization, in presynaptic calcium entry, and in blocking L-type calcium currents and potentiating T-type calcium currents.[31]

A receptor for the extended FMRFamides (CG2114) has been cloned, sequenced, and characterized in *D. melanogaster*[7,26] and predicted in *A. gambiae*, *T. castaneum*, and *A. mellifera*. The cDNA sequence codes for a protein of 549 amino acid residues, which contains 7 transmembrane domains and potential N-glycosylation sites. Reverse pharmacology by the use of the receptor in Chinese hamster ovary (CHO) cells reveals that the receptor responds to the *D. melanogaster* extended FMRFamides, the most potent of which is PDNFMRFamide. Interestingly, other extended FMRFamides are much less effective. These results imply that there are other receptors for the remaining extended FMRFamides. This receptor can also be activated by some other RFamide peptides, including the *D. melanogaster* sNPF and the *D. melanogaster* myosuppressin, which leads to some debate on the true physiological relevance of this FMRFamide receptor. Northern blot analysis reveals that the *Drosophila* receptor is expressed in all stages but mostly in larvae and adults. Expression analysis by RT-PCR illustrates that the receptor is present in the trachea, which might therefore contaminate the positive results for CNS, fat body, intestine, and Malpighian tubules.

There have been a few studies examining the structure activity of the dipteran-extended FMRFamides. The question of functional redundancy has been addressed in *D. melanogaster* and *C. vomitoria* where multiple extended FMRFamides are encoded on the same gene.[18,21] By examination of twitch tension of body wall muscles, it was concluded that the *D. melanogaster* FMRFamides are functionally redundant. By contrast, the use of a heart rate or crop assay showed that some of the *D. melanogaster* FMRFamides are functionally distinct with some showing activity and others not. The *D. melanogaster* FMRFamide receptor expressed in CHO cells shows differential potency to the extended FMRFamides.[26] A similar functional distinctiveness has been observed in *C. vomitoria* where the semiisolated heart and salivary glands respond to some of the *C. vomitoria* FMRFamides but not to others.[21]

Myosuppressins

Two *D. melanogaster* GPCRs have been cloned and characterized (CG8985, CG13805), which are specific for the *D. melanogaster* myosuppressin and which do not react with other *D. melanogaster* neuropeptides.[26] The corrected genes from the database (coding for receptor 1 and 2) have multiple exons and introns. The cDNA codes for a protein of 478 amino acid residues (receptor1) and 488 amino acids (receptor 2), which each contains 7 transmembrane domains. The extracellular *N*-terminus contains potential N-glycosylation sites. Northern blot analysis illustrates that receptor 1 is strongly expressed in the adult head (essentially absent in the thorax and abdomen), with receptor 2 present in the adult head, thorax, and abdomen. Similarly, a GPCR closely related to the *D. melanogaster* myosuppressin receptor has also been identified in the *A. gambiae* Genome Project database and subsequently cloned and characterized.[26] *Anopheles gambiae* seems to have only one myosuppressin receptor, as does *T. castaneum* and *A. mellifera*,[6,7] in contrast to the two sequenced from *D. melanogaster.* An *in vitro* binding assay has been used to characterize putative receptors for *L. migratoria* myosuppressin associated with the oviduct and CNS of *L. migratoria*.[21] The specific binding for oviducts suggests the presence of 2 receptor types of high and low affinity.

The structure–activity relationships of the myosuppressins have been examined in *L. maderae* hindgut and *L. migratoria* oviduct.[21] In hindgut, VFLRFamide seems to be the active core for inhibitory biological activity. In oviduct, the amide is critical for both binding with the receptor and inhibitory biological activity. Interestingly, VFLRFamide is the minimum sequence required for receptor binding, whereas HVFLRFamide is the minimum sequence for comparable inhibitory biological activity. The nonpeptide benzethonium chloride (Bztc) shares several chemical features with the sequence VFLRFamide, and Bztc mimics the biological activity of myosuppressins in a variety of, but not all, target tissues.[21] A molecular dynamic/modeling study identified plausible structural explanations for this activity. Myosuppressin analogs containing restricted conformational components have also been developed and shown to antagonize the myosuppressin receptors.[21]

Neuropeptide Fs

The *Drosophila* genome has a genomic sequence with similarity to NPY receptors.[3,16] This gene [CG 1147] for *D. melanogaster* NPF receptor 1 has been cloned and sequenced. The deduced protein is 481 amino acids long and is predicted to have 7 transmembrane domains. This receptor resembles the vertebrate Y_2 receptors and is most closely related to the *Lymnaea* NPY receptor. CHO-K1

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY
Copyright Elsevier 2024

cells expressing the RNA of the NPF receptor 1 have been used in radioreceptor binding assays. The NPF receptor 1 also inhibits forskolin-stimulated adenylyl cyclase activity in transfected CHO cells. In situ hybridization indicates that the transcripts for this receptor are found in many cells of the larval CNS and midgut. The *A. gambiae* genome contains sequences encoding for an NPF receptor, and the cDNA has been cloned and sequenced.[3] The deduced protein is 424 amino acids and is predicted to have seven transmembrane domains. This receptor has also been stably expressed for radioligand-binding analysis and exhibits high affinity for *A. gambiae* NPF. RT-PCR analysis reveals that the receptor transcript is present in all life stages. A phylogenetic analysis of NPY/NPF receptors has been performed.[3]

Structure–activity studies have not been reported in any detail for the NPFs. Functional expression of the receptors was used to identify the ligands for the receptor, so the NPF receptors are, by definition, more responsive to NPFs than to other extended RFamides. By functional expression and radioligand-binding analysis, the *A. gambiae* NPF receptor exhibits high-affinity binding for *A. gambiae* NPF but lower affinity for the NPFs from *A. aegypti* and *D. melanogaster*.[3]

Short NPF

A gene from the *Drosophila* Genome Project database has been cloned and represents a seven transmembrane GPCR that shows some structural similarity to vertebrate NPY_2 receptors and is activated by the sNPFs of *D. melanogaster*.[3] This sNPF receptor (CG7359), expressed in CHO-K1 cells, is not activated by other peptides. Functional expression of the sNPF receptor illustrates that the activated receptor produces inward rectifying potassium currents by a pertussis toxin-sensitive G-protein-mediated pathway. The *D. melanogaster* sNPFs are more potent than long NPFs.[3] The sNPF receptor is enriched in the brain, eye, VNC, and spermatheca of adults. The sNPF receptor has now been identified in the fire ant *Solenopsia invita*, and mosquito *A. gambiae*, and predicted *in silico* from a number of other insect species genomes.[16] In fire ant queens, expression is highest in the brain and is also found in the midgut, hindgut, Malpighian tubules, fat body, and ovaries. Similarly, in the mosquito, the receptor is expressed in the head, dorsal thorax, ventral thorax, abdominal wall, midgut, hindgut, and Malpighian tubule.[16]

BIOLOGICAL ACTIONS

A range of biological actions have been established for FLPs by the use of *in vitro* bioassays, injection, and molecular techniques. It is often difficult to correlate these actions with the particular families, because of the likelihood of the higher doses of peptides crossreacting with receptors for a different family. However, many target tissues for FLPs have been identified, and many biological processes seem to be influenced by these peptides, including reproduction, growth, feeding, circulation, ecdysis, and development.[3,10,13,15–17,21,31] The FLPs seem to act as neurotransmitters, neuromodulators, or neurohormones.

Extended FMRFamides and Extended FL/IRFamides

The extended FMRFamides influence heart rate, gut mobility, and skeletal muscle activity in a variety of invertebrates.[10,15,16,31] The first FLP, FMRFamide, was identified as a cardioexcitatory peptide in *M. nimbosa*.[24] Further work in molluscs, revealed that heart excitatory motoneurons contain FMRFamide and FLRFamide and that these regulate heart activity in *L. stagnalis*.[31] The visceral white interneurons contain extended FLRFamides (along with other extended RFamides), and these regulate respiration and heart rate.[31] Other suggested effects in molluscs include osmoregulation, reproduction, feeding, and chromatophore migration.[13]

In arthropods, DRNFLRFamide is released from the POs of the crayfish *P. clarkii* and is thought to act as a neurohormone.[15] This FLP increases the amplitude of EJPs in the deep extensor muscles (an action thought to be presynaptic) and also is mysostimulatory on superficial abdominal extensor muscles and hindgut.[15] In the lobster, *Homarus americanus*, the gastropyloric receptor neurons contain FLPs suggesting a sensory role in the stoatogastric system. FLPs are also associated with crustacean eyestalk and so might play a role in the visual system.[2] In insects, such as *D. melanogaster*, these various extended FMRFamides have differing effectiveness.[18,21] In *C. vomitoria*, a similar functional distinctiveness is suggested by the fact that only 2 of the 6 *C vomitoria* extended FMRFamides tested are active on the semiisolated heart, and only 3 of the 6 tested on salivary gland are active sialogogs.[21] The extended FL/IRFamides also influence oviduct contractions in *L. migratoria*, contractions of the antennal heart in *P. americana*, and reduce spike frequency of dorsal unpaired median neurons in *P. Americana*.[21,23]

Myosuppressins

Myosuppresins, as their name implies, reduce the frequency of spontaneous contractions of visceral and cardiac muscle.[18,21] In some insect species, they have also been shown to enhance the force of neurally evoked contractions of skeletal muscle. Myosuppressins also stimulate enzyme secretion and inhibit short-circuit current in midgut, and inhibit the release of adipokinetic hormones. Injection of the cockroach myosuppressin into *B. germanica* inhibits food intake, with food accumulating in the foregut.[30]

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Neuropeptide Fs

The NPY signaling pathway is implicated in the stimulation of food uptake in the vertebrates and in the regulation of food conditioned foraging behaviors in *Caenorhabditis elegans*.[16] The presence of NPF in buccal and cerebral ganglia of *A. californica* suggests a role in feeding circuitry and modulation of the feeding motor program, and there is now good evidence for this.[13,31] In addition, NPF is present in bag cells (together with egg-laying hormone) implying a role in reproduction and renal functions that are under the control of bag cells. Similarly, in *H. aspersa*, NPF is associated with the neurons that release ovulation and egg-laying hormone, again implying an action in reproductive behavior.[13,31]

In *D. melanogaster*, NPFs have been implicated in diverse functions, such as foraging, feeding and motivation, ethanol sensitivity, stress responses, reproduction, clock function, and learning.[16] For example, the NPF neuronal network in *D. melanogaster* has been described, and its food-dependent modifications have been examined. Gustatory stimulation by sugar is sufficient to trigger long-term changes in the NPF neuronal circuit.[27] Expression of *D. melanogaster* NPF is high in the brain of larvae attracted to food, and its downregulation coincides with food aversion, hypermobility, and cooperative burrowing in the older larvae. Young transgenic larvae that have lost their NPF signaling prematurely display the behavioral phenotype associated with the older larvae. Overexpression of NPF in older larvae prolongs feeding and suppresses hypermobility and cooperative burrowing behaviors.[32] NPF is also expressed in male clock neurons, and it has been suggested that NPF might be involved in clock-regulated sex dimorphic behavior and in male aggression.[16] The hemolymph titer of *A. aegypti* NPF changes in females shortly after a blood meal and during the course of the reproductive cycle.[3] Bioassays have shown that NPFs can inhibit muscle contraction of hindgut preparations in *R. prolixus* and *R. flavipes*.[4,19]

Short NPFs

The involvement of sNPFs in feeding has also drawn some attention, but sNPFs are also implicated in growth and development, osmotic and metabolic stress, locomotion, the circadian clock, olfaction, and hormone release.[16] For example, in *D. melanogaster*, sNPF mutants in which the pathway is overexpressed have elevated food intake, whereas mutants in which the pathway is suppressed have reduced food intake.[11] Injection of *A. aegypti* head peptide inhibits host-seeking by females and its hemolymph titer is low before a blood meal but peaks at 36–48h post blood meal.[28] Blood feeding also results in an increased titer of RFamide peptides in the hemolymph of *R. prolixus* that peaks at 3, 6, and 10h postfeeding.[21] A sNPF in *L. decemlineata* is a potent gonadostimulin in *L. migratoria*, stimulating oocyte length after injection.[9] Within, *L. decemlineata* itself, the 2 sNPFs are absent from the brains of insects in diapause.[9] In *B. mori*, sNPF is found in the intrinsic cells of the corpora cardiaca,[33] and the NPF receptor is located to the corpus allatum (CA), which is the site of synthesis and release of juvenile hormone (JH). sNPF is an allatostatin, inhibiting the production of JH. Receptors for allatotropin are found on the sNPF cells, and it has been suggested that allatotropin might inhibit the sNPF cells, thereby removing inhibition to the CA.[33]

Clearly, the extensive distribution of FLPs throughout the invertebrates (and indeed the vertebrates) illustrates the importance that this group of peptides has in integration and regulation of biological functions. Numerous biological processes are influenced by these peptides, including circulation, reproduction, ecdysis, and development; however, these peptides seem to be particularly involved in aspects of feeding, digestion, and/or food transport.

Chapter 36

Free-Living Nematodes

Edward.P. Masler

ABSTRACT

Nematodes use a wide array of peptide messengers to control nearly all life processes. Molecular similarities and differences among nematode species with differing life histories, such as free-living and parasitic types, facilitate the application of research results across the phylum and advance our understanding of the roles, complexity, and diversity of biologically active peptides in nematodes. Processes as diverse as hatching and locomotion, mating and feeding, defense, and metabolism are controlled and influenced by nematode peptides comprising exceedingly complex families. This complexity results from a large number of genes encoding related amino acid sequences, as in the case of the FMRFamide-like peptides, from intricate variations of molecular architectures, as seen among members of the insulin-like peptides family and from the broad variety of peptides comprising neuropeptide-like proteins, including those peptides that have antimicrobial functions. These peptide families are briefly described for free-living nematodes, along with their established and proposed functions, including receptor information.

INTRODUCTION

Nematodes are second only to insects in the number of species, breadth of distribution, and amount of biomass, occupying every ecological niche. They include parasites of animals, insects and plants, as well as nonparasitic, microbivorous free-living species. Most are microscopic, although some animal-parasitic species are quite large. Nematodes are unsegmented roundworms having a longitudinal nerve cord and nerve ring. The nervous system is accompanied by a simple anatomy comprising muscular mouthparts with a pharyngeal pump to facilitate feeding, an intestine that serves as a metabolic organ somewhat analogous to the mammalian liver, a muscular body wall, and cuticle, gonads, and sexually dimorphic features such as the uterus. All nematodes have an egg stage, three external larval stages, and one or more adult forms.[11a] As parasitic species are covered elsewhere in this volume, this chapter focuses on free-living species.

A discussion of peptides in free-living nematodes necessarily focuses on *C. elegans*, which contains the first completely sequenced animal genome and has become an important organism for molecular genetic and cellular biology research. Peptides in other free-living species have been studied, including the related *C. briggsae* and other *Caenorabditis* species, *Oscheius* spp., *Panagrellus redivivus*, and *Pristionchus pacificus*, but the bulk of peptide-related information from free-living nematodes has been generated from work with *C. elegans*. Studies on biologically active peptides in nematodes are extensive, but the number of different peptide families discovered thus far is small compared with higher invertebrates and vertebrates. Nevertheless, complexity and variety of peptide sequences within each family can be quite high, and genomic analysis suggests that the actual number of families is substantial. Here, we consider three large families of peptides in free-living nematodes, one of which has been the quite extensively studied biologically.

FMRFAMIDE-LIKE PEPTIDES (FLPS)

1. Discovery and structure. By far, the most extensively studied family of peptides in nematodes comprises the FMRFamide-like peptides (FLPs). They are hormones affecting neuromuscular, behavioral, reproductive and other activities and have been comprehensively reviewed and cataloged.[12–14,16,18] Free-living nematode FLPs are neuropeptides of 4 to approximately 15+ amino acids, characterized by an amidated C-terminus with an RF_{NH2} motif. This is a common posttranslational modification of biologically active peptides and requires a glycine residue at the C-terminus of the precursor. Thus, the "RFG" pattern has been used to scan precursor peptides for the presence of potential FLPs. Beyond this signature, there is sequence variation toward the N-terminus. Nematodes possess more than one *flp* gene,[13,18] with many genes expressing multiple FLP sequences, presenting a broad peptide diversity. This is best illustrated in *C. elegans*, where 31 *flp* genes have

been characterized, encoding precursor peptides predicting over 80 unique FLP sequences. Most predicted FLPs have been confirmed, many of the predicted peptides have been isolated, functions assigned, and some receptors identified (Table 1).

Ten of the *C. elegans flp* genes each encode a single unique FLP (Category I, Table 1), and six genes (*flp-6, flp-8, flp-9, flp-14, flp-20, flp-22*) encode multiple copies of single amino acid sequence. The majority of *flp* genes encode multiple unique peptides (Categories III and IV), with two genes encoding seven peptides (*flps-1*, *-13*) and *flp-13* encoding nine unique sequences. In addition to encoding multiple unique amino acid sequences, some *flp* genes in Category IV also code multiple copies of some sequences as well. Most of the genes that encode multiple sequences produce peptides in which the last four residues are identical. Exceptions are *flp*-11, *flp*-13, *flp*-17, *flp*-19. All FLPs have neuromuscular effects, but not all the effects are the same, leading to the hypothesis that a variety of FLP receptors exists. This argument is supported by the large number of unique sequences identified.

Among the many FLPs identified, KHEYLRF (*flp-14*) is present in all nematode species examined and is the most abundant FLP in *C. elegans* and *P. redivivus*. In *C. elegans*, *flp-14* encodes four copies of the peptide. KSAYMRF (*flp-6*) is also present in all species examined, and six copies are encoded by *C. elegans flp-6*. Also, SADPNFLRF and SDPNFLRF (*flp-1*) are widely distributed. The abundance and/or distribution of these FLPs indicate a fundamental importance.

2. Expression. At least nineteen *flp*s are expressed throughout larval and adult stages in *C. elegans*, including both hermaphrodite and male adult stages.[8,14,28] Expression is distributed among various sets of neurons and is conservatively estimated to be present in approximately 160 of the 300 total neurons in the worm. A number of *flp*s are expressed in male-specific neurons associated with mating, as well as in other neurons. Although all detected *flp*s are expressed in neurons, some are also expressed in nonneuronal cells including head muscle (*flp-2*, *flp-11*), pharyngeal muscle (*flp-5*, *flp-15*), sheath cells (*flp-11*, *flp-15*), vulval cells (*flp-10*) and uterine cells (*flp-2*, *flp-11*). *flp-15* is also detected in late embryos. *flp-4* and *flp-8* expression increases in the developmentally quiescent dauer, or diapause, stage. When the worm exits dauer diapause and resumes development, expression of these two genes ceases in a specific set of neurons. The large number and variety of unique FLPs indicate redundancy to ensure that critical physiological and developmental events occur and may also enable flexible and specific regulation of such events. Receptors, for example, may use multiple ligands to modulate responses to various similar, but distinct, messages.[8]

3. Receptors and function. Over a dozen receptors have been characterized from *C. elegans*. All are G protein-coupled, 7-transmembrane members of the rhodopsin family.[17] NPR-1 (gene **C39E6.6**)[10,28] is a 457aa protein that specifically binds ligand products of *flp-18* (EMPGVLRF) and *flp-21* (GLGPRPLRF). Two naturally occurring versions of the receptor differ by a single residue at position 215 (NPR-1-215F, NPR-1-215V), with NPR-1-215F coded by the ancestral gene. *C. elegans* strains exhibit either social or solitary feeding behaviors, and NPR-1-215V suppresses social feeding and is functionally dominant over NPR-1-215F. Each variant, expressed in *Xenopus laevis* oocytes, binds FLP-21 equally, whereas only NPR-1-215V binds FLP-18 (EMPGVLRF). In contrast, both receptors expressed in *C. elegans* pharyngeal muscle bind each ligand equally. This suggests that the receptors may respond differently to the cellular environment. Overexpression of *flp-21* or injection of FLP-21 suppresses social feeding in NPR-1-215F animals, whereas *flp-21* deletion promotes social feeding in animals expressing either receptor variant. A homolog is predicted by *C. briggsae* gene CBG14540.

FLP-15 peptides GGPQGPLRF and RGPSGPLRF are ligands for receptor NPR-3, encoded by **C10C6.2**.[11] The 376 aa receptor protein was expressed in Chinese hamster ovary cells and exhibited low ligand binding at 37°C. Only after a shift of the culture to 28°C was robust binding obtained, as was also observed with NPR-1.[11] Gene knockout using RNAi produced phenotypes with greatly impaired locomotion and paralysis.[7] A homolog is predicted by *C. briggsae* gene CBG06153.

The gene **C26F1.6** coding for receptor VRFa-1 was cloned and expressed in a human kidney cell line.[22] The expressed protein (360aa) was selectively activated by *flp-7* product TPMQRSSMVRF and AMRNALVRF from *flp-11* at similar ligand doses (1–1.3μM). The receptor specificity was determined by the entire length of the ligand, indicating that variations toward the N-terminus are functionally important. RNAi gene knockout in *C. elegans* produced an increase in egg laying and progeny. A homolog is encoded by *C. briggsae* gene CBG20584.

FLPs SPREPERF and LRGEPIRF (*flp-2*) were confirmed as ligands for **T19F4.1.**[21] Two alternative splice variants of the receptor were isolated (**T19F4.1a**, **T19F4.1b**). The **T19F4.1b** protein (432aa) and **T19F4.1a** protein (402aa) differ primarily in the C-terminal region, suggesting different specificities in G protein coupling. SPREPER-F_{NH2} activated both receptor isoforms at approximately 50nM EC_{50}, whereas EC_{50} for $LRGEPIRF_{NH2}$ was >6μM for each variant. In contrast to other *C. elegans*, FLP receptors expressed in mammalian systems, **T19F4.1** is active at 37°C. A homolog is encoded by *C. briggsae* CBG19036. The orphan GPCR **Y59H11AL.1**, similar to insect tachykinin and neuropeptide-Y receptors, was expressed in human

The number following a gene is the WormBase sequence identifier. The C-terminal glycine predicts amidation of the mature peptide. The number in brackets following a peptide sequence is the copy number per gene. The number in parentheses following peptide sequence is confirmed receptor. [C]amidated product isolated from *C. elegans*, [P]amidated product isolated from *P. redivivus*. Categories used: I-single sequence, single copy; II-single sequence, multiple copies; III-multiple sequences, single copies; IV-mixed multiple and single copies. Data from WormBase, GenBank and references cited in the text.

(HEK-293) kidney cells and activated by a number of nematode FLP ligands.[20] Products of *flps-1*, *-7*, *-9*, *-11*, *-13*, and *-22* bound to the receptor, with *flp-7* SPMERSAMVRF $_{NH2}$ the most potent ($EC_{50} < 1.1\mu M$) effector.

NEUROPEPTIDE-LIKE PEPTIDES (NLPS)

1. Discovery and structure. Not all nematode neuropeptides are FLPs. Immunochemical screens using antisera against vertebrate and invertebrate antigens provide circumstantial evidence for numerous other neuropeptides in nematodes. More directly, however, a rigorous examination of the *C. elegans* genome was made for neuropeptide-like protein encoding genes (*nlp* genes) using a combination of structural and alignment searches,[19,24] and evaluation of related ESTs in other species. The search actively eliminated any genes encoding peptides ending in RFG; that is, *flps*. Forty-seven *C. elegans nlp* genes encode over 130 unique putative neuropeptides.[13,18] The peptides sort into eleven families based upon conserved motifs and similar ESTs and neuropeptides in other species. The authors[24] list the families in decreasing order of

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

confidence that neuropeptides are encoded: **(1)** homology to orcokinin myotropic neuropeptide: *nlp-14* and *nlp-15* contain a C-terminal GFxGF, *nlp-8* and *nlp-15* encode peptides structurally related to those of *nlp-14* and *-15*; **(2)** homology to myomodulin peptides: *nlp-2*, *nlp-22*, *nlp-23* contain FRPG, with the glycine predicting amidation; **(3)** homology to buccalin neuropeptide neurotransmitter: *nlp-1*, *nlp-7*, *nlp-13* contain C-terminal MSFG and related motifs; **(4)** homology to insect allatostatin, buccalin: *nlp*-5 and *nlp*-6 contain C-terminal MGLG and MGFG; **(5)** *nlp-24*, *nlp-25*, and *nlp-27* through *nlp-32* encode YGGWG and YGGYG C-terminal motifs: similar encoded peptides in other nematode and insect ESTs; **(6)** *nlp-9* and *nlp-21* encode GGARAF: similar motifs in other nematodes; **(7)** *nlp-18* and *nlp-20* code for FAFA and related motifs, similar to motifs predicted in other nematode ESTs; *nlp-20* (**F45E4.8**) may reside in an operon with an endopeptidase (**F45E4.7**); **(8–11)** *nlp-4*, *nlp-10* through *nlp-12*, *nlp-17*, and *nlp-19* encode peptides sorted into 4 groups based upon C-terminal motifs and have hallmarks of neuropeptides but are not clearly related to established neuropeptides.

2. Expression and function. Postembryonic expression in *C. elegans* was detected for a number of *nlp*s. Neurons in the ventral nerve cord express *nlp-7*, *-9*, *-14*, *-15*, and *-21*. Pharyngeal neurons express *nlp-3*, *-8*, *-13*, *-18*, *-19*, *-20*, *-21*, and *-24*. Two *nlp*s, *nlp-21* and *nlp-31*, are expressed in embryos. NLP-37 **(F48B9.4)** is expressed in head neurons and affects locomotion and acts through receptor **C13B9.4**. In addition, receptors for *nlp-12* (**T23B3.4**, **Y39A3B.5**) and *nlp-44* (**K10B4.4**) have been identified.[15] Beyond the potential functions inferred from homologous neuropeptides, at least two NLPs (NLP-29, **B0213.4** and NLP-31, **B0213.6**) are proposed to function in the immune response (section 5.2.).

INSULINS (INSS)

1. Discovery and structure. Thirty-nine insulin-like peptides (INSs) are predicted from the *C. elegans* genome. They range in length from 67 to 218 residues and exhibit remarkably little sequence homology. Multiple alignments of INS-1 through INS-38 (WormBase) show that only 2 sequences have as much as 60 percent homology (INS-7, INS-8), 2 are 47 percent homologous (INS-25, INS-29), and two pairs are 40 percent homologous (INS-22, INS-23; INS-25, INS-29). All other alignments reveal <39% homology, with the majority <30%. Clearly, this family of peptides is not characterized by sequence identity. Only through the combined use of an extensive array of multiple sequence search tools, expression searches and molecular modeling were the INS sequences identified.[26]

Caenorhabditis elegans insulin genes predict three basic peptide precursor structures.[25] All structures contain a signal sequence and the B-chain and A-chain peptides characteristic of vertebrate insulin. INS-1 and INS-18 precursors have an intervening C-peptide between the A- and B-chain peptides, similar to human insulin precursor. INSs 2–9 have an F-peptide between the signal sequence and B-chain peptide but no C-peptide. The A- and B-chain peptides are contiguous. Notable here is a dauer-associated (see 3. Receptors and function below) gene, *daf-28* (**Y116F11B.1**), encoding an insulin-like peptide with INSs 2–9 precursor structure.[15] All the remaining INSs have only the signal sequence and contiguous A- and B-peptides.

In addition to signal sequences, and the A-chain and B-chain peptides shared with vertebrate insulins, all *C. elegans* INSs have highly conserved cysteines essential to formation of interchain and intrachain disulfide bonds.[19,20] Based upon the architectures of disulfide bond formation, and the comparison of these architectures with that of human insulin, *C. elegans* INSs have been sorted into three structural groups-α, β, and γ.[20] These are illustrated in Fig. 1 using representative *C. elegans* INS sequences and human insulin as reference. Because sequence homologies are so low, only those portions of the molecules containing the important A-chain peptide and B-chain peptide insulin signatures are compared. α- and β-group members form 3 interchain bonds (B1–A2, B2–A4, B3–A5) and one intrachain bond (A1–A3). The disulfide intrachain bond (A1–A3) is absent from the α-group, but it is suggested that substitute residues (italics, Fig. 1) form hydrophobic interactions to stabilize the structure.[19] The γ-group has two interchain bonds and one intrachain bond and in this respect is most similar to vertebrate insulins. All *C. elegans* INS sequences have residues predicted to enable the formation of α-helices (Fig. 1, underlined). Despite little primary structural homology among their group, and to vertebrate insulin, all *C. elegans* INSs are capable of forming stable tertiary structures recognized by insulin receptors. In fact, INS-6 (**ZK84.6**) can bind to the human insulin receptor.[4]

2. Expression. Insulin genes are widely expressed throughout development and in a number of tissues.[26] Expression patterns for fifteen *ins* genes (*ins-1* through *ins-9*, *ins-11*, *ins-18*, *ins-21*, *ins-22*, *ins-23*) reveal that all except *ins-9* are expressed in the embryo, all are expressed in larval stages, and all but *ins-2* in the adult. All *ins* genes are expressed to varying degrees in the nerve ring and sensory neurons. All except *ins-9* are expressed in nonsensory neurons. Six genes (*ins-1*, *ins-2*, *ins-4*, *ins-5*, *ins-8*, *ins-18*) are also expressed in nonneuronal tissues including vulva, intestine, pharynx, and hypodermis.

3. Receptors and function. A single insulin receptor (*daf-2*; Y55D5A.5) has been described in *C. elegans*, although additional receptors are proposed.[2] DAF-2 is a transmembrane receptor tyrosine kinase homolog of the mammalian insulin/IGF receptor family.[26] It is a central

B-peptide **A-peptide**

FIGURE 1 Multiple alignment (ClustalW) amino acid sequences encompassing the B-peptide and A-peptide portions of human insulin precursor (Hu; SwissProt P01308) and selected insulin-like peptides from *Caenorhabditis elegans*; INS-1 (**F13B12.5**), INS-2 (**ZK75.2**), INS-3 (**ZK75.3**), INS-4 (**ZK75.1**), INS-6 (**ZK84.6**), INS-7 (**ZK1251.2**), INS-8 (**ZK1251.11**), INS-9 (**C06E2.8**), INS-17 (**F56F3.6**), INS-18 (**T28B8.2**), INS-24 (**ZC334.3**), INS-26 (**ZC334.1**), INS-30 (**ZC334.2**), INS-36 (**Y53H1A.4**); gene identifiers from WormBase. Numbers at the top are position numbers for human insulin. Numbers at the bottom indicate cysteines (shaded) participating in disulfide bonds (see text in Insulins (INSS)/Discovery and structure). Dark shading indicates additional cysteines not found in human or γ-group sequences. Underline indicates residues predicted to enable formation of α-helices. Residues that substitute for cysteines in intrachain bonding of type α-group insulins are italicized.

member of a complex pathway regulating a number of basic events including nematode development, longevity, stress response, and dauer formation. *Caenorhabditis elegans* larvae respond to environmental stress, such as crowding or lack of food, by entering the arrested dauer stage. Upon return of favorable conditions, larvae resume development. Stimulation of DAF-2 promotes increased metabolism, growth, and aging. Downregulation of the receptor can induce larval dauer formation or extended adult lifespan.[9,15,19,26,29] Insulins are proposed to regulate metabolism as ligands of DAF-2. INS-1 (**F13B12.5**) is an antagonist of DAF-2, enhancing dauer arrest,[26] whereas INS-18 (**T28B8.2**) activates DAF-2 and regulates lifespan.[15] Another insulin-like peptide (DAF-28; **Y116F11B.1**) also may be a DAF-2 agonist and prevent dauer arrest. Expression of *ins* genes in sensory neurons and their interaction with DAF-2 support their roles as regulators of response to external and internal cues. Including insulins, nearly 120 genes encoding over 250 neuropeptides have so far been reported in free-living nematodes, but these numbers are most likely conservative.[13]

ANTIMICROBIAL PEPTIDES

1. Discovery and structure. Animals respond to pathogen challenge through the mobilization of complex molecular defenses in the forms of adaptive and/or innate mechanisms. Adaptive systems are characterized by the ability to remember specific antigens and render long-lasting immunity, as in the higher vertebrates. Innate immunity is a more basic, rapid response to infection characterized by phagocytosis and production of antimicrobial peptides. Both types of immunity are present in higher vertebrates, while lower animals, including nematodes, depend solely on innate immunity as defense against pathogens. In nematodes, the production of antibacterial peptide factors (ABFs) in response to bacterial challenge was demonstrated in the animal parasite *Ascaris suum*,[27] in which a family of antibacterial factor like peptides (ASABFs) has been reported.[5,27] The screening of sequence databases with the ASABF amino acid sequence revealed homologies to two peptides both in the *C. elegans* database.[6] Genes for the *C. elegans* homologs (*abf-1* and *abf-2*) were isolated and characterized.[6] They are organized sequentially, produce a polycistronic mRNA, and are thought to form an operon. The product peptides ABF-1 and ABF-2 possess structural properties generally found in antimicrobial peptides, including conserved cysteine residues necessary to stabilize the molecule and preserve activity.[5] Antimicrobial peptides are a rapidly evolving group and sequence comparisons usually reveal limited homologies with no significant sequence homology outside of the nematodes.[30] A BLAST search done for this report using *C. elegans* ABF-1 (BAA89489) and ABF-2 (BAA89490) detected significant homologs outside of *C. elegans*. Two examples of high scoring

FIGURE 2 Antibacterial peptides. Multiple alignment (ClustalW) of full length amino acid sequences of antibacterial peptides from *Ascaris suum* (AsABF, BAA11943), *Caenorhabditis elegans* (ABF-1, BAA89489; ABF-2, BAA89490), and *C. briggsae* (CbABF, **CAP31030**). Identical positions are shaded and include 8 conserved cysteines; signal peptides are underlined and italicized. Predicted signal sequence is underlined only. Accession numbers are from GenBank.

sequences from *A. suum* ASABF (BAA11943) and *C. briggsae* **CAP31030** (CBR-ABF2), are compared with the *C. elegans* sequences in Fig. 2. Sequence homology of ABF-1 is low (35–36 percent to the other 3 peptides), while homology of ASABF is 52 and 54 percent, respectively, to ABF-2 and CAP31030. ABF-2 has antibacterial activity,[6] and is 72 percent homologous to CAP31030. Signal peptides are present in ASABF and both *C. elegans* ABFs (Fig. 2, underlined, italicized), and a signal sequence is suggested for the *C. briggsae* peptide (underlined only). All 4 sequences share a number of identical residues in 13 locations (Fig. 2, shaded boxes), including the conserved cysteines (8 total).

2. Expression and function. ABF-2 was detected immunologically only in the pharyngeal region of larval and adult hermaphrodite stages of *C. elegans*.[6] *abf-1* and *abf-2* transcripts were detected in adult hermaphrodites and eggs. Protein expression was detected in larval and adult hermaphrodite stages but not in pre-hatch embryos. ABF-2 was observed in the pharynx, pharyngeal neurons, and excretory cells, whereas ABF-1 was detected in the pharynx and body wall muscle.[6] Only in *A. suum* has *in vivo* bacterial challenge been shown to induce production of nematode antibacterial peptides,[27] but *in vitro* experiments and structural analyses of candidate peptides argue strongly that *C. elegans* ABFs are true antibacterial peptides.[6,30] It is interesting that expression of two neuropeptide-like proteins (NLP-29 and NLP-31) was induced in *C. elegans* exposed to fungal or bacterial pathogens,[1] and that synthetic NLP-31 has both potent antifungal and moderate antibacterial activities. NLP-29 and NLP-31 each have <22 percent homology to any of the peptides in Fig. 2 and lack the conserved cysteines. Also, the DAF-2 signaling pathway seems to function in pathogen resistance.[3,23]

TABLE 2 Overview of 3 Peptide Gene Families in *C. elegans*

Measure	FLP	NLP	INS
Number of genes	31	48	42
Total peptides	101	153**	84

Number of genes encoding known ligands†	14	4	8

Data used for summaries obtained from WormBase and references cited in the text.
*Includes unique sequences and multiple copy sequences.
†9 flp genes encode some sequences associated with more than one receptor, and some receptors are associated with more than one gene.
**Includes antimicrobial sequences.

SUMMARY

Free-living nematode peptides occupy 3 large families containing 31–42 genes that encode 84–153 peptides. Most of the genes encode multiple peptides (Table 2). One family (NLPs) contains a subset of antimicrobial peptides that might be considered as a fourth, smaller family. Information on gene expression, receptor recognition and identification, and biological activity continues to grow. With this information, analyses of the complex and varied environment of nematode peptides will continue to add to our understanding of the development, evolution, and mechanism of signaling systems.

Chapter 37

FXPRLamide (Pyrokinin/PBAN) Family

Miriam Altstein, Aliza Hariton and Ronald J. Nachman

ABSTRACT

The pyrokinin/pheromone biosynthesis-activating neuropeptide (PK/PBAN) family is one of the most studied neuropeptide (Np) families in insects and is one of the most important in insect physiology regulation. Physiological functions regulated by the PK/PBAN peptides include development, mating, muscle contraction, and tanning. Members of the family are found in many Lepidopteran and other insect species. In this chapter, we briefly present a historical perspective of the discovery of the PK/PBAN peptides, provide details on the structure of the PK/PBAN genes and the processing of their prohormone to bioactive peptides, describe the distribution of the mRNA and peptides in the insect nervous system, and summarize the current knowledge on the PK/PBAN receptors, their signaling mechanisms, and their biological activity. Employment of the PK/PBAN family of peptides as a basis for designing a novel generation of insect-control agents based on Np antagonists is also briefly discussed.

INTRODUCTION

The pyrokinin/pheromone biosynthesis-activating neuropeptide (PK/PBAN) family of peptides is one of the most studied neuropeptide (Np) families in insects and is one of the most important in regulating their physiology. Physiological functions regulated by the PK/PBAN peptides include development and mating, as well as muscle contraction activities and induction of cuticular melanization. The family is present in a wide variety of insects and comprises the following C-terminally amidated peptides: PKs; myotropins (MTs); PBANs; diapause hormone (DH); and β- and γ-subesophageal Nps (SGNPs), all of which share a common sequence (FXPRLa). PK/PBAN peptides have been studied for nearly 30 years, mainly in moths, during which many new members have been identified, the genes of the peptides and their receptors have been cloned and characterized, and their distribution in the nervous system studied in many moth species; their physiological roles have been determined through physiological and behavioral analyses at the whole-organism level, complemented by molecular and cellular studies. The PK/PBAN peptides also form a basis for the development of new-generation insect-control agents based on their antagonists.

In this chapter, we review the current knowledge of the PK/PBAN family of peptides, most of which is based on studies with PBAN and DH in Lepidopterans and describe the application of this knowledge to the generation of highly potent, selective, and readily bioavailable potential insect-control agents. The amount of information accumulated on this family is too large to be covered within the framework of this chapter, and the reader is referred to the reviews cited in the text. For the convenience of the reader, and to minimize confusion that might arise from the complexity of the peptide terminology, each of the main sections below is divided into subsections based on *pban* or *capa* gene-encoded peptides and their characteristics in Lepidopteran or non-Lepidopteran species.

DISCOVERY OF THE PK/PBAN FAMILY OF PEPTIDES: HISTORICAL PERSPECTIVE

PBAN

The first member of the family to be discovered was leucopyrokinin (LPK), identified in the cockroach *Leucophaea maderae* in 1986.[14] It was followed in 1989 by the pheromone biosynthesis activation neuropeptide (PBAN), first reported by Raina and Klun[29] as a Np that regulates sex pheromone production in the female moth *Helicoverpa zea*; Raina et al.[28] isolated and characterized it as a 33 amino acid, C-terminally amidated Np, which was designated *Hez*-PBAN. Since 1989, the primary sequences of 24 PBAN molecules from many other moth species have been determined[3] (Table 1). PBAN molecules were also found in insects belonging to orders other than Lepidoptera, for example, *Drosophila melanogaster*, *Anopheles*

Bold letters indicate conserved amino acid sequences. DH – diapause hormone; PBAN – pheromone biosynthesis-activating neuropeptide; PK – pyrokinin; MT – myotropin; PT – pheromonotropin; SGNP – subesophageal ganglion neuropeptide.
**A member of the family but with the difference that X = Lys or Ilu. The sequence of α-SGNP is the same in all Lepidopterans (VIFTPKLa). References for the listed peptides can be found in Ref. 3 Ort-PBAN and Sol-PBAN were published in Refs. 8, 34, respectively. Additional sequences of PBAN, DH, α-, β-, and γ-SGNP can be found in Ref. 16.*

gambiae, *Aedes aegypti*, *Tribolium castaneum*, and aphids. These peptides were not cloned but were predicted from the genome sequences of the insects.[16] Comparisons among the primary sequences of the PBAN molecules revealed that the Lepidopteran peptides share a high degree of homology (Table 1). Regardless of their length and degree of homology, all PBANs contain the C-terminal pentapeptide signature sequence FSPRLa.

Other Peptides of the Family

Further studies of insect Nps revealed that other peptides also have a very similar C-terminal sequence: FXPRLa (X = S, T, G or V). To mention just a few, PKs (e.g. LPK,[14] Lom-PK-I and Lom-PK-II) and the myotropins (e.g., Lom-MT-I to IV), which are myotropic peptides isolated from the migratory locust, *Locusta migratoria*; PK

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

peptides of *Periplaneta americana* —Pea-PK-5 and Pea-PK-6—and the myotropic peptide of *Schistocerca gregaria* (Scg-MT-1). Additional peptides that were found to share the same consensus sequence are β- and γ-SGNPs; pheromonotropin (PT)—an 18 amino acid peptide isolated from *Pseudaletia (Mythimna) separate*—which is now included in the β-SGNP group; and DH, which induces embryonic diapause in *Bombyx mori* and terminates pupal diapause in *Helicoverpa/Heliothis* moths. For review, see Ref. 3 and Table 1. As the number of available sequences has increased, the *X* in the consensus sequence has been extended to include I (as in *Bom*-β-SGNP) and K (as in *Drm*-β-SGNP, see Table 1). All peptides sharing the above sequences were grouped into one family, which was designated the FXPRLa family or the PK/PBAN family, named after PBAN and Lem-PK, which was the first member of this family to be identified[14] and had myostimulatory ("kinin"-like) action and a pGlu residue at its N-terminus, (and thus termed pyrokinin).

More recently, in light of genomic database records, sequence similarities to previously annotated genes and actual gene sequencing, it became apparent that PK/PBAN peptides are encoded by two genes, which are found in many Lepidopteran and non-Lepidopteran insect species.[16,26] These findings help to categorize the FXPRLa peptides into two main groups that are processed from either the *pban* gene or the *capa* gene. To avoid terminological confusion, in this chapter, these peptides will be designated as *pban* gene-encoded peptides (PBAN, DH, β-, and γ-SGNPs) or *capa* gene-encoded peptides (CAPA-PKs), respectively. Exploration of the *capa* gene also reveals two additional periviscerikinin peptides sharing just the PRLa C-terminal sequence; they are termed CAPA-1 and 2 or PVK-1 and 2, and are not addressed in this chapter. For further information on the *pban* and *capa* gene peptides, the reader is referred to Refs. 16, 24, 26 and references therein.

STRUCTURE OF THE mRNA/GENE

PK/PBAN peptides are encoded by two genes: the *pban* gene (also termed *dh-pban* gene)[3,16] and the *capa* gene, which are present in almost all insects.[16,26]

pban Gene

The *pban* gene was first isolated from *H. zea* in 1989 by Raina[28] and encodes the PBAN preprohormone and three additional peptides—DH, β-SGNP and γ-SGNP—all of which contain the family's consensus sequence and one FXPKLa peptide (α-SGNP)[16] (Table 1). To date, the *pban* gene has been cloned from 19 species of Lepidopteran moths, in all of which it encodes all five PK/PBAN peptides. PBAN, DH, and β-SGNP are also produced in many other—non-Lepidopteran insects (e.g., the fire ant, the mosquito and the red flour beetle *Tribolium castaneum*), whereas α- and γ-SGNP are not always encoded.[16] In *Drosophila*, only two peptides are encoded by the *pban* gene (termed *hugin* gene).[16]

capa Gene

The *capa* gene was first identified in *D. melanogaster*. It encodes a CAPA-PK and two periviscerokinins—PVK-1 and PVK-2—which contain a PRLa sequence at their carboxy terminus.[16,26] CAPA-PK is also termed DH-like PK (because of the C-terminal-consensus WFGPRLa sequence typical of all DH Nps), CAPA-3 or myotropin-1 in *Drosophil*a, PK-1 in *Manduca sexta*, and PK-5 and PK-6 in *P. americana* (Table 1). The *capa* gene is present in many insect species, including Lepidopterans, and it encodes CAPA-PK in all tested insects other than *Apis mellifera.*[16] To the best of our knowledge, the *pban* or *capa* genes have not yet been cloned from *L. migratoria*, *S. gregaria* or *P. americana* although CAPA-PKs have been isolated, or predicted in light of sequence homologies, and localized in various parts of the nervous system.

PROCESSING OF THE PRECURSOR

pban Gene and *capa* Gene

The *pban* gene and the *capa* gene are translated into typical Np preprohormones, which contain, at their N-terminus, a signal sequence that is removed before their transfer to the Golgi apparatus. In both genes, all bioactive peptides in the prohormone are separated by single or pairs of basic amino acids at their N-terminus, and by a Gly followed by a single or pair of basic amino acids at the C-terminus, which serve as post-translational sites for processing and C-terminal amidation enzyme, respectively (e.g., see a *pban* gene structure and processing sites of *Orgyia thyellina*[34] and a *capa* gene of *M. sexta*).[19]

Peptides derived from the *capa* gene undergo cell-type-specific sorting and packaging and were the first insect Nps shown to be differentially processed. Differential processing has been shown in *D. melanogaster* and in *B. mori* and in *P. americana* in which it exhibits an interesting and uncommon phenomenon, that different peptides originating from the *capa* gene could be individually packaged and fuse with each other and with other peptide-containing vesicles in the cytoplasm, after leaving the trans-Golgi network. A detailed description of the *capa* gene prohormone processing, alternative-splicing mechanism, sorting, and packaging is presented in Refs. 26, 30.

DISTRIBUTION OF THE PEPTIDE/mRNA

Peptides

pban Gene-Derived Peptides

PBAN in Lepidoptera

PBAN distribution was studied by immunochemical methods (radioimmunoassay, enzyme-linked immunosorbent assays (ELISA) and immunocytochemical (ICC) methods) in adult females, males and larvae of various Lepidopteran species (e.g., *H. zea*, *M. sexta*, *B. mori*). These studies found PBAN-immunoreactive (IR) neurons in the brain and subesophageal ganglion (SOG) that projects to the corpora cardiaca (CC) and in ganglia of the ventral nerve cord (VNC). In the SOG, PBAN is found in seven pairs of neurosecretory cells. PBAN-IR is also found in the CC and in a pair of cells in the thoracic and abdominal ganglia. The ICC studies also reveal two pairs of axons originating from cell bodies in the SOG, which extend the entire length of the VNC and terminate in the terminal abdominal ganglia. ELISA studies indicate that the brain–SOG complex contains the highest level of PBAN-like IR, followed by the CC and the thoracic ganglia, and that abdominal ganglia contains low levels of the peptide. A more detailed analysis of PBAN-IR-containing cells, by means of matrix-associated laser desorption/ionization combined with mass spectrometry (MALDI/MS), reveal a basically similar distribution. For review, see Refs. 11, 27.

DH in Lepidoptera

DH distribution was studied by ICC analyses in *H. armigera* and *B. mori*. In *H. armigera*, DH is localized in the mandibular, maxillary, and labial cell clusters of the SOG, in a pair of ventral midline lateral neurons, and in each thoracic ganglion at all the developmental stages (embryo, larva, pupa, and adults).[33] In *B. mori*, immunoreactive neural processes with varicosities are in the CC and the corpus allatum (CA); as in *H. armigera*, IR is detected at all developmental stages.[21]

PBAN in Non-Lepidopteran Species

ICC testing of the distribution of PBAN in the fire ant *Solenopsis invicta* found that the peptide-producing neurons are located in the SOG and CC in all adult sexual forms. PBAN-IR is also detected in two segmented thoracic and four segmented abdominal ganglia, which project to the neurohemal perisympathetic organs (PSOs), indicating release of PBAN to the hemolymph.[9]

Other FXPRLa-Containing Peptides in Non-Lepidopteran Species

More recently, detailed bioinformatic studies were combined with MALDI-TOF and electrospray ionization quadrupole (ESI-Q)-TOF MS to make an inventory of Nps containing the PK/PBAN consensus sequence in different parts (ganglia and nerves) of the central nervous systems (CNSs) of *L. migratoria* and *S. gregaria*. In both species, the peptides are detected in the SOG, in the retrocerebral complex, which comprises the CC and the CA, and in the hypocerebral ganglion, which is part of the stomatogastric nervous system. In *S. gregaria* FXPRLa-containing peptides are also detected in the recurrent and esophageal nerves (which are also part of the stomatogastric nervous system).[10] Because the *pban* gene and *capa* gene have not yet been cloned from locusts, it is difficult to relate these peptides (termed PKs in the above study) to any of the PK/PBAN family gene products.

capa Gene-Derived Peptides

CAPA-PKs in Lepidopteran and Non-Lepidopteran Species

CAPA-PK peptides are the characteristic and most abundant Nps in the abdominal neurohemal system. The location and projection of CAPA neurons was studied in D. melanogaster, P. americana and M. sexta. So far, CAPA-PKs are expressed only in the CNS and not in any other tissue. The peptides are synthesized in median neurosecretory neurons of the abdominal ganglia and are released from the PSOs into the hemolymph. In Drosophila, a truncated form of CAPA-PK was detected in the neurosecretory cells of the SOG, in the retrocerebral complex, and in the larval ring gland, it was also found in the SOG of M. sexta. In P. americana, CAPA-PKs also occur in interneurons, from which they may be released into the CNS. A detailed review on the distribution of CAPA peptides by MS is presented in Ref. 26.

Gene/mRNA

pban Gene Expression in Lepidopteran and Non-Lepidopteran Species

pban gene distribution and expression were determined by Northern blotting, real-time polymerase chain reaction (RT-PCR), and in situ hybridization, and the results are similar to those obtained by immunochemistry. PBAN mRNA is expressed in both male and female moths and is detected in the SOG as well as in the brain, thoracic ganglia, and abdominal ganglia of larvae, pupae, and adults of several moth species (*H. zea*, *H. armigera*, *M. sexta*, *and B. mori*). Expression is predominantly in the SOG, where gene transcripts are located in the same DH-PBAN-producing neurosecretory cells as detailed above (Ref. 27 and references therein).

pban gene transcripts are also found in the head, thorax, and abdominal ganglia of the female fire ant, *S. invicta*. The strongest transcriptional signal and highest number of *pban* gene copies are detected in the head, and much weaker and

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

fewer ones in the thoracic and abdominal ganglia, where the numbers of copies were almost negligible.[9]

capa Gene Transcripts in Lepidopteran and Non-Lepidopteran Species

In situ hybridization of CAPA mRNA was performed in Lepidopteran and non-Lepidopteran species. In *M. sexta*, about 15 pairs of CAPA interneurons were detected in the brain of first-instar larvae. The number of neurons decreased during postembryonic development and only one pair expressed CAPA mRNA in the adult brain.[19]

RECEPTORS AND SIGNALING CASCADE

PK/PBAN Receptors

A variety of techniques—bioinformatic, biochemical, molecular, physiological, pharmacological, and histochemical—were used to predict, clone, isolate, locate, and characterize the PK/PBAN receptors in various insects. The great majority of the studies focused on the receptors that mediate the pheromonotropic activity in moths. Early studies had suggested that PBAN might act on a target other than the pheromone gland (see Ref. 3 and references therein), but since the late 1990s, it became clear, beyond any doubt, that in most moth species, PBAN acts directly on the pheromone gland via the PK/PBAN receptors. A histochemical study of the pheromone gland cells of *H. peltigera* yielded the first direct indication of the presence of the PK/PBAN receptors in the pheromone gland.[1]

Similarly to Nps of other vertebrates and invertebrates, the PK/PBAN Nps activate cellular processes via G-protein-coupled receptors (GPCRs). At the turn of the century, many studies on cloning of insect Np GPCRs, including those of the PK/PBAN family, were stimulated by the *Drosophila* Genome Project,[13] and by completion of genome sequences of other insects. In light of these data, it is now apparent that all the PK/PBAN receptors fall into two groups: receptors for *capa* gene peptides—herein termed PK-1/DH-receptors (PK-1/DH-R); and receptors for the *pban* gene peptides—herein termed PK-2/PBAN-R. Both receptor types are found in a wide variety of insects and are activated by PK/PBAN/DH peptides, although at differing affinities. In general, PK-1/DH-R exhibits high affinity (at low nM doses) toward WFPRLa-containing peptides (DH signature sequence), whereas other PK/PBAN peptides activate the receptors at much higher concentrations; the PK-2/PBAN-R exhibit high (nanomolar) affinity to PBAN and lower affinity toward other FXPRLa peptides.

So far, 13 PK-2/PBAN-Rs from moths, *Drosophila* and mosquitoes and 2 PK-1/DH-Rs (from *B. mori* and from *Drosophila*) were cloned and expressed in cell lines. Another 12 were annotated according to sequence homologies with already-cloned PK-2/PBAN-R or PK-1/DH-R genes (Table 2). The first receptors were cloned in light of the assumption of Hewes and Taghert[13] that PK/PBAN-R might be homologous to the mammalian neuromedin U receptor (NmU-R) because their ligands—NmU and the PK/PBAN Nps—contain similar motifs at their C-termini, that is, FRPRNa and FSPRLa, respectively, and PBAN was found to activate an NmU-R in *Drosophila*. Primers based on the consensus sequences of NmU and on sequences of genes CG8784 and CG8795, CG9918 and CG14575—which, in the *Drosophila* Genome Project were predicted as coding for GPCRs were designed and were successfully used to clone two *D. melanogaster* receptors (PK-2-1/PBAN and PK-2-2/PBAN, originally termed CG8784 and CG8795, respectively), two *Anopheles* receptors (PK-1/DH and PK-2/PBAN), the *D. melanogaster* PK-1 receptor (PK-1/DH-R also termed, CG9918), and the *B. mori* and *H. zea* PBAN-Rs (Table 2). A few additional PBAN receptors from pheromone glands of adult female moths were cloned later, based on the already published PK/PBAN-R sequences (for example, *H. virescens*, *H. peltigera*, *H. armigera*, *Plutella xylostella*, and *Spodoptera exigua*), and from several different larval instars (for example, *S. littoralis*, *H. virescens*). A DH-R was cloned from pupal ovaries of *B. mori* (Table 2). Interestingly, multiple isoforms were identified in *H. virescens* and *M. sexta* and, most recently, an isoform of the *H. zea* PBAN-R, which contains a long C-terminal tail similar to that of *B. mori* was annotated (*Hez*-PBAN-R-iso; Table 2). In all of the studies, other than that on the *B. mori* pupal ovary, expression was monitored by observing Ca^{2+} influx; in the case of the *B. mori* pupal ovary receptor, it was monitored by voltage clamping. The occurrence of PBAN-R in adult male moths has also been reported.[4] Receptor characterization is detailed in Refs. 3, 16–18, 20 and references therein.

A detailed evolutionary trace analysis, based on sequence alignments of the actually cloned and the predicted PK-2/PBAN-Rs and PK-1/DH-Rs, aimed to discover highly conserved and group-specific amino acids that might predict global and group-specific putative ligand recognition and docking sites was conducted. In both groups, the study reveals several highly conserved trans-membrane (TM) amino acid residues that form, most probably, the binding sites that activate the receptors and some group-specific sequences in the extracellular domains, which could indicate specificity toward different *pban* gene and *capa* gene peptide ligands.[16] A preliminary verification of this hypothesis already was obtained from computer-modeled structure analysis of mutated and/or modified chimeric receptors. All of the studies add important information on the receptor's structure/activity relationship (SAR) and reveal the extracellular and intracellular domains responsible for receptor stability, ligand recognition, and binding.[6,7,17]

SIGNALING CASCADE

PK-2/PBAN-R in Lepidopterans

Response to PBAN in Sex Pheromone Biosynthesis

In all moth species tested so far, Ca^{2+} is necessary for the biological response to PBAN and activation of the PBAN-R by the ligand results in an influx of extracellular calcium and a subsequent increase in cytosolic Ca^{2+}. Depletion of Ca^{2+} causes loss of pheromonotropic activity (for review, see Ref. 20).

Although extracellular Ca^{2+} has proved to be absolutely necessary for the bioactivity of PBAN in all moth species tested so far, the intracellular signal transduction cascade stimulated by the Np differs among moth species. In some moths, for example, *Heliothinae* species and *Argyrotaenia velutinana*, the cyclic nucleotide second messenger, cAMP, is a critical component in PBAN signaling, whereas in others, (e.g., *B. mori* and *S. litura*), cAMP do not seem to be involved, hinting at a possible correlation between the steps in the sex pheromone biosynthetic pathway affected by PBAN (early or late) and its ability to activate cAMP. The signaling pathways affected by PBAN in the pheromone gland were extensively studied in *B. mori* and several *Heliothinae* species; detailed reviews on PBAN signal transduction and its downstream cascade of events in biosynthesis of bombykol (the *B. mori* sex pheromone) and other sex pheromones of other moth species can be found in Refs. 17, 20.

Response to PBAN in Cuticular Melanization

PBAN signaling was also examined in a larval receptor of *S. littoralis*, where it induces activation of a matrix-associated protein (MAP) kinase via a signaling mechanism that was protein kinase C (PKC)-dependent but Gαi-independent. As with the pheromone gland receptors, the larval receptor is dependent on Ca^{2+} and responds to PBAN analogs and PT (β-SGNP) by MAP kinase activation.[35]

PK-2/PBAN-R in Non-Lepidopterans

Response to pban Gene–Derived Peptides

Ca^{2+} is also involved in the activation of the PK-2/PBAN-R in *D. melanogaster* and *A. gambiae*, as indicated by Ca^{2+} elevation in CHO cells that express the cloned *Drm*- or *Ang*-PK-2/PBAN-R in response to nanomolar concentrations of *Drm*- or *Ang-pban gene*-derived peptides.[25,31]

PK-1/DH-R in Lepidopterans

Response to DH in Embryonic Diapause

PK-1/DH-R signaling was tested with a *B. mori* pupal ovary receptor, which regulates embryonic diapause. The receptor is also dependent on Ca^{2+} and is coupled to a Gq protein with downstream signaling action involving protein kinase C.[15]

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

PK-1/DH-R in Non-Lepidopterans

Response to CAPA-PK

Although the biological function of the CAPA-PK peptides is still unknown, similar results were obtained regarding involvement of Ca^{2+} in activation of the PK-1/DH-R by nanomolar concentrations of *Drm*- or *Ang*-CAPA-PK.[5,25]

BIOLOGICAL ACTIONS

The PK/PBAN family of peptides is a ubiquitous, multifunctional family that plays a major physiological role in regulating a wide range of developmental processes in insects: pupariation, diapause, cuticular melanization, feeding, that is, gut muscle contraction and mating behavior, that is, sex pheromone production. For a review, see Ref. 3. The wide distribution of these peptides and their receptors in all insects hints at the possibility that additional functions of the *pban* gene and *capa* gene peptides may be found in the future.

pban Gene-Derived Peptides

PBAN in Sex Pheromone Biosynthesis in Females

The first function that was discovered to be mediated by a member of the PK/PBAN family was stimulation of sex pheromone biosynthesis in female moths.[29] Now, after nearly 30 years of research, it is well established that PBAN regulates sex pheromone production in a circadian manner in many, but not all, moth species. PBAN is released to the hemolymph via the CC and reaches its target organ, the pheromone gland, where it exerts its activity. PBAN regulates either the initial or the terminal steps in the pheromone biosynthetic pathway, as indicated in the signaling cascade section. The cellular mechanisms by which PBAN regulates sex pheromone production were studied in detail and are reviewed in Refs. 17, 20.

PBAN in Sex Pheromone Biosynthesis in Males

A putative role of PBAN in the regulation of free fatty acids in male moths is hypothesized to be involved in chemical communication between the two sexes.[4] The mechanism by which PBAN affects male attractants is still unclear.

PBAN in Melanization

PBAN peptides are involved in cuticular melanization—the last step in the molting processes—in many noctuid moths. The possible involvement of this family of Nps in the control of larval cuticular melanization was first raised by Ogura and coworkers in studies of the common army worm, *Leucania separata*. The hormone—termed melanization and reddish coloration hormone (MRCH)—was later found to be identical with *Bom*-PBAN, which initiates melanization of the integument of many moth larvae. For a detailed review, see Ref. 3 and references therein.

DH in Embryonic and Pupal Diapause

As studies on the bioactivity of the *pban* gene peptides progressed, it became apparent that a *pban gene*-encoded peptide, DH, plays a major role in development processes. Studies since the late 1990s have found that DH induces embryonic diapause in *B. mori* and terminates pupal diapause in *Heliothinae* species. The effect of DH on embryonic and pupal diapause is reviewed in Ref. 32. DH is an important inducer of seasonal reproductive polyphenism in *O. thyellina*, inducing diapause that might be orchestrated via seasonal signaling pathways to accomplish seasonal adaptation.[34] Other functions of *pban* gene-encoded peptides are summarized in Ref. 3.

Bioactivity of Other FXPRLa-Containing Peptides in Lepidopteran and Non-Lepidopteran Insects

PK/PBAN Nps also accelerate pupariation in wandering larvae of the fleshfly (*Sarcophaga bullata*). Lem-PK (LPK) accelerate the switch from wandering behavior to immobilization/retraction behavior, and subsequently affect puparial tanning. By accelerating both aspects of puparium formation, Lem-PK mimick the effects of the pupariation factors by affecting the central motor neurons.[22] Studies by Altstien et al.[2] reveal that LPK and Lom-MT-II can also stimulate sex pheromone biosynthesis in *H. peltigera* adult females and cuticular melanization in *S. littoralis* larvae.

capa Gene-Derived Peptides

In contrast to the *pban gene*-encoded peptides, the physiological effects of the CAPA-PKs have not been investigated in detail and their role(s) in insect physiology is/are currently unknown.

The involvement of *pban*-gene-encoded Nps in the above functions, with the exception of myotropic activity, was determined by means of a variety of *in vivo* bioassays, for example, pheromonotropic, melanotropic, diapause, and pupariation assays. The myotropic activity was performed using an isolated cockroach hindgut. These studies revealed that most of the above functions could be stimulated by more than one member of this peptide family, sometimes at differing doses, and that the peptides are not species specific; this subject is reviewed in Ref. 3. Gene silencing was used to study the role of PBAN in sex pheromone biosynthesis in *P. xylostella*,[18]

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

PBAN signaling pathways regulating sex pheromone synthesis in *B. mori*,[20] and the role of PBAN in male moths.[4]

THE PK/PBAN PEPTIDES FAMILY AS POTENTIAL TARGETS FOR PEST MANAGEMENT

As is evident from the studies described above, PK/PBAN Nps regulate many physiological and behavioral processes during development and mating and maintain visceral activities. Peptides involved in the regulation of vital functions are prime targets for advancement of the understanding of insect physiology and, therefore, are also targets for the development of novel insect-control strategies based on interference with their activity by means of receptor-selective antagonists.

Despite the vast scientific and insecticidal/insect-control potential of antagonists and, to some extent, of agonists, their application in insects has not been widely implemented so far. This is mainly because of lack of defined methods for obtaining antagonists based on known Np agonists, and because of the inability to predict which conformation will lead to a highly potent inhibitory or stimulatory receptor-selective activity. In addition, peptides are highly susceptible to proteolytic degradation and have poor bioavailability. Therefore, their conversion into an insecticide prototype necessitates rendering them resistant to peptidase degradation, and designing them with high bioavailability. For many years, the approach most commonly used by the agrochemical industry for insecticide discovery was based on random screening of large chemical or natural libraries of nonpeptide compounds and then optimizing a lead molecule with respect to the desired properties. In the past decade, a parallel approach, based on rational drug design—or structure-based design—has evolved which integrates and implements the vast amount of information on the genes encoding the peptides and their receptors, as well as their SARs.

In the past years, we have applied an integrated strategy, termed **I**nsect **N**p **A**ntagonist **I**nsecticide (INAI), based on a rational design approach of small-molecule antagonists based on a known Np agonist for the design of antagonists and, especially, to determine the properties that give them high stability and bioavailability. We have used the PK/PBAN Np family as a model system. A large variety of cyclic and linear peptides have been designed, synthesized, and tested for antagonistic activity on PK/PBAN-mediated functions, and their metabolic stability and bioavailability, that is, ability to penetrate the insect cuticle and to reach and activate the target organ, have been extensively examined.

Highly potent and highly bioavailable antagonists that can penetrate the insects cuticle and effectively inhibit several key functions in moths were discovered; also—most important—a large amount of information has been gained on the agonistic and antagonistic structural requirements of the PK/PBAN peptides. For instance, experiments with restricted-conformation analogs provide compelling evidence that PK/PBAN peptides adopt a *trans*Pro, type I β-turn within the shared C-terminal pentapeptide region to achieve an agonist receptor response.[23] Information has also been gleaned on the requirements needed to obtain high metabolic stability and cuticular and digestive tract penetrability. For example, PK/PBAN analogs featuring enhanced biostability and bioavailability efficiently penetrate the insect cuticle[3,12,23] and gut and have demonstrated pheromonotropic activity when fed to *H. virescens*.[23] In other studies, potent biostable PK/PBAN agonists[23] have been shown to prevent pupal diapause in treated *H. zea* larvae that had been programmed for diapause, and a novel antagonist with a dihydroimidazole *trans*Pro motif[23] inhibited the termination of *H. zea* pupal diapause initiated by the DH. The results suggest potential for the development of novel control strategies that derail the success of overwintering in pest insects.[23] In addition, two PK/PBAN-Rs—one from *S. littoralis* larvae and one from the pheromone gland of *H. peltigera* adult females—have been cloned and stably expressed in a cell line. These receptors are currently being characterized and used in the development of microplate high-throughput binding assays for screening libraries obtained from various sources for occurrence of potential insect-control agents capable of binding to these receptors.

Knowledge on the conformational requirements needed to acquire highly potent, metabolically stable, and bioavailable antagonists, and the availability of stably expressed PK/PBAN cloned receptors, together with the many *in vivo* and *in vitro* assays that we have developed to monitor bioactivity and bioavailability, enable to proceed toward the design and synthesis of insecticide prototypes based on already available antagonists. In this context, the overall know-how, together with the generic nature of the strategy, will facilitate application to other insect Np families, in the development of Np-based insect-control agents. For detailed reviews on these topics, see Refs. 3, 12, 23 and references therein.

SUMMARY AND FUTURE PROSPECTS

Intensive studies of the PK/PBAN peptides have yielded a vast amount of important information on the chemical and molecular nature of the peptides in Lepidopteran and non-Lepidopteran insects: their genes, post-translational processing, distribution, receptors, signaling mechanisms, and bioactivity. Nevertheless, many questions about these peptides are still unresolved, especially regarding their mode(s) of action, and much remains to be learned about the structural, chemical, and cellular basis of their activity and also about downstream cellular events, species specificity, receptor heterogeneity, and the mechanisms that underlie their functional diversity.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

The investigation of the transcriptional factors that regulate the *pban* gene and *capa* gene expression, which might be influenced by a circadian clock, is still in its infancy, as is that of the mechanisms of Np biosynthesis. The finding of the differential processing of the CAPA prohormone has provided a good opportunity to study the still poorly understood mechanism of packaging and sorting of Nps in the insect, and of the stimuli that regulate their release. The large number of cloned receptors provides a good basis for further studies of their SARs, and their stable expression in different cell lines invites further studies on the signaling pathways of the *pban*- and *capa* gene-encoded peptides—studies that might provide insights into the full range of cellular mechanisms that underlie the bioactivity of this multifunctional family in Lepidopteran and non-Lepidopteran insects. The vast number of insects—from diverse species and taxa—that all contain FXPRLa peptides and exhibit differential expression of the gene products calls for further studies on the bioactivity of the peptides, especially in non-Lepidopteran species, where knowledge is currently very scarce. Such studies could improve our understanding of their physiological role and shed light on their phylogenetic relationships during the course of evolution. The information that has already been accumulated, together with the currently available and developing bioinformatic, peptidomic, molecular, biological, and chemical analytical tools offer great potential for further exploration of the above issues. Apart from—and beyond—the high scientific value of the above findings, the strategies and approaches that were developed in the course of PK/PBAN research also offer great potential for practical application, by providing a basis for generation of insect Np antagonist-based insect-control agents, as described in this chapter.

Chapter 38

Insulin-Like Peptides

Yevgeniya Antonova-Koch, Michael A. Riehle, Anam J. Arik and Mark R. Brown

ABSTRACT

Insulin-like peptides (ILPs) are encoded by multiple, distinct genes in insects as in other metazoans. This chapter summarizes our understanding of the diversity, secretion, signaling, and function of ILPs in insects. Studies of the fruit fly, *Drosophila melanogaster*, and other insects showed that ILPs activate insulin receptor orthologs and a specific cascade of intracellular proteins, known as the insulin signaling pathway. This pathway is responsive to nutritional status as modulated through the "target of rapamycin" pathway. Together, these pathways help regulate the growth, development, aging, and reproduction of insects. Little is known about how the diverse ILPs act as hormones, neurotransmitters, or growth factors to regulate these processes and others necessary for survival, such as nutrient apportionment, diapause, and innate immunity. Nevertheless, the diversity of ILP structure and function known for insects is remarkably similar to that characterized for mammals, suggesting a strong evolutionary conservation across the metazoan phyla.

INTRODUCTION

Insulin-like peptides (ILPs) epitomize the conservation of hormone structure and function across higher invertebrate and vertebrate animals. They are encoded by multiple, distinct genes within each species and, on secretion, serve as hormones, neurotransmitters, and growth factors. The unique structure of the ILP propeptide with continguous B, C, and A chains defines this superfamily. Bioactivity depends on the formation of two disulfide links between the B and A chains, a third intra-A chain disulfide bond, and cleavage of the C chain, with the exception of the vertebrate insulin-like growth factors (IGFs). Cysteine positions in the B and A chains are remarkably conserved across the superfamily, as are proteolytic cleavage sites for the C chain. The sequence divergent ILPs are transduced in target cells by either insulin receptor tyrosine kinases or G protein-coupled receptors to networks of signaling proteins that directly affect biochemical pathways and gene expression. Of the higher invertebrate groups, our accumulated knowledge of ILP endocrinology is the deepest for insects.

Studies of the model insect, *Drosophila melanogaster* (referred to as *Drosophila*) and other insects continue to elucidate the remarkable complexities of the insulin-signaling pathway (ISP) through its key role in metabolism, growth, reproduction, and aging. Still, little is known about the secretion of ILPs, receptor interactions, and their direct effects on specific processes in the target tissues of insects. Previous reviews of insect ILP endocrinology provide an extensive collation of earlier studies,[3,16,23,29,30,34] and herein, we offer of a summary of these reviews and more recent studies. Companion reviews are available in this handbook for the endocrinology of insulin and related peptides in vertebrates.

CHARACTERIZATION OF INSECT AND INVERTEBRATE ILPS

The first invertebrate ILP was discovered in the silkworm *Bombyx mori*,[20,22] and now >38 ILPs are known for this species, far more than in other lepidopteran species.[3] Only single ILPs were isolated and characterized to date for locust species.[5] Genomic and EST sequencing combined with bioinformatics has identified multiple ILP genes in other insect species.[3] This strategy first revealed seven ILP genes in *Drosophila* (DILP1-7, and recently DILP-8,[8,12] that presumably are ligands for the single insulin receptor (IR) homolog.[3,16,17,23,29,30,35] Their homologs are now known for another 11 *Drosophila* species.[3] In *Anopheles, Aedes* and *Culex* mosquitoes, five to eight ILPs were characterized in each of the species examined.[3,18,21,33] Strong structural conservation of ILPs across the Phylum Arthropoda is supported by the recent identification of ILP encoding genes in the water flea *Daphnia pulex*,[11] American dog tick *Dermacentor variabilis*, deer tick *Ixodes scapularis*, pea aphid *Acyrthosiphon pisum*, kissing bug *Rhodnius prolixus*, human body louse *Pediculus humanus humanus*, flour beetle *Tribolium castaneum*, honeybee *Apis melifera*, parasitic wasps *Nasonia longicornis* and *Nasonia giraulti*, and leaf cutter ant, *Atta cephalotes*[28] (see Ref. 3 for all others).

Multiple ILPs have been identified in species of another major invertebrate phylum, Mollusca, and in species

representing early groups of the Deuterostomia.[3] More than 200 ILPs are identified for these groups and arthropods; well-supported clades arose from closely related species, and there is evidence for ILPs in the common protostomian ancestor of Arthropoda and Mollusca.[3] Structural comparisons also indicate that at least two vertebrate ILP subfamilies, insulin, and insulin-like growth factors (IGFs), are conserved among insects, but there is no clear evidence for relaxin/ILP homologs.

EXPRESSION, PROCESSING AND SECRETION OF ILPS

Approximately 40 genes encoding a variety of peptide hormones, including ILPs, are expressed in specific cells in both the nervous system and midgut of insects.[32] The ILPs are the only peptide hormones encoded as multiple genes, whereas others are proteolytically cleaved and processed from a single propeptide into smaller, mature forms (e.g., FMRFamides). One or more of the ILP genes in an insect are expressed in specific bilateral cell clusters, called medial neurosecretory cells (MNCs), in the *pars intercerebralis* region of the brain.[3,23] Axons from the cells in each cluster crossover and extend as separate bundles out of the brain to neurohemal release sites associated with the aorta, corpora cardiaca (CC), and along the midgut.[3,23,34] Another putative ILP source is the gut, which contains neuroendocrine cells and hundreds to thousands of isolated endocrine cells. However, few studies have detected ILP expression in this tissue.[3,23,34] As peptide hormones, ILPs are stored or secreted from their cellular sources in a bioactive form, thus transcript levels do not necessarily correlate with release or storage. Release of ILPs into the hemolymph for transport to target tissues likely rises and falls in response to internal and external cues mediated in the brain, and ILPs probably are degraded by proteases in the hemolymph or after binding to receptors and being internalized.

Studies of *Drosophila* provide a comprehensive survey of the expression of *DILP* and other peptide hormone genes, as well as their known receptor genes, in the adult nervous system and all regions of both the larval and adult gut in *Drosophila*.[13,17,23,24,32,35] The *DILP1-5* genes are expressed in the MNCs, probably reflecting their clustering within a 26 kb section of chromosome III. Only *DILP3* expression is detected in the larval and adult midgut, and it is localized to muscle bands in the anterior region.[32] As well, *DILP2*, *DILP4*, *DILP5*, and *DILP6* are expressed in the embryonic or larval gut, and *DILP5* transcripts are observed in the follicle cells of ovaries and Malpighian tubules.[3,16,23,32] Expression of the individual *DILP* genes varies in the MNCs during development, in response to different cues and *DILP* gene deletions, suggesting different promoter/enhancer elements. DILP2 and DILP5 accumulate in the MNCs of nutrient-deprived larvae, and their secretion is enhanced by feeding, targeted depolarization, and a fat-body-derived specific factor.[13] DILP secretion from MNCs is mostly complete after 30 min, as quantified by immunofluorescence microscopy, and there is no increase in *DILP* expression. Other studies have implicated serotonin and short neuropeptide F[23] in the regulation of DILP secretion based on the proximity of stained axons/neurons and genetic manipulations.

The MNCs originate from a single pair of neuroblasts that divide and differentiate into *DILP*-expressing cells at the end of embryogenesis.[7,23] The site of MNC origin is adjacent to other neuroblasts that separate and differentiate into CC cells that are part of the ring gland and produce adipokinetic hormone (AKH). Both sets of neuroblasts originate in a domain of the neuroectoderm of *Drosophila* embryos that shares homology with the hypothalamic–pituitary axis in the vertebrate brain. Vertebrate IGFs and relaxins are expressed and functional in the brain, whereas insulin production is shifted to gut endocrine cells in the mammalian pancreas. Organization and function of insulin-secreting cells in the pancreas are regulated by the transcription factor PAX6, a homolog of the *Drosophila* gene *eyeless* required for DILP MNC differentiation.[7] This finding is a striking example of functional conservation across animals and tissues.

DILP6 and DILP7 differ from the other DILPs in their structure and tissue expression pattern. *DILP6* expression surges and falls in the fat body during the pupal stage, and its deletion blocks development.[24] Based on similar structure, source, and function, DILP6 is an apparent IGF homolog. DILP7, a putative relaxin-like peptide, is localized in eight pairs of cells in the thoracic/abdominal ganglia.[3,16,17,23,35] Axons from these cells project to the *DILP* MNCs and out of the ganglia to other tissues. Based on its neuronal distribution, DILP7 may function more as a neurotransmitter than a peptide hormone.

Similar expression patterns are known for ILPs in other insects.[3,34] In mosquitoes, most *ILP* genes are expressed in the brain (head) across all life stages.[3,18,21,33] Specific ILPs were localized by immunocytochemistry in either the MNCs or more lateral brain neurosecretory cells and in other cells along the ventral ganglia of female mosquitoes.[3,21] Transcripts for mosquito *ILP2*, *ILP5* (DILP7 ortholog), and *ILP6* (IGF homolog) are expressed in other female tissues and body regions. Midgut endocrine cells in female *Aedes aegypti* are immunostained with an ILP antiserum but not in *Anopheles gambiae* or *Anopheles stephensi*.[3,21] In all three species, ILP immunostained axons extend from the brain MNCs along the anterior midgut in adults. This tissue is the site of sugar digestion and absorption, which may be regulated by ILPs released from the axons. Brain MNCs are the probable sources of two ILPs structurally characterized for the cotton leafworm, *Spodoptera littoralis*,[20] and an

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

ILP isolated and characterized for the desert locust, *Schistocerca gregaria*.[5] Transcript expression of the locust *ILP* is highest in the brain and fat body of both sexes. The two ILP genes in the honeybee, *Apis mellifera*, are transcribed in the brains of different castes,[2,9] but expression in other tissues was not examined. An IGF-like peptide was isolated from the hemolymph of *B. mori* pupae as a single unprocessed 8 kDa peptide with B, C, and A domains.[24] It is similar in structure to the dipteran ILP6 and vertebrate IGFs and secreted by the fat body.

The dynamics of ILP processing, storage, and release are not fully characterized for insects. One possibility is that unprocessed ILPs may be secreted by undifferentiated cells or tissues during embryogenesis and metamorphosis, as reported for proinsulin during vertebrate development.[3] Dose-responsive bioactivity or receptor binding exists for one *B. mori* ILP (bombyxin-II), two *Samia cynthia* ILPs (ILP-A1, ILP-B1), and two *Ae. aegypti* ILPs (ILP3 and ILP4).[3,33] A recombinant form of DILP5 competitively displaces radioactively labeled insulin bound to human and *Drosophila* cells.[25]

Before secretion, ILPs are packed in secretory granules presumably with their processing enzymes. The C peptide of vertebrate proinsulin is cleaved by two prohormone convertases and a carboxypeptidase. These same enzymes process proforms of numerous neuropeptides in vertebrates, and their homologs likely have similar functions in insects. In *Drosophila*, the gene encoding a prohormone convertase 2 (PC2) homolog (*amontillado*) is expressed in neurosecretory cells through the nervous system and gut, and coexpression of a helper protein, 7B2, is probably required for activity.[3] Although *PC2* expression is required for *Drosophila* development and in particular for AKH function and processing, its role in ILP processing is yet to be determined.

After secretion into the hemolymph, ILPs may be transported to target cells by binding proteins (BPs) that facilitate ILP action. In vertebrates, specific BPs protect and store circulating IGFs (IGFBPs) and also activate IGF receptor signaling and other intracellular pathways. The first putative IGFBP characterized for insects is a 27 kDa protein secreted by *Sp. fugiperda* cells that binds human insulin and IGFs in culture.[3] Its native function has not been resolved. Studies of the *Drosophila* homolog, imaginal morphogenesis protein-late 2 (Imp-L2), suggest a role in ILP signaling. Imp-L2 is expressed in brain DILP MNCs and other tissues, and binds unprocessed, tagged DILPs in solution.[3,4] *Imp-L2* expression is not required for normal development, but it is essential for larval survival during starvation. Imp-L2 protein also binds to a homolog of the vertebrate acid labile subunit (ALS), which in vertebrates stabilizes the IGFBP/IGF complex in circulation. *Drosophila* ALS is expressed in the brain MNCs and in the fat body. Overexpression of tagged ALS and DILP2 in larval fat body yielded a putative complex in hemolymph, whereas reduced *ALS* expression limits carbohydrate and lipid mobilization in fed larvae.[4] In the tick, *Amblyomma americanum*, expression of *IGFBP* genes in different tissues was responsive to blood feeding.[3] Silencing the genes by RNAi resulted in the ticks taking smaller blood meals and increased mortality. A locust neuropeptide, neuroparsin, has limited sequence similarity to IGFBPs and binds a locust ILP in solution.[5] Homologs are known for all insect and arthropod groups examined to date, except for the *melanogaster* subgroup of *Drosophila*.[5] Neuroparsin and ILPs are secreted by different, but neighboring, brain MNCs in locusts, other *Drosophila spp.*, and other insects. Alternatively spliced transcripts of the neuroparsin gene are expressed in the nervous system and other tissues, thus complicating the assessment of its many functional roles.[5] Other putative IGFBP genes were identified in the genome of a mosquito baculovirus or in transcripts from the venom gland of the wasp *Eumenes pomiformis*, suggesting other levels of ILP interaction.[3]

Circulating ILPs probably are degraded by proteases, but once ILPs are bound by receptors, the complex may be internalized, where the ILP is degraded and the receptor recycled to the surface. Another possibility is that internalized ILPs may interact with cytoplasmic and nuclear proteins and activate signaling pathways in insects, as shown for insulin, IGFs, and IGFBPs in mammalian cells. An insulin-degrading enzyme (IDE, a zinc metalloendopeptidase) is highly conserved from yeast to mammals, and a *Drosophila* homolog is expressed in all life stages and cell lines.[31] *Drosophila* and human IDE bind and cleave mammalian insulin under the same conditions, but DILPs have not been tested. Homozygous *IDE* knockout renders viable and fertile flies with increased trehalose levels,[31] suggesting a specific effect on DILP regulation of metabolism.

INSULIN SIGNALING

Although insect genomes contain multiple ILPs, typically they encode only one IR, which is an approximately 500 kDa homodimer membrane protein consisting of two extracellular α subunits and two intracellular β tyrosine kinase subunits linked by disulfide bonds. ILP binding to the IR activates either the canonical ISP or the MAPK pathway in insect and mammalian cells. However, it is unknown for most insects whether some or all ILPs bind to the native IR, alternatively spliced/hybrid IR forms, or other receptor types. To date, specific binding of insect ILPs to native receptors has been shown only for two mosquito ILPs. *Ae. aegypti* ILP3 binds to the native IR (~500 kDa), and ILP4 to a yet unknown 55 kDa membrane protein.[33] Putative relaxin GPCR homologs are known for this species and *Drosophila*, but they remain orphan receptors.[3]

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Mining the genomes of insects has revealed all components of the mammalian ISP, even though insect ISPs are less complex due to fewer protein isoforms.[3] Insulin signaling unfolds when binding of an ILP to the IR initiates a sequence of phosphorylation events resulting in activation of either the ISP (Fig. 1) or MAPK branches. Additionally, components of the ISP branch activate the target of rapamycin (TOR) signaling pathway (Fig. 1), which is also activated through amino acid sensing.[3,18,29] The convergence of these pathways regulates metabolism, cell survival and differentiation, longevity, and fertility. Signaling through the MAPK branch is activated primarily by IGF binding to an IR ortholog in mammalian cells and results in activation of ERK-1/2, JNK, and p38 proteins kinases regulating cell proliferation, differentiation, and cell survival.[3,29] Crosstalk between MAPK and PI3K has been demonstrated in *Drosophila*, where a component of the MAPK pathway, GTPase Ras, is required for maximal PI3K signaling.[29]

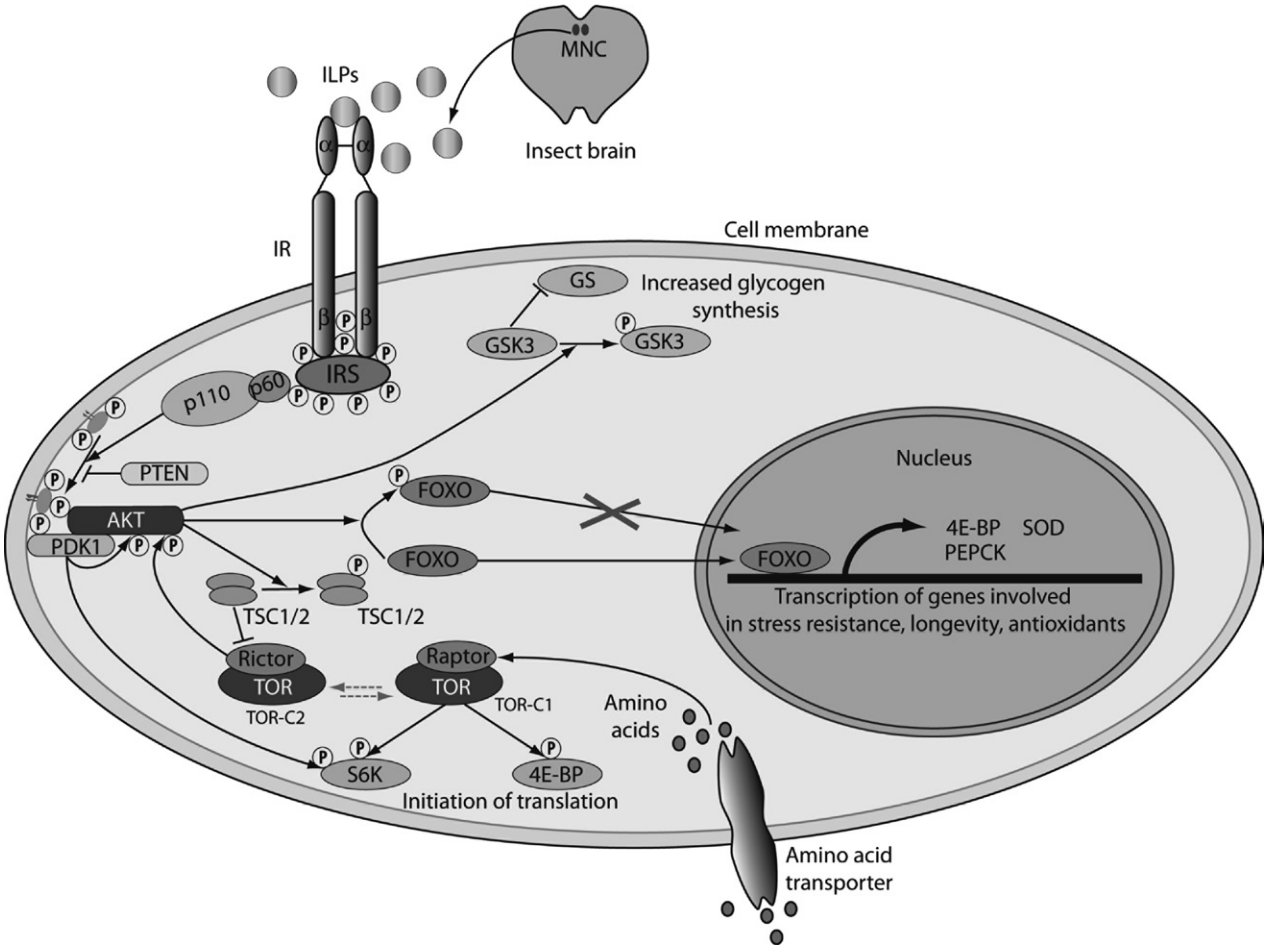

FIGURE 1 Activation of insulin and TOR signaling by insulin-like peptides and amino acids in insects. Insulin-like peptides (ILPs) are secreted by medial neurosecretory cells (MNC) in the brain into the hemolymph. Insulin signaling is activated when an ILP binds to the α-subunits of the membrane-associated insulin receptor (IR). This binding causes a conformational change and autophosphorylation of tyrosine residues on the β-subunits of the IR. In turn, the β-subunits phosphorylate an adaptor protein, insulin receptor substrate (IRS), providing docking sites for the regulatory subunit of phosphatidylinositol 3-kinase (PI3K), p60. Binding of p60 to IRS activates the catalytic subunit of PI3K, p110, which phosphorylates membrane-anchored phosphatidylinositol bisphosphate (PIP_2) and converts it into phosphatidylinositol trisphosphate (PIP_3). Both, 3-phosphoinositide-dependent protein kinase 1 (PDK1) and Akt kinase, bind to PIP_3 at the membrane, where PDK1 phosphorylates and activates both Akt and p70 S6 ribosomal kinase (S6K). For full activation, Akt also requires phosphorylation by rapamycin-insensitive companion of "target of rapamycin" (TOR) kinase (Rictor) in the TOR-complex 2 (TOR-C2). Activated Akt is a nexus for many downstream molecules including glycogen synthase kinase-3 (GSK-3) that increases glycogen synthesis, tuberous sclerosis complex (TSC1/2)—a negative regulator of the TOR kinase pathway, and FOXO transcriptional factors. When phosphorylated by Akt, FOXO cannot enter the cell nucleus and initiate transcription of a variety of genes, such as eukaryotic translation initiation factor 4E-binding protein (4E-BP), phosphoenolpyruvate carboxykinase (PEPCK), and supper-oxide dismutase (SOD).The ISP inhibitor phosphatase and tensin homolog (PTEN) dephosphorylates PIP_3 to PIP_2, thereby resetting the ISP to a preactivated state. The TOR pathway is activated by both the uptake of amino acids and by Akt (see above). TOR kinase participates in two molecular complexes, TOR-C1 and TOR-C2. Rapamycin-sensitive companion of TOR (Raptor) is associated with TOR-C1, whereas Rictor is associated with TOR-C2. TOR-C1 phosphorylates S6K and an inhibitor of translation, 4E-BP, leading to initiation of translation. TOR-C1 is activated autonomously by an influx of free amino acids and changes in the ATP: ADP ratio and oxygen levels.

REGULATORY ROLES OF INSULIN-LIKE PEPTIDES

Through genetic manipulation, a great range of physiological processes in *Drosophila* were found to be regulated by ILPs through the ISP and TOR pathway.[3,16,17,23,29,30,35] However, evidence that endogenous DILPs directly affect any physiological process in *Drosophila* is still lacking. Mammalian insulin is used as a substitute for native ILPs in this and most other insects, but it is bioactive at relatively high concentrations. A few recent advances establish functional roles for ILPs or show direct bioactivity of native ILPs in insects.

GROWTH AND DEVELOPMENT

Growth and postembryonic development of insects are regulated through diverse signaling pathways activated by juvenile hormone (JH), ecdysteroid hormones (ECDs), and neuropeptides, including ILPs. Over the past decade, a general consensus has emerged that growth and development are regulated jointly by the ISP and TOR pathway.

The functional redundancy of DILPs is seen by knockout of the expression of individual and combinations of *DILPs* to determine the effects on growth, metabolism, reproduction, and lifespan.[17,35] Single *DILP* mutants are viable and generally exhibit normal growth/adult body weight, with *DILP6* mutants being the smallest. Combined *DILP* knockouts reveal that one lacking all but *DILP6* develop into adults, whereas combinations with the *DILP6* knockout are lethal, suggesting that fat body expressed DILP6 and DILPs expressed in the MNCs act redundantly. Mutation combinations of *DILP1-5*, all expressed in the MNCs, render viable flies with reduced growth/body weight, again supporting the redundancy of developmental and growth-controlling DILP action.

ILP treatment directly stimulates the growth or proliferation of cells in different organs and imaginal discs.[3,27,34] In Lepidoptera, hemocyte discharge by hematopoietic organs *in vitro* is stimulated in a dose-responsive manner by synthetic ILP (bombyxin-II) and bovine insulin, and addition of 20-hydroxyecdysone (20-ECD) enhances the effects. Wing discs from last instar larvae of the lepidopterans, *Precis coenia* or *Manduca sexta*, are synergistically stimulated to grow *in vitro* by 20-ECD and an ILP (bombyxin-II or partially purified brain extract) treatment. Commitment to pupal development in wing discs *in vivo* is stimulated by the injection of mammalian insulin or purified *M. sexta* ILP into newly molted, starved last instar *M. sexta* larvae, and further indicates that these ILP treatments suppress JH action later in the instar. The native *B. mori* IGF-like peptide, isolated from the larval hemolymph, stimulates the growth of genital imaginal discs *in vitro*.[24] Secretion of this peptide by the fat body occurs only in early pupae and is regulated by a surge of ECD. The structural homolog in *Drosophila*, DILP6, also promotes growth based on the negative effects of *DILP6* mutations, and its expression in pupae is regulated by ECDs.[24] The receptor and signaling pathways activated by these putative IGFs are yet to be determined.

In the *Drosophila* adult midgut, replacement of damaged/dead cells by stem cell division is reduced in IR, IRS, and MNC-ablated mutants, but is restored in mutants overexpressing IR or *DILP2*.[1] Midgut stem cells of lepidopteran larvae also proliferate after treatment with synthetic ILP (bombyxin-II) and insulin, and this effect is enhanced by the presence of fat body extract, suggesting the presence of an IGF.[15] As shown by these studies, insect tissues and cells are amendable to culture and experiments to investigate the direct effects of ILPs on the ISP and their specific functions.

ECDYSTEROID HORMONE PRODUCTION

Ecdysteroid hormones are the primary regulators of insect development, molting, and metamorphosis. In the larval stages, ECDs are synthesized from dietary cholesterol in the prothoracic glands (PG) and released into the hemolymph for circulation to target tissues. Several neuropeptides stimulate or inhibit ECD production.[20] Prothoracicotropic hormone (PTTH) was the first one structurally and functionally characterized, and its receptor tyrosine kinase, Torso, more recently identified. The first invertebrate ILP, known as "small PTTH" and later bombyxin, was isolated from *B. mori* based on its stimulation of pupal molting and ECD production by the PG of another silkworm, *Sa. cynthia*. Bovine insulin also stimulates ECD production by the PG of last instar *B. mori*, and activates the ISP but not MAPK signaling. Two other native ILPs stimulated the pupal–adult molt of a related silkmoth, *Sa. cynthia*. Cross species activity was shown for a synthetic *B. mori* ILP that stimulates ECD production by the PG of the hemipteran *Rhodnius prolixus.* These results suggest ILPs may regulate ECD production by the PG in the larval/nymphal instars of insects.

METABOLISM

The small size and high-energy demands of insects require that the regulation of metabolism be highly sensitive, so that nutrients are allocated between immediate energy needs and storage to facilitate growth, development and reproduction. Two neuropeptides and their signaling pathways balance the energetic needs of insects between storage and mobilization of nutrients. Of the multiple ILPs encoded in an insect, one or more are probably functional homologs of vertebrate insulin, as first shown for mosquitoes.[3,33] Insulin induces cells to take up glucose and convert it to glycogen, and to shift from catabolic to anabolic lipid and protein metabolism. AKH is the structural and functional

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

homolog of mammalian glucagon, an insulin antagonist, in many different insects.[26] Acting through a G protein-coupled receptor and cAMP/inositol triphosphate signaling, AKH activates the mobilization of carbohydrate, proline, and lipid stores.

The fat body is the primary site of intermediary metabolism and nutrient storage, and thus responsive to ILP/TOR and AKH signaling. These processes also occur in the midgut and in hemocytes distributed throughout the body and govern the fat body through unknown mechanisms. The particulars of ILP and AKH signaling in the fat body during larval and adult stages are best understood for *Drosophila*.[3,29] Studies suggest that DILP1-5 either alone or in combination regulate carbohydrate and lipid metabolism in an insulin-like fashion, based on single and combinatorial *DILP* deletions.[17,35]

Synthetic ILPs directly affects metabolic processes in insects. A silkmoth ILP (bombyxin-II), when injected into neck-ligated larvae, lowered trehalose and glycogen levels, apparently promoting consumption of carbohydrate reserves and not the accumulation of reserves, as for insulin in mammals.[3,34] Synthetic *Ae. aegypti* ILP3 injected into decapitated, sugar fed female *Ae. aegypti* stimulates trehalose depletion and glycogen and lipid storage in a dose-responsive manner.[33]

Quantitative analyses of ILP and ISP gene expression have been used to determine the effect of feeding or starvation in *Drosophila* and to identify other genes affected by nutrient intake.[3,29] Notably, none of the *DILPs* show any significant change in expression for up to 13 h after starved females are fed, nor do *Akt*, *FOXO*, or *TOR* (see Fig. 1 for acronyms). However, the expression of *IR*, *IRS*, and *PDK1* is greatly decreased within 2 h after feeding and for the whole period. These trends suggest that the regulation of *DILP* and ISP gene expression is not uniformly responsive to nutrient intake.

REPRODUCTION

As with growth and development, JH, ECDs, and neuropeptides, including the ILPs, are implicated in the regulation of insect reproduction. For most insect groups, JH is considered the primary gonadotropic hormone in females, and for dipteran species that require protein food to produce eggs, ECDs assume this function. Ovaries are the primary source of circulating ECDs in females, because the PG degenerate in transition to the adult stage, and follicle cells surrounding the oocytes are the site of ECD biosynthesis.[3,18,33,34] These steroids are either stored in the oocytes for use during embryonic development or released into the hemolymph. The gonadotropic action of JH or ECDs is to activate the fat body and follicle cells to secrete vitellogenin and other yolk proteins (YP) for uptake by the maturing oocytes.

The interaction between nutrient, JH, ECD, and ILP signaling is best characterized for *Drosophila* and mosquito females,[3,18,30] and for both, JH is required for the development of the fat body and ovaries. A study comparing the effects of knocking out single and multiple *DILPs* found that flies lacking only *DILP6*, the IGF homolog, or the combination of *DILP2-3-5* have the greatest reduction in lifetime fecundity compared with wild-type flies, and other single or combined *DILP* mutations or had less of an effect.[17] The mechanisms by which DILPs regulate processes associated with egg maturation in *Drosophila* are not well defined, but both JH and the ISP are implicated in the activation of ovarian ECD production. Females with a mutation in the *IRS* gene are small and sterile but maintain a normal range of JH and ECD production given their size, thus suggesting the ISP plays a primary role in egg maturation. Oogenesis is dependent on DILP activation of the ISP in the stem cells and their progeny to form egg chambers.[3] The TOR pathway affects this process via ISP dependent and independent mechanisms. Synthesis of YPs by the fat body and follicle cells is dependent on ISP and ECD signaling.

The role of ILPs in the endocrine cascade that regulates egg maturation is well defined for female *Ae. aegypti*.[3,18,33] The mosquito IR homolog is expressed in ovaries, and mammalian insulins stimulate ovary ECD production *in vitro* through the ISP. Insulin similarly stimulates this process in the ovaries of the blowfly *Phormia regina.*[3,34] Of the eight ILPs encoded in *Ae. aegypti,* ILP3 is most similar in structure to mammalian insulin and produced in the brain MNCs.[33] In response to the ingestion of blood, ILP3, and possibly other ILPs, are released and stimulate three key processes required for egg maturation: ovary ECD production, serine protease digestion of the blood meal, and expression of vitellogenin for uptake by oocytes.[18] Full activation of these processes *in vivo* and *in vitro* by ILP3 is dependent on IR expression and the presence of amino acids, affirming the interaction of insulin and TOR pathways. Both synthetic ILP3 and ILP4 stimulate ECD production by ovaries in a dose-responsive manner, at concentrations 100-fold less than required for mammalian insulin, but ILP4 interacts with a different receptor.[33]

DIAPAUSE

Diapause is an endocrine-mediated metabolic and developmental arrest induced by changes in abiotic cues that indicate the onset of adverse environmental conditions.[10] This arrest occurs in a species-specific life stage, and in adult diapause, reproduction halts. Injection of mammalian insulin terminates diapause and promotes development in the pupae of two lepidopterans, *Sa. cynthia* and *Pieris brassicae* pupae, as well as stimulates ECD production.[10,34] Likewise, alterations in the ISP affect adult diapause in dipterans. Female *Culex pipiens* mosquitoes enter diapause in the autumn with large fat reserves and arrested ovarian

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

development. Knockdown of the IR by RNAi in nondiapausing females arrests primary oocytes development, as in the diapause state.[10] By contrast, knockdown of *FOXO* expression in females preprogrammed for diapause greatly decreases lipid storage and lifespan, and RNAi knockdown of *ILP1* halts ovarian development in nondiapausing females. The above studies suggest that inactivation of the ISP facilitates diapause induction and its activation terminates or prevents diapause. This concept seems to contradict the anabolic role played by the ISP in nondiapausing insects, but it is in accord with its role in the nematode, *Caenorhabditis elegans*.

BEHAVIOR

Different ILPs are expressed in the central nervous system of insects and probably activate the ISP in specific neuronal pathways that govern behaviors associated with nutrient acquisition.[3,16,23,29] Downregulation of *DILP* expression and the ISP in fed *Drosophila* larvae increases food ingestion and acceptance of food containing noxious chemicals, whereas overexpression reduces these behaviors in starved larvae. This pathway also negatively interacts with neuropeptide F signaling that promotes foraging over a range of aversive conditions.

Caste determination and behavioral differentiation in the honeybee *Apis mellifera* are in part regulated through ILP expression and the ISP.[2,9] Expression levels of *ILP-1* and the *IR* are higher in queen larvae than in specific worker larval instars. By contrast, *ILP-2* is expressed at greater levels in workers than in queens. Worker duties shift from young bees nursing larvae to older bees foraging for nectar and pollen. Foragers have significantly higher transcript levels of *ILP-1* in heads and *InR1* and *InR2* in abdomens than nurse bees.

IMMUNITY

The innate immune system in insects coordinates pathogen recognition with induction of defenses to block infection. The ISP plays a role in balancing the cost of an immune response with survival and reproduction.[3,6,16,19,21] In *Drosophila, Mycobacterium marinum* infection reduces Akt and glycogen synthase kinase-3 phosphorylation, and infected flies die sooner than *FOXO* mutants. *IRS* mutants also display increased resistance to bacteria and increased lifespan. Starvation attenuates the ISP in *Drosophila* and activates the immune response without pathogen challenge, as shown by increased antimicrobial peptide (AMP) expression. Mutations disrupting ISP, feeding wild-type adult flies with an inhibitor of PI3K signaling, or starvation of larvae all increase AMP expression in noninfected animals. By contrast, AMP expression is reduced in *FOXO* mutant flies, starved flies, and flies treated with PI3K inhibitor, suggesting a direct link between FOXO signaling and activation of AMP expression.

The link between ISP and immunity has also been shown in the midgut of mosquitoes consuming *Plasmodium falciparum* infected blood. Feeding high concentrations of human insulin to *An. stephensi* and *An. gambiae* results in a twofold increase in the number of *Plasmodium* oocysts on their midguts.[21] *Plasmodium*-derived glycosylphosphatidyl inositol is an insulin mimetic in mammals, and when fed to Anopheline females, stimulates Akt phosphorylation and nitrogen oxide (NO) synthase expression in the midgut epithelium.[19] This enzyme produces toxic levels of NO, a potent anti-*Plasmodium* molecule. Human insulin induces NO and hydrogen peroxide production in cultured *An. stephensi* cells and in the midgut, resulting in increased oxidative stress that is harmful for the malaria parasite. Moreover, *An. stephensi* fed *P. falciparum* infected blood has increased expression of the genes encoding *AnsILP2* and *AnsILP3* in heads and midguts and *AnsILP5* in the head.[21] *Ae. aegypti* ILP3 stimulates proliferation of hemocytes, major mosquito immune cells.[6] Male dragonflies, *Libellula pulchella*, infected with gut parasites (Apicomplexa, *Hoplorhynchus*) exhibit poor mating success and increased trehalose levels in hemolymph and thoracic lipid stores.[3] Injection of human insulin reduced trehalose levels in healthy males and increased levels in infected ones. Together, these studies suggest that insects chronically infected with pathogens also display the "metabolic syndrome" associated with chronic infection, obesity, and insulin resistance of type-2 diabetes in humans.

AGING

Dietary, genetic, and molecular interventions that reduce insulin signaling increase lifespan in many organisms including *Drosophila* and mosquitoes.[3,16,17,30] Altering the ISP in the nervous system, fat body, and midgut directly affects the dynamics of aging in *Drosophila*. Reduced expression of *DILP2* in the nervous system increases lifespan, as do mutations in genes for ISP proteins in other tissues, e.g. *IR*. Similarly, overexpression of the ISP antagonists *FOXO* and *PTEN* in the nervous system and fat body also extends lifespan. Studies in the mosquito *An. stephensi* show that ILP expression may be age dependent.[21] Also the midgut acts as a "signaling center" for the regulation of aging in mosquitoes, and overexpression of an active Akt specifically in the midgut of transgenic mosquitoes significantly reduced adult lifespan.[21]

CONCLUSIONS

The great diversity and success of insects results in part from the central regulation exerted by multiple ILPs through the ISP and associated pathways that coordinate growth, development, and reproduction, in response to external and internal cues regarding food ingestion, nutritional state, and

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY
Copyright Elsevier 2024

pathogen infection. Studies of *Drosophila*, mosquitoes, and other insects reveal the structural conservation of ILPs and signaling proteins and substantiated their regulatory properties, largely through changes in gene expression in response to nutritional or physiological manipulations. Still, few studies have confirmed direct and dose-responsive effects of ILPs and their binding to the IR or other receptors in insects or other invertebrates. Little is known for insects about the dynamics of ILP secretion and titer, particularly the internal and external cues that govern ILP release and binding to the IR or other proteins. An overarching question is how do multiple ILPs interact with a single IR to regulate and coordinate diverse physiological and behavioral processes in different tissues, so that growth, development, and reproduction can be successfully completed?

Our understanding of the intricacies of insulin signaling in diverse insects has also revealed its interactions with other signaling pathways, including activin/transforming growth factor beta signaling.[14] Substantive evidence indicates that ILPs acting through the ISP may regulate ECD and JH secretion, and thus direct or coordinate development and reproduction. Sensing of nutrients acquired through ingestion or mobilized/stored internally through different mechanism affects both the ISP and TOR pathway in an apparent positive feedback loop, and modulates expression of many genes or any number of different biochemical processes in tissues. Another question is how does pathogen infection alter ISP regulation of metabolic homeostasis and modulate innate immune responses? With the genomes of insects and invertebrates being characterized at an unprecedented pace, the expansion of genetic techniques into nonmodel organisms, and improvements in ILP synthesis and biochemical approaches, our understanding of this fundamental signaling cascade should significantly advance in the next few years.

Chapter 39

Molluscan Bioactive Peptides

Anna Di Cosmo and Gianluca Polese

ABSTRACT

In this chapter, we try to provide a detailed summary of the studies reporting: discovery, gene organization, distribution, receptors, and biological action of peptides in the phylum Mollusca. Peptides have been collected in families or groups according to molecular structure. In separate subsections, we group structurally different peptides sharing a common biological action. According to these criteria, the RFamide peptides, and tachykinins, have been discussed as members of one peptide family. Other peptides are presented according to their involvement in energy flow, growth, feeding behavior, osmoregulation, and reproduction. Finally, a detailed analysis of peptides involved in egg laying and sexual behavioral repertoires is also reported.

INTRODUCTION

During the past six years, the discovery of novel peptides and hormones from Mollusc phylum, enabled by the availability of whole genomes, transcriptomes, and peptidomes, now provides ample tools for studying the structural evolution of peptides and hormones and redefining the phylogenetic relationships of key families of peptide and hormones across ecdysozoans, lophotrochozoans, and chordates. In this framework, the article of Veenstra J.A. (2010) that reports the genome sequence of limpet *Lottia gigantea* and the initiated large-scale molluscan transcriptome projects (i.e. Di Cosmo A. and Moroz L., "Euroceph Meeting", 2011), offer an excellent opportunity to look at the neuropetides and neurohormone genes. These are the fastest evolving intercellular signals; in particular, cephalopods developed a number of specific innovations in their repertoire of secretory molecules that might support their unique features. Most of the older references are present in our chapters in the first edition of this book.[11,12]

FMRFamide, FMRFamide-RELATED PEPTIDES (FaRPs)

Discovery

The tetrapeptide Phe-Met-Phe-Arg-NH_2 (FMRFamide) was discovered in the ganglia of the clam *Macrocallista nimbosa* (Price and Greenberg, 1977), and it is the first member of the extended family of FaRPs (also named RFamide peptides). They are known as molluscan cardioexcitatory peptides, but their roles as neurotrasmitters and neuromodulators in the central nervous system have been done. Sequences variations of RFamide family members occur mainly in the N-terminal region. Lately, novel RFamide neruopeptides have been characterized in *Haliotis asinina*[8] and in *Sepia officinalis*,[35] so that peptides of the RFamide family have been described through all the molluscan classes.[19] See related RF chapters in this and the Brain Peptides section of the book.

Structure of the Precursor mRNA/Gene

Characteristics common to all the RFamide peptides is the shared sequence Arg-Phe-NH_2 (exactly RFamide) at the C-terminus. These peptides are translated from specific genes as propeptides. These contain multiple copies of either the same or different peptides, the latter sharing in almost all cases only the C-terminal RFamide. Each peptide contained in the propeptide is proteolytically cleaved and amidated during posttranslational processing. The gene coding for FMRFamide has been identified in the gastropods *Lymnaea stagnalis*, *Aplysia californica*, *Helix aspersa*, and *Haliotis asinine*,[8] in the bivalve *Mytilus edulis*, and in the cephalopods *Loligo pelaeii*, *Loligo opalescens*, *Sepia officinalis*, *Octopus vulgaris*, and *Idiosepius notoides*.[11,34,35] The FMRFamide locus of *Lymnaea* is one of the best characterized (see Santama and Benjamin, 2000). This gene consists of five exons (I–V) punctuated by four introns. Two differentially spliced transcripts have been identified: one that consists of exons I and II (precursor 1) and another that comprises exons I, III, IV, and V (precursor 2). Exons II encodes a battery of tetra- and pentapeptides species. The sequence of exon III contains the heptapeptides and pentapeptides. Exon V encodes two hexapeptides, whereas the sequence of the heptapeptide SKPYMRFamide is formed at the splicing junction between exons II and IV. Posttranslational processing of the two *Lymnaea* FaRP precursor allow the formation of two

long non-FaRP peptides: the 22aa peptide, called SEEPLY, encoded in precursor 1 and the 35aa peptide, named acidic peptide, present in precursor 2.

Distribution of the mRNA/Peptide

In *Lymnaea*, the alternate mRNA expression of FMRFamide gene is specific to single identified neurons. The two different transcripts are expressed in a mutually exclusive manner in different neurons of adult CNS (Santama and Benjamin, 2000). By *in situ* hybridization and immunocytochemistry with peptide-specific antibodies, it was revealed that all neurons that express precursor 1 mRNA contain SEEPLY immunoreactivity and, similarly, all precursor 2 mRNA-expressing neurons contain the acidic peptide. In the developing stages of *Sepia officinalis* FaRP immunoreactivity is detected in fibers located in the neuropile and in cell bodies located in the posterior chromatophore lobe and in the liovisceral lobe. Furthermore, *in situ* hybridization with high density of strongly stained cells in the optic tract region suggests the involvement of FaRPs in all parts of the chromatophore control pathway.[1] Similar results were also obtained in *Idiosepius notoides*.[34] In *Limax valentianus*, immunoreactivity against FMRFamide is found in the procerebrum cell bodies, within the cell mass, and fibers in the terminal mass and internal mass layers.[18]

Receptors and Signaling Cascades

A G protein-coupled receptor (GPRC) was cloned from the mollusc *Lymnaea stagnalis*. The ligand for this receptor was purified and identified as an RFamide peptide, the *Lymnaea* cardioexcitatory peptide (LyCEP), which displays significant similarity to the *Achatina* cardioexcitatory peptide (ACEP-1). In the *Lymnaea* brain, the cells that produce the egg-laying hormone represent the predominant site of RFamide receptor gene expression.

Biological Actions

The cardioacceleratory action of RFamide peptides has been documented in numerous gastropods. The well-characterized central network controlling cardiorespiration in *Lymnaea* represents a good system to study the physiological consequences of alternative splicing of this neuropeptide gene. Most of the effects of the peptides from both precursors are inhibitory, and it has been suggested that the global inhibitory action of a released mixture of peptides may be more effective than the specific action of each peptide. FMRFamide also affects feeding in *Lymnaea*, *Aplysia*, *Limax*, and *Helisoma*. Moreover, FaRPs seem to be involved in osmoregulation in *Helisoma trivolvis*, *Helisoma duryi*, and *Melampus bidentatus*. In *Aplysia*, FMRFamide inhibits the 30-min period of firing of the bag cell neurons of *Aplysia californica* (after discharge), which causes the animal to undergo a long-lasting sequence of stereotypical reproductive behaviors (Fisher et al., 1993) and presynaptically inhibits the sensory neurons of the gill- and siphon-withdrawal reflex of *Aplysia* (Mackey et al., 1987). In the slug, *Limax valentianus*, FMRFamide regulates oscillatory activity of the olfactory center.[18] In cephalopods, FMRFamide exerts a positive contractile action on muscles of both male and female reproductive system.[24] In the CNS, this tetrapeptide seems to be involved in the inhibition of both secretory activity of the endocrine optic gland[10] and the screening pigment migration in combination with dopamine.[15] Also in cephalopods, involvement of FaRPs may occur in all parts of the chromatophore control pathway. Several FaRPs are potent stimulants of the chromatophore muscles, regulating their contraction.[29]

INSULIN-RELATED PEPTIDES AND NPY

Discovery

The neuroendocrine light green cells (LGCs) in the cerebral ganglia of *Lymnaea stagnalis* have been suggested to be involved in the control of growth. In these neuroendocrine cells, molluscan insulin-related peptides (MIPs) have been found. To date, many members of MIP family in the *Lymanea*, from pedal ganglions of *Anodonta cygnea*, and lately in *Lottia gigantea* have been identified and characterized (reviewed in Ref. 33).

Differential screening of cDNA libraries of the CNS of parasitized and nonparasitized snails also reveal specific alteration in neuropeptide encoding gene expression. Among these, one of the significantly upregulated genes encodes for *Lymanea* neuropeptide Y homolog (LyNPY). Moreover, peptides with striking similarity to NPY/peptideYY (PYY)/polypeptideY (PY)/pancreatic polypeptide (PP) have also been isolated in other molluscs.[33]

Structure of the Precursor mRNA/Gene

Seven MIP have been characterized from the pond snail *L. stagnalis*, one in *Aplysia californica*, whereas in *Lottia gigantea* genome, two genes encode for the homolog of *Lymnaea* MIP, insulin 1 and insulin 2, and other two insulin genes: one encodes a peptide quite similar to vertebrate insulin, and the fourth encodes a homolog of *Drosophila* insulin-like peptide.[33] In *L. stagnalis*, the MIPs are all produced by a single cell type in the cerebral ganglia, which has been extensively characterized. Also see the chapter on insulin-like peptides in this section of the book.

The invertebrate counterpart of NPY peptides resembles more neuropeptide F (NPF), which shares structural similarity to members of the vertebrate NPY/PYY/PY/PP

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

superfamily. NPY genes have been characterized in *L. stagnalis*, *Aplysia*, and *Lottia gigantea* (reviewed in Ref. 33).

Distribution of mRNA/Peptide

In *Lymnaea*, LGCs express genes encoding the molluscan MIPs: type-A cells express all MIP genes, whereas type-B cells do not express the MIP-I gene. Gene III is relatively strongly expressed in type-B cells. Genes II and V are moderately expressed in both cell types. Uniquely, the molluscan MIP VII gene is also expressed in neurons that may form part of the feeding circuitry in *Lymnaea*. *In situ* hybridization and specific immunoreactivity for NPY have been reported in *Lymnaea* and *Aplysia*. In *Lymnaea*, LyNPY-positive cells contact in a nonsynaptic way the neuroendocrine centers involves in the regulation of reproduction, ovulation, egg laying, and growth. In *Aplysia*, bag cell neurons are positive for NPY, and Northern blot analysis indicates that the peptide is abundantly expressed in the CNS.[21]

Receptors

Receptors for both MIP and NPY have been found in the nervous system of *Lymnaea*. Typical insulin receptor features, including a cysteine-rich domain, a single transmembrane domain, and a tyrosine-kinase domain, are conserved in the cloned putative MIP receptor. The *Lymnaea* cloned NPY receptor is a typical GPCR.

Biological Actions

In contrast to vertebrate insulins, the MIPs are produced by neuroendocrine cells of the CNS. The MIPs of LGCs are involved in the regulation of growth of both the soft body parts and the shell, as well as for protein and carbohydrate metabolism. MIP VII may also be involved as a neuromodulator in the feeding circuitry. In *Lymnaea*, female reproductive effort is decreased early by NPY action on caudodorsal cells. Growth is also suppressed almost immediately by the action of NPY on the MIPs-producing LGCs. By contrast, after treatment with NPY, food consumption is unchanged, suggesting a different role for this peptide in invertebrates.[11,21]

PEPTIDES AND FEEDING BEHAVIOR

Discovery

In gastropods, three families of peptides are directly involved in the control of the accessory radula closer (ARC) muscle in *Aplysia*: myomodulins, buccalins, and small cardioactive peptides (SCPs). All these peptides are localized in the motoneurons B15 and B16 of the buccal ganglia of *Aplysia* (reviewed in Elliott and Vehovszky, 2000). Myomodulin is also present in several other molluscs, and three myomodulin-related peptides has been purified and sequenced from extracts of snails *Helix aspersa*. Small cardioactive peptides (SCP_A, SCP_B) have been isolated from a wide range of molluscan groups. In *Aplysia*, other peptide families have been added to the list of feeding behavior controlling peptides: the enterins, the feeding circuit-activating peptides (FCAPs), cerebrin, and the pentapeptide PRQFVamide. There is also a novel peptide "allatotropin-related peptide" (ATRP) in *Aplysia* feeding motor system that contributes to a form of feedforward control.[16]

Structure of the Precursor mRNA/Gene

Myomodulin (A-I) has been characterized from the motor neuron B16 and ARC muscle in *Aplysia californica*. The complete sequence of this cDNA encodes a 42-kD prepropeptide. The myomodulin-related peptides have been also characterized in *Aplysia*. In the snail *Lymnaea*, a single gene encodes five structurally similar forms of myomodulin. Buccalin cDNA from *Aplysia* contains 19 distinct buccalin-related peptides, several of which are present in multiple copies. The small cardioactive peptide (SCP) gene of *Aplysia* encodes a precursor protein that contains two peptides related in structure and other unrelated peptides. In the snail *Lymnaea*, the SCP gene encodes a prepropeptide containing two structurally related SCPs. Enterin cDNA codes for a total of 35 copies of 20 distinct but related amidated peptides named enterin A (ENa) through enterin T (ENt). Analysis of the precursor structure encoded in the FCAPs cDNA predicts eight different structurally related peptides, named FCAPs through FCAPh. Cerebrin cDNA codes for a precursor containing a single copy of the peptide and one additional peptide. The C-terminal glycine indicates that the peptide is amidated at the C-terminus. PRQFVamide cDNA codes for a total of 33 copies of PRQFVamide and four related pentapeptides.

Distribution of mRNA/peptides

The myomodulin and buccalin mRNA are localized in specific neurons in each ganglia of the *Aplysia* CNS, mainly in the motoneurons B16. Buccalin transcript is also localized in the motor neurons B15. *In situ* hybridization analysis indicates that in *Lymnaea* the myomodulin gene is widely and abundantly expressed in all ganglia of the brain. In *Aplysia* and *Lymnaea*, SCPs are present mainly in the buccal ganglion. In *Lymnaea*, SCP and myomodulin genes are expressed within some large motoneurons (B1–B4). Both the enterin and FCAP mRNA are unevenly distributed throughout the central ganglia of

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Aplysia. Cerebrin RNA distribution studies performed on *Aplysia* showed detectable levels only in the cerebral ganglia, whereas the PRQFVamide precursor is abundant in the abdominal ganglion.

Another peptide seems to be involved in a feedforward compensatory mechanism mediated by its central and peripheral actions: the ATRP. *In situ* hybridization and immunostaining detection show that ATRP is mainly present in the buccal and cerebral ganglia and it is also present in the abdominal, pleural, and pedal ganglia.[16]

Biological Actions

In *Aplysia*, several of these peptides act in concert to enhance acetylcholine-induced contractions in a specific muscle of the buccal mass. Myomodulins induce potentiation, depression of the amplitude of the contractions, and acceleration of the relaxation rate of ARC muscle, whereas buccalins decrease the size of contractions of the ARC muscle. SCPa and SCPb are capable of acting postsynaptically on the muscle to potentiate the action on the primary neurotransmitter, acetylcholine. The concerted action of SCPs and myomodulin on the feeding behavior and the innervation of the foregut have also been demonstrated in *Lymnaea*.

Enterins are active in both the gut and the CNS. They play an inhibitory role on the contractions of the gut, inducing the switch from egestive to ingestive behavior. Conversely, FCAPs are capable of initiating rhythmic feeding motor programs mainly ingestive. Also, cerebrin has a profound effect on the feeding motor pattern, dramatically shortening the duration of the radula protraction in a concentration-dependent manner. PRQFVamide decreases the excitability of some but not all neurons of the buccal feeding circuit. A novel peptide that regulates feeding behavior is ATRP. ATRP produces a dose-dependent increase in the tonic contraction of the I2 muscle, promotes short protraction and long retraction, and has higher activity of protraction motoneurons.[16]

PEPTIDES AND RENAL FUNCTION

Discovery

Apart from the evidence that FaRP are involved in osmoregulations, other peptides are involved in maintaining the water balance in molluscs. A bradykinin peptide is present in the left upper quadrant cells in *Aplysia californica*, which extensively innervate the kidney. Moreover, peptides contained in the neuron R15 present in the abdominal ganglion of *Aplysia* increase the water content in this gastropod. In *Lymnaea*, the peptide lymnokinin PSFHSWSamide, which belongs to a leukinin family of peptides and the sodium-influx-stimulating peptide, has been characterized.

Structure of the Precursor mRNA/Gene

A bradykinin clone encodes a putative 16.3-kD precursor peptide, which contains potential proteolytic cleavage sites that could generate smaller mature peptides. A cDNA cloned from R15 neurons encoded for a propeptide contains three major peptides that are named R15α, R15β, and R15γ peptides. R15 mRNA undergoes alternative RNA splicing to yield two different mature mRNA species, R15-1 and R15-2. Lymnokinin was only purified with classical HPLC/MALDI approaches, and a cDNA clone, encoding to prohormone of the sodium-influx-stimulating peptide of the freshwater snail *Lymnaea stagnalis* has been isolated and characterized.

Distribution of mRNA/Peptides

In *Aplysia*, the expression of bradykinin RNA is seen only in neuron L5 among the LUQ cells, whereas R15 peptide is mainly localized in that neuron. *In situ* hybridization showed that the *Lymnaea* sodium-influx-stimulating peptide gene is expressed by the neuroendocrine Yellow Cells of the central nervous system.

Receptors

The cloned GPCR receptor GRL104 from *Lymnaea* represents the leucokinin-like peptide receptors, and only lymnokinin is able to activate GRL104 at the nanomolar level (Cox et al., 1997).

Biological Actions

In *Aplysia*, bradykinin is supposed to regulate some renal functions. On the contrary, substantial evidence indicates that neuron R15 is involved in the regulation of extracellular water volume or ionic composition. Unfortunately, there is a paucity of data concerning the role of leucokinin-like peptides (lymnokinin) in molluscs. Indeed, the *Lymnaea* sodium-influx-stimulating peptide controls the activity of sodium pumps in the integument, pericardium, ureter, and nephridial gland.

TACHYKININ

Discovery

Tachykinins (TKs) constitute the largest vertebrate neuropeptide family with multifunctions in central and peripheral tissues. See the chapter on tachykinin in this section of the book. In several invertebrate species, two types of structurally related peptides, tachykinin-related peptides (TKRPs) and invertebrate tachykinins (inv-TKs), have been identified.[32] The first tachykinin to be sequenced was isolated from the posterior salivary glands of cephalopods *Eledone moschata*

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

and *Eledone aldrovandi*. Two other TKs were sequenced from the *Octopus* salivary gland and named OctTK-I and OctTK-II. Seven tachykinin-related peptides (from OctTKRP-I to OctTKRP-VII) were isolated from the *Octopus vulgaris*.[17] Finally, a type of tachykinin-related peptide receptor (TKRPR) was isolated from the bivalve *Anodonta cygnea*, and more recently, a novel TKRPR from the cephalopods *Octopus vulgaris* has been described.[17]

Structure of the Precursor mRNA/Gene

The cDNA of preproOctTK-I and preproOctTK-II are very similar.[17,32] OctTKs were included in the sequences flanked by a typical dibasic signal at the N-terminal and an amidation signal and a single basic residue at the C-terminal. Most inv-TKs peptides possess a characteristic C-terminal-FX1GX2R-NH2 consensus sequence that has never been found to exist in vertebrates.[32]

Distribution of mRNA

The mRNA of preproOctTK-I is expressed in some mucous-containing cells of (type A) epithelium of the salivary glands of *Octopus vulgaris*. Oct-TKRP receptor is abundantly expressed in the brain, buccal ganglion, gastric ganglia, olfactory and peduncle lobes, and optic lobe.[17]

Biological Actions

Functioning as paracrine or autocrine factors or as endocrine messengers, tachykinins are also involved in the regulation of various other physiological processes such as intestinal motility, smooth muscle contraction, and cardiovascular function.[32] Inv-TKs are present exclusively in the salivary glands of several species. Furthermore, inv-TKs do not exhibit any action on invertebrate tissues at physiological concentrations. Therefore, despite high sequence similarity to vertebrate TKs, inv-TKs are not anticipated to be the functional counterparts of vertebrate TKs.[32] The undecapeptide eledoisin that shows vasodilatory and smooth muscle stimulatory actions in mammals has an obscure presence in the *Octopus* salivary glands; it may have no function in the nervous system of cephalopods: OctTK I and - II show immediate contractile activities when applied on the longitudinal muscle of the guinea ileum. The OctTKs, in particular OctTK-I, are secreted in mucous saliva as a venomous substance acting on vertebrates such as fishes that are prey and/or natural enemies of the *Octopus*.

PEPTIDES AND REPRODUCTION

Egg-laying Hormones (ELHs)

Discovery

The caudodorsal cell (CDC) system of *Lymnaea* and the bag cells of *Aplysia* function as a peptidergic command center that initiates and coordinates ovulation and egg mass production with a fixed sequence of overt behaviors: cessation of locomotion, turning, modulation of feeding movements, oviposition, and inspection. In *Lymnaea*, egg laying and correlated processes are initiated and coordinated by CDC, neuroendocrine cellS located in the cerebral ganglia near the intercerebral commissure (COM), the neurohemal area of the CDC. Around the time of ovulation, all CDC display a synchronous spiking activity (discharge), which allows peptide release. In a similar way, the bag cells of *Aplysia*, two clusters of neuroendocrine cells located in the abdominal ganglion, show a prolonged and synchronous burst of electrical activity (after discharge) that precedes egg-laying behavior. At least nine peptides are released during this activity, including the egg-laying hormone (ELH), αBCP, βBCP, δBCP, and γBCP. Two additional peptides, the acidic peptide (AP) and εBCP, have been chemically characterized. Peptides A and B, as well as three peptide complexes, have been isolated from the atrial gland in the reproductive tract of *Aplysia*. The two peptides, and the complexes as well, are able to induce egg-laying behavior. Three other biologically active peptides, califin A, B, and C, were isolated and characterized from the atrial gland. Immunolocalization of ELH-like peptide in the neuroendocrine bag cells and their processes in *Aplysia dactylomela* confirms the key role of this peptide in *Aplysia* reproduction.[7]

Structure of the Precursor mRNA/Gene

In *Lymnaea*, the CDCs express three different caudodorsal cell hormone (CDCH) genes: CDCH-1, -2, and -3. The CDCH-1 gene leads to nine different peptides, including the caudodorsal cell hormone-l, the ε-peptide, the calfluxin, the α-caudodorsal cell peptide, the δ-peptide, β1- and β2-peptides, and the carboxyl terminally located peptide, from the cerebral commissure. The CDCH-2 gene encodes the same peptides, except for caudodorsal cell hormone-2, which is different from the ovulation hormone. At least five distinct genes for ELH exist in *Aplysia*. Transcription of this small multigene family results in the expression of at least five distinct RNA transcripts encoding ELH. The pattern of transcripts differs strikingly in different tissues: bag cells express three distinct mRNA species, whereas the atrial gland expresses two distinct mRNAs. AlI cDNAs contain an exon that spans the coding region (exon III) and one or two additional exons. Genomic clones encoding peptides A and B have been isolated and subjected to nucleotide sequence analysis.

Two genes coding homologous hormones are located close to each other in the genome of *Lottia gigantea*.[33] A single EST was found for ELH 2, none for ELH 1, and an EST encoding a homologous *Crassostrea* hormone was also found. The *Lottia* ELH genes seem to be quite different from those in *A. californica*. The transcript isolated from *A. dactylomela*[7] encoded a partial ELH precursor protein

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

containing an *A. dactylomela* ε-BCP (δ-BCP), acidic peptide (dAP), and a 36 amino acid ELH (dELH) that are each flanked by paired basic cleavage sites. An alignment of the dELH with other Aplysiidae ELHs and *Lymnaea* ELH shows high conservation. The predicted amino acid sequence of *A. dactylomela* as shown by phylogenetic analysis is 91.7% identical to *A. californica* and *A. brasiliana* ELH. Comparing the primary structure of *Aplysia* ELH-related peptides reveals a pattern of highly conserved regions near both the N- and C-termini. This is critical for receptor recognition/binding site; the removal of the N-terminal amino acid (ELH2–36) or extension of the C-terminus by one residue (ELH-Gly37) results in a loss of egg-laying activity. Based on MALDI-TOF MS, performed on bag cell segments of the abdominal ganglion, a peptide of 3193 Da represents dELH cleavage at Leu26. Finally, a recombinant egg-laying hormone was generated.

Distribution of mRNA

In *Lymnaea*, *in situ* hybridization experiments show CDCH genes expressed in the CDC, while a group of small neurons in the cerebral ganglia express only the CDCH-I gene. There is widespread expression of the CDCH genes in peripheral tissues. Sensory neurons in the head skin and mantle edge express the CDCH-I gene. In *Aplysia*, >90% of the ELH genes family expression occurs in the bag ceIls, but these genes are expressed also in the atrial gland and in an extensive system of neurons distributed in four of the five ganglia of the central nervous system.

Biological Actions

In *Lymnaea stagnalis*, during discharges, CDCH-I is released into the blood, where it acts as a hormone that stimulates ovulation and egg mass formation and synthesis of secretory products in the female accessory sex glands and affects neurons in the neuronal circuits controlling locomotion and feeding. During the discharge, calfluxin stimulates the release and/or synthesis of perivitelline fluid and, in addition, affects feeding movements, and α-CDCP elicits electrical discharge activity in all CDCs, causing the maximal release of hormone and induces the transition from cessation of locomotion to the turning phase of egg-laying behavior. Egg laying in *Aplysia californica* is controlled by the bag cells, which have similar morphological and electrophysiological characteristics to the CDCs. They release a battery of peptides, including ELH and bag cell peptides αBCP, βBCP, and γBCP. ELH induces ovulation and alters the electrical activities of several neurons in the abdominal, buccal, and pedal ganglia. αBCP mimics bag cell-induced inhibition of several identified and unidentified neurons. Two additional peptides released by bag cells the acidic peptide and εBCP have no known biological or pharmacological activities. Egg-laying procedures can induce *A. dactylomela* to lay eggs by injection of *A. dactylomela* recombinant ELH.[7] Similar to all the mature ELH peptides identified, dELH functions by inducing egg laying when injected into animals.

APGWamide

Discovery

APGWamide is a tetrapeptide with the sequence Ala-Pro-Gly-Trp-NH_2 and is cleaved from a longer precursor peptide. It was isolated from ganglia of prosobranch mollusc *Fusinus ferrugineus*. In *Lymnaea stagnalis* and in *Helix aspersa*, APGWamide seems to be localized mainly in the neurons of asymmetrical right lobe of the cerebral ganglion. APGWamide-related peptides are also found in bivalves. In the cephalopod *Sepia officinalis*, the dipeptide GWamide has been purified from the optic lobe. Immunoreactivity occurs in the nervous system and in the oviducal gland of *Octopus vulgaris* APGWamide and in neurons and fibers of *Idiosepius pygmaeus* with a greater number of immunoreactive cells in the male.[28] It is a common neurotransmitter/neuromodulator peptide found in many species of molluscs and is often related to sex organ growth or reproductive behavior.

Structure of the Precursor mRNA/Gene

The complementary DNA encoding this tetrapeptide has been cloned from *Lymnaea stagnalis*, *Mytilus edulis*, and *A. californica*, whereas an APGW-related peptide-containing cDNA has been found in *Mytilus edulis*. In *Lymnaea stagnalis*, the primary structure of the APGW preprohormone deduced from the cDNA sequence predicts that the prohormone can be endoproteolytically cleaved to give rise to 10 copies of the sequence APGWG and a C-terminal peptide of 40 residues, called CALP (C-terminal anterior lobe peptide). Both the APGWG and a CALP are posttranslationally amidated.

In *Aplysia*, sequence analysis of cDNA clone show that it contains a 209 amino-acid APGWamide precursor. In *Mytilus*, the nucleotide sequence of the APGWamide related peptide cDNA clone encodes a 196 amino acid preprotein (reviewed in Ref. 21). The full processing of the *Mytilus* precursor has the potential to generate five RPGWamide peptides, one KPGWamide, one TPGWamide, and a C-terminal peptide, but no copies of APGWamide.

Distribution of mRNA/Peptide

The gene encoding the precursor of APGWamide is mainly expressed in the neurons of the right anterior lobe of the cerebral ganglia of *Lymnaea stagnalis* (Smit et al., 1992). In addition, gene expression was detected in the left cerebral ganglion and in several neurons in other parts of the CNS.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

In *Aplysia*, Northern blot analysis of total RNA indicates that a major transcript was expressed predominantly in the right cerebral and right pedal ganglia (Fan et al., 1997). In *Idiosepius pygmaeus*, APGWamide immunoreactivity is found in both neurons and fibers in the palliovisceral lobe of the posterior subesophageal mass, in the optic tract region, in the olfactory lobe, the vertical lobe and the dorsal basal lobe while in the supraesophageal mass, APGWamide immunoreactivity is detected only in neurons. Most immunoreactive neurons are found in the palliovisceral and olfactory lobes of both sexes.[28]

Biological Action

In *Lymnaea*, APGWamide inhibits contraction of the penis retractor muscle and functions as a neurotransmitter within the CNS, inhibiting the activity of certain neuroendocrine cells and coordinating the activity of different populations of penial motoneurons. APGWamide and related peptides have also been suggested to play a key role in the control of male copulation behavior in other gastropods such as *Helix aspersa* and to function as an inhibitory neurotransmitter in the CNS of both *Helix aspersa* and *Achatina fulica*. APGWamide in *Haliotis asinina*, besides its function inducing spermiation,[6] may regulate somatic growth: exogenous administration of APGW amide significantly stimulates body growth in juveniles.[5] APGWamide-related peptide of *Mytilus* shows similar potency on contraction of both the pedal retractor and anterior bissus retractor bivalve muscles.[21] The cephalopod *Sepia officinalis*, the peptide GWamide purified from the optic lobe shows a strong inhibiting action on the motility of the mature oviduct. APGWamide in *Octopus vulgaris* is strictly linked and associated to those systems and lobes that directly process close and distant chemical signals (reviewed in Ref. 21). In *Idiosepius pygmaeus*, based on the significantly higher number of APGWamide-immunoreactive neurons in male brain versus female brain, it has been supposed its a major role in the control of male reproduction.[28]

GnRH AND RELATED PEPTIDES

Discovery

Gonadotropin-releasing hormone (GnRH) is a decapeptide neurohormone crucial for the regulation of reproductive and neural functions in vertebrates[25] (also see chapter in the Brain Peptides section of the book). Multiple reports indicate the presence of bioactive molecules that immunologically and biochemically resemble vertebrate GnRH in gastropods, bivalves, and cephalopods.[30] Many groups have immunolocalized GnRH-like peptides in diverse species of molluscs. Using antimammalian (m)GnRH antibody it has been detected neurons in the pedal ganglion and cerebral ganglion of both sexes of *Patinopecten yessoensiis*.[22] Using an antiserum against oct-GnRH, other authors have localized the peptide in the dorso-lateral basal, olfactory lobes, the two neuropeptidergic centers controlling the activity of the gonadotropic optic gland, and ovary of *Sepia officinalis*.[14] Minakata et al. (2009), according to our previous findings,[10] first identified GnRH in the central and peripheral system of *Octopus vulgaris*, they found Oct-GnRH immunoreactive signals in the glandular cells of the mature optic gland. Using the same antiserum, immunoreactive neurons in all CNS ganglia of *Aplysia californica* were found. Two putative isoforms of GnRH-like peptides have been localized in neural ganglia and ovary of female abalone, *Haliotis asinina*, using antilamprey (l)GnRH-III and antitunicate (t) antibodies.[23] Amano et al. (2008, 2010) found in some lobes of the nervous system of *Loligo bleekeri*, in some ganglia of *Haliotis discus hannai* and in the cerebrobuccal ring of *Acanthopleura japonica* cell bodies and fibers crossreacting with a mouse monoclonal LRH13 and cGnRH-II antibodies suggesting the existence of two putative isoforms of GnRH in these species of molluscs. In *Aplysia californica*, Tsai et al.[31] showed by immunohistochemistry and radioimmunoassay analyses that pedal ganglia, followed by cerebral ganglia, abdominal ganglia, and then buccal, contain the highest level of ap-GnRH peptide. Treen et al.,[30] using antioctopus GnRH-like peptide antibody, showed the presence of GnRH-like peptide in neural tissue of *Crassostrea gigas*. Bigot et al.[4] characterized two GnRH-related peptides (Cg-GnRH-a and Cg-GnRH-G) by mass spectrometry from extracts of the visceral ganglia of the Pacific oyster *Crassostrea gigas*. These peptides show a high degree of sequence identity with GnRHs of other molluscs and annelids and to a lesser extent with those of vertebrates or with AKH and corazonins of insects. Significant differences in transcriptional activity of Cg-GnRH encoding gene are recorded in the ganglia along the reproductive cycle and according to trophic conditions suggesting the involvement of Cg-GnRHs as synchronizers of nutritional status (reviewed by Minakata, 2012).

Structure of the Precursor mRNA/Gene

A GnRH precursor cDNA has been cloned from the cephalopod *Octopus vulgaris*.[20] The precursor peptide contains 87 amino acids. The *Octopus* GnRH-like peptide contains two additional amino acids at positions 2 and 3, but the general motif of a pyroglutamyl residue at the N-terminus and amidated glycine residues at the C-terminus is conserved. A peptide similar to the chicken I form of GnRH (cGnRH-I) has been partially purified in the same species of *Octopus*. It is probable that *Octopus* GnRH-like peptide is different from the peptide described by Di Cristo et al.,[13] since it is unlikely that these two peptides share identical immunological and biochemical properties given the marked structural differences. cDNAs encoding GnRH-like precursors have been described

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

from *A. californica* differing from oct-GnRH by only two amino acids (Zhang et al., 2008) representing one of the only two GnRH-like molecules found outside phylum *Chordata*. These results provide valuable support for an ancient origin of GnRH during metazoan evolution. A GnRH sequence cloned from the brain, ovary, and eggs of *Sepia officinalis* of 269-bp PCR product[14] shares 100% sequence identity with the open reading frame of GnRH isoform isolated from *Octopus vulgaris*. This sequence encodes a peptide that is organized as a preprohormone from which, after enzymatic cleavage, a dodecapeptide is released. Onitsuka et al. (2009) isolated the full-length cDNA of a GnRH-like molecule from the central nervous system of the squid *Loligo edulis*. This GnRH is identical to *Octopus* GnRH in the deduced amino acid sequence of the peptide and 80.5% similar in base sequence. In *Lottia* genome, a gene codes for a similar peptide, and its expression is shown by two ESTs.[33] Treen et al. (2012) cloned the cDNA transcripts of prepro GnRH-like peptides from two species of bivalve molluscs, the Yesso scallop *Patinopecten yessoensis*, and the Pacific oyster *Crassostrea gigas*.

Distribution of mRNA

In situ hybridization analysis in *Octopus vulgaris* shows Oct-GnRH mRNA-expressing cell bodies in the supraesophageal and subesophageal parts of the CNS. GnRH neurons are mainly present in the posterior olfactory lobule. These neurons send axons to the secretory cells of the optic gland. GnRH is also present in the subpedunculate area that controls the same gland. GnRH neurons have also been localized in both the subesophageal and supraesophageal masses, as well as in the plexiform layer of the deep retina in the optic lobe. Recently, Zhang et al. (2008) found the transcript for *Aplysia* GnRH widely expressed in the CNS, the ovotestis, and the atrial gland. In *Loligo edulis*, the prepro-GnRH mRNA was expressed mainly in the CNS (Onitsuka et al., 2009). Using a set of experiments aimed at manipulating a putative glutamate/NMDA/NO signal transduction pathway, Di Cristo et al.[14] showed by quantitative real-time PCR that NMDA enhances the expression of GnRH mRNA in a dose–response manner. The reverting effect of a selective antagonist of NMDA receptors (NMDARs), 2-amino-5-phosphopentanoic acid (D-APV), confirms that such an enhancing action is an NMDA receptor-mediated response. The results suggest that in *Octopus* l-glutamate could be a key molecule in the nervous control of sexual maturation.

Receptor

A GPCR expressed in the gonad of the pacific oyster *Crassostrea gigas* named Cg-GnRH-related receptor (Cg GnRHR) exhibits a high degree of amino acid sequence identity with both vertebrate GnRH receptors and insect AKH receptors. Quantitative RT-PCR shows a specific expression of Cg-GnRH-R in both male and female gonads during the reproductive cycle. This finding gives an insight into the involvement of a GnRH receptor ortholog in the control of reproduction in a protostomian invertebrate.[26] However, the characterization of multiple transcripts encoding GnRH-R orthologs (Cg-GnRH-RII-L/Cg-GnRH-RII-S) includes a truncated receptor (Cg-GnRH-R-TF) generated by the alternative splicing of a single mRNA precursor. The differential structure of these receptors suggests the existence of two receptor subtypes with regard to ligand specificity. Pattern of expression of these transcripts suggests that Cg-GnRH-R cognate ligand is specifically involved in the control of gametogenesis while Cg-GnRH-RII-L and Cg-GnRH-RII-S ones likely do not control reproductive functions.[26,27] A GnRH receptor (oct-GnRHR) specific for oct-GnRH from *Octopus* brain that includes domains and motifs typical of vertebrate GnRH receptors has been identified by Kanda et al. (2006) and Minakata et al., (2009). The intron-inserted positions are conserved between oct-GnRHR and the chordate GnRHR genes. The oct-GnRHR was responsive to oct-GnRH but not to any other HPLC fractions of the *Octopus* brain extract. These results show that oct-GnRHR is an authentic receptor for oct-GnRH. Southern blotting of reverse-transcription PCR products revealed that the oct-GnRHR mRNA was widely distributed in the central and peripheral nervous systems and in several peripheral tissues. *In situ* hybridization showed that oct-GnRHR mRNA was expressed in lobes deputed to the control of feeding, memory, and motor coordination. In a recent review, Tsai et al.[31] presented preliminary proof for a cognate *Aplysia californica* GnRH receptor (ap-GnRHR) detecting an abundant putative ap-GnRHR transcript in the central nervous system and the foot.

Biological Action

In *Helisoma trivolvis*, CNS extract was capable of stimulating gonadotrophin release from dispersed goldfish pituitary cells. In addition, the application of mammalian GnRH to *Helisoma* CNS elicited diverse electrophysiological and morphological effects on individual neurons. Application of vertebrate GnRH to bag cells of *Aplysia californica* inhibited the electrical response, a finding supported by a previous study on *Lymnaea* stagnalis. The reproductive and neural involvement of the molluscan GnRH was further corroborated by studies on the bivalves and cephalopods. These studies demonstrated a strong mitogenic action of GnRH on bivalve gonadal cells and a spatial distribution of GnRH-IR in the CNS that is highly suggestive of reproductive regulation. In *Octopus*, GnRH was proposed to act on the secretory cells of the gonadotropic optic gland. Interestingly, GnRH neurons in *Octopus* are located in the olfactory lobe consistently with the known relationship between GnRH and chemosensory system observed in vertebrates. These results

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

are reinforced by the presence of GnRH in the osphradium of *Aplysia californica*. It has also been proposed that GnRH in *Octopus* is involved in the control of reproductive ducts and the contractions of the heart.[12]

Oct-GnRH was shown by Kanda et al. (2006) to induce steroidogenesis of testosterone, progesterone, and 17β-estradiol in *Octopus* ovary and testis, where oct-GnRHR was abundantly expressed. These results suggest that functions of the GnRH family are evolutionarily conserved between octopuses and chordates according to the recent findings of De Lisa et al.[9] Nakamura et al. (2007) demonstrated through *in vitro* experiments the increase of mitotic activity of spermatogonia at phase II induced by mGnRH in the scallop *Patinopecten yessoensiss*. The same mitotic activity was observed in the hemocyte lysate. Tsai et al.[31] in an elegant review discussed the deviation of *Aplysia californica* GnRH from a traditionally assumed role in reproductive stimulation, calling for a reassessment of the phylogenetic reconstruction of the physiological role played by ap-GnRH. They proposed that "protostomian GnRHs, assuming they are orthologous to chordate GnRH, have taken different functional trajectories during 600–800 million years of evolution and are not universally important to the reproductive activation in extant protostomes." However, they compared the results to the available functional data from *Octopus vulgaris* and concluded that protostomian GnRH-like molecules are likely to assume a wide range of physiological roles, and reproductive activation is not an evolutionarily conserved role of these molecules. In this context, we would like to highlight that in a recent article,[9] it has been demonstrated that the stimulation of the olfactory lobes of the *Octopus*, neuropeptidergic centers controlling the activity of the gonadotropic optic gland, with 17β-estradiol increases the oct-GnRH mRNA, confirming the existence of a strong coupling between 17β-estradiol and the transcriptional activity of oct-GnRH neurons. This finding is in agreement with the existence of an axis "area subpedunculate-olfactory lobe-optic gland" responsible for the reproductive behavior of *O. vulgaris*, in which the activity of oct-GnRH neurons is regulated by 17β-estradiol. The *Octopus* may therefore be an ideal model to further investigate the functional role of oct-GnRH revealing conserved roles of the protostomian GnRH-like molecules. Finally, Treen et al.[30] demonstrated that putative GnRH-like peptide stimulated spermatogonial cell division in cultured Yesso scallop *Patinopecten yessoensis* testis.

VP/OP

Discovery

The members of the vasopressin (VP) and oxytocin (OT) superfamily are widely distributed throughout the animal kingdom. In the snail *Lymnaea stagnalis*, Lys-conopressin is the only member present, whereas cephalotocin (CT) and octopressin (OP) were found in *Octopus vulgaris*.[12] The structure of the precursor mRNA/Gene in *Lymnaea stagnalis*, conopressin cDNA, encodes far a precursor that is organized very similarly to the prohormones of the vasopressin/oxytocin superfamily with a hydrophobic signal peptide, a nominal peptide, a neurophysin domain, and a C-terminal copeptin homologous extension of the neurophysin domain. In *Octopus vulgaris*, the OP and CT precursor cDNAs predict a polypeptide of 145 and 152 amino acids, respectively. The two genes of the oxytocin/vasopressin superfamily in *Octopus vulgaris* lack introns and consist of a single exon in their protein-coding regions, unlike most vertebrates and Lys-conopressin precursors.[12] The N-terminal sequences of the OP precursor and the CT precursor are different from each other. Both the remaining parts are identical except for two nucleotide bases. Bardou et al.,[3] by using antibodies raised against mammalian OT and VP, immunolocalized in the nervous system of *Sepia officinalis* several populations of OT-like and VP-like immunoreactive cell bodies and fibers widely distributed in lobes involved in learning, behavioral communication, feeding, reproduction, and motor coordination. No double-immunolabeled cell bodies or fibers were found in any lobes of the CNS, indicating, the existence of distinct oxytocinergic-like and vasopressinergic-like systems.[20]

Distribution of mRNA

In situ hybridization on *Lymnaea* CNS showed that the conopressin gene is expressed in a few neurons in both pedal ganglia. In *Octopus*, *in situ* hybridization using CT- and OP-specific cRNA antisense probes on adjacent sections was performed. The expression of CT mRNA was primarily limited within the ventral median vasomotor lobe of the subesophageal brain. OP mRNA was expressed in the superior buccal, anterior basal, median basal, dorsal basal, vertical, subvertical, posterior brachial, and palliovisceral lobes.[12]

Receptor

A receptor for vasopressin-related Lys-conopressin has been cloned in *Lymnaea stagnalis* (LSCPRl). Expression of this receptor mRNA was detected in central neurons and peripheral muscles associated with reproduction. In addition, a novel Lys-conopressin receptor subtype, named LSCPR2, was found. In *Octopus* brain, a GPCR specific to CT (CTRl) was cloned. This cDNA coded for an orphan receptor that was activated by CT. An additional CT receptor, CTR2, and a novel OP receptor, OPR, were later found in the CNS of *Octopus vulgaris*. CTR2 mRNA is present in

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

various peripheral tissues, and OPR mRNA is detected in both the nervous system and peripheral tissues.

Biological Actions

Very little is known about the functions of these peptides in molluscs. In *Lymnaea*, Lys-conopressin excites the vas deferens *in vitro* in a dose-dependent manner. Upon application, Lys-conopressin also excites pacemaker neurons in the anterior lobe of the right cerebral ganglion, acting on the inward current. Bardou et al.[2] showed the role of two VP/OT superfamily peptides, octopressin (OP) and cephalotocin (CT), on long-term memory (LTM) formation of a passive avoidance task in a cephalopod mollusc, the cuttlefish, *Sepia officinalis*.

Chapter 40

Parasitic Nematode Peptides

Nikki J. Marks and Aaron G. Maule

ABSTRACT

Nematode parasite peptides and/or their encoding gene transcripts have been characterized from a small number of species including the animal parasites *Ascaris suum*, *Haemonchus contortus*, and *Trichostrongylus colubriformis* and from the plant parasites *Globodera pallida*, *Meloidogyne incognita*, and *Bursaphelenchus xylophilus*. While peptide purification and sequencing efforts seeded the early peptide discovery phase database mining and mass spectrometric approaches in *A. suum* have provided significant impetus to the discovery of FMRFamide-like peptides (FLPs) and neuropeptide-like proteins (NLPs). Recent genome annotations have provided information on the complement of FLPs and NLPs in *M. incognita* and *B. xylophilus*. Insulin-like peptides (INSs) have only been reported from the genome annotation efforts in *B. xylophilus*. Functional data are centered on FLPs, and the vast majority derive from physiology studies in *A. suum* and some reverse genetic studies in plant parasitic nematodes. Neuropeptides play important roles in many aspects of parasitic nematode biology.

INTRODUCTION

In spite of its structural simplicity (e.g., comprising only 298 neurons in the female *Ascaris suum*), the nematode nervous system exhibits remarkable biochemical diversity, encompassing a diverse array of neuropeptides. At present, three peptide groupings have been identified within the parasitic members of the phylum Nematoda, namely, FMRFamide-like peptides (FLPs), neuropeptide-like proteins (NLPs), and insulin-like peptides (INSs). Although FLPs and INSs encompass recognized peptide families, the NLPs are an amalgamation of non-FLP or INS neuropeptides from numerous distinct families that have been identified in nematodes. In addition to peptides belonging to these large groupings, a putative peptide fragment of chromogranin has been reported. Antibacterial peptides, some of which in *Caenorhabditis elegans* have been designated NLPs, are considered elsewhere.

Parasitic nematode peptides have been discovered largely through peptide sequencing approaches in the large gastrointestinal parasite of pigs, *Ascaris suum* with complementary small-scale studies in the sheep gastrointestinal parasite, *Haemonchus contortus*.[18] These efforts have been expanded markedly through the combined exploitation of nucleic acid sequence resources and mass spectrometric methods.[9,10,34] Large-scale expressed sequence tag (EST) analyses across phylum Nematoda have revealed the occurrence of putative orthologs of numerous known FLPs[21] and NLPs,[23] providing evidence for the conservation of peptide sequences between species. Targeted mass spectrometric methods applied to *A. suum* have generated data on both peptide structure and localization. The genomes of two plant parasitic nematodes, the sedentary endoparasitic cyst nematode *Meloidogyne incognita*[1] and the migratory endoparasitic pine wood nematode *Bursaphelenchus xylophilus*,[12] have had their *flp* and *nlp* complements annotated with *ins* genes also being recorded in the latter species.

Functional data center on the FLPs, with most arising from whole animal, tissue, or cell level physiology studies in adult *A. suum*.[4,20,27,28,31,35] Two small-scale studies report the impact of *flp* gene RNA interference (RNAi) in *M. incognita* and the potato cyst nematode *Globodera pallida*.[5,16] In all the functional studies undertaken, FLPs have dramatic effects on nematode parasite physiology/behavior.

FMRFamide-LIKE PEPTIDES (FLPs)

FLP Discovery – Structure of the Precursor mRNA/Gene

The majority of peptides known from parasitic nematodes are FLPs, neuropeptides that encompass a C-terminal signature sequence comprising Xi-Xii-RFamide, where Xi is any amino acid except cysteine and Xii is any hydrophobic amino acid except cysteine. Currently, FLPs comprise the largest known peptide family in parasitic nematodes.

Some 40 distinct FLPs have been structurally characterized from *A. suum* and designated AF1–AF11 and AF13–AF41 (only a partial sequence is available for AF12; note that AF17 comprises a FMHFamide C-terminus, the only member which deviates from the FLP signature and is only tentatively assigned) (Table 1).[2–4,6,7,9,29,34,35] Two of these peptides (KHEYLRFamide, AF2 and KSAYMRFamide,

*Peptides not conforming to recognized FLP signature. Note that those peptides not assigned names are putative peptides predicted from Genbank database searches.[10,26,28,34,35]

AF8) and one novel peptide (LQPNFLRFamide) have also been structurally characterized from the third larval stage of *H. contortus* a common parasite of the abomasum of sheep.[8,13,18] In both parasites, AF2 is the most abundant peptide detected.

FLPs are encoded on *flp* genes and a genome wide BLAST survey identified ESTs encoding known *C. elegans* FLPs in numerous parasitic nematode species.[21] More than 1000 putative FLP-encoding ESTs have been identified across 32 parasite species with the identification of homologs of 29 *C*

elegans flp genes and two additional *flp* genes (*flp-30* and *flp-31*) that appear to be unique to some sedentary endoparasites of plants; note that a *flp-31* homolog (*As-flp-31*) has recently been reported in *A. suum*.[10] Cloning and sequencing-based confirmation of *flp* gene transcripts have only been performed for selected genes in adult *A. suum*[17,35] and second stage larval *G. pallida*.[14] In *A. suum*, full length *flp* gene sequences have been designated *afp-X* (*Ascaris* FMRFamide-like Precursor proteins; X represents the gene number assigned chronologically upon discovery) genes; here, each will be co-designated by its *C. elegans* homolog, that is, *As-flp-X*. FLP-encoding genes characterized from *A. suum* include *afp-1* (*As-flp-18*), *afp-3* (*As-flp-6*), *afp-4* (*As-flp-14*), *afp-6* (*As-flp-11*), *afp-12* (*As-flp-24*), and *afp-13* (*As-flp-13*); these encode 15 FLPs and, in addition to FLPs, *afp-13* encodes three non-FLP neuropeptides (TPPEEDLLGRFT, TNIMGENRLNRNL, GNSYRSFFNPNEYTVVE).[9,26,35] Other *afp* genes have been predicted from sequence resources available for *A. suum*.[10] Five *flp*-encoding genes have been characterized from *G. pallida*, namely, *Gp-flp-1*, *Gp-flp-6*, *Gp-flp-12*, *Gp-flp-14*, *and Gp-flp-18*[14]; these encode 13 distinct FLPs (Table 2). Another four have been characterized from *M. incognita* (*Mi-flp-1*, *Mi-flp-7*, *Mi-flp-12*, *Mi-flp-14*) and one from *Meloidogyne minor* (*Mm-flp-12*) (Table 2).[11]

Published genome sequences for two plant parasitic nematodes have provided preliminary data on the neuropeptide complements for *M. incognita*[1] and *B. xylophilus*.[12] Both have reduced complements of FLP-encoding genes compared with *C. elegans* with *M. incognita* having 19 *flp* genes and *B. xylophilus* having 21 *flp* genes compared to *C. elegans* 29 *flp* genes (Table 3). There seems to be general consistency in the complement of *flps* occurring across nematode parasites.

FLP Distribution/Expression

Carboxy-terminal FLP antisera (mostly with undetermined specificity) promiscuous for a diverse array of FLP ligands have provided an insight into the widespread distribution of FLPs in nematode parasite nervous systems. Up to 75% of the *A. suum* nervous system expresses FLPs with staining occurring in all neuronal subtypes including interneurons, motorneurons and sensory neurons.[17] A number of studies report the localization/expression of individual FLPs or *flp* genes using a variety of methods including immunocytochemistry (ICC) with specific antisera, *in situ* hybridization (ISH) of the gene transcript and cell/ganglion specific mass spectrometry.[17] Although these studies are relatively few in number, they provide significant added value to peptide functional data based on physiology or phenotype.

The first study to use an antiserum specific for an individual FLP localized AF2 to a subset of neurons in the brain and pharynx as well as single neurons in the dorsal and ventral nerve cord that synapse with muscle and inhibitory motorneurons.[6] A mass spectrometric map of the major neuronal elements in adult *A. suum* reveals the complement of FLPs in each of the major neuronal elements (circumpharyngeal nerve ring, dorsal ganglion, lateral line ganglia, retrovesicular ganglion, ventro-dorsal commissures, ventral ganglion, segments of the dorsal and ventral nerve cords) and confirms that individual FLPs have distinct and variably overlapping expression patterns that provide for unique FLP fingerprints in each neuron/neuronal subset.[34]

The most compelling results on FLP localization have been provided for three distinct FLPs encoded on the *afp-6* (*As-flp-11*) gene, which were identified in the nerve ring and ventral ganglion of *A. suum* using mass spectrometry and by ICC and ISH in a single ventral ganglion neuron designated as an RIS-like neuron based on the *C. elegans* neuronal map.[35] Transcripts for *afp-1* (*As-flp-18*), *afp-3* (*As-flp-6*), and *afp-4* (*As-flp-14*) were each localized to a distinct subset of neurons using ISH.[26] A combination of mass spectrometry methods and ICC using a specific AF1 (KNEFIRFamide) antiserum localized this peptide to the paired URX and RIP head neurons, two pairs of lateral ganglion neurons, unpaired PQR, PDA, and PDB tail neurons that extend along the ventral nerve cord and three pairs of pharyngeal neurons.[29] A series of *afp* genes have been localized to individual neurons from the dorsal ganglion of *A. suum* using mass spectrometry.[10]

ISH was used to examine the expression pattern of five *flp* genes from the plant parasitic nematode, *G. pallida*.[15] Four *flp* genes (*Gp-flp-1*, *Gp-flp-6*, *Gp-flp-12*, and *Gp-flp-14*) are expressed in neurons of the infective J2 stage of *G. pallida*. Expression of *Gp-flp-1*, which encodes peptides terminating in the C-terminal motif FLRFamide, is localized to VA/VD and DA/DB-like motorneurons and RIF-, RIG-, AVG-, and SAB-like interneurons. *Gp-flp-6*, which encodes KSAYMRFamide, is expressed in neurons associated with the anterior nerve ring, PHA- and PHB-like sensory neurons and lumbar ganglion interneurons. In comparison, the expression of *Gp-flp-12* encoding KNKFEFIRFamide is localized to the retrovesicular ganglion D/V-like motorneurons, preanal ganglion motorneurons, lumbar ganglia interneurons associated with body wall, and vulval motorneurons, the BDU-like interneurons that are associated with the HSN vulval motorneuron, and an ADE-like sensory neuron. *Gp-flp-14* which encodes AF2 (KHEYLRFamide) is expressed in the anterior ganglion and several paired cells, which are posterior to the circumpharyngeal nerve ring; specifically the RMED-, RME-, and RMG-like cells associated with the head motorneurons and ADA-like interneurons. The study however did not report the expression of *Gp-flp-18*. Surprisingly, ISH of *Mi-flp-12* and *Mi-flp-14* indicated expression patterns that differed from those reported for the same transcripts in *G. pallida*.[11]

The three *H. contortus* peptides listed have been structurally characterized, and all others are putative peptides predicted from characterized gene transcripts.[8,11,13,14,18]

Although only a small number of species have been studied, one remarkable feature of the FLP localization data in parasitic nematodes is that identical or near-identical peptides display unique distributions in individual nematode species. This variation in expression may contribute to the neuronal plasticity seen across nematodes in spite of a structurally very simple nervous system.

FLP Receptors

Although the peptide PF4 (KPNFIRFamide) seems to activate a ligand-gated chloride channel,[20] most other FLPs appear to associate with G protein-coupled receptors (GPCRs). Although currently no FLP receptors have been fully characterized from a parasitic nematode, a number of

X indicates the presence of the ortholog of *Caenorhabditis elegans* gene; NA indicates genes not annotated in *C. elegans* and/or genes not relevant here; a,b denotes the existence of two *ins-1* subtypes; ? denotes variant *ins*-like sequences. Data derived from Refs. 1, 12.

Ascaris FLPs have however been identified as ligands to a G protein-coupled FLP receptor from *C. elegans*, namely, the NPR-1 receptor. Both AF9 (GLGPRPLRFamide) and PGV-LRFamides, which are encoded on *afp-1* (*As-flp-18*), were identified as ligands for this receptor.[24] A few FLPs have been identified as ligands (although potency was low) for the latrophilin-like receptor in the sheep parasite *H. contortus*.[25]

BIOLOGICAL ACTIONS OF FLPs

Ascaris suum Body Wall Muscle

Much data pertaining to the bioactivity of FLPs have been amassed using either innervated or denervated *A. suum* somatic body wall muscle strips. The bioactivity recorded for at least 25 distinct FLPs has been assigned to four response types, designated as body wall response types

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY
Copyright Elsevier 2024

(bwRT) 1– 4. Bioactivity comprises an array of diverse activities ranging from bwRT-1, which consists of both presynaptic and postsynaptic inhibition causing a slow prolonged response. By contrast, bwRT2 comprises a fast and transient response, whereas bwRT3 is excitatory inducing increased contractility. Finally, bwRT4 produced a biphasic response comprising an initial transient relaxation followed by a period of increased contractility.[24]

AF1 (KNEFIRFamide) and AF2 (KHEYLRFamide) induce qualitatively similar biphasic activities on somatic muscle that comprise a transient relaxation followed by a sustained period of contractility (sequential, rapid contractions and relaxations) consistent with bwRT4,[2,4,20,30] although AF2 is up to 1000-fold more potent than AF1. Denervation of the muscle strip abolishes the excitatory phase of the biphasic response suggesting the involvement of distinct receptors;[20] AF2 also enhances membrane potential responses to the excitatory neurotransmitter acetylcholine believed to be through its interaction with muscarinic-type acetylcholine receptors.[31] Further studies reveal that AF2 increases transient inward calcium currents in *A. suum* muscle.[33]

AF3 (AVPGVLRFamide) and AF4 (GDVPGVLRFamide) cause bwRT3-like contractions of *A. suum* dorsal body wall muscle strips.[3] Other FLPs including AF5 (SGKPTFIRFamide), AF9 (GLGPRPLRFamide), AF10 (GFGDEMSMPGVLRFamide), AF13 (SDMPGVLRFamide), AF14 (SMPGVLRFamide), AF17 (FDRDFMHFamide), and AF20 (GMPGVLRFamide) also induce bwRT3 responses.[3,6] AF11 (SDIGISEPNFLRFamide), AF6 (FIRFamide), and AF19 (AEGLSSPLIRFamide) cause slow and persistent inhibition of body wall muscle typical of bwRT1, whereas bwRT4 effects have been reported for AF8 (KSAYMRFamide).[6,20] AF7 (AGPRFIRFamide) and AF16 (ILMRFamide) have little or no effects on *A. suum* somatic body wall preparations.[6]

More recently, AF21 (AMRNALVRFamide), AF22 (NGAPQPFVRFamide), and AF23 (SGMRNALVRFamide) have all been shown to induce transient dorsal body wall muscle relaxations in *A. suum.*[35] The largest relaxations are induced by AF22 as are the largest muscle cell hyperpolarizations.

Ascaridia galli and *Haemonchus contortus* Body Wall Muscle

A small number of peptides are active on the body wall muscle of the sheep parasite *H. contortus* and the chicken parasite *Ascaridia galli*.[18,32] In *A. galli*, AF3 and AF4 elicit an increase in the propagation of phasic spontaneous activity and cause contractions of body wall muscle, actions reported as being independent of the cholinergic system. In *H. contortus*, the injection of AF2 inhibits acetylcholine-induced contractions, whereas AF8 enhances both spontaneous and acetylcholine-induced contractions.[18] Selective application of AF8 to *H. contortus* isolates sensitive or susceptible to the cholinergic agonist levamisole revealed differential susceptibilities to AF8 consistent with the hypothesis that it modulates cholinergic signaling.[18]

Ascaris suum Ovijector

A wide variety of FLPs modulate the activity of the *A. suum* ovijector, which regulates egg output. As with body wall muscle effects, multiple ovijector response types have been recorded (ovRT1, inhibitory; ovRT2, excitatory; ovRT3, transient contraction; ovRT4, transient contraction/paralysis; ovRT5, contraction frequency increase). AF2 and AF8 induce ovRT1 effects, AF3, AF4, and AF9 induce ovRT2 effects, whereas AF1 induces ovRT4 effects. The other ovRT categories were recorded after the addition of FLPs identified from the free-living nematode *Caenorhabditis elegans* FLPs.[24]

Ascaris suum Pharynx

Two studies report the effects of six FLPs on serotonin-induced pharyngeal pumping activity in adult *A. suum*. Although AF1 and AF8 inhibit the serotonin-induced excitation, AF2, AF3, AF4, AF6, and AF16 have no significant effects on this activity.[24] More recently, the impact of AF21, AF22, and AF23 on both spontaneous small amplitude spikes that occur in the absence of pumping and on larger, serotonin-induced, larger amplitude spikes was reported.[35] All three FLPs reversibly inhibit both spontaneous small and induced large amplitude spiking. The AF22 effects are the most persistent, lasting for 8–9min compared to the 1–3min effects of AF21 and AF23.

Parasite Behavior, Body Length, Phenotype

The influence of peptide injection into the body cavity (pseudocoel) of adult female *A. suum* on body length and behavior/posture has been examined for a variety of FLPs. Most commonly, test peptides are administered via injection into the pseudocoelomic cavity of female *A. suum* that have been ligatured by the head to initiate an undulating waveform. The injected peptides disrupt locomotory behavior in one of two ways. First, by either completely abolishing all rhythmical movements and producing a straight worm or secondly, reducing the number and propagation of locomotory waveforms. [28]

The injection of AF1 or AF2 inhibits locomotory wave propogation, reduces waveform formation, and diminishes body length;[4,27] AF2 induces occasional abrupt, jerky movements.[7] Further, injections of AF1, AF2, AF5, or AF7 reduce locomotory activity with AF1 and AF5 also causing a linearization of body posture.[7] AF8 injections abolish locomotory activity and induce ventral coiling and head tremors.[7,27] AF9

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

reduces worm motility and head searching activity with postural changes comprising anterior linearization and highly variable posterior coiling phenotypes; AF17 also reduces worm movement but increased body length. By contrast, the peptide products of *afp-1* (*As-flp-18*), including AF3, AF4, AF10, AF13, AF14, and AF20, induced exaggerated postures while increasing waveform frequency, head-thrashing and coiling; head searching activity is blunted and AF10 also decreases body length.[7,27]

Head searching and locomotory activities are abolished by AF15, AF17, AF19, AF21, AF22, and AF23;[7,27,35] with the injection of AF15, AF17, or AF19 the resultant inactive worms display a curved body posture. Additional observations on the effects of AF21, AF22, and AF23 center on persistence with AF21 effects diminishing within 2–3h, whereas those for AF22 and AF23 persisted for >11h and for 6–9h, respectively.[35] AF6 and AF16 injections have little obvious impact on worm posture/behavior.

One study showed that FLRFamide enhances body movement frequency in the plant parasite *M. incognita* although there is no effect on stylet activity.[19]

The development of RNAi-based reverse genetics approaches in some parasitic nematodes has facilitated the selective knockdown of *flp*-encoding genes and subsequent assessment of the phenotypic consequences using behavioral assays. At this time, two studies report that *flp* gene knockdown alters normal behavior in the infective J2 stage of the plant parasitic nematodes *G. pallida* and *M. incognita*.[5,16] The silencing of any one of five *flp* genes in *G. pallida* J2 worms (*Gp-flp-1*, *Gp-flp-6*, *Gp-flp-12*, *Gp-flp-14*, *Gp-flp-18*) or of *Mi-flp-18* in *M. incognita* J2 worms trigger profound motor dysfunction with a subsequent reduction in the ability of worms to migrate through a sand column. After 24h of continuous exposure to the specific RNAi trigger (double-stranded RNA or short interfering RNA complementary to the target gene transcript), migration is dramatically reduced by between 71% and 100% for all genes examined (*Gp-flp-1*, 98%; *Gp-flp-6*, 94%; *Gp-flp-12*, 100%; *Gp-flp-14*, 71%; *Gp-flp-18*, 100%; *Mi-flp-18*, 98%). The influence of silencing genes that encode a single FLP (*Gp-flp-6*, *Gp-flp-12*, *Gp-flp-14*) is as dramatic as RNAi of *flp* genes encoding multiple structurally related FLPs (*Gp-flp-1*, *Gp-flp-18*, *Mi-flp-18*). Observations of the *G. pallida* J2 worms post-RNAi reveal distinctive phenotypes associated with the knockdown of each gene transcript, with worms appearing as slow, stationary, twitching, coiled, or straight. Taken together, these RNAi data support critical roles for each of these *flp* genes in worm migratory behavior.

Ascaris suum Motorneuron Activity

Since demonstration of the inhibitory effects of AF1 on *A. suum* dorsal (DI) and ventral inhibitory (VI) motorneurons,[4] the effects of AF5, AF7, and AF11 were tested on multiple motorneuron subtypes,[6] a further 14 *Ascaris* FLPs (AF2, AF3, AF4, AF6, AF8, AF9, AF10, AF13, AF14, AF15, AF16, AF17, AF19, AF20) were tested on *A. suum* DI and dorsal excitatory 2 (DE2) nerves[7] and a further three FLPs (AF21, AF22, AF23) were tested on DI, dorsal excitatory 1 (DE1), and DE2 motorneurons (35). A wide variety of FLP effects on *A. suum* motorneurons have been shown and, before the work on AF21, AF22, and AF23, these were subdivided into five motorneuron response types (designated here as mnRT1 to mnRT5).

The first response type (mnRT1) occurs upon the addition of the FIRFamides (AF1, AF5, AF6, and AF7), which induces depolarizing effects on DE2 and hyperpolarizing effects on DI motorneurons. Although AF1 causes the most dramatic reductions in DE2 input resistance, the effects of AF6 and AF7 on both DE2 and DI are weak. The mnRT2 is observed upon superfusion with AF2, which induces a unique biphasic response in the input resistance of DE2 motorneurons; this response comprises an early transient increase followed by a sustained increase in input resistance. The AF2-induced DE2 depolarization is the largest recorded for any FLP. AF2 has no significant effects on DI motorneurons. A weak, transient DE2 hyperpolarization followed by a prolonged depolarization, sustained in the absence of input resistance, changes typifies the mnRT3 effects of AF9. AF9 effects on DI comprise a weak, transient hyperpolarization. AF8 induces mnRT4, which encompasses a profound depolarization of DI and a small hyperpolarization of DE2 motorneurons. AF17 and AF19 both induce mnRT5 dominated by strong hyperpolarizations and input resistance decreases in both DE2 and DI. Indeed, the strongest DE2 hyperpolarizations are seen with AF19.

Delineation of the effects of the *afp-6* (*As-flp-11*) encoded peptides AF21, AF22, and AF23 on *A. suum* motorneurons does not include mnRT assignments.[35] Although AF21 and AF23 cause marked depolarizations of DE1, DE2, and DI motorneurons concomitant with strong input resistance increases, AF22 causes hyperpolarization of the same three motorneuron subtypes with associated, small input resistance increases. Notably, AF23 induces hyperpolarizations of DE2 and DI motorneurons completely reverse AF21 and AF23 induced depolarizations of these neurons and seem to involve a calcium-dependent mechanism. It has been hypothesized that the apparently antagonistic actions of the hyperpolarizing AF22 versus the depolarizing AF21/AF23 could be allayed by the differential distribution of their cognate receptors/sites of action.

Second Messenger Signaling Components

The influence of numerous parasitic nematode FLPs on levels of the second messengers cyclic adenosine monophosphate

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

(cAMP) and cyclic guanosine monophosphatre (cGMP) has been examined in *A. suum*; additionally, the influence of AF3 on cAMP levels in *A. galli* have been reported.[27,28,30,32] Levels of cAMP in *A. suum* muscle strips or whole worms increase significantly after treatment with the FLPs AF1 or AF2; although the effects of AF2 on cAMP are the most dramatic, it has no effects on cGMP whereas AF1 significantly increases the levels of both cAMP and cGMP in whole worms.[28] AF1 increases cAMP levels in the head region of *A. suum*. By contrast, AF3, AF5, and AF17 induce decreases in cAMP levels, although the effects of AF5 are small; AF3 also decreases cAMP levels in *A. galli*.[27,28,32] Surprisingly, *afp-11* (*As-flp-1*) encoded peptides have a variety of effects on cAMP levels in *A. suum*, including no significant effect (AF11, AF27 {PADPNFLRFamide}, AF28 {SAEPNFLRFamide}, AF32 {GSDPNFLRFamide}, AF33 {SNQAQNFLRFamide}), reduced cAMP levels (AF25 {NNFLRFamide}, AF26 {KPNFLRFamide}, AF29 {NAEPNFLRFamide}, AF41 {KPNFIRFamide}) or increased cAMP levels (AF31); AF26, AF28, AF33, and AF41 all reduce cGMP levels in whole worms.[28] Of the other FLPs tested on *A. suum* whole worms, AF9, AF19, AF30, and AF34 (DSKLNDPLIRFamide) significantly diminish cAMP levels; AF19 also reduces cGMP levels.[28] AF21, AF22, and AF23 all caused a significant reduction in whole *Ascaris* cAMP levels, but only AF23 has an effect on cGMP levels, also causing a significant reduction. AF3, AF4, AF8, AF10, AF11, AF13, AF15, AF27, AF32, AF35 (DPQQRIVTVETVLRFamide), and AF36 (VPSAADMMIRFamide) have no significant effects on the levels of *A. suum* cAMP or cGMP in whole-worm preparations.[27,28,30]

NEUROPEPTIDE-LIKE PEPTIDES (NLPs)

Discovery—Structure of the Precursor mRNA/Gene

Originally described in *C. elegans*, NLPs comprise a disparate group of neuropeptides that encompasses peptides from a diverse array of conserved peptide families and other peptides that appear to be unique to nematodes.[17] Currently, the total number of annotated *C. elegans nlp* genes is 47. A targeted BLAST survey of nematode parasite genomes and transcriptomes for a repertoire of 45 *C. elegans nlp* genes identified 26 of these as occurring in multiple nematode species[23]; the discovery of *nlp-46* in *C. elegans* and multiple nematode parasites was also reported (Table 4). Note that *nlp-24* to *nlp-33*, inclusive, are proposed to be antibacterial peptides and will not be discussed further here. Of the remaining 36 putative NLP-encoding genes in *C. elegans*, genes/gene transcripts encoding structurally similar NLPs from 26 of these genes have been identified in parasitic nematodes, including *nlp-1*, *nlp-2, nlp-3*, *nlp-5*, *nlp-6*, *nlp-7*, *nlp-8*, *nlp-9*, *nlp-10*,

**Peptides in bold typeface have been confirmed by mass spectrometry. a,b, indicate more than one genome survey sequence predicted to encode some common and some different NLPs. For NLP sequences in bold typeface, C-terminal amides or Gly residues are shown where these have been confirmed by mass spectrometry; C-terminal amides have been inserted on those predicted peptide sequences, which are coencoded with known amidated peptides, that is, C-terminal Gly residues in sequences not given in bold could indicate amidation. Data derived from Refs. 10, 22, 23, 34.*

nlp-11, *nlp-12*, *nlp-13*, *nlp-14*, *nlp-15*, *nlp-17*, *nlp-18*, *nlp-19*, *nlp-20*, *nlp-21*, *nlp-22*, *nlp-37*, *nlp-38*, *nlp-42*, *nlp-43*, *nlp-44*, and *nlp-46*. The vast majority of these await confirmation of peptide sequence and expression.

Mass spectrometric–based peptidomic studies on neuronal ganglia of *A. suum* were the first to report identification of some non-RFamide peptides including peptides that were NLP-12-like (DYRPLQFamide, DGYRPLQFamide, KSYRPLQFamide, SYRPLQFamide, qDRDYRPLQFamide) and two WNamides (NRRRNAAARWNamide and NRRRNATNRWNamide) that were also identified on an *A. suum* EST.[34] The *nlp-12* transcripts from *A. suum* (*As-nlp-12*) and the sheep parasite *Trichostrongylus colubriformis* (*Tc-nlp-12*) were cloned and sequence confirmed.[22] More recently, a combination of database mining and tandem mass spectrometry identified multiple NLPs in adult *A. suum*.[10] This study identified a variety of putative *A. suum nlp* genes within the genome survey sequences using BLAST and peptides encoded on nine of these *As-nlp* genes were verified by mass spectrometric methods (Table 4).

As with *flp* genes, analysis of two published plant parasitic nematode genome sequences[1,12] for *nlp* genes reveal a reduced NLP complement compared to *C. elegans* with *M. incognita* having 21 and *B. xylophilus* having 17 *nlp* genes compared with *C. elegans* 47 *nlp* genes (Table 3).

NLP Distribution/Expression

The polymerase chain reaction (PCR) was used to detect *Tc-nlp-12* transcript in both the adult and infective third larval stage (L3) of *T. colubriformis*; ISH detected transcript in the tail, matching the expression pattern known for *C. elegans.*[22] Peptide masses matching those predicted on *As-nlp-3*, *As-nlp-5*, *As-nlp-7*, *As-nlp-8*, *As-nlp-9*, *As-nlp-15*, *As-nlp-21*, and *As-nlp-23* were identified in *A. suum* head extracts.[10] Mass spectrometry detected NLP-12 peptides in the *A. suum* nerve ring, retrovesicular ganglion, and ventral and dorsal nerve cords; the same approach detected RWNamides in the nerve ring, ventral ganglion, and retrovesicular ganglion.[34]

Biological Actions of NLPs

To date, a small number of *A. suum* NLPs have been tested for biological activity.[22,23] The NLP DYRPLQFamide (encoded on *As-nlp-12*) causes contraction of both dorsal and ventral *A. suum* body wall muscle strips, effects, which are not nerve cord dependent.[22] This peptide is inactive on the *A. suum* ovijector. Selected *C. elegans* NLPs are also active on *A. suum* body wall muscle including AVNPFLD-SIamide (*nlp-3*) and AFAAGWNRamide (*nlp-23*), which are both inhibitory, and AIPFNGGMYamide (*nlp-10*), which is excitatory.

INSULIN-LIKE PEPTIDES (INSs)

Discovery—Structure of the Precursor mRNA/Gene

INS peptides are typically characterized by A and B chain polypeptides, and in *C. elegans*, they modulate development, growth, and reproduction and are intrinsically linked with the development of the dauer or resting stage of this nematode. Currently, data on INSs in parasitic nematodes are restricted to the identification of putative *ins* genes in the genome of the plant parasitic nematode *B. xylophilus;*[12] these authors reported only three *ins* genes in *M. incognita* (unpublished). The *B. xylophilus* genome encodes seven *ins* gene orthologs, significantly less than *C. elegans*, which has 40 (including 39 *ins* genes and *daf-28*) (Table 3). Although this is only a small snapshot of INS diversity in parasitic nematodes, it could suggest that compared with *C. elegans* the INS peptides are even more dramatically constricted within the parasitic nematodes than the FLPs or NLPs.

Chapter 41

Pigment Dispersing Factor

Liesbet Temmerman, Ellen Meelkop and Liliane Schoofs

ABSTRACT

Pigment-dispersing hormones (PDHs) and pigment-dispersing factors (PDFs) make up a conserved family of signaling molecules thus far only identified from invertebrate sources. They all act on their respective G-protein-coupled receptors and can act both as neurotransmitters and neurohormones. Although PDF receptors are homologs of the vertebrate VPAC2 receptor, PDF sequences have never been found in vertebrates and only a functional homology to VIP has been described. In all invertebrate PDF systems studied, a clear role in the modulation of and response to environmental signals has been described. In crustaceans, PDH is an activator of rapid pigment dispersion in response to bright light. Insect PDFs, and possibly crustacean PDH, are of crucial importance to the endogenous biological clock that keeps track of the day/night rhythm. In nematodes, PDFs exert an overt role in the regulation of locomotion. This chapter summarizes the different invertebrate PDH-like signaling systems.

DISCOVERY

The first evidence of the existence of pigment dispersion controlling hormones dates from the beginning of the twentieth century. Injection of hemolymph from a dark colored shrimp (*Crangon crangon*) into a pale one caused the latter to darken by pigment dispersion as well. The eyestalks turned out to be the source of a peptide now known as pigment-dispersing hormone (PDH).[17] The first PDH peptide to be fully characterized at the protein level was isolated from *Pandalus borealis*.[4,10] This octadecapeptide belongs to the family of α-PDH peptides, which are distinguished from β-PDH peptides by a Gly and Met at positions three and four respectively. Although the occurrence of α-PDH seems to be restricted to *Pandalus* and *Macrobrachium* species, β-PDH peptides could be identified in a wide variety of (mostly decapod) crustaceans.[20]

The first PDH-like peptide in insects was identified in the grasshopper *Romalea microptera* by proving its pigment-dispersing activity in the crab *Uca pugilator*.[19] It is more closely related to β-PDH than to α-PDH and was named pigment-dispersing factor (PDF), as indeed are all other identified PDH-like peptides in insects and nematodes.

Although the first PDH-like peptides in crustaceans and insects were identified by their pigment-dispersing abilities, more advanced techniques such as mass spectrometry and the molecular cloning of *pdh* and *pdf* genes in EST databases led to the vast expansion of known PDH-like peptides among arthropods. The elucidation of the complete genome of the nematode *Caenorhabditis elegans* allowed for the identification of these peptides via reverse pharmacology. The predicted PDF receptor was cloned and subsequently used to search for the nematode's PDF ligands.[8] Although some crustaceans express both α- and β-PDH peptides—or several β-PDHs—by alternative splicing of their mRNA precursor, most insect species seem to contain only a single *pdf* gene. Nematodes, in contrast, express two different *pdf* genes: *pdf-1* and *pdf-2*, encoding for three PDF peptides: PDF-1a, PDF-1b, and PDF-2.[9]

STRUCTURE OF THE mRNA/GENE

Although cDNA sequences are available for several decapod crustaceans, the only crustacean with a completely sequenced genome is the cladoceran *Daphnia pulex*. The *pdh* gene of *D. pulex* contains two exons which give rise to a 169 amino acid (aa) long precursor protein (Fig. 1). This precursor contains a 28 aa long signal peptide, a 120 aa long PDH precursor related peptide (PPRP), and an 18 aa long PDH peptide.[22]

The *Drosophila melanogaster* PDF-encoding gene is intronless and encodes the 102 aa long preproPDF. This precursor contains a 16 aa long signal peptide, followed by a sequence of 63 aa termed PDF-associated peptide (PAP) (Fig. 1). The PAP region contains another cleavage site that could result in peptides of 18 and 43 amino acids.[16] The PAP region is highly diverged from those of the crustacean precursors, although the primary structure of the mature PDF is highly conserved among all members of the pigment-dispersing hormone family.

FIGURE 1 Alignment of PDH and PDF precursor proteins. *D. pulex* (*Dp*), *D. melanogaster* (*Dm*), and *C. elegans* (*Ce*) precursor proteins are similarly structured, starting with a signal peptide (italic), followed by a PDH precursor related peptide (PPRP), PDF-associated peptide (PAP), or linking peptide (bold) and the actual PDH/PDF peptides at the C-terminal end. Identical amino acids are highlighted in black, conserved amino acids in dark gray. Proteolytic cleavage and amidation sites are in lower case, and PDH/PDF peptides are underlined (aligment made with MUSCLE[2] and BoxShade v3.21).

The *C. elegans pdf-1* gene is a three exon containing gene generating two different transcripts through alternative splicing: *pdf-1a* and *pdf-1b*. Both precursors contain both PDF-1a and PDF-1b peptides (Fig. 1).[9] In addition, *pdf-1a* and *pdf-1b* precursors encompass a 29 aa signal sequence and a linking peptide, which were found in the HPLC fractions of *C. elegans* peptide extracts (SPLLYRAPQMYDDVQFV and SPLLYRAPQYQMYDDVQFV). The two different precursors differ from each other in two amino acids in this linking peptide of unknown function. The *pdf-2* gene also includes three exons but generates only one transcript and one pre-pro-protein containing one PDF-2 peptide. No linking peptide was found in the PDF-2 precursor.[9]

PROCESSING OF THE PRECURSOR

All PDH and PDF precursor proteins are similarly structured, containing a signal peptide on the N-terminal side followed by a PPRP (crustaceans), PAP (insects), or linking peptide (nematodes) of unknown function, a cleavage site, the mature peptide and a processing site. Note that the PPRP of *D. pulex* and the PAP of *D. melanogaster* include potential cleavage sites. The processing sites of the fly's preproPDF seem to be different from those of crustacean PDH and nematode PDF precursors. The proteolytic cleavage site preceding the mature PDF consists of triple basic amino acids (RKR), in contrast to the dibasic crustacean and nematode cleavage site (KR). Also, the α-amidation signal for decapod crustacean PDHs and *C. elegans pdf-1a* and *b* (GRR) is different from that of the fly's PDF and *C. elegans pdf-2* (GK). *D. pulex* forms an exception by containing a single Gly.

DISTRIBUTION OF THE mRNA/PEPTIDE

The PDF system probably represents the best studied invertebrate neuropeptide network. For several decades now, numerous studies of detailed *pdf* mRNA and/or PDF peptide localization have been conducted. Even though substantial interspecies differences exist, there is always a tight association with the visual system for crustaceans and insects. Initial studies of PDH localization have logically focused on the eyestalk expression patterns, but later studies also included the entire brain and the abdomen. Comparison of

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

these localization studies reveals that the majority of PDH-immunoreactive cells and projections are indeed in the eyestalks and the median protocerebrum.[1,5] The identity and number of abdominal PDF-positive neurons tend to vary most between species. It has been suggested that in the abdomen, PDF could be released into the hemolymph, subsequently acting as a hormone.[18] Both PDH and PDF are observed throughout all developmental stages into adulthood.[5,6]

Nearly all hemimetabolan insects studied so far are hallmarked by three distinct PDF-positive neuron clusters per brain hemisphere: one at the anterior edge of the medulla (PDFMe) and two at either the posterior dorsal or the posterior ventral edge of the lamina (PDFLa) (Fig. 2). Nevertheless, the number of neurons in a cluster and the individual neuron size may differ between species. The contralateral projections of the PDFMe neurons are believed to be involved in the coupling of the two brain hemispheres, which is essential for the proper functioning of the biological clock (see below).[15] This is also true for holometabolan organisms, which however do not seem to express PDF in the PDFLa clusters. The PDFMe clusters comprise the only PDF-positive neurons in the brain of adult *D. melanogaster*, but in other holometabolans, additional clusters can be present. The fruitfly differs slightly from the general holometabolan PDF neuron architecture in that the PDFMe neurons do not project to the lamina. Therefore, although *D. melanogaster* is by far the best-studied insect considering the PDF system, here the more general holometabolan network organization is exemplified by the blowfly PDF system (Fig. 2).[11,15]

As a result of the close association with the visual system and the regulation of biological rhythms (see below), researchers have put effort into adding information on temporal changes of *pdf* mRNA/PDF peptide to the spatial distribution patterns. However, no general conclusions can be made. For some species, daily changes in mRNA and/or peptide levels have been reported, but for several others, no such changes could be detected.[12]

Because of the different body architecture, a comparison of crustacean PDH/insect PDF patterns with *C. elegans* localization studies is not directly possible. Via use of endogenous transcription of fluorescent reporter proteins under control of the *pdf-1/2* and *pdfr-1* promoters, several cells belonging to the nematode PDF system could be identified. PDF peptides are mainly detected in (chemo)sensory neurons, interneurons, and motorneurons, as well as in a few nonneuronal cells. *pdf-1* and

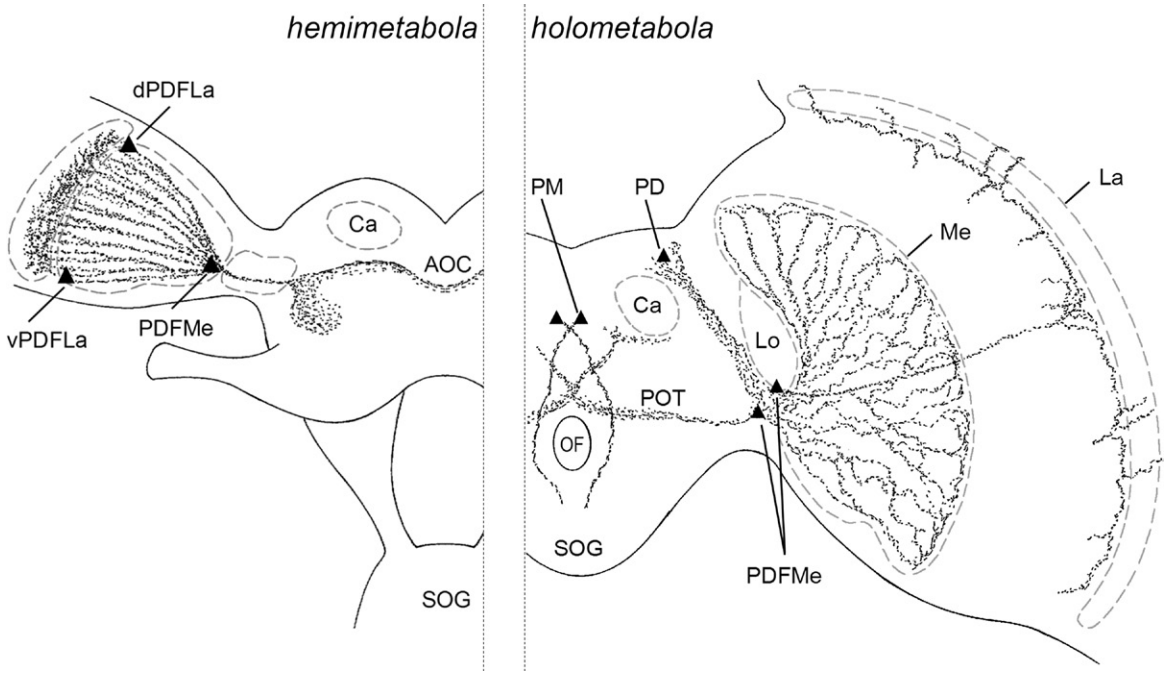

FIGURE 2 General PDF architecture of the hemi- and holometabolan brain. Three clusters of hemimetabolan PDF-producing cells (dPDFLa, dorsal PDFLamina cells; vPDFLa, ventral PDFLamina cells; PDFMe, PDFMedulla cells) provide fanlike ramifications in lamina (La), medulla (Me), and lobula (Lo) of the optic lobe and the lateral regions of the protocerebrum, and connect both hemispheres (AOC, anterior optic commissure). No PDFLa clusters are present in holometabolan representatives, PDFMe project in the lamina and the lateral region and connect both hemispheres (POT, posterior optic tract). Blowflies have two additional PDF-producing clusters per hemisphere in the posterior dorsal (PD) and medial (PM) regions of the brain. Ca, calyx of the mushroom body; OF, esophageal foramen; SOG, subesophageal ganglion; triangles represent cell clusters and not individual neurons (image adapted from Ref. 12 with permission from Elsevier).

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

pdf-2 patterns only partially overlap, suggesting at least in part specific functions. Expression of *pdfr-1* was also observed in several sensory and motorneurons, some of which coexpress the peptides. Prominent receptor expression is observed in all muscles of the body wall. *C. elegans pdf* mRNA levels do not vary over the course of the day.[8,9]

RECEPTORS AND SIGNALING CASCADES

The discovery of the *D. melanogaster* PDF receptor, several years after the peptides had been identified, represented an immense breakthrough to the field.[14] So far, of all invertebrates studied, only the fruitfly and worm PDF receptors have been found. They are all class B G-protein-coupled receptors that influence adenylate cyclase via Gαs (*D. melanogaster* PDFR and *C. elegans* PDFR-1a/b) or via Gαi (*C. elegans* PDFR-1c).[8]

D. melanogaster pdfr mutants phenocopy *pdf* mutant defects (see below), thus confirming the role of the PDF signaling system as a whole. In addition, several of the PDF-producing cells also present PDFR at their surfaces, supporting the hypothesis that the system feeds back on itself. Similar to the earlier mentioned *C. elegans* receptor, fruitfly PDFRs have been observed in several non–neuronal cells.[7]

Detailed studies in the fruitfly have added more insight into the "upstream" regulation of the PDF signal itself, thus contributing to the further elucidation of the signaling pathways. Molecular changes of several components of the endogenous biological clock (Cryptochrome, Clock, Cycle. PAR-domain protein-1) control the PDF signal. In addition other genes (Neurofibromin-1, Disconnected, Lark) play a role in this signaling system.[12] As PDF is contained within dense core vesicles, it is not surprising that membrane excitability, which regulates vesicle release, is an important level of control. As such, the ion channels Shaw, Narrow abdomen and Slowpoke, and the Slowpoke-binding protein, which interacts with the latter channel, are important in PDF signal regulation.[12]

After the peptide has been released, it may act directly as a neuromodulator or diffuse to more distant sites, functioning in a nonsynaptic, paracrine way.[13] Such a neurohormonal action is supported by the finding of PDFR at relatively remote sites.[7]

PDF signaling not only triggers further molecular changes, in flies the peptide also influences daily changes in size and shape of the L1 and L2 interneurons, which receive direct input from the photoreceptor cells of the retina.[13] Regulating neuron plasticity could also participate in the control of downstream (visual) information transmission.[3]

One of the major insights that the identification of the PDFR brought into the field, concerns the level to which this signaling system is conserved in vertebrates. Although the invertebrate peptides do not have sequence homologs in vertebrates, the PDFR sequence finds well-conserved vertebrate counterparts in the VPAC2 and calcitonin receptors. VPAC2 is a receptor for both vasoactive intestinal peptide (VIP) and pituitary adenylate-cyclase-activating peptide (PACAP). VIP is considered the functional homolog of PDF, and the VIP-VPAC2 system is of crucial importance to the vertebrate circadian clock.[12]

BIOLOGICAL ACTIONS

Logically inferred from its name, the peptide must have some connection with invertebrate pigment dispersion. It is indeed this exact function that caused the naming of crustacean PDH, which was found to regulate both integumental and eye pigment migrations. Integumental pigment dispersion caused by PDH is involved in rapid reversible color changes in crustaceans in response to several changes such as light condition, background color, temperature, stress, molting, or even mating. A circadian rhythm in these pigment migrations has been described, which is in part regulated by PDH.[12]

In addition, crustaceans have pigments in the eyes that regulate light sensitivity, acting as a natural pair of sunglasses. Daily migrations of two subsets of the eye pigments, named the distal and the reflecting pigments, are under the control of PDH.[12] The actions of PDH are nonetheless not limited to the control of pigment dispersion. PDH influences the sensitivity of the retinal response to light over the day–night cycle by interfering directly with photoreceptor depolarization.[25]

The identification of PDH-like peptides in insects soon made it clear that although these molecules could elicit pigment-dispersing responses when applied to crustaceans, they do not serve a similar purpose in insects. Because at that time, there was doubt about the endogenous mode of action in insects, the peptides were designated pigment-dispersing factors (PDFs), rather than hormones. Even though there is increasing evidence for a hormonal function in insects as well,[18] the terminology remained.

PDF has been studied as the major output factor of the insect circadian (24 h) clock, where it confers time information to the periphery. The circadian clock can most easily be seen as an endogenous rhythm generator consisting of several so-called clock neurons, which communicate with each other and with all other tissues in an animal to adapt an organism's physiology to the time of the day. PDF's output function is exemplified by the observation that both *pdf* and *pdfr* mutants gradually lose their daily activity rhythms when kept under constant darkness. Wild-type flies under these conditions have no trouble in communicating with their endogenous clocks, which keeps

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

them rhythmic in the absence of the external light–dark cycle.[21] PDF serves not only as an output factor but it also functions as a crucial network coordinator, enhancing the communication between different individual clock cells. When acting as a network regulator, PDF signaling adjusts circadian periods of target clock neurons, with a shortening or lengthening effect depending on the specific target cell.[27] The clock's systemwide modulating actions are taken to the next level when looking at social insects, where there is plasticity of circadian rhythms among colony members, depending on their specific tasks in the hierarchy. For example, small bumblebees stay in the nest to tend brood arrhythmically around the clock, whereas large bees display strong circadian rhythmicity and work outside the colony during daytime. It has been suggested that PDF could be responsible for regulating the system plasticity in such societies.[26] A function for PDH in the crustacean circadian clock has been proposed as well, but it needs further investigations.

In insects, PDF is widely studied, and apart from its actions in the central brain clock, additional functions in activity, reproduction, arousal, and geotaxis have been proposed. Geotaxis refers to the intriguing phenotype that induces a preference of movement away from or towards the source of gravity. Both *pdf* and *pdfr* mutant *D. melanogaster* display a higher tendency toward negative geotaxis (flying upwards) than wild-type flies do.[14,24] So far, no functional consequences of such preference could be assigned, and the phenotype, observed for a few other and apparently non-related gene mutations as well, remains a curiosity.

Deciphering the nematode PDF system is a slightly more challenging task, because the worms not only contain three distinguishable peptides but also produce three different receptor isoforms, which can all be activated by all peptides. *C. elegans pdf* genes are mainly expressed in neurons that fulfill a task in sensing and integration of environmental stimuli. Although these worms can detect light, they do not have a clear visual system such as that of insects or crustaceans. Nevertheless, based on its localization in neurons active in mechanosensation, oxygen sensing, chemosensation, or the control of locomotion, one can expect similar modulating actions of PDF on environmental perception and associated behavior. Although *pdf-1* mutants show an obvious locomotion phenotype, it has not yet been shown that the PDF peptides are also involved in the regulation of circadian activity, and the exact function of the PDF signaling system in this phylum remains elusive.[8,9,23]

Chapter 42

Proctolin

Angela B. Lange and Ian Orchard

ABSTRACT

The neuropeptide proctolin (RYLPT) was discovered in the cockroach, *Periplaneta americana*, where it was considered a neurotransmitter associated with hindgut visceral muscle. Proctolin was the first insect neuropeptide to be sequenced and is now known to be widely distributed in the nervous systems of arthropods and to be extremely active on a variety of arthropod muscle preparations. The genes for proctolin and its receptor have been cloned in a variety of insects but seem to be absent from the genomes of some other insects. Structure–activity studies have identified the critical positions in the proctolin structure for binding and biological activity, and agonists and antagonists have been designed. Many biological processes are influenced by proctolin, and proctolin is involved in regulating central neurons, and muscles associated with posture, and the digestive, reproductive, and circulatory systems. Proctolin may also be a neurohormone and may also act as a hormone-releasing factor.

DISCOVERY

The pentapeptide proctolin (RYLPT) was the first insect neuropeptide to be sequenced and synthesized.[26] The name is derived from its ability to stimulate hindgut (proctodeum) contractions in *Periplaneta americana* and by its presence within axons of the proctodeal nerve. Proctolin is present in a number of arthropods (insecta, crustacea, and chelicerata), identified more recently by mass spectrometry, where it is extensively distributed throughout the nervous system. Proctolin seems to be unique to arthropods, and there is no convincing evidence for its presence in other invertebrates or vertebrates. Unlike many biologically active peptides, proctolin is nonamidated and is not considered to be a member of an extended family of peptides; it has an identical amino acid sequence in all arthropods studied. There is one report, however, of the presence of proctolin along with an alternative sequence (AYLPT) in *Leptinotarsa decemlineata.*[25]

STRUCTURE OF THE mRNA/GENE

Proctolin is a small peptide, and early searches of the *Drosophila* genome databases failed to identify the proctolin gene.[28] However, several expressed sequenced tags (ESTs) were recognized in the *Drosophila melanogaster* genome database that encodes predicted genes containing the sequence RYLPT. One of these (CG7105) probably encodes the *Drosophila* proctolin precursor.[28] The predicted protein sequence for this gene has potential peptide cleavage sites flanking the RYLPT sequence (Fig. 1). The gene has 3 exons, and the preproprotein is 140 amino acids in length. This conceptual preproproctolin contains a secretion signal peptide (amino acids 1–38) followed by a single copy of the proctolin sequence, which is *C*-terminally flanked by a 94-amino acid peptide. A similar protein structure is found in *D. pseudoobscura.*[7] Interestingly, proctolin is yet to be chemically identified in *Drosophila*. The proctolin gene has now been predicted or cloned from a small number of insect species, including the red flour beetle *Tribolium castaneum* and the pea aphid *Acyrthosiphon pisum*.[5,6,15,29] No proctolin gene has been identified in searches of the genomes of honey bee *Apis mellifera*, mosquito *Aedes aegypti*, or silkmoth *Bombyx mori*, in which proctolin (and its receptor) are now considered absent.[24] Similarly, the gene for proctolin was suggested to be absent in the kissing bug *Rhodnius prolixus*,[19] but a reexamination has recently identified the gene (Fig.1) and authentic proctolin.[21] Recently, the first noninsect arthropod proctolin gene was reported, by way of an EST (FE183480), in the Pacific white shrimp, *Litopenaneus vannamei.*[16]

PROCESSING OF THE PRECURSOR

The biochemistry of proctolin biosynthesis and processing from its precursor in *Drosophila* has been suggested.[7,28] A signal peptidase probably cleaves Gly38-Arg39 and Gly31-Arg32 peptide bonds of the preproproctolin in *D. melanogaster* and *D. pseudoobscura*, respectively. This exposes the *N*-terminal Arg of proctolin without the need for a proprotein convertase (PC)-like endoprotease. It has been proposed that a second cleavage occurs at Arg44-Ser45 by a PC, since 2 of the 3 *D. melanogaster* PCs (FUR1 and FUR2) recognize and cleave between Arg–Ser of prodynorphin. This

FIGURE 1 Alignment of predicted proctolin-encoding prepropeptides in insects. Sequences were aligned with Clustal X for *Rhodnius prolixus*, *Tribolium castaneum*, *Acyrthosiphon pisum*, and *Drosophila melanogaster*. Amino acids highlighted in black are identical; those in gray are similar. Black bar indicates a possible second peptide. Note the conserved RYLPT for proctolin.

cleavage generates an Arg-extended proctolin intermediate that would need to be converted to proctolin in secretory granules by the action of a carboxypeptidase D. In all of the preproproctolin sequences, there is a suggestion of a second peptide immediately following the proctolin sequence, as shown in Fig. 1. It is unknown if this proctolin precursor associated peptide is actually processed or if it has any biological relevance.

DISTRIBUTION OF mRNA/PEPTIDE

In arthropods, immunohistochemical studies have indicated the presence of proctolin-like immunoreactive neurons distributed throughout the nervous system, but in insects, unlike many neuropeptides, no proctolin-like immunoreactive endocrine cells are associated with the midgut. Proctolin-like immunoreactivity is found in a variety of neuronal cell types, including interneurons, identified motoneurons projecting to visceral and skeletal muscles, and neurosecretory cells projecting to neurohemal areas.[2,14,20]

With the identification of the putative *Drosophila* proctolin gene, the power of in situ hybridization has now been combined with immunohistochemistry to provide a complete map of proctolinergic neurons in *D. melanogaster*. In situ hybridization with a probe against the *Drosophila* CG7105 transcript results in staining of cell bodies in the brain and ventral nerve cords of the third instar larvae of *D. melanogaster*.[28] The pattern of labeled cell bodies is very similar to that reported for proctolin-like immunoreactivity in *D. melanogaster*.[18,28] Neither immunohistochemistry nor in situ hybridization reveals any endocrine-like cells in the midgut. With regard to the ventral nerve cord, in situ hybridization reveals both lateral and medial cell body clusters, with both clusters showing stronger signals in the abdominal neuromeres than in the thoracic neuromeres. In the brain, there are hybridization signals in 2–3 lateral cell bodies in the protocerebrum and a set of 3 cell bodies lying ventrally within the tritocerebrum near the esophageal foramen. Interestingly, proctolin-like immunoreactive staining reveals that the 2–3 lateral cells of the protocerebrum are neurosecretory cells with axons projecting to the corpora cardiaca (CC) portion of the ring gland. In the CC, there are numerous varicose terminals displaying proctolin-like immunoreactivity.[28] Similarly, in crustaceans, proctolin-like immunoreactive neurosecretory cells project to the neurohemal pericardial organs (POs).[10]

RECEPTORS AND SIGNALING CASCADE

Early attempts at isolating proctolin receptors[7,12,20] made use of tritiated proctolin to bind to crude membrane preparations from locust hindgut and oviduct (two tissues highly responsive to proctolin). Proctolin binding was found to be time dependent, proportional to the concentration of membrane protein, saturable, specific, and reversible. Further work isolated proctolin-binding fractions from hindgut and from oviduct tissues by isoelectric focusing, anion exchange, HPLC, and size exclusion HPLC. The specific binding was detected in fractions with an elution volume equivalent to a molecular weight of 50 kDa. The G protein-coupled receptor (GPCR) CG6986 from the *Drosophila* genome database has been identified as a putative proctolin receptor[3,9] and verified by use of G protein-coupled receptors-β-arrestin2 interactions.[8] This *Drosophila* proctolin receptor is a typical GPCR with seven transmembrane regions. The unmodified protein has a mass of 62 kDa and shows only weak identity with other known GPCRs. The *D. pseudoobscura* genome possesses a highly homologous gene. The cloned DNA of the *D. melanogaster* proctolin receptor gene has been expressed in mammalian cells, and screening with neuropeptides reveals that the expressed receptor is specific for proctolin with an EC_{50} of 0.3 or 0.6nM.[3,9] Membrane preparations of mammalian cells transfected with the proctolin receptor have been used in competition studies. The putative proctolin receptor binds proctolin with high affinity (IC_{50}, 4nM).[9] Microarray analyses reveal the receptor transcript in head mRNA of different genotypes and under different environmental conditions. Northern blot analyses indicate that the proctolin receptor is only weakly expressed in embryos, larvae, pupae, and in the thorax and abdomen

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

of adult flies but is strongly expressed in the heads of adult flies.[3]

Immunohistochemistry with antibodies against the receptor reveals immunoreactive signals in the hindgut, heart, and in distinct neuronal populations within the CNS, and Western blot analyses reveal a band in tissue homogenates similar to the predicted size of the protein. Immunohistochemistry reveals the receptor is present in several neuropil regions and is associated with neurosecretory cell bodies in the adult and larval brain, but there is little evidence of proctolin receptor expression in thoracic and abdominal ganglia. Strong immunostaining is obtained in muscle layers of the *Drosophila* adult and larval hindgut, the aorta, and on neuronal endings in adult heart.[7]

Screening of the *A. gambiae*, *A. mellifera*, and *B. mori* genome databases has failed to reveal any potential proctolin receptor,[3,7] matching the absence of a proctolin gene in these species.

A few studies have examined the signaling cascade leading to target cell responses, and the majority of these have focused on the effects of proctolin upon muscle contraction. Proctolin uses different second messengers depending upon the target tissue. Thus, cAMP seems to mediate proctolin-induced increases in Ca^{2+} channel activity in crayfish muscle, proctolin-induced changes in voltage-dependent Ca^{2+} activity and nonvoltage sensitive K^+ activity in isopod muscle, and proctolin-induced increases in myogenic rhythm in some specialized locust muscle.[23] In several other arthropod muscles, proctolin increases inositol 1,4,5-trisphopsphate (IP_3) content and activates protein kinase C (PKC). Proctolin requires extracellular Ca^{2+} to elicit contractions in oviduct of *L. migratoria*. A model for proctolin's action on this preparation proposes that proctolin acts on a receptor to mediate an activation of receptor and voltage-operated Ca^{2+} channels, thereby resulting in an influx of extracellular Ca^{2+}.[30] Proctolin also stimulates the production of diacylglycerol and IP_3 suggesting the involvement of intracellular Ca^{2+} stores. The increased levels of intracellular Ca^{2+} act via calmodulin to stimulate muscle contraction. The increasing levels of Ca^{2+} are then buffered by an increase in efflux via a Na^+/Ca^{2+} exchanger and by sequestration into intracellular stores. In isopod muscle, proctolin induces a decrease in cGMP content via a PKC-dependent inhibition of guanylate cyclase, resulting in an increase in contraction.[23]

Numerous analogs have been synthesized in an attempt to gain an insight into the structure–activity requirements of proctolin and its receptor. These experiments have focused on the contractions of foregut, hindgut, oviduct, and cardiac muscle in a variety of insect species. Radioactively labeled proctolin has also been used to study the binding characteristics of receptors in membranes prepared from target tissues. These results have been well reviewed by a variety of authorse[12,22] In early studies,[27] it was found that removal of the *C*-terminal Thr, or its replacement with Ser, resulted in a loss of 99% of the peptide's activity. Replacement of any of the amino acids with its D isomer or with Ala illustrated that each of them are necessary for full activity with activities for the analogs ranging from 5 to 16% of the activity of equimolar proctolin. A number of di-, tri-, and tetra-peptide fragments are also inactive. One analog with significant activity, three times more potent as proctolin, was [Phe(*p*-OMe)^2]-proctolin. Other super analogs have also been made by modifying the second residue, and indeed, some antagonists have also been generated.[11,12] These latter observations, combined with the observation that Phe^2-proctolin has only 15% of proctolin's potency, leads to the conclusion that the aromatic ring in the second position is important in receptor binding. Other studies have also concluded the importance of the aromatic ring in the second position and further evidence for this has been derived from a theoretical analysis.[1] Thus, the total energy for the 5 most probable conformations of proctolin indicates the preferred conformation is a quasi-cyclic structure with the tyrosyl side chain pointing outwards. This would place it in an ideal position to interact with active sites on the receptor.

The majority of the published results concern the exchange of one or more of the 5 amino acids of proctolin with other natural or non-natural α-amino acids. In addition, some analogs have been generated, which modify the peptide backbone. As summarized,[12] of 100 synthetic proctolin analogs produced, 45 have myotropic activity on various insect visceral muscles. Of these, 40 are agonists, and 5 are antagonists, with [α-MeTyr^2]-proctolin being the most potent antagonist. The agonistic property is dependent on the *para* substitution at position 2, and on the presence of the peptide bond hydrogen atom between Arg^1 and Tyr^2 and between Tyr^2 and Leu^3. Additional substitution at the *meta* position of the Tyr phenyl ring facilitates interaction with the receptor. The Arg^1, Leu^3, and Pro^4 residues are essential for myotropic activity.

Classical structure–activity studies have certainly provided an insight into the possible interaction between the proctolin molecule and its receptor, and the importance of the individual amino acid residues in these interactions. They have also been important for identifying super analogs and antagonists of the proctolin receptor for applied purposes. Unfortunately, no studies have examined the effects of these analogs on functionally expressed receptors.

Once proctolin has activated its receptor, there must be some means of inactivating, removing, or otherwise terminating its action. Proctolin, injected into the hemolymph of *P. americana*, has a half-life of about 4min.[20] By following the fate of radioactively labeled proctolin, it was suggested that the initial inactivation step is cleavage of the Arg–Tyr bond followed by the cleavage of the

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Tyr–Leu bond, indicating an aminopeptidase as the primary inactivation mechanism. A number of *in vitro* studies have further indicated peptidases as responsible for the metabolic inactivation of proctolin.[7,20] By the use of a variety of tissue homogenates from *P. americana* (hindgut, leg muscle, brain, and terminal abdominal ganglion), a soluble aminopeptidase was identified as a key proctolin inactivating enzyme. These tissues also contained another peptidase that removed the *N*-terminal dipeptide of proctolin by the cleavage of the Tyr–Leu peptide bond. The Tyr–Leu cleavage site seems to be more important in tissues that are richer in proctolin, leading to the suggestion of the existence of a proctolinase. Hemolymph also contains the soluble aminopeptidase activity, but the second peptidase seems mainly responsible for proctolin degradation in cockroach hemolymph *in vitro* at neutral pH. Similar peptidases are found in homogenates of brain and thoracic ganglia of *Schistocerca gregaria*.[7] The enzyme responsible for cleaving the *N*-terminal dipeptide is mainly cytosolic, whereas the aminopeptidase is enriched in locust synaptic membranes and might therefore be considered a neuronal proctolinase. This proctolinase has a K_m of 23μM and is inhibited by amastatin. A similar amastatin-sensitive aminopeptidase is also considered to be the major proctolin degrading enzyme associated with locust oviduct and hindgut membranes. The enzyme responsible for removing the *N*-terminal dipeptide of proctolin has activity resembling that of mammalian dipeptidyl-aminopeptidase III (EC 3.4.14.4, DPP-III), which is an enzyme associated with the metabolism of enkephalin and angiotensin. Two proteins with relative molecular masses of 80 and 76K have been isolated from foregut membranes of the cockroach, *Blaberus craniifer*, and identified as insect orthologs of mammalian DPP-III.[17] The purified cockroach enzyme hydrolyzes proctolin with a K_m of about 4μM. The cockroach DPP-III is a metalloenzyme, inhibited by EDTA and by tynorphin, a peptide inhibitor of mammalian DPP-III. Subsequent analysis of the *D. melanogaster* DPP-III gene (CG7415) and cDNA sequences predicts the expression of two insect variants (89,194 and 81,937Da) resulting from different translational start sites.[17] When the smaller cDNA is expressed in S2 cells, there is the generation of the 82kDa DPP-III and an 86kDa protein, suggesting that some DPP-III undergoes posttranslational modification that influences protein mobility in SDS-PAGE. The majority of the recombinant DPP-III is located in the soluble fraction of transfected S2 cells, but a significant amount is also detected in washed membranes. A search of the genome databases of *D. pseudoobscura* and *A. gambiae* reveals DPP-III proteins that, like *D. melanogaster*, have amino acid sequences similar to the mammalian DPP-III with complete conservation of key catalytic and zinc-coordinating residues.[7]

BIOLOGICAL ACTIONS

Proctolin was originally isolated from *P. americana* based on its myostimulatory action on the hindgut and subsequently shown to be a potent stimulator of contraction of a variety of arthropod visceral and skeletal muscle.[20] Much of the research on proctolin has focused on its effects on muscle contraction, prompted in part because of the presence of proctolin within identified motoneurons projecting to various muscles. However, proctolin's relevance extends to other physiological and behavioral processes.

In addition to the cockroach hindgut, proctolin stimulates contractions of the foregut in *S. gregaria* and the midgut of *Diploptera punctata* and *L. migratoria* and therefore might be regarded as a major neuromuscular modulator in the gut of insects and crustacea.[10,12,20,22] Proctolin is also a potent modulator of reproductive tissue, stimulating contractions of the oviducts in *P. americana*, *Leucophaea maderae*, *L. migratoria*, and spermathecae in *L. migratoria* and *R. prolixus*. In addition, proctolin influences egg-laying activity of *A. mellifora* queens and promotes the onset of vitellogenesis in *B. craniifer*.[7,12] Proctolin also seems to be a cardioacceleratory peptide, increasing the rate and amplitude of contractions of hearts in several insects and crustacea, although interestingly the hearts of *Manduca sexta* and *Stomoxys calcitrans* are not responsive to proctolin. In addition, proctolin enhances contractions of skeletal muscle, such as the extensor tibiae in *L. migratoria*, the coxal depressor in *P. americana*, the ventral protractor muscle and the ovipositor opener muscle of *L. migratoria*. *In vivo* application of antiproctolin antiserum in *Gryllus bimaculatus* indicates that proctolin, which is present in antennal motoneurons, stabilizes the prolonged antennal forward position during flight.[4] Proctolin seems to be necessary to induce a large enough muscle tension to hold the antenna in a forward position during flight. This matches the observation that proctolin is found in slow motoneurons that control skeletal muscle involved in maintaining posture.[18] Within the skeletal and visceral muscle preparations described above, it is accepted that proctolin is a cotransmitter that acts alongside a more classical neurotransmitter, such as glutamate.

Immunohistochemistry and in situ hybridization indicate that proctolin is present within interneurons within the CNS. Dorsal unpaired median neurons can be activated by proctolin, and proctolin influences ovipositional digging behaviors when applied to abdominal ganglion VIII and alters the rhythmic bursting of centrally generated action potentials recorded from the oviducal nerve in *L. migratoria*.[13,14,18] However, the functional roles of proctolin centrally are not well understood in insects,[18] although more is known about proctolin's central actions in crustaceans. For example, proctolin activates the rhythm generating networks in the crayfish swimmeret system and the crab stomatogastric and cardiac ganglion. Proctolin is often colocalized along with other neuroactive chemicals that act in different

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

combinations as neuromodulators in these crustacean preparations.[10,18]

As mentioned earlier, immunoreactivity and *in situ* hybridization for proctolin reveal its presence in insect and crustacean neurosecretory cells. This, coupled with the detection of proctolin in insect hemolymph, is consistent with proctolin acting as a neurohormone.[2,7,14] A number of tissues that are not innervated (e.g., Malpighian tubules and upper lateral oviducts of *L. migratoria* and the heart of *P. americana* and *Tenebrio molitor*) are sensitive to proctolin, and so proctolin may be acting upon these tissues in its capacity as a neurohormone. Similarly, proctolin is found in the POs of crustaceans suggesting a neurohormonal role, but proctolin is yet to be demonstrated in the hemolymph. Criticism of this neurohormonal concept has been made because of the short half-life of proctolin when injected into the hemolymph. However, it has been pointed out that the concentration of any active peptide in the vicinity of a receptor is determined by a number of factors, including the rate of release, hemolymph flow, and distance from the release site to the receptor and therefore is not only a function of the rate of metabolism.[7] These points, along with the fact that responsive tissues are activated very quickly by proctolin at low concentrations suggest that a half-life of 4min does not argue against proctolin as a neurohormone. The role of proctolin in lateral neurosecretory cells projecting to the CC/CA in *L. migratoria* and to the CC in *D. melanogaster* has been investigated. In *L. migratoria*, proctolin may well be a neurohormone[2,14] but may also be a releasing factor for other hormones associated with the CC/CA. Thus, proctolin stimulates the release of adipokinetic hormones from the glandular lobe of the CC and also stimulates the production and release of juvenile hormone from the CA in *L. migratoria*.[2] In *D. melanogaster*, proctolin is colocalized with corazonin in the lateral neurosecretory cells in the brain. Corazonin has different actions in different insect species and seem to be involved in the control of heart, morph-specific color changes, silk gland activity, larval ecdysis behavior, and the circadian clock system. Ectopic expression of the proctolin gene in the CNS and midgut of *D. melanogaster* has been used to overexpress proctolin in pupae. Within these pupae, there is a 14% increase in the heart rate suggesting a cardioacceleratory endocrine function for proctolin.[28] Thus, there can be no doubt as to the importance of proctolin as a neuroactive chemical in arthropods, where it functions in quite diverse roles, roles that far exceed the original discovery of it being a cockroach hindgut neurotransmitter.

Chapter 43

Sulfakinins

Liliane Schoofs, Tom Janssen and Ronald J. Nachman

ABSTRACT

Sulfakinins constitute a family of arthropod neuropeptides that typically contain the C-terminal heptapeptide Y(SO_3H)GHMRFamide. They display structural and functional similarities to the vertebrate gastrin-cholecystokinin family of peptides. Sulfakinins are synthesized by a limited number of neurosecretory cells and exhibit several effects, including myotropic activities, inhibition of food intake, and stimulation of digestive enzyme release. In many cases, the sulfate group is a requirement for biological activity. The gastrin/CCK and sulfakinin signaling system is a good example of the coevolution of neuropeptides and their receptors.

DISCOVERY

Sulfakinins are arthropod neuropeptides that typically contain a sulfated tyrosine residue—hence their name. They are characterized by the C-terminal heptapeptide XY(SO_3H) GHMRFamide (X = D or E) and display structural and physiological similarities to gastrin and cholecystokinin (CCK), their sulfated neuropeptide counterparts in vertebrates.[27] The initial evidence indicating that gastrin/CCK-like peptides are present in invertebrates came from immunocytochemical studies using gastrin and CCK antibodies on the insect neuroendocrine system and on various tissue extracts of 26 other species of invertebrates, including the phyla of Mollusca, Annelida, Arthropoda, and Ectoprocta. The first sulfakinins were isolated by conventional bioassay-monitored chromatographic purification of thousand(s) of nervous tissue extracts.[6,27] The release of insect genomes (from *Drosophila melanogaster*, *Anopheles gambiae*, *Aedes aegypti*, *Bombyx mori*, *Apis mellifera*, *Triboleum castaneum*) combined with very sensitive mass spectrometry has provided a powerful tool for peptidomic experiments. These reduce not only the starting material needed but also the time required to isolate and sequence the peptides from years to days and allowed the identification of sulfakinins in numerous arthropods, except for the parasitic wasp, *Nasonia vitripennis* and the pea aphid.[1,3,12–14,31,32,34] Sulfakinins have also been identified in chelicerate[2,7] and crustaceans.[4,5,16,20,33] Interestingly, one of the isolated forms in *Litopenaus vannamei* is disulfated,[33] a feature also found in cionin, the CCK in the protochordate *Ciona intestinalis*. At present, around 40 sulfakinin sequences are known (Fig. 1).

STRUCTURE OF THE mRNA/GENE

To date, genes encoding sulfakinins have been identified in *D. melanogaster*, *Calliphora vomitoria*, *Anopheles maculates*, *A. gambiae*, *A. mellifera*, and *Gryllus bimaculatus*.[6,13,22,28,31] Northern blot analysis in *Gryllus* showed that the sulfakinin gene is only expressed in the brain, as a single transcript.[22] The translation product generally contains an N-terminal signal peptide, followed by a long interspace sequence, ending with the highly conserved sulfakinins (two) encoding region, directly followed by a stop codon. The sulfakinin-encoding sequences are separated by conventional dibasic cleavage sites. Recognition of other dibasic endoproteolytic cleavage sites in nonconserved regions would result in the processing of additional peptides that are not similar to each other, nor to the sulfakinin peptides. Such an additional neuropeptide (DSK 0) in *Drosophila* shares the SFamide C-terminus with myotropins found in nematodes and sea urchins.[29]

PROCESSING

After cleavage from their inactive propeptide sulfakinin precursor (most likely by subtilisin-like proprotein convertases), sulfakinins undergo further posttranslational modification.[30] The tyrosine residue can be sulfated, most likely by a tyrosyl protein sulfotransferase. Both nonsulfated and sulfated forms have been biochemically isolated, although it is not clear whether this is due to the loss of the unstable sulfate group during isolation procedures. The N-terminal glutamate can be modified into a pyroglutamate residue. Further, the presence of a naturally occurring perisulfkinin with O-methylated glutamic acid has also been shown. Finally, all sulfakinins are amidated at their C-terminus (most likely by a peptidyl-amidating monooxygenase).

TISSUE DISTRIBUTION

Sulfakinins are expressed in the CNS of all developmental stages in dipterans and decrease with age in female crickets.[22,28] In Diptera, they occur in a limited set of neurons in the brain (four pairs in *C. vomitoria*) and in extensive arborizations of dendrites in the CNS neuropile (Fig. 2), suggesting a neurotransmitter or neuromodulator function. Such a neurotransmitter function for sulfakinins seems to be a general characteristic feature across insect orders. In contrast to flies and crickets, the expression of sulfakinins does not seem to be restricted to neurons and axons in the CNS and are also localized in the sympathetic nervous system innervating the crop in the cockroach *Periplaneta americana*.[10,30] In the latter and in the mosquito, *A. aegypti*, endocrine cells of the midgut were immunostained as well. Mass spectrometric profiling unambiguously identified sulfakinins in the brain and in the stomatrogastric nervous system of adult locusts, including esophageal nerves innervating the foregut, but neither in the corpora cardiaca nor in the thoracic or abdominal ganglia.[3] The hormonal role of sulfakinins is questioned because no evidence for a release site has been found.[3,6]

An immunoreactive fiber projects away from the central nervous system in an abdominal ganglion (filled arrow). Bar: 50 μm. From R. Nichols and I.A. Lim, Spatial and temporal immunocytochemical analysis of drosulfakinin (Dsk) gene products in the *Drosophila melanogaster* central nervous system. *Reproduced from Ref. 28, with the kind permission of Springer Science and Business Media.*

RECEPTORS

CCK and sulfakinin G-protein-coupled receptors share a very high degree of sequence similarity (>60%) and are considered to originate from a common ancestor. *Drosophila* has two sulfakinin receptors (DSKR), encoded by two loosely linked genes (~30 kb apart).[17] Interestingly, the two orthologous *Caenorhabditis elegans* receptors represent splice isoforms encoded by the same gene.[15] So far, sulfakinin receptors have also been identified in the insects *A. aegypti*, *A. gambiae*, *Culex quinquefasciatus, T. castaneum* and are predicted in the crustacean *Daphnia pulex* and the chelicerates *Ixodes scapularis* and *Dermacentor variabilis* as well as several nematodes, including *Brugia malayi* and in the flatworm, *Clonorchis sinensis*.[7,15]

In a cellular system, expressing the *Drosophila* sulfakinin receptor, unsulfated sulfakinin is 3000 times less potent than the sulfated form, indicative of the importance of the sulfate moiety for receptor activation. However, for the nematode receptors, no difference in response to sulfated and nonsulfated peptides was found.[15] The observed calcium signaling in cells expressing the DSKR was PTX insensitive, indicating that the receptor couples exclusively to the Gq type of Gα subunit. This is in agreement with mammalian CCK receptors where CCK-8 activates phospholipase C, triggering an increase in IP_3 production. The minimum sequence (active core) capable of eliciting a response is the C-terminal hexapeptide, Tyr(SO_3H)–Gly–His Met–Arg–Phe–NH_2, the His (or alternate aromatic residue), Arg (or alternate basic residue), and Phe residues being critical for activity. Human CCK-8 and gastrin II were unable to activate the drosulfakinin receptor.[17] However, replacement of the Asp residue with Arg in both gastrin and CCK can confer activity in the insect bioassay.[24] For myotropic activity, the sulfated tyrosine is a strict requirement for activity, although its position within the sequence[26] is not critical. This indicates that the sulfakinin receptor site demonstrates a degree of flexibility with respect to the interaction with the sulfate group and suggests that the movement of this group could occur during the molecular evolutionary process. The sulfate group is also a requirement for food intake inhibition activity in locusts and cockroaches.[18,26,35] Replacement of the acidic, unstable Tyr(SO_3H) group in sulfakinins by stable, acidic α-aminosuberic acid, which lacks a phenyl ring, is accompanied by the retention of cockroach myotropic and locust food intake–inhibition activity.[26] Replacement of the basic Arg in the sulfakinins and acidic Asp in the analogous position of CCK with neutral Pro is accompanied by a significant retention of bioactivity,[25] leading to an argument that these residues do not directly interact with the receptor but may stabilize the active conformation. This is consistent with an aqueous solution conformation study of a sulfakinin, which revealed a

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

relatively rigid a-helical loop structure stabilized by alternating salt bridges between Arg and two acidic residues in the N-terminal region and between His and Tyr(SO_3H).

BIOLOGICAL ACTIONS

Sulfakinins affect several biological processes. They increase the frequency and amplitude of foregut,[18] hindgut,[27,30] and heart[4,19,29] contractions in arthropods. Comparable with the satiety effect of CCK observed in mammals, the injection of sulfakinins inhibits food intake in locusts[26,35] and cockroaches[18] and inhibits carbohydrate (but not protein) feeding in the fly, *Phormia regina*[8] and blood feeding in the horse fly, *Tabanus nigrovittatus*.[9] Silencing sulfakinin gene expression by RNAinterference results in an increase of food intake in *G. bimaculatus*.[21] In addition, sulfakinins stimulate the release of the digestive enzyme amylase from the insect digestive tract in the beetle *Rhynchophorus ferrugineus* and in the moth *Opisina arenosella*.[11,23] Both sulfated and nonsulfated sulfakinins stimulate the heart contractions but differ in their activities depending on the developmental stage.[29] The pleiotropic effects of sulfakinins are illustrated in a study showing that in the beetle *Zophobas atratus*, sulfakinin decreases the contractions of the heart, ejaculatory duct, and oviduct and also displays hyperglycemic activity.[19] The absence of sulfakinin and its receptor in the pea aphid[14] and in the parasitic wasp, *N. vitripennis*[12] indicates that these species may have lost the sulfakinin signaling system during evolution, causing or being the result of specific adaptations in behavior, feeding or habitats, compared with other insects.

Two CCK/sulfakinin receptors in the nematode, *C. elegans* and their activating ligands, two unsulfated sulfakinin-related peptides encoded by the NLP-12 prescursor protein, have been identified and characterized.[15] Interestingly, the amylase secretion is significantly lower in the receptor mutants. In addition, the lack of either receptor or peptide results in a highly increased fat content in the worm, which is in agreement with a similar phenotype in mice lacking the CCK-2 receptor.

In sum, the gastrin/CCK/sulfakinin signaling system represents a good example of the coevolution of neuropeptides and their receptors. The sulfakinins do not only seem to display structural but also physiological similarities to the vertebrate peptides gastrin and CCK. So far, sulfakinin peptides have only been isolated from arthropods and nematodes, but related peptides have been detected by immunological methods in annelids and snails. The elucidation of additional sulfakinins in species belonging to nonecdysozoan phyla of the protostomian lineage will shed light on the (still debated) common evolutionary origin of CCK/gastrin and sulfakinins.

Chapter 44

Tachykinin Peptides

Dick R. Nässel

ABSTRACT

Peptides related to vertebrate tachykinins have been identified in many invertebrates, including annelid worms, mollusks, crustaceans, and insects. Two major types can be distinguished, tachykinin-related peptides (TKRPs) with an FXGXRamide C-terminus and invertebrate tachykinins (invTKs) with FXGLMamide. The TKRPs are present in the nervous system and intestine, whereas the invTKs have been found only in the salivary glands. Receptors for TKRPs, ancestrally related to vertebrate neurokinin receptors, have been identified in many invertebrates. In some species, two different receptors are known. The TKRPs have a wide neuronal distribution and a broad spectrum of actions including myostimulatory, diuretic, and neuromodulatory actions. In *Drosophila*, genetic interference with TKRP signaling reveals roles in locomotor control, olfactory sensory processing, stress responses, and regulation of insulin signaling.

DISCOVERY

Tachykinins constitute a large and structurally varied family of multifunctional peptides present in the nervous system, gastrointestinal tract, and many other tissues. Members of this family have been identified in annelids, mollusks, arthropods, as well as in vertebrates (reviewed in Refs. 3, 5, 21, 22, 27, 33). Already in 1931 the first tachykinin, substance P, was isolated from horse brain. Substance P was followed by a large number of related peptides isolated from various vertebrates, all characterized by a common C-terminal sequence FXG$\underline{L}$Mamide.[22,23] The first tachykinin to be identified from an invertebrate was eledoisin, isolated from the salivary glands of the cephalopod *Eledone moschata* in 1962.[6] In 1990, the first insect peptides with similarities to tachykinins were identified from the locust *Locusta migratoria*.[28] The amino acid sequences of these two locust nonapeptides, designated locustatachykinin-I and -II, differ in a major way from vertebrate tachykinins and eledoisin by having a C-terminal pentapeptide FXG$\underline{V}$Ramide. Subsequently, it became apparent that tachykinins derived from the nervous system and intestine of insects and several other invertebrates share this structural feature (Table 1).[19,20,27] Thus, these invertebrate peptides are not referred to as tachykinins but as tachykinin-related peptides (TKRPs). Interestingly, vertebrate type of FXGLMamide-containing tachykinins are produced in the salivary glands of mosquitoes and two cephalopod species but not in the CNS of any invertebrate.[14,27] The salivary gland-derived tachykinins are henceforth referred to as invertebrate tachykinins (invTKs), as suggested by Satake et al.[27]

The first insect TKRPs were identified by their myostimulatory actions in the cockroach hindgut muscle contraction bioassay, an assay used for the isolation of a large number of novel peptides from HPLC-purified tissue extracts.[9,28] Most invertebrate TKRPs have been identified either by this hindgut bioassay, a combination of this and an immunoassay with antiserum to locust TKRP, or by searching genome or EST data bases, followed by mass-spectrometric identification in tissue. Thus, sequence data are now available for TKRPs from mollusks, annelids, the annelid-like worm *Urechis unicinctus*, a tardigrade, many insects, a few arachnids, some decapod crustaceans, and the cladoceran crustacean *Daphnia* (Table 1).[4,5,7,21,27,32,33] Many of the predicted peptide sequences in these organisms, but not all, have been confirmed by mass-spectrometric analysis of tissue.[5,7]

The invTKs have been identified in the salivary glands of two cephalopods and a mosquito, *Aedes aegypti*. In one of the cephalopods, *Octopus vulgaris*, typical TKRPs have in addition been identified in the CNS,[14,27] suggesting that TKRPs are neuronal (and intestinal) peptides, whereas invTKs are nonneuronal and can exist in the same organism.

STRUCTURE OF PRECURSOR mRNAs AND GENES

The three principal mammalian tachykinins, substance P, neurokinin A, and neurokinin B, are processed from two precursors, preprotachykinin A and B.[23] More recently additional tachykinins, the hemokinins, were identified on a third precursor gene, preprotachykinin C, expressed in hematopoietic cells.[23]

The first invertebrate cDNA to be identified for a TKRP precursor was isolated from the worm *U. unicinctus*.[27] This precursor consists of 243 amino acid residues, from which 7 different TKRPs can be liberated. Next, a gene

TABLE 1 Sequences of Representative Members of the Extended Tachykinin Family

Species	Designation	Sequence
TKRPs (FXGXRamide)		
Octopus vulgaris[*]	Oct-TKRP-III	TVSANAFLGSRa
Hypsibius dujardini[#]	TKRP	AKPSGFWGARa
Decapod crustaceans	CabTRP-I	APSGFLGMRa
Daphnia pulex[$]	DappuTKRP-1	TPNSRAFLGMRa
	DappuTKRP-2	KMHGEKFLGMRa
	DappuTKRP-3	APSSNSFMGMRa
L. maderae[**]	LemTRP-1	APSGFLGVRa
	LemTRP-2	APEESP**KR**APSGFLGVRa
	LemTRP-3	NGERAPGS**KK**APSGFLGTRa
	LemTRP-3[11–19]	APSGFLGTRa
Drosophila[***]	DTK-1	APTSSFIGMRa
	DTK-2	APLAFVGLRa
	DTK-3	APTGFTGMRa
	DTK-4	APVNSFVGMRa
	DTK-5	APNGFLGMRa
	DTK-6	AALSDSYDLRGK**Q**QRFADFNSKFVAVRa
Stomoxys calcitrans[†]	StcTK-I	APTGFFAVRa
Anodonta cygnea[*]	AncTK	PQYGFHAVRa
InvTKs and substance P (FXGLMamide)		
Eledone moschata[*]	Eledoisin	PEPSKDAFIGLMa
Octopus vulgaris[*]	Oct-TK-II	KPPSSSEFVGLMa
Aedes aegypti[†]	Sialokinin I	SGNTGDKFYGLMa
C. elegans	nlp-8[‡]	SFDRMGGTEFGLMa
Mammals	Substance P	RPKPQQFFGLMa

The dibasic cleavage sites in LemTRPs and putative cleavage site in DTK-6 are indicated in bold. The G to A substitution in some TKRPs is indicated by underlining. Note that in ***Octopus***, both TKRPs and invTKs have been identified.
[*]*Mollusca.*
[#]*Tardigrade.*
[$]*Phyllopod crustacean.*
[**]Leucophaea maderae *(cockroach).*
[***]D. melanogaster.
[†]*Mosquito.*
[‡]*The* C. elegans *putative invTK has no designation but is derived from the* nlp-8 *gene.*

(*Dtk*; CG14734) coding for multiple TKRPs was identified in *Drosophila*.[29] The *Drosophila* precursor consists of 289 amino acids derived from an 870-bp open reading frame. There are 6 predicted TKRPs (DTK-1 to DTK-6) in the *Drosophila* precursor, five of which could be confirmed in the brain by mass spectrometry[35] the bona fide DTK-6 has not yet been identified (see however Ref. 24).

Through data mining and classical cloning techniques, we now know the sequences of many additional TKRP precursors from annelids, insects, crustaceans, arachnids, and mollusks.[3,5,26,27,32,34] Thus, there are, for example, 7 TKRPs on the precursor from the Honeybee *Apis mellifera*, 3 in the mosquito *Anopheles gambiae*, 13 in each of the cockroaches *Periplaneta americana* and *L. maderae*, 7 in *Octopus vulgaris*,

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

and 7 each in the crayfish *Procambarus clarkii* and spiny lobster *Panulirus interruptus*, whereas in *Daphnia* 3 different types were found.[5,20,25,27]

The crayfish and lobster precursors, which are very similar to each other, each contain 7 identical TKRPs (CabTRP-I) and no further peptides. This is unique, so far, among the TRP precursors. In all other organisms (including the phyllopod crustacean *Daphnia*) multiple, closely related TKRP isoforms were found on the precursors. The decapod crustacean precursors may provide insights into the evolution of tachykinin isoforms. Possibly precursors, such as the decapod ones (but not *Daphnia*), with several identical copies of a peptide are more ancestral, and such a precursor could evolve by diversification into one with multiple closely related peptides.

An interesting feature of the cockroach TKRPs is that two N-terminally extended TKRPs exist that have internal dibasic cleavage sites (Table 1). These sites seem more likely to be used by processing enzymes in the brain than in the intestine. As a consequence, the nonapeptides LemTKRP-1 and LemTKRP-3[11–19] are much more abundant in the brain than LemTKRP-2 (17mer) and LemTKRP-3 (19mer), whereas the extended forms are prominent in the intestine.[25] Thus, there might be a differential posttranslational processing of these peptides in the brain and the gut. In total, the *L. maderae* precursor can yield up to 15 TKRP isoforms, as confirmed by MALDI-TOF mass spectrometry. Two of these are produced posttranslationally.

Judging from cDNAs, the sequences of the TKRP precursors of different invertebrates are conserved mainly in the peptide progenitor regions. The sequences providing spacing between peptide progenitors vary in length between species: from being just the dibasic cleavage sites and amidation signals (*Urechis*), to substantial spacer sequences (several of the insects). In cockroaches, there is a mix between the two spacer lengths. The genomic organization of the TKRP precursor gene, *Dtk*, in *Drosophila* reveals three exons separated by introns.[29] The DTK-1 to DTK-4 peptides are located on exon 2 and DTK-5 and 6 on exon 3. No evidence for alternative splicing of the precursor mRNA is available.

The precursor of the invTK of *Aedes* is small (96 amino acids, 406-bp cDNA) and codes for a single peptide, Sialokinin. The Sialokinin gene consists of three exons. Also the *Octopus* invTK precursor, OctTK-I is small (87 residues, 489 bp cDNA) and predicts one peptide.[14,27] The *Caenorhabditis elegans* gene *nlp-8* predicts three peptides, one of which has the C-terminal tetrapeptide identical to that of substance P (Table 1).[17] Because the other two peptides of the precursor are clearly unrelated, it is not probable that *nlp-8* is ancestrally related to genes coding for tachykinins and TKRPs.

DISTRIBUTION OF mRNA AND PEPTIDES

The localization of TKRP precursor transcript and/or peptides is known for several insects and crustaceans. In *Drosophila*, in situ hybridization has revealed a distribution of *Dtk* transcript in interneurons of the CNS and endocrine cells of the intestine. Immunocytochemistry confirms the presence of TKRPs (DTKs) in the same set of neurons. The number of neurons is relatively small in late third instar larvae (~40–50 neurons in the total CNS, of these 30–36 are in the brain) and somewhat higher (~200 neurons in the total CNS, ~150 in brain) in adult *Drosophila*.[35] Immunocytochemistry reveals neuronal arborizations in specific brain neuropils, such as optic lobes, antennal lobes, central body, and pars intercerebralis (area of branches of protocerebral neurosecretory cells). Additionally, a set of 10 large neurosecretory cells are in the brain; their axon terminations are found in neurohemal release sites on the aorta and in the corpora cardiaca.[12]

The principal distribution of TKRP containing neuron processes follows a basic pattern in the insects investigated.[19,20] In all insects studied, the same neuropils as listed for *Drosophila* are supplied by TKRP immunoreactive branches, but there is some variation between species in some other parts of the brain. In honeybees, there is additional expression of the TKRP gene transcript in intrinsic neurons (Kenyon cells) of the mushroom bodies.[31] The mushroom bodies are higher olfactory centers and also important for olfactory learning and memory. Thus, TKRPs may have a role in higher olfactory processing or even in olfactory learning in honeybees.

In the brain of decapod crustaceans, the distribution of TKRP immunoreactive neurons is similar to that of insects: in olfactory interneurons, optic lobe interneurons, and in the central body complex.[19] The neuronal distribution of TKRPs has also been studied in the snails *Helix pomatia* and *Lymnaea stagnalis*.[19] Numerous TKRP containing neurons were found especially in cerebral ganglia, and neuronal processes arborize in every ganglion. There is no report on the distribution of TKRPs in *U. unicinctus*, but mass spectrometry analysis has indicated that the TKRPs are expressed in the CNS and not in the intestine.

The invTK precursor distribution has been mapped by in situ hybridization in *Aedes* and *Octopus*. In the mosquito, the transcript is present only in adult female salivary glands, and in the cephalopod, it is found in a portion of the salivary glands only. The distribution of the *C. elegans* "invTK" encoded by *nlp-8* is seen in sets of identified neurons throughout the animal and processes on the gut.[15]

PEPTIDE PROCESSING

The TKRPs are probably liberated from their precursor proteins by common endoproteolytic enzymes such as prohormone convertases.[11] Enzymatic inactivation is an important

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

means of terminating neuropeptide action. Several enzyme activities are known to cleave insect TKRPs and thus render them inactive: dipeptidyl peptidase IV (DPP IV), angiotensin converting enzyme (ACE), and nephrilysin (NEP)[11] (see the Peptide Biosynthesis/Processing section of the book).

RECEPTORS OF TKRPS

In mammals, three types of G protein–coupled receptors (GPCRs) for tachykinins have been identified,[22,23] as has been discussed in the tachykinin chapter of the Brain Peptides section of this book. These are designated NK1-3 and display preferential affinities for substance P, neurokinin A, and neurokinin B, respectively. The hemokinins seem to associate with the NK1 receptor. In invertebrates GPCRs for the TKRPs have been identified in several species of insect, and in the worm *U. unicinctus*.[8,20,27] Two main types of GPCRs with TKRPs as ligands have been distinguished in *Drosophila* among a set of six GPCRs that fall in the class of neurokinin-like receptors.[1,8,24] The first to be identified, designated DTKR, has been fully characterized with endogenous *Drosophila* TKRPs (DTK-1 to 6). GPCRs closely related to DTKR have been identified in most insects. The second type of TKRP receptor, NKD, can be activated by DTK-6 only in *Drosophila*[24] and has an ortholog in *Anopheles* and a few other insects.

The DTKR type of tachykinin receptors display sequence similarities to mammalian tachykinin receptors and the gene organization is similar in terms of location of intron-exon boarders.[27] Thus, the invertebrate and mammalian receptors are probably ancestrally related. The *Stomoxys* receptor STKR has been extensively investigated in different cellular expression systems.[32] It responds to its native ligand, StcTK, of *Stomoxys*, and also to other insect TKRPs. In heterologous expression systems, the STKR can couple both to calcium and cyclic AMP signaling systems. The *Drosophila* receptor DTKR when expressed in HEK-293 cells could be activated equally well with the six native DTKs (DTK-1 to DTK-6), and it coupled both to calcium and cyclic AMP signaling. On prolonged exposure of DTKR to DTKs β-arrestin, translocation is initiated and the receptor internalizes.

Antisera to a portion of DTKR were used for immunocytochemical mapping of the receptor protein in the CNS and intestine of *Drosophila*.[1] The distribution of DTKR immunoreactivity in the CNS matches that of the DTK peptide distribution. High density of DTKR is seen in the antennal lobes, central body, and pars intercerebralis. Peripheral sites of DTKR expression seem to be the intestine and Malpighian tubules. Both the intestine and the tubules are known to respond to TKRPs in several insect species. The protein of the other TKRP receptor, NKD, is distributed in *Drosophila* in a set of neurons distinct from those expressing DTKR and in intestinal endocrine cells.[24]

STRUCTURE ACTIVITY AND ACTIVE CONFORMATION

The insect and *U. unicinctus* TKRPs have been investigated with respect to structure activity relations. At least, the C-terminal hexapeptide is required for full biological activity of insect TKRPs in a few bioassays,[19,27] whereas in cells transfected with the *Stomoxys* STKR a pentapeptide seems sufficient for activation. Several amino acid substitutions are possible in this C-terminus, but in principle, FX_1GX_2Ramide is required. However, a substitution of the G for an A in this sequence changes the bioactivity only slightly. Natural isoforms with an $FX_1\underline{A}X_2$Ramide do exist in *Stomoxys* (Stc-TK) and *Drosophila* (DTK-6) as well as in mollusks (Table 1).[27] The Ramide is very critical for biological activity: substitution of Ramide to Mamide renders the invertebrate TKRPs inactive on invertebrate receptors such as STKR and UTKR (*U. unicinctus*).[27] Conversely, if the Mamide of a mammalian tachykinin is changed to an Ramide, the peptide can activate the invertebrate receptors.

A comparison was made of the aqueous solution conformations of a conformationally restricted bioactive analog of an insect TKRP and an analogous substance P conformer.[16] NMR spectra and molecular dynamics calculations show that the insect and mammalian peptides adopt similar active conformations.

BIOLOGICAL ACTIONS

A range of biological actions of TKRPs has been established in insects, using *in vitro* bioassays: modulation of different types of muscle, weak diuretic activity, neuromodulatory activity, and induction of adipokinetic hormone release.[19,20] TKRPs increase spontaneous muscle contractions in cockroach foregut, *Drosophila* midgut, cockroach hindgut, locust and cockroach oviduct, and the heart (dorsal vessel) of beetles and to modulate contractile properties of hindleg muscles in a locust. A neuromodulatory action occurs on locust dorsal unpaired median neurons. These neurons respond to TKRPs by depolarization, possibly mediated by activation of adenylate cyclase.

In arthropods, TKRPs seem to be generally involved in olfactory processing because insects and crayfishes express this type of peptide in olfactory interneurons. The TKRPs are colocalized with the inhibitory neurotransmitter γ-aminobutyric acid (GABA) in olfactory interneurons (at least in cockroaches and *Drosophila*). Thus, the peptide may act as cotransmitter and/or neuromodulator in GABA signaling in antennal lobes. In *Drosophila*, the receptor DTKR is expressed in the olfactory sensory neurons (OSNs) of the antennae and the DTK-expressing antennal lobe interneurons presynaptically modulate the sensitivity of OSNs to certain odors.[10] The DTKs also act as neuromodulators in the central complex (CX) of the *Drosophila*

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

brain. When DTK levels are genetically knocked down in specific neurons innervating the CX locomotor activity patterns are specifically altered.[13]

In crustaceans, the neuromodulatory action of TKRPs has also been established. In the lamina of the crayfish visual system amacrine neurons contain colocalized TKRP and GABA and application of these two substances to retinal photoreceptors produces a dose-dependent hyperpolarization.[20] This action follows two time courses, a short latency hyperpolarization in the order of seconds and another evolving over minutes. The TKRP action involves a reduction of the photoreceptor potential and the light-elicited current and a potentiation of the presynaptic inhibitory action of GABA. The GABA and TRP actions may subserve lateral inhibition or feedback inhibition of the primary visual synapse (over seconds) and possibly light adaptation of photoreceptors (over minutes).

In another crustacean, the crab *Cancer borealis*, a TKRP has been identified in the neurons of the stomatogastric ganglion, STG.[18] Different overlapping subsets of STG neurons form networks that generate rhythms controlling chewing and filtering behaviors of the foregut. An endogenous TKRP localized in one of the neurons innervating the STG triggers a specific pyloric motor pattern. In this neuron, the TRP is colocalized with proctolin and GABA and the three substances act together to elicit the appropriate response.[18]

A set of 10 large neurosecretory cells in the *Drosophila* brain expresses DTK together with short neuropeptide F (sNPF) and ion transport peptide.[12] Targeted knockdown of DTK (or sNPF) in these cells renders the flies more sensitive to desiccation as determined by survival and water retention capacity, suggesting a role of these peptides in water and ion balance.[12] In *Drosophila*, DTKs also regulate the release of insulin-like peptides (ILPs) from insulin producing cells in the brain and Malpighian tubules.[2,30] In both cases, the peptidergic regulation of ILP signaling via the DTKR receptor affects organismal stress responses, and in the brain, ILP transcript levels were affected by DTKR knockdown.[2]

CONCLUDING REMARKS

Tachykinins, invTKs, and TKRPs constitute a large family of multifunctional neuropeptides whose signaling mechanisms seem to be partially conserved through evolution.[21,23,27] Although the vertebrate tachykinins and invertebrate TKRPs and their precursors display only limited sequence identities, their GPCRs display more striking similarities, suggesting ancestral relationships.[27] The invTKs, which display strong similarities to vertebrate tachykinins, seem to have evolved separately in the salivary glands of some invertebrates that use saliva in their interactions with vertebrate prey organisms. Thus, these invTKs may have evolved by mimicry to cause vasodilation or other actions in the prey vertebrates.

In invertebrates, the complete spectrum of functions of TKRPs remains to be determined. With the development of powerful genetic tools, *Drosophila* has emerged as a good model for analysis of peptide function. Findings so far suggest that the TKRPs have multiple functions distributed in different parts of the CNS, intestine, renal tubules, and maybe in other tissues.

Chapter 45

Bradykinin Peptides

J. Michael Conlon

ABSTRACT

Bradykinin (BK)-related peptides are synthesized sporadically in the skin of certain frog species belonging to the families Bombinatoridae, Heleophryninae, Hylidae, Leiopelmatidae, and Ranidae. BK, identical in structure to the mammalian peptide, larger molecular forms of BK extended from either the N- or C-terminus by additional amino acids, and molecular variants of BK containing amino acid substitutions have been identified. The frog skin BK peptides are not generated by the activation of the kallikrein–kinin system, as in mammals, but by the action of processing enzymes cleaving at the site of single arginyl residues in precursors that generally contain multiple tandem copies of a BK containing domain. The frog skin BK-related peptides show a wide range of potencies in eliciting contractile or relaxant responses in mammalian smooth muscle preparations and peptides derived from probradykinins with weak antagonistic and BK-potentiating activities have also been identified.

DISCOVERY AND DISTRIBUTION

The skin of amphibians has proved to be a remarkably rich storehouse of myotropic peptides, including kinins. A BK-like ability to elicit a hypotensive response and to contract rat uterine and gastrointestinal smooth muscle has been found in the skin extracts of a wide range of frogs from Africa,[25] North and South America,[13] Australia, Papua New Guinea,[14] and Europe[26] by Erspamer and coworkers. In particular, the skin of certain frogs from the genus *Rana* are associated with very high concentrations of such BK-like bioactivity, and the skin of the European common frog *Rana temporaria* contains a peptide whose amino acid sequence is identical to that of mammalian BK.[2] The occurrence of BK and related peptides among the different families of frogs, and even among species belonging to the same genus, is sporadic. For example, the skins of the European frog *R. temporaria* and the African frog *R. galamensis* contain BK equivalent to >150 μg/g tissue, but BK was undetectable in the skins of *R. dalmatina, R. graeca and R. latastei*.[25,26] Similarly, among the North American ranids, the skin secretions *R. muscosa* contain high concentrations of BK although the peptide is undetectable in the secretions from those of its sister taxa *R. aurora* and *R. draytonii*.[24] The observation that high concentrations of BK are present in the skin of the Japanese brown frog *R. tagoi okiensis* but not *Rana tagoi tagoi* provides evidence to support the proposal that these frogs should be regarded as separate species rather than conspecific subspecies.[11,29]

As well as from frogs belonging to the family Ranidae, BK and/or BK-related peptides have been isolated from the species belonging to the families, Bombinatatoridae,[6–8,15–17] Heleophryninae,[23] Hylidae,[1,30] and Leiopelmatidae.[12] The tailed frog *Ascaphus truei* (Leiopelmatidae) occupies a unique position in phylogeny as the most primitive extant anuran and is regarded as the sister taxon to the clade of all other living frogs. Consequently, the identification of BK in skin secretions from this species demonstrates that dermal BK production arose early in anuran evolution.

BIOSYNTHESIS OF BRADYKININ AND RELATED PEPTIDES

The pathways of biosynthesis of BK-related peptides in frog skin are quite different from those in the blood and tissues of mammals. The kallikrein–kinin system in mammals involves the sequential action of several well-characterized proteolytic enzymes and is illustrated schematically in Fig. 1 (see also bradykinin chapters in the Cardiovascular Peptides section of this volume). The activation of Factor XII (Hageman factor) in blood results in the activation of plasma prekallikrein and subsequent generation of BK by the cleavage of high molecular mass kininogen. This protein contains only a single copy of the BK sequence. Alternative splicing of the primary transcript of the kininogen gene gives rise to a second mRNA that directs the synthesis of low molecular mass kininogen. This protein is a substrate for glandular or tissue kallikrein, a serine protease that is localized predominantly in kidney, pancreas, and pituitary, generating either [Lys^0]-BK in the human or [Arg^0]-BK in the rat. BK-related peptides have been generated in the

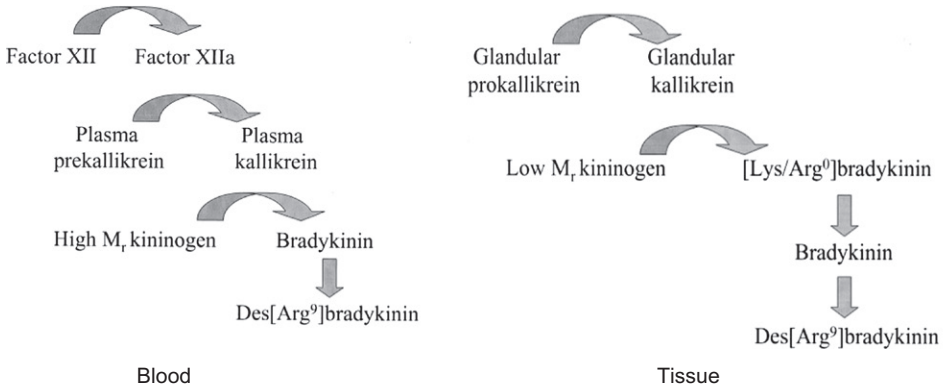

FIGURE 1 Generation of BK in the plasma and tissues of mammals by the activation of the kallikrein–kinin system.

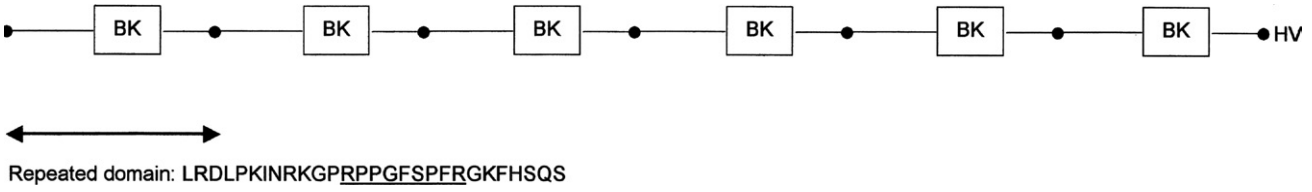

FIGURE 2 A schematic representation of the biosynthetic precursor of BK deduced from the nucleotide sequence of a cloned cDNA from the skin of *Bombina maxima.* The probradykinin contains six identical repeated copies of the domain shown. The BK sequence is underlined.

plasma of several species of reptile and fish by incubation with porcine pancreatic kallikrein and/or trypsin but similar attempts to generate BK in the plasma of a range of frog species have been unsuccessful.[9]

The primary structure of the biosynthetic precursor of a frog skin BK was first determined for the Chinese red-bellied toad *Bombina maxima*.[15] As shown schematically in Fig. 2, the probradykinin comprises six copies of the 28 amino acid residue repeated domain LRDLPKINRKGPRPPGFSPFRGKFHSQS. Thus, the generation of BK (sequence underlined) involves cleavage at the site of single arginyl residues by an as yet uncharacterized processing enzyme(s) rather than by the action of the kallikrein–kinin system as in mammals. As well as BK, the posttranslational processing of *B. maxima* probradykinin generates the N-terminally extended peptide, bombinakinin M (DLPKINRKGPRPPGFSPFR). It has been further shown that several preprobradykinin genes are expressed in the skin of *B. maxima*[6,16,17] and a cDNA encoding a bombinakinin M variant (DLSKMSFLHGIPPGFSPFR) that does not contain the full sequence of BK has been identified. It has been suggested that environmental factors may influence which particular bombinakinin M gene is expressed.[17] Subsequent work has shown that structural organization of probradykinin in the skins of the piebald odorous frog *Odorrana schmakeri*[18] the Yunnanfu frog *Odorrana grahami*,[5] the pickerel frog *Lithobates palustris*,[21] and the fire-bellied toad *Bombina orientalis*[8] is similar to that of the *B. maxima* precursor, comprising multiple BK-containing tandem repeats.

Amplification of a preprobradykinin cDNA encoding two copies of the analog [Arg^0,Leu^1,Thr^6,Trp^8] BK from a total RNA preparation of the skin of *Rana sakuraii* was accomplished by a 3′-RACE procedure with a primer that was designed from conserved regions of the 5′-UTR of *R. temporaria* preprotemporins.[28] The temporins are antimicrobial peptides widely distributed in the skins of ranid frogs (see the chapter on this peptide in this section of the book). The signal peptide region of the preprobradykinin is identical to that of preprotemporin-1SKa from *R. sakuraii* except for the substitution Ser^{18} → Asn (Fig. 3). At this time, there is no evidence to suggest that the genes encoding the BK-related and temporin-related peptides are derived from a common ancestral gene but the nucleotide sequence similarity in the 5′-UTR and the signal peptide regions suggests the possibility of a linked evolutionary history.

MOLECULAR VARIANTS OF BK

The different pathways of posttranslational processing of probradykinin in frog skin give rise to peptides in which the BK sequence is extended from either the N- or the C-terminus by additional amino acid residues. As shown in Fig. 4, a peptide comprising BK extended from its N-terminus by -Gly-Val-Ile-Pro-Leu-Leu and three peptides comprising BK extended from its C-terminus by -Ile-Ala, -Ile-Ala-Pro-Ala-Ser-Thr-Leu, and -Ile-Ala-Pro-Ala-Ser-Ile-Leu were purified from *R. temporaria*.[10] Related studies in other species have led to the isolation of BK-related peptides

extended from the C-terminus by -Ile-Tyr(SO_3) (phyllokinin from *Phyllomedusa rohdei*),[1] by -Gly-Lys-Phe-His (bombinakinin O from *B. orientalis*),[32] by -Val-Ala-Pro-Ala-Ser (ranakinin N from *Pelophylax nigromaculatus*),[31] and by Val-Asp (peptide RD-11 from *A. truei*).[12] Metabolites of BK, identified as the (1–7) and the (1–8) fragments, have been isolated in high yield from the skins of *R. temporaria* and *R. esculenta* and [hydroxyprolyl[3]]-BK has been purified from *R. temporaria* and from the South African frog *Heleophryne purcelli* (Heleophryninae).[9]

In general, the primary structure of BK has been poorly conserved in vertebrates with only two amino acid residues (Gly[4] and Arg[9]) remaining invariant during the evolution of the peptide.[9] As shown in Fig. 5, BK-related peptides (and their N- and C-terminally extended forms) whose amino acid sequences are not the same as mammalian BK include [Thr[6]]-BK from *Glandirana rugosa*,[33] *R. tagoi okiensis*,[29] and *B. orientalis*;[32] [Val[1],Thr[6]]-BK from *P. nigromaculatus*,[22] *Hylarana nigrovittata*,[20] *Amolops loloensis*,[19] and *Phyllomedusa hypochondrialis*;[30] [Thr[6],Leu[8]]BK from *L. palustris*;[3] [Leu[5],Thr[6]]BK from *O. grahami*;[5] [Ala[3],Thr[6]]-BK and [Val[1],Thr[3],Thr[6]]-BK from *B. variegata*;[7] [Leu[1],Thr[6],Trp[8]] BK from *R. sakuraii*;[28] and [Pro[1],Val[2],Leu[5]]-BK from *A. truei*[11] (Fig. 5). [Arg[0],Trp[5],Leu[8]]BK, a peptide that is generated in the plasma of several teleost fish by activation of the kallikrein–kinin system,[9] together with [Thr[6],Leu[8]]BK was identified in the skin of *P. lessonae*.[27] Among the frog skin BK-related peptides only Gly[4], Pro[7], and Arg[9] are invariant.

BIOLOGICAL ACTIVITIES

The myotropic activities of several of the naturally occurring larger molecular forms of BK have been investigated. Phyllokinin [BK-Ile-Tyr(SO_3H)] was two to three times more potent and longer acting than BK in producing a hypotensive response in the anesthetized dog, but the peptide was less potent than BK in contracting a range of extravascular smooth muscle preparations. Removal of the sulfate group from phyllokinin resulted in an appreciable loss in potency.[1] By contrast, removal of the C-terminal extension to the BK sequence in ranakinin N with trypsin results in a 20-fold increase in potency in smooth muscle bioassays.[31] *Rana sakuraii* BK ([Arg[0],Leu[1],Thr[6],Trp[8]] BK) is 28-fold less potent than mammalian BK in effecting B2 receptor-mediated relaxation of mouse trachea.[28] BK-Val-Asp from *A. truei* is a full agonist at the B2 receptor in mouse trachea but the BK-related peptide AR-10 (APVPGLSPFR) and its C-terminally extended form AV-12 (APVPGLSPFRVV) function as low potency, partial agonists.[12]

Bombinakinin M from *B. maxima* is about fourfold less potent than BK in eliciting contraction of the guinea pig ileum. By contrast, the bombinakinin M variant containing the substitution Arg[1] → Ile in the BK domain is itself inactive in this preparation but potentiates the action of BK up to two-fold.[17] The predicted amino acid sequence of one of the multiple biosynthetic precursors of bombinakinin M contains at its extreme C-terminus the domain Arg-Gln-Ile-Pro-Gly-Leu-Gly-Pro-Arg-Gly. A peptide derived from this domain (pGlu-Ile-Pro-Gly-Leu-Gly-Pro-Arg.NH_2) has been termed kinestatin and acts as a weak antagonist at the B2 receptor in the rat tail artery.[6] Similarly, the peptide Asp-Tyr-Thr-Ile-Arg-Thr-Arg-Leu-His.NH_2 encoded by a different *B. maxima* probradykinin gene also weakly inhibits the contractile activity of bombinakinin M at the guinea pig ileum.[16] As well as the bombinakinin M precursor that contains six tandem repeats,[15] cDNA cloning has identified a larger precursor that contains eight identical copies of the bombinakinin M sequence plus one copy of a 28 amino acid residue peptide, termed bombinakinin M gene associated peptide.[16]

FIGURE 5 Molecular variants of BK isolated from skin extracts or skin secretions of frogs. Those amino acid residues in the BK domain that differ from mammalian BK are shaded.

This component shows limited structural similarity to mammalian cocaine- and amphetamine-regulated transcript (CART) and intracerebroventricular administration of the peptide induces a significant decrease in food intake in rats.

The biological function of myotropic peptides, such as BK, in the skin of amphibia is unclear, but it is reasonable to speculate that they may represent an important component of the organism's survival strategy, protecting the animal against ingestion by predators. Release of large amounts of BK, or a related peptide, into the lumen of the stomach of a predator will stimulate gastric and esophageal motility, which may lead to activation of the vomiting reflex and ejection of the prey unharmed.

Chapter 46

Bombesin Peptides

Eliot R. Spindel

ABSTRACT

The bombesin-like peptides were originally isolated from frog skin, but the discovery of extensive effects in mammals led to the search for and discovery of mammalian homologs. In frogs, four groupings of bombesin-like peptides have been described, the bombesins, the ranatensins, and the phyllolitorins, which are present in skin and gastrin-releasing peptide (GRP) which is not present in skin. In mammals, two bombesin-like peptides have been described, GRP and neuromedin B (NMB). Whether mammals have additional bombesin-like peptides related to the frog skin bombesin-like peptides remains to be determined. The receptors for amphibian bombesin-like peptides are 7-transmembrane G protein-coupled receptors linked to the generation of IP3. The bombesin-like peptides in frog skin are located at very high concentrations in myoepithelial glands, and secretion can be triggered by norepinephrine. Despite investigation, the exact role of bombesin-like peptides in frog skin remains unknown.

INTRODUCTION

The bombesin-like peptides are one of the classic examples of peptides first discovered in frog skin and then later found to be widely distributed in mammals. The prototypical bombesin-like peptide, bombesin, was isolated from the skin of the frog *Bombina bombina* by Anastasi et al.[2] in 1971. The bombesin-related peptides ranatensin and Leu-8 phyllolitorin were subsequently isolated from the skin of *Rana* and *Phyllomedusa* species by Nakajima et al.[22] and by Yasuhara et al.[29] As discussed below, different genera of frogs contain different, characteristic, bombesin-like peptides. In frog skin the bombesin-like peptides are located in cutaneous granular glands (Fig. 1). These are myoepithelial glands under adrenergic regulation such that subcutaneous injection of norepinephrine causes massive secretion of the contents of the glands.[1,3,5] Typically, the levels of peptides found in frog skin are 100- to 1000-fold higher than the levels in mammalian tissues. Peptides are probably secreted from frog skin as a defensive function or potentially as a means of communication. The exact function of bombesin-like peptides in frog skin remains unknown.

The mammalian bombesin-like peptides are gastrin-releasing peptide (GRP) and neuromedin B (NMB). Phylogenetic analysis of the prohormones encoding the bombesin-like peptides suggests that there are three distinct branches of bombesin-like peptides, the GRP branch, the NMB branch, and a branch that contains the multiple bombesin-like peptides found in amphibian skin. This raises two interesting questions: "Do frogs have bombesin-like peptides that fall in the NMB phylogenetic branch?" and "Do mammals have bombesin-like peptides that fall in the skin peptide branch?" To some extent, the grouping of the skin-derived amphibian bombesin-like peptides into different families is primarily historic because it is becoming increasingly clear that many amphibians have multiple bombesin-like peptides of differing structures in their skin[9,19] and that all the skin bombesin prohormones show close evolutionary relationships as discussed further below.

With the advent of more sophisticated mass spectrometry techniques and transcriptome sequencing by "Next Gen" sequencing techniques, the numbers of known bombesin-like peptides from amphibian species will probably increase dramatically in the coming years.

AMPHIBIAN BOMBESINS

Bombesin was originally isolated from the skin of the fire-bellied toad, *B. bombina* by Anastasi, Erspamer, and coworkers.[2] Bombesin is a tetradecapeptide with the structure shown in Fig. 2. Bombesin is also found in the skin of other *Bombina* species including *Bombina variegata* and *Bombina orientalis.* The original form of bombesin as isolated by Anastasi et al.[2] is characterized by a Leu as its penultimate residue. This penultimate residue was initially believed to differentiate the bombesin-like peptides isolated from *Bombina* species from the bombesin-like peptides isolated from *Rana* species that contain a Phe residue as the penultimate residue. This is not the case, however, as many frog species contain multiple forms of bombesin-like peptides in their skin with both Leu and Phe as penultimate residues. This is illustrated by the presence

Human Neuromedin B	Gly-Asn-Leu-Trp-Ala-Thr-Gly-His-Phe-Met.NH2

FIGURE 2 Structures of amphibian bombesin-like peptides. Amino acids conserved across all members of the family are shown in gray. A. Peptides classically designated as bombesin-like. B. Peptides classically designated as phyllolitorin-like. C. Peptides classically designated as ranatensin like. Notes: 1, also the same structure in *Bombina bombina* and *Bombina variegata*; 2, listed here as bombesin-like as per Samgina et al.;[24] 3, examples of 15 amino acid bombesins from *Odorrana grahami*;[9] 4, from skin of *Sanguirana varians* from Miao et al.;[16] 5, from Wang et al.;[27] 6, from Shen et al.[25] though the exact N-terminal cleavage site is not established. As more bombesin-like peptides are isolated from more diverse amphibian species, it is not clear how useful this historic classification will remain. More useful classification will however require more receptor binding and biological function information than is presently available.

of three forms of bombesin in the skin of *B. orientalis*, Leu-13 bombesin, Phe-13 bombesin, and Ser-3, Arg-10, Phe-13 bombesin (SAP bombesin) (Fig. 2) as reported by Nagalla et al.[19] The Analysis of genomic DNA shows that these three forms of bombesin are derived from separate genes. As well as being expressed in the skin at high levels, lower levels of these peptides are also expressed in the brain, lung, and gut.[19]

The presence of multiple form of bombesin in a single frog has similarly been reported by Li et al.[9] who found nine different bombesin-like peptides in the skin of *Odorrana grahami* including both Leu- and Phe-forms. Notably some

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

of the peptides (bombesin B4, Fig. 2) seem to have different effects on smooth muscle contraction than expected.[25] The bombesins from *O. grahami* are 15 amino acids as opposed to the canonical 14, but similar 15 amino acid forms of bombesin have also recently been isolated from *Sanguirana varians*[16] and from *Rana suchinae*[27] (Fig. 2). Samgina et al.[24] have also described a Phe-form of bombesin from *Rana ridibunda.* Shen et al.[25] described a novel proline-rich variant of bombesin from *Bombina maxima* (Fig. 2) though how its biological functions may differ from typical bombesins is not yet known.

In the bombesin prohormones, the sequence of bombesin follows a small N-terminal extension peptide that follows the signal peptide. A Gln residue provides the signal for the C-terminal pyroglutamate, a Gly residue provides the nitrogen for the N-terminal amide followed by two basic amino acids to signal the C-terminal cleavage. After the two basic amino acids, is a C-terminal extension peptide of varying length.[19] Frog skin is rich in enzymes similar to the mammalian prohormone convertases, so processing of frog skin bombesin is likely to be highly homologous to processing of neuropeptides in mammals.

The receptor for Phe-13 bombesin was cloned by Spindel and coworkers.[18] It has 377 amino acids and is a 7-transmembrane, G protein-coupled receptor linked to increased IP3 formation. The amphibian Phe-13 bombesin receptor is clearly homologous to the mammalian receptors for bombesin-like peptides. In *B. orientalis*, the Phe-13 bombesin receptor is expressed primarily in brain. The affinity of the Phe-13 bombesin receptor is 0.2 nM for Phe-13 bombesin, 0.9 nM for Leu-13 bombesin, and 100 nM for SAP bombesin.[18] These differing affinities suggest that distinct receptors for the other forms of amphibian bombesin will also be present in the frog. Consistent with this, partial cDNA sequences of receptors homologous to the Phe-13 bombesin receptor have been identified in frog brain by PCR.[18] In terms of the standardized nomenclature for bombesin receptors, the receptor for Phe-13 bombesin has been designated as the BB4 receptor. Interestingly, the Phe-13 bombesin receptor is most homologous to the BRS-3 receptor raising the possibility that the BRS-3 ligand in mammals when characterized may fall in the same phylogenetic branch as the frog skin bombesin-like peptides. This is discussed more in Section 6.

Although the function of bombesin in frogs is unknown, bombesin produces diverse physiologic effects in mammals in the brain, GI tract, and lung. Within the GI tract, bombesin stimulates the secretion of many GI hormones including gastrin, somatostatin, VIP, GIP, and glucagon as well as the release of pancreatic exocrine enzymes.[14] Within the CNS, bombesin is a potent regulator of central homeostatic mechanisms including regulation of appetite, blood sugar, cardiac function, and gastric acidity[7,13,26] and in lung, bombesin stimulates lung cell growth.[10] These effects of bombesin in mammals are mediated by the interaction of bombesin with the mammalian GRP and NMB receptors as discussed in other chapters of this book. Because the multiple forms of bombesin occur in frog brain together with their receptors, it is safe to conclude that bombesin-like peptides also function as neurotransmitters in frog brain.

AMPHIBIAN PHYLLOLITORINS

The phyllolitorins were initially characterized by Yasuhara et al.[29] from the skin of *Phyllomedusa sauvagei*. They form a distinct class of bombesin-like peptides characterized by the Ser residue at the third position from the C-terminus as opposed to the His residue which characterizes all other bombesin-like peptides (Fig. 2). Just like bombesin, the phyllolitorins exist in multiple forms distinguished by their penultimate amino acid, a Phe-8 form resembling ranatensin and a Leu-8 form resembling bombesin. Generally, the Leu-8 form shows more bioactivity.[12] The phyllolitorins have distinct pharmacologic profiles that differentiate them from the other bombesin-like peptides and, even though their binding to the known bombesin receptors is lower than for other related bombesin-like peptides, they produce similar effects as bombesin on the induction of scratching and grooming behavior and effects on hypothermia.[12] Peripherally, phyllolitorins lower systemic blood pressure[23] in dogs and monkeys in contrast to the hypertensive effects of bombesin and ranatensin.

In an unusual mechanism, the two forms of phyllolitorin are produced by RNA editing of a single gene that encodes Phe-8 phyllolitorin.[20] The single primary transcript of the Phe-8 phyllolitorin gene is either processed unedited to the Phe-8 phyllolitorin mRNA or the uracil (U) residue in the codon encoding the Phe-8 is edited in the RNA to a cytosine (C) residue to create the codon encoding the Leu residue in Leu-8 phyllolitorin. Such U to C RNA editing while less common than C to U RNA editing has been reported in other systems including insect sodium channels.[11]

The phyllolitorins like bombesin are found in the highest levels in skin in the cutaneous granular glands. Lower levels of phyllolitorin mRNA are also present in brain and GI tract.[20] The receptors for phyllolitorins have not been characterized, but almost certainly are 7-transmembrane receptors that will be highly homologous to the receptor for Phe-13 bombesin. As for bombesin, the function of phyllolitorin in frog skin remains unknown.

RANATENSIN-LIKE PEPTIDES

At about the same time that Anastasi et al.[2] described the isolation of bombesin from the skin of *B. bombina*, Nakajima

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

et al.[22] independently described the isolation of the related peptide ranatensin from the skin of *Rana pipiens*. As shown in Fig. 2, bombesin and ranatensin are highly homologous, the most critical difference being the penultimate residue which is Leu in bombesin and Phe in ranatensin. Different *Rana* and *Litora* species have slightly different but highly related ranatensin-like sequences, though peptides more closely related to bombesin have also been isolated from *Rana* species.[24] In mammals, ranatensin has a variety of effects. Ranatensin has strong effects on smooth muscle and blood pressure[4] and also replicates many of bombesin's effects on GI and CNS function, but with less potency.[17]

The ranatensin cDNA is similar in structure to the cDNAs for the other bombesin-like peptides. As in the bombesin prohormone, the sequence of ranatensin follows a short N-terminal extension peptide that immediately follows the signal peptide. If ranatensin is not cleaved from its N-terminal extension it gives a peptide highly similar to ranatensin-R (Fig. 2B) and to NMB-32, the larger form of mammalian NMB. In *R. pipiens*, the highest levels of ranatensin mRNA are found in the skin, but the ranatensin mRNA is also clearly detectable in brain. Highly homologous RNAs are also found in other *Rana* species including *Rana catesbeiana* and *Rana esculenta*. A full length cDNA for the ranatensin receptor has not been characterized, but sequence analysis of cDNA fragments amplified from RNA prepared from *R. pipiens* brain suggests that the ranatensin receptor will be highly homologous to the Phe-13 bombesin receptor.

GASTRIN-RELEASING PEPTIDE

Shortly after amphibian bombesin was isolated, its ability to stimulate the release of gastrin was used by McDonald and coworkers[15] to isolate a homologous peptide from porcine stomach that was named GRP. For many years GRP was considered the mammalian homolog of amphibian bombesin until Kim et al. showed that *Xenopus laevis* expressed a 29 amino acid peptide in stomach highly homologous to mammalian GRP[5] and Nagalla et al.[21] cloned cDNAs encoding GRP from *B. orientalis* to demonstrate that the same frog expressed different mRNAs to encode both bombesin and GRP. Phylogenetic analysis shows that frog GRP is far more closely related to mammalian GRP than to frog bombesin (Fig. 3). The prohormone structure of amphibian GRP is also highly similar to the prohormone structure of mammalian GRP, with the sequence for GRP immediately after the signal peptide. As for mammalian GRP, there is an Arg residue in frog GRP that allows processing of the 29 amino acid large form of GRP to the C-terminal decapeptide of GRP (GRP-10). The distribution of frog GRP is also quite distinct from that of bombesin in that frog GRP is not present in skin but rather is present in the highest quantities in gut and brain. In situ hybridization analysis of GRP expression shows expression of the frog GRP mRNA in cells in the basal layers of the gastric pits.[21] Kim et al.[26] have also shown that in *X. laevis* GRP effects contractility of stomach muscle. The localization and function of GRP in stomach suggest that amphibian GRP likely has similar functions in the GI tract of frogs as mammalian GRP does in mammals. Sequence analysis of partial cDNAs isolated from *B. orientalis* suggests that the amphibian GRP receptor is highly homologous to the mammalian GRP receptor.

PHYLOGENETIC CONSIDERATIONS AND IMPLICATIONS FOR ADDITIONAL MAMMALIAN BOMBESIN-LIKE PEPTIDES

Despite the 40 years of study of bombesin-like peptides in both frogs and mammals, there are several fundamental unanswered questions about the peptide family. In mammals, there are three receptors, the GRP receptor, the NMB receptor, and the BRS-3 receptor. The ligand for the BRS-3 receptor is unknown, and phylogenetic analysis shows that the Phe-13 bombesin receptor is closest to the BRS-3 receptor. Thus, it is tempting to speculate that the ligand for the BRS-3 receptor will be the true mammalian bombesin and phylogenetically more closely related to amphibian bombesin than to GRP or NMB. If this is the case, this suggests that one or more mammalian bombesin-like peptides closely related to the frog skin bombesins remain to be characterized. This would be similar to the characterization of the urocortins,[8] the mammalian homologs of amphibian sauvagine (see the CRH/Urocortin chapter

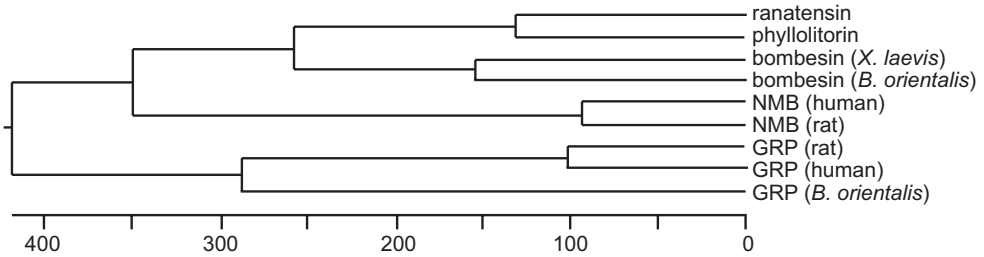

FIGURE 3 Phylogenetic tree derived from multiple comparisons of the known bombesin-like prohormones using MegAlign by DNAstar. As can be seen, the skin peptides are all closely related and distinct from GRP and neuromedin B.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

in the Brain Peptides section of the book). Given that frog species tend to have several forms of bombesin, this would suggest that the true mammalian bombesin, like the urocortins, will exist in multiple forms. Another possibility is that frogs also have a BRS-3 receptor in which case frogs would also have a BRS-3 ligand that is distinct from the skin bombesin-like peptides. Another question is if frogs have a NMB like peptide distinct from the skin bombesin-like peptides in that an amphibian homolog of NMB has yet to be definitively characterized, though *Xenopus* have a peptide in brain that resembles NMB but is phylogenetically more closely related to *B. orientalis* bombesin.[28] However, because frogs have Phe-form bombesin-like peptides present in brain (Phe-13 bombesin, Phe-8 phyllolitorin), it is possible that these peptides take the place of NMB in amphibians.

Chapter 47

Bombinins

Vincenzo Luca, Donatella Barra and Maria Luisa Mangoni

ABSTRACT

The skin secretion of *Bombina* species contains antimicrobial peptides with interesting biological properties. These peptides can be grouped into two distinct subfamilies, the bombinin and the bombinin H. The former comprises 27 amino acid residue peptides with a large spectrum of antimicrobial activity but virtually devoid of lytic effect on human erythrocytes. The latter includes 20 or 17 residue hemolytic peptides, some of which contain a D-amino acid in the second position of their sequence, as a result of a posttranslational modification. A brief description of the genes coding for these two peptide families, their biological activities along with the underlying molecular mechanism, are reported. Importantly, the presence of a single D-amino acid substitution represents a new approach naturally developed not only to modulate peptide stability *in vivo*, but also to confer the all-L peptide and its diastereomer distinctive biological features.

BOMBININS: GENERAL FEATURES

From the skin secretion of amphibian Anura, a multiplicity of antimicrobial peptides (AMPs) have been isolated and characterized.[1,25,31] Here we report a brief overview on the structure and function of AMPs from *Bombina* species. These are members of an ancient group of frogs which, according to some herpetologists, belongs to a separate family, the Bombinatoridae of the suborder Archaeobatrachia.[4] Besides the three main species, *Bombina bombina*, *B. variegata* and *B. orientalis*, a few others, most notably the Chinese red belly toad *B. maxima*, have been identified. Studies on the skin secretions of the two European species *B. bombina* and *B. variegata* started in the early sixties, when the pentapeptide Glu-His-Phe-Ala-Asn-amide was purified from this source.[24] About ten years later, it was shown that it corresponds to the carboxyl-end of a larger peptide (24 residues long) extracted from *B. variegata* and named bombinin.[5] Subsequently, by means of peptide sequencing and screening of a cDNA library prepared from the skin of *B. variegata*[23] and *B. orientalis*,[6] a family of AMPs related to bombinin was discovered. Members of this family (bombinin-like peptides, BLPs) contain 27 amino acids. They are amidated at the C-terminus and differ, at some positions in their N-terminal half, while the rest are identical.[23] It is possible that the original sequence of bombinin, derived from a mixture of similar peptides, contained some sequencing errors. The primary structure of BLPs is reported in Table 1. Interestingly, from the analysis of the BLP precursors by cDNA cloning, the existence of several variants of another peptide prototype was predicted. These peptides were then isolated by reversed-phase HPLC from the skin secretions of these frog species and named bombinins H,[20,23] with reference to their high hydrophobic character with respect to that of BLPs (Table 1) and because of their hemolytic activity (Table 2). Differences among the various bombinins H occurs at 3 positions, but the most surprising outcome in some of them is the presence of a D-alloisoleucine at the second N-terminal residue (Table 1), as a result of a posttranslational modification of the respective gene-encoded L-isoleucine (there is no codon for a D-amino acid).[12,22] Although peptides endowed with a D-amino acid have been found in the skin of other frogs[13] and in the venom of the male platypus,[28] and in a variety of invertebrate species,[7,10,11,27] bombinins H represent the first case of AMPs containing such a modification. An enzyme responsible for the change of chirality of an amino acid in peptide linkage was first described by Heck et al.[7] from the venom of a funnel web spider. This enzyme catalyzes the partial isomerization from the L- to the D-isomer of a serine close to the carboxyl-end of ω-agatoxin IV.[13] A peptidyl-aminoacyl-L/D-isomerase converting L-isoleucine to D-alloisoleucine at position 2 of mature peptides has been characterized from *Bombina* skin secretions.[9] The inversion of chirality occurs via de-protonation/protonation at the alpha carbon, and the reaction apparently proceeds without the addition of any cofactor.[9] Surprisingly, this enzyme has a rather low selectivity for residues at position 2, but the presence of a hydrophobic amino acid at position 1 and a small residue at position 3 of the substrate are essential.[8] From the skin of *B. orientalis*, two shorter (17 amino acids), more hydrophobic isoforms of the previously identified bombinins H, were also isolated.[6,21] They have an L or D-leucine

as the second residue and lack the lysine-lysine-isoleucine motif at the C-terminus (Table 1, H6 and H7). Moreover, from the sequences of two BLP genes,[18,19] two additional peptides related to bombinins H, were predicted (Table 1, GH-1 and GH-2), but they were never detected in skin secretions. In contrast to other amphibian peptides bearing a D-amino acid, that is, the opioid dermorphin and deltorphins (see the chapter on these peptides in this section of the book and the Opioid Peptides Section), where the all-L isoform is apparently not detectable as a mature peptide and is not active (the presence of D-amino acids is essential for the interaction with opioid receptors), the all L-bombinins H are considerably active, although with different potency and cell selectivity from the corresponding D-amino acid–containing isoforms.

In 2002, from the skin of *B. maxima*, two other families of AMPs equivalent to bombinins and bombinins H were characterized. They are designated as maximins and maximins H, respectively (Table 1).[14] Remarkably, they have been found in the brain of *B. maxima*, but their function in this anatomical area is not yet clear.[15] More recently, from the skin of this *Bombina* species, a new group of AMPs consisting of 14 (maximin S1) or 18 (maximin S2–S5) amino acids has been discovered 29 (Table 1). The presence of a D-amino acid in maximin peptides has not been investigated.[14]

SOLUTION STRUCTURE

Either bombinins (net charge +4/+5) or bombinins H (net charge ranging from +1 to +3) are able to adopt α-helical conformations in hydrophobic environments such as 70% trifluoroethanol. More specifically, the helical conformation of BLPs is mostly amphipathic, as they contain polar residues properly spaced in the sequence, while bombinins H have basic residues confined at the C-terminal region (H1-H5). Furthermore, bombinins H are particularly rich in glycines (25%), which should make the formation of an amphipathic α-helix rather unlikely. As found in NMR solution structure, both H2 and H4 display well-defined

α-helices between residues 5 and 18, whereas a distorted conformation is present at both termini.[30] However, the presence of several glycine residues confer bombinins H a high structural flexibility. Indeed, β-sheet conformers have been detected by Fourier transformed infrared spectroscopy in oriented bilayers of different lipid composition, with an aggregation tendency for the all-L-bombinin H2.[17]

THE GENE STRUCTURE OF BLPS AND BOMBININS H

Genes encoding the precursors of BLPs were cloned from *B. orientalis*.[18,19] These contain two exons separated by large introns (1–2kb). The first exon codes for the signal peptide, whereas the second exon codes for the mature AMP and for acidic and spacer peptides. The genetic information differs between the two genes that have been characterized: The first one (*BLP-3*) contains the information for two copies of a bombinin-like peptide (BLP-3) and a single copy of a bombinin H-related peptide; the second gene (BLP-7) codes only for a single copy of each peptide. The same organization was found in the cDNA clones isolated from *B. variegata*. Canonical Lys–Arg sequences flank the N-terminal end of the mature products for their correct processing, while a Gly residue adjacent the carboxyl-terminus of the peptide is necessary for its amidation. In the promoter regions of these genes, binding sites for NF-κB and NF-IL6 are present. A common regulatory pathway for the expression of AMP genes occurs in amphibians involving cooperation of a large number of transcription factors, such as those acting in the activation of the mammalian acute-phase response. In contrast with bombinins and maximins, the precursors of the homolog maximins S show a completely new arrangement: not a simple assembly of one or two copies of a BLP (maximin-like) plus a bombinin H (maximin H-like) peptide but a complex number and position of copies of active and spacer peptides.[29]

BIOLOGICAL PROPERTIES (ANTIBACTERIAL, ANTIFUNGAL, ANTIPARASITIC, AND CYTOLYTIC ACTIVITIES)

The antimicrobial activity of BLPs and bombinins H was initially distinguished on the basis of their cytolytic properties. BLPs are specifically active against Gram-positive (*Bacillus megaterium*, *Staphylococcus aureus*) and Gram-negative (*Escherichia coli*, *Yersinia pseudotuberculosis*,

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Pseudomonas aeruginosa) bacteria, as well as against *Candida albicans*, with no appreciable hemolytic capacity (Table 2). Differently, bombinins H have a lower antibacterial potency but a higher hemolytic activity.[20,21,23] Afterward, the interest of researchers addressed the functional significance of the incorporation of a D-amino acid in the sequence of bombinins H (either the 20 or the 17 residue peptides). These studies, based on the comparison of the activity of pairs of isomers (e.g. the all-L peptide and the corresponding D-amino acid-containing diastereomer), led to a deeper knowledge of their biological features.[16] Interestingly, when tested in liquid medium assay to determine the MIC value, the D-isoform H4 had a higher activity on Gram-negative bacteria, while an opposite outcome was found against Gram-positive strains, displaying the all-L H2 a 2-4 lower MIC (Table 3). However, our previous results using the inhibition zone assay had shown a stronger antimicrobial activity of H4 with respect to H2, against the Gram-positive *S. aureus.*[16] This could result from a different solubility and diffusion of the peptides through a solid medium. Furthermore, when the two isomers were analyzed in liquid medium for their bactericidal activity on *S. aureus*, both of them were able to cause 99.9% killing of the microbial population at the same concentration.[3]

Regarding the hydrophobic H6 (all-L) and H7 (the D-isomer), they behave in a different way, because only H7 could kill some bacterial strains.[16] An increase in hydrophobicity does not enhance the efficacy of bombinins H and the single positive charge of H6/H7 is not an essential requirement for their antimicrobial activity.[16] In support, the anionic maximin H5 is endowed with antimicrobial properties.[14] Antifungal activity against *Phytophthora nicotianae* spores shows a minimal fungistatic and fungicidal concentration, corresponding to 18 or 10μM, for H2 and H4, respectively. In addition, H2 has a 50% inhibition of *P. nicotianae* hyphae growth, at 18μM.[26] The couple H2/H4 was then tested against the worldwide spread protozoa *Leishmania*: H4 is the most active peptide, being lethal to both the insect stage (promastigote) and the mammalian pathological form (amastigote) of this parasite, at concentrations significantly lower than H2.[17]

To evaluate the cytotoxic effect of the peptides on mammalian cells, the hemolytic activity on human erythrocytes was investigated in physiological solution at different peptide concentrations. Bombinin H6 has the greatest activity, causing approximately 78% hemolysis at 15μM, whereas a hemolytic capacity around 20% was detected for its diastereomer H7 (Table 2). Regarding the couple H2/H4, a higher level of hemolysis is reached by the D-amino acid–containing H4 (28% compared with 11% of the all-L H2). GH-1_L and GH-1_D peptides encoded by the BLP-3 gene, are both devoid of cytotoxic effect at all concentrations used. By contrast, significant lysis was manifested by the maximins H[14]

TABLE 3 Minimal Inhibitory Concentration (MIC) of Bombinin H on Different Bacterial Strains

Peptide	H2	H4
	MIC (μM)	
Gram-negatives

BOMBININS H: MECHANISM OF ACTION OF ANTIMICROBIAL ACTIVITY

Previous studies described the ability of H2 and H4 to permeate the membrane of Gram-negative bacteria causing the release of intracellular enzymes, such as β-galactosidase, with a stronger effect for the D-isoform H4, according to its higher growth inhibitory activity on Gram-negative strains.[16] Analogously, the membrane perturbation activity of these two diastereomers on Gram-positive bacteria (i.e. *S. aureus* ATCC 29213) determined by measurement of the intracellular influx of SYTOX Green, shows that H4 increases the membrane permeability more than H2, although H4 has a 2-fold higher MIC than H2 against this strain (Table 3). Presumably, at low concentrations, H2 is more efficient than H4 in inhibiting the growth of Gram-positive bacteria, without affecting the integrity of their plasma-membrane and, as a result, their viability. Differently, at higher concentrations, H4 would have an easier capability to produce membrane breakages causing cell death, compared with H2. This would explain the achievement of a bactericidal effect equal to that exhibited by H2 (99.9% killing of the microbial population at 50μM) despite the higher MIC of H4 with respect to H2. The ability of the two peptides to destabilize bacterial membranes by a nonstereospecific process was confirmed by their capacity to cause the release of calcein from calcein-loaded phosphatidylethanolamine/phosphatidylglycerol (PE/PG) and phosphatidylglycerol/cardiolipin

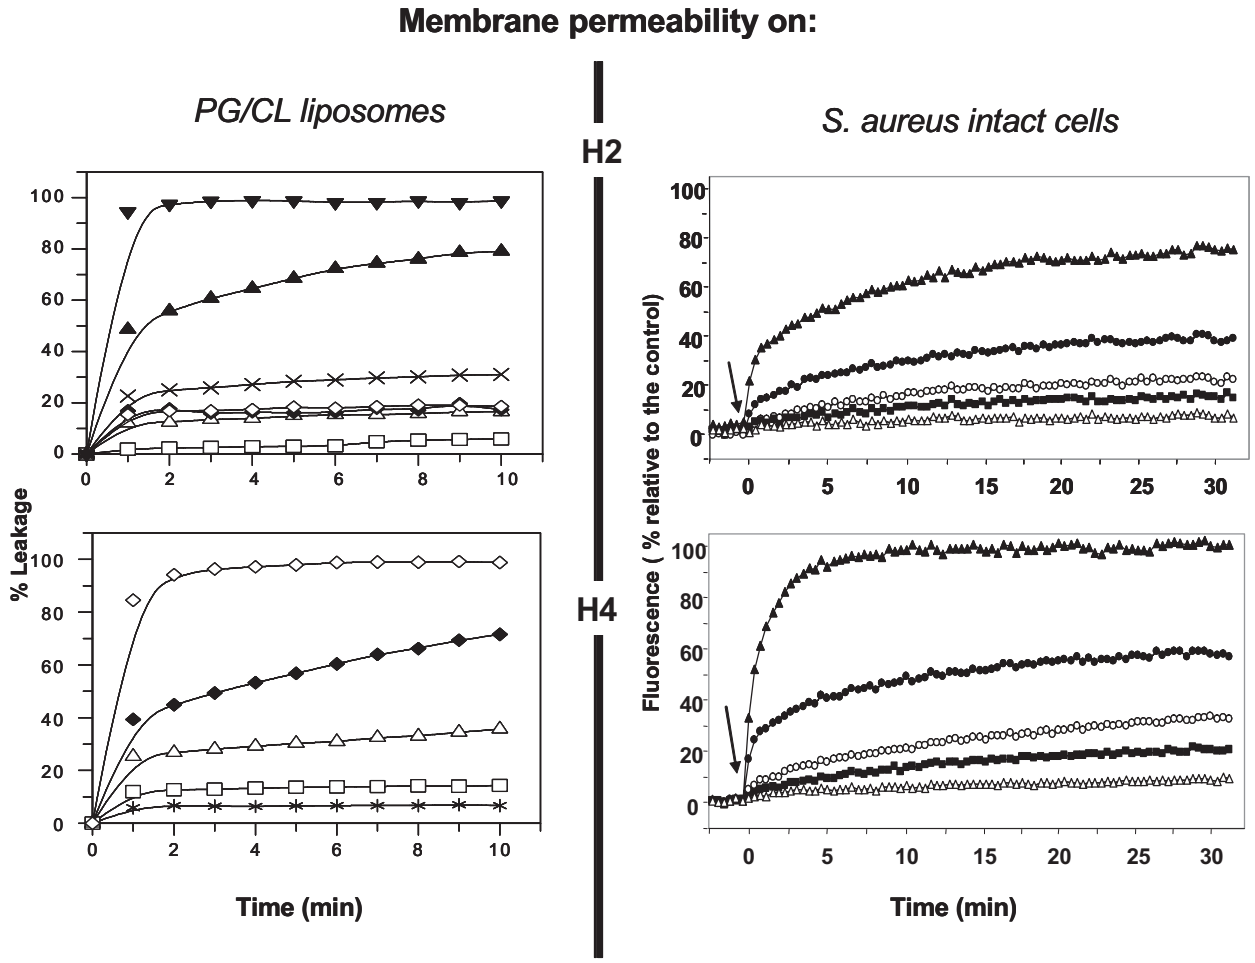

FIGURE 1 Effect of bombinins H2 and H4 on the membrane permeation of PG/CL liposomes (left panels) and of *S. aureus* ATCC 29213 (right panels). Left panels: Calcein leakage from PG/CL (6:4, w/w) vesicles, after peptide treatment. Calcein release from liposomes (50μM final concentration) was detected fluorimetrically ($\lambda_{exc}=490$nm, $\lambda_{ems}=517$nm). The percentage of leakage was calculated as described in Ref. 3. Peptide concentrations used were the following: 0.25μM (○); 0.5μM (*); 0.75μM (●); 1μM (□); 1.5μM (□); 2.5μM (Δ); 3μM (u); 3.5μM (◊); 7.5μM (×); 10μM (▲); 15μM (▼). Right panels: Intracellular influx of SYTOX Green. Cells were incubated with 1μM probe in PBS. Once basal fluorescence reached a constant value, the peptide was added (arrow, $t=0$) and changes in fluorescence were monitored ($\lambda_{exc}=485$nm, $\lambda_{ems}=535$nm) and plotted as the percentage of fluorescence, relative to that of bacteria fully permeated by the addition of Triton X-100 (1%, v/v, final concentration). All readings were normalized by subtracting fluorescence values of control (bacteria without peptide). Peptide concentrations used were the following: 3.125μM (Δ); 6.25μM (□); 12.5μM (○); 25μM (●) and 50μM (▲).

(PG/CL) liposomes.[3] These two lipid compositions were used to mimic the membrane of Gram-negative and Gram-positive bacteria, respectively. The higher affinity of H4 toward PG/CL phospholipid bilayers and its higher perturbing activity on this type of model membrane (Fig. 1), with respect to H2, supports the notion that the higher activity of the D-isoform is not mediated by recognition of a chiral target. Interestingly, working with PE/PG vesicles to mimic the lipid composition of *E. coli* inner membrane, both diastereomers similarly disturb the structure of these vesicles.[3] This suggests that the discrepancies found between the two isoforms in permeating the membrane of intact Gram-negative bacteria result from differences in their diffusion process through the microbial cell wall before reaching the target cytoplasmic membrane. A possible reason is that the D-amino acid–containing peptide is less aggregated in solution compared with the all L-bombinin H; therefore, it may be easier for it to penetrate through the peptidoglycan layer into the plasma-membrane. Indeed, the stereochemical isomerization of residue 2 to D-alloisoleucine in H4 peptide drastically decreases its tendency to form intrapeptide contacts,[2] causing conformational changes that may also alter the formation of interpeptide interactions. In the past years, lethal activity against promastigotes and amastigotes of Leishmania protozoa has been studied in depth for H2 and H4. The peptides cause extensive membrane blebbing with increased intracellular vacuolization, loss of electron dense intracellular space, while cytoplasmic organelles lose their regular shape (Fig. 2). Also against this pathogen, both diastereomers have a membrane-perturbing activity correlated to the degree of parasite's death.

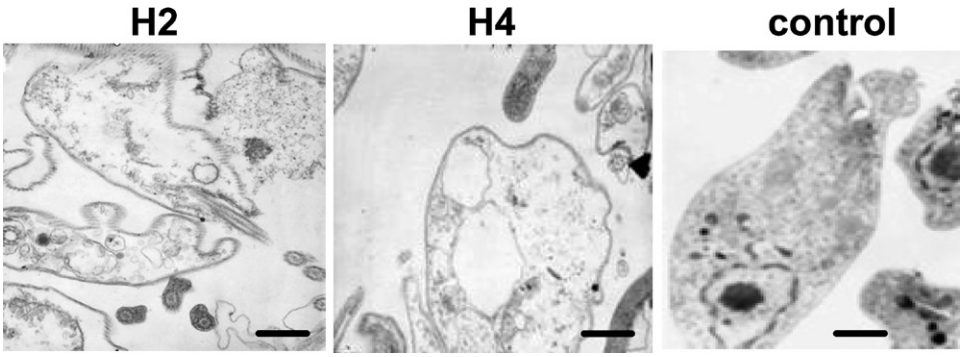

FIGURE 2 Electron microscopy of *Leishmania* promastigotes treated with bombinins H. Parasites were incubated for 1h with bombinins H2 and H4 at the concentration causing 80% killing (bar = 0.5μm).

Differently, for the other pair H6/H7, only the D-amino acid containing H7 permeates the membrane, but in a milder way than the more cationic H2/H4.[16] Indeed, it allows the intracellular influx of small molecules, for example, the chromogenic β-galactosidase substrate (*o*-nitrophenyl-β-galactoside, ONPG) but not the extracellular leakage of large compounds, such as the β-galactosidase.[17]

Chapter 48

Caeruleins

John H. Bowie

ABSTRACT

Caerulein [pEQDY(SO_3H)TGWMDF-NH_2] is a common host-defense peptide of tree frogs of the genus *Litoria*, which has also been identified in several other frog genera. Caerulein is a hypertensive and smooth muscle active peptide that shows gastrin-like bioactivity similar to that of cholecystokinin 8 (CCCK-8), namely, smooth muscle activity, reduction of blood pressure, together with modification of satiety, sedation, and thermoregulation. Many modified caerulein-type peptides also occur in tree frogs, while some of these, *Litoria splendida*, *Litoria rothii*, *and Litoria peronii* change their caerulein content seasonally. The preprocaerulein sequence from *L. peronii* is different from those of other active skin peptides from tree frogs of the genus *Litoria*, suggesting that the ancestral gene producing caerulein is different from that producing other active peptides from *Litoria*.

INTRODUCTION

Amphibians have rich chemical arsenals that form an integral part of their defense systems and also assist with the regulation of dermal physiological action. In response to a variety of stimuli, host-defense compounds including peptides are secreted from specialized glands onto the dorsal surface and into the gut. The peptides exhibit a range of bioactivities, including antimicrobial, anticancer, antiviral, antifungal, and smooth muscle activity.[3,11,18]

Skin secretions may be obtained by electrical stimulation of the glands on the dorsal skin.[23] This benign process may be repeated at monthly intervals and does not harm the frogs. The active form of the peptide is stored in inactive form [as the pronative peptide (derived from the original prepropeptide or signal-spacer-peptide)] in the skin gland and is released in active form onto the skin with the spacer section removed. Often, some peptides, particularly antimicrobial peptides, are cytotoxic to the frog and after a suitable period on the skin (usually about 5–10 min) a protease degrades the active peptide to deactivate it.[18,19] In the particular case of the tree frog *Litoria splendida*, the two major peptides formed in the breeding season are caerulein and the antimicrobial caerin 1.1 hinged peptide [GLLSVLGSVAKHVLPHVVPVIAEHL-NH_2], and the frog can deactivate these peptides by removing the sulfate from caerulein and clipping off the first two amino acid residues (GL) from caerin 1.1.[18] Normally, the bioactive peptides may be identified using HPLC separation of the components of one secretion from one animal. The sequence of each peptide is usually identified by a combination of Edman sequencing and electrospray mass spectrometry. Caerulein-type molecules have a posttranslationally modified N-terminal group, which means that Edman sequencing is not appropriate. Caerulein also has a Tyr (SO_3H) group; the sulfate group is labile using positive ion mass spectrometry, and negative ion mass spectrometry should be used to identify such peptides.[6]

THE CAERULEIN PEPTIDES

Caerulein (Table 1) was first isolated from dried skins of the common Australian Green Tree Frog (*Litoria caerulea*) by Erspamer and colleagues in 1968[2] and subsequently from the African Clawed Frog (*Xenopus laevis*) and *Leptodactylus labyrinthicus*.[1] Erspamer's early survey of bioactive peptides from anurans leads to the isolation of phyllocaerulein from the South American hylid frog *Phyllomedusa sauvagei*, Asn^2Leu^3 caerulein from the South African hyperoliid frog *Hylambates maculata*, [$Glu(OMe)^2$ caerulein from *Nyctimystes disrupta* and Leu^3 caerulein 3–10 from the Philippine ranid frog *Rana erythraea* (for sequences, see Table 1).[11] Many caerulein precursor fragments have recently been identified from several other *Xenopus* species.[8] Caerulein has been identified, after electrical stimulation of the skin glands, in the following *Litoria* species: *L. aurea*, *L. dahlii*, *L. ewingi*, *L. genimaculata*, *L. gilleni*, *L. gracilenta*, *L. infrafrenata*, *L. lesueuri*, *L. raniformis*, *L. splendida*, *L. subglandulosa*, and *L. xanthomera*.[3] More recently, caerulein together with the modification caerulein 1.2 (see Table 1) have been identified from *L. splendida* in winter[27] and also *L. rothii*.[22] A variety of modified caerulein-type peptides (see Table 1) have been isolated from *L. citropa*[26] and *L. subglandulosa*.[7]

**Added in proof. Caerulein B1 [pEQDY(SO_3)GTGWMDF(NH_2)] and caerulein B2 [pEDY(SO_3)TGWMDF(NH_2)] have been isolated from the secretions of the African frogs* Xenopus borealis *and* Xenopus amieti. *[Zahid OK, Mechkarska M, Ojo OO, Abdel-Wahab YHA, Flatt PR, Meetani MA, Conlon JM. Caerulein and xenopsin-related peptides with insulin-releasing activities from skin secretions of the clawed frogs* Xenopus borealis *and* Xenopus amieti *(Pipidae). Gen Compar Endocrinol 2–11;172:314–320].*

Caerulein is similar in sequence to mammalian cholecystokinin 8 (CCK-8)[10] and hexagastrin[15] and the immunomodulator from the pouch of the Tammar wallaby *Macropus eugenii*[4] carrying young. The sequences of these mammalian peptides are listed in Table 1.

Caerulein is stored as inactive pro (spacer) caerulein in the skin glands and when the frog is attacked or is sick, a protease clips off the spacer peptide and the active caerulein is exuded onto the skin of the frog. Preprocaerulein has been sequenced using mRNA and cDNA methods,[20,21,28] and most recently from *Litoria peronii*.[14] Three caerulein clones of very similar amino acid sequence were identified from *L. peronii*; the amino acid sequence of one of these is shown in Table 2. This is compared with the sequence of signal-spacer-caerin 1.1 (preprocaerin 1.1),[24] whose pre (signal) sequence is conserved with those of a variety of other antimicrobial peptides from *Litoria*[22] together with a range of host-defense peptides from some American and European hylid and ranid frogs.[24] It is clear from the data shown in Table 2 that caerulein and caerin 1.1, although present in the secretions of the same frogs, arose via different ancestor genes.

During our initial studies, we assumed that the peptide profiles from the skin glands of tree frogs of the genus *Litoria* were essentially constant throughout the year. That this is not so was demonstrated during a monthly, 3-year study of male and female *L. splendida*, where it was shown that the male sex pheromone splendipherin [GLVSSIGKALGGLLADVVKSKGQPA-OH] was only present in the male secretion during the breeding season, and that the caerulein content varied, for both male and female, seasonally. In the reproductive (summer) season caerulein is the major

hypertensive, analgesic, and smooth muscle active component. In the winter (inactive season) at least half of the caerulein is converted into the less active desulfated caerulein [pEQDYTGWMDF-NH_2] and a new caerulein-type peptide (caerulein 1.2) is produced where the Met8 of caerulein is replaced with Phe8.[27]

The related *L. citropa* and *L. subglandulosa* have quite different antibiotic peptides compared with those of *L. splendida*. However, although the seasonal changes in caeruleins of these species are complex, they follow the same trend as that outlined above for *L. splendida*. Both species form many caeruleins in summer, namely, caerulein itself, together with caerulein 2.1, 3.1, and 4.1 (see Table 1). In winter, significant amounts of these four caeruleins are hydrolyzed to their desulfated forms, and four new caeruleins are produced (caeruleins 1.2, 2.2, 3.2, and 4.2). In all cases, Met8 has been replaced by Phe8. Their structures have been confirmed by negative ion electrospray mass spectrometry.[26,7] Why these two species of frog require such a complex cocktail of caerulein-type peptides is not clear.

The most complicated scenario for a species of the genus *Litoria* that has so far been studied occurs for *L. rothii.* In this case, both the antibiotic peptides and the smooth muscle active peptides vary seasonally.[22] Caerulein and caerulein 1.2 (Phe8 caerulein) are the major-smooth muscle active peptides in the summer. Caerulein is a very minor component in the winter: major "neuropeptide-type" components identified in the winter are caerulein 1.2 (Phe8 caerulein) and the unrelated immunomodulator rothein 1 (SVSNIPESIGF-OH).[22]

To complicate the situation even further, the related species *L. peronii*[5] varies its antibiotic peptides seasonally but keeps its "neuropeptide"—content constant. In this case, caerulein itself is present together with a range of small smooth muscle active peptides, for example, peroniin 1 (pEPWLPFG-NH_2), which shows moderate activity to 10^{-7} M.

The question here is "Why do some tree frogs markedly change the activity of their 'neuropeptides' from the reproductive season (summer) to the inactive season (winter)?" The answer presumably lies in the activities of these peptides, particularly the caeruleins. Caerulein is a primary host-defense peptide, and it also regulates dermal physiological action in the frog. It exhibits a spectrum of activity similar to those of the mammalian intestinal hormones gastrin and cholecystokinin (CCK). There is an extensive literature concerning the pharmacology of caerulein and CCK-8: for a detailed record, see the comprehensive and definitive review by Erspamer.[11] Both CCK-8 and caerulein contain a tyrosine sulfate residue; the bioactivity is significantly reduced if the sulfate group is removed. So hydrolysis of the sulfate is a method of reducing the activity of caerulein, particularly, if after exposure on the skin, caerulein shows some cytotoxicity toward the host anuran. Caerulein induces potent smooth muscle contraction at better than the nanomolar concentration; has gastrin-like activity; modifies satiety, sedation, and thermoregulation; and reduces blood pressure at less than nanograms per kilogram of body weight. Caerulein is recorded to be an analgesic 100–1000 times more potent than morphine: the particular figure depends on the biological system being tested. Caerulein has been used clinically before gall bladder surgery is performed.[11] During the last decade, there have been >300 references in the literature dealing with caerulein induced pancreatitis, mainly in mice and rats: this is beyond the scope of this article.

Of the caeruleins 1–4, apart from caerulein itself, only caerulein 1.2 has been tested for smooth muscle activity. The results indicate that changing Met8 of caerulein to Phe8 of caerulein 1.2 reduces the smooth muscle activity by some 50%.[22] No activity testing of the caeruleins 2, 3, and 4 has been undertaken. Frogs removing the sulfate of caerulein and converting caerulein to caerulein 1.2 in winter are reducing the caerulein smooth muscle activity seasonally from summer to winter. No comment can be made on possible changes in other activities.

CCK-8 and caerulein bind to G protein-coupled CCK receptors.[25] There are two types of CCK receptor: CCK_1 and CCK_2—differing in anatomical location and actions.[9] CCK_1 receptors are present on smooth muscle, and when activated, contract smooth muscle directly. In contrast, CCK_2 receptors act indirectly, causing release of acetylcholine from cholinergic nerves on the myenteric plexus, the acetylcholine then activates muscarinic receptors on smooth muscle. The sequences of the CCK receptors are known,[16] and models of their 3D structures have been reported.[16,17] Both NMR and other experimental data have been used to determine where the partial helix CCK-8 binds to these receptors,[12,13,16,17] but similar data are not available

for caerulein. Caerulein and CCK-8 are able to act through both CCK_1 and CCK_2 receptors, whereas caerulein 1.2 (and rothein 1) act solely through CCK_2 receptors.[22]

ACKNOWLEDGMENTS

The Australian Research Grants Council funds our research on amphibian peptides and mass spectrometry. Associate Professor M.J. Tyler provided the glandular secretions of the *Litoria* species mentioned in this article.

Chapter 49

Chromogranins/ Secretogranins

Maité Montero-Hadjadje, Charlène Delestre, Maité Courel and Youssef Anouar

ABSTRACT

Chromogranins/secretogranins (Cg/Sg) belong to a class of acidic, secretory proteins that occur in endocrine, neuroendocrine, and neuronal cells. Cloning and characterization of chromogranin A, chromogranin B, and secretogranin II revealed that selective sequences within these proteins, bounded by potential processing sites, have been remarkably conserved between amphibian and mammalian species. Peptides such as secretoneurin, vasostatin, and serpinin, which occur in these regions, exert several biological activities. Cg/Sg may also be involved in the formation of secretory granules in amphibians as in mammals. Recent results obtained on the function of Cg/Sg as propeptide precursors and as granulogenic factors in different vertebrate species are discussed.

DISCOVERY

The chromogranin story started with the biochemical studies performed in the midsixties on chromaffin granules that were aimed at understanding the physiology and the pharmacology of catecholamines. Thus, analysis of the secretion of catecholamines from chromaffin cells revealed the existence of a granule-specific, high-molecular-weight protein coreleased with the hormones on splanchnic nerve stimulation.[20] The term chromogranin A (CgA) was coined for this abundant secretory granule protein of chromaffin cells. Subsequently, hormone and neurotransmitter-containing organelles have been characterized in other tissues, and CgA was generally found in these organelles.[3,20] In fact, a large family of chromogranins corresponding to acidic, heat-stable, and soluble proteins has been characterized in the secretory granules of endocrine, neuroendocrine, and neuronal cells where these proteins are stored and released with hormones, peptides, and neurotransmitters in response to a variety of stimuli. Chromogranin B (CgB) was the second member of this family that was also identified in chromaffin cells, while the third chromogranin-like protein was first characterized in anterior pituitary cells and initially named chromogranin C. However, this protein is now known as secretogranin II (SgII) because it exhibits no sequence homologies with CgA and CgB, which are structurally related to each other.[20] This class of acidic, secreted proteins present in secretory granules is currently known as the granin family and has expanded to include other more recently described members such as secretogranins III to VI also called 1B1075, HISL-19, 7B2, and NESP55, respectively.[3]

STRUCTURE AND PROCESSING OF THE PRECURSORS

An important breakthrough in the field of the granins was the elucidation of their primary structures that were deduced from the cloning of the corresponding cDNAs in the mideighties.[20] It was noticed that CgA encompasses in its sequence numerous pairs of basic amino acids that are potential cleavage sites for prohormone convertases (Table 1). In addition, sequence comparisons showed that CgA may represent the precursor of a peptide named pancreastatin (PST) that has been previously isolated from the porcine pancreas and shown to inhibit glucose-induced insulin secretion.[20] These observations suggested that, akin to the precursors of hormones and neuropeptides, CgA could be a prohormone precursor that is processed to give rise to smaller bioactive peptides such as PST.[20] It was subsequently found that CgB, SgII, and all the granins identified to date contain multiple dibasic sites, further supporting the notion that granins may serve as precursors of biologically active peptides. Molecular cloning of granins in mammals also reveals the high content of acidic amino acids, which explains the acidic nature of these proteins (Table 1). This characteristic underlies the propensity of granins to aggregate in high calcium and acidic pH conditions, which are found in the intragranular milieu. It was thus proposed that granins may participate in the sorting and packaging of hormones and neuropeptide precursors into the secretory granules.[6]

CgA, chromogranin A; CgB, chromogranin B; SgII, secretogranin II; ND, not determined.
The molecular mass was deduced from the primary structure. The apparent molecular mass was determined by SDS-polyacrylamide gel electrophoresis.
†Multibasic sites refer to sites with two or more consecutive R or K residues.

Interest in granins in nonmammalian species started when a 33-amino-acid peptide that derives from the endoproteolytic cleavage of SgII was isolated from the frog brain.[29] The characterization of the first granin-derived peptide in a nonmammalian vertebrate, whose sequence has been highly conserved between frog and mammals, reinforced the idea that granins could be considered as propeptide precursors. A homologous peptide was subsequently characterized in mammalian species and named secretoneurin (SN) based on its abundance in the brain and its effects on neuronal activity.[10] It was then hypothesized that the molecular characterization of granins in nonmammalian species would allow the delineation of the sequences that have been preserved during evolution and that may represent the functional determinants of these proteins.

The cloning of the first nonmammalian granins CgA, CgB, and SgII was undertaken in the frog *Rana ridibunda*. Amphibians, which are the first vertebrates that have evolved to a terrestrial life, are a group of particular interest in which to investigate the neurochemical aspects of evolution. Because there was the possibility that the sequences of granins could considerably vary in frog, cloning of short DNA fragments corresponding to SN or the C-terminal regions of CgA and CgB that are strongly conserved in mammals was performed. These short sequences were amplified from the endocrine tissues of frog such as the pituitary or the adrenal and used as probes to isolate the full-length sequences encoding granins from a pituitary cDNA library.

The deduced frog CgA, CgB, and SgII amino acid sequences all contain signal peptides, which would be cleaved to generate mature proteins comprising 381, 580, and 574 amino acids, respectively.[1,2,27] As their mammalian homologs, frog granins are characterized by a high content of acidic amino acids and the occurrence of multiple dibasic cleavage sites, and the existence of two cysteine residues at the N-terminal part of CgA and CgB that have been shown to form a disulfide loop in mammals (Table 1). The abundance of acidic residues in frog granins largely explains the high apparent molecular weight observed for these proteins on SDS–polyacrylamide gel electrophoresis, as previously reported for their mammalian homologs.[20] However, the overall sequence identity for each of these proteins with the corresponding mammalian ortholog does not exceed 40–50% (Fig. 1). This is even more striking if the specific regions of these proteins are compared between mammals and frog. Thus, although certain discrete regions of frog granins display strong sequence conservation with the mammalian counterparts, the majority of the sequences of these proteins exhibit a rather loose homology between the two vertebrate groups. Interestingly, the sequences with high identity between amphibians and mammals are bounded by dibasic cleavage signals (Fig. 1), suggesting that these regions can be processed to generate peptides that may occur ubiquitously, at least in vertebrate species. The most highly conserved region in SgII is that encompassing SN and a flanking peptide (Fig. 1A) that was characterized in various mammalian species and named EM66 in consideration of its N- and C-terminal residues, and its size of 66 amino acids.[19] Cloning of SgII from another amphibian species, *Xenopus laevis*, from goldfish, from chicken,

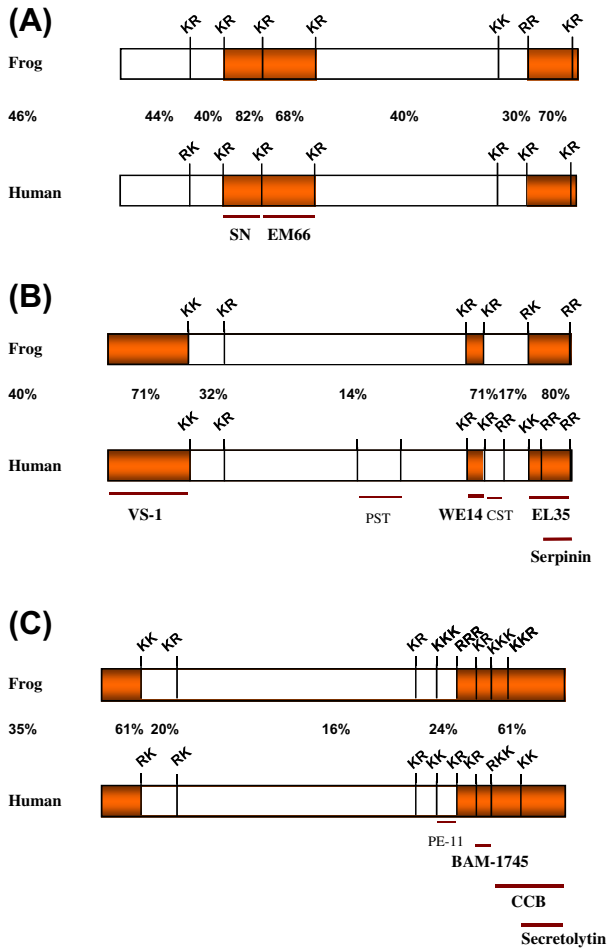

FIGURE 1 Comparison of the primary structures and the putative processing signals of human and frog SgII (A), CgA (B), and CgB (C). The shaded regions represent the highly conserved peptides that can be potentially generated by proteolytic cleavage at the dibasic sites. The percentages of identity between the amino acid sequences of frog and human granins are indicated. Conserved peptides are indicated in bold.

and from lizard[14,28] confirmed the sequence conservation of these peptides.

Within CgA and CgB, the most highly conserved regions occur at the N and C termini of the proteins, which show up to 80% sequence identity, whereas the rest of the two granins markedly diverge; the middle part of these proteins exhibits approximately 20% identity (Fig. 1B and C, see the supplemental disk). It has been shown that CgA is processed in a tissue-specific manner to yield several peptides, some of which are endowed with biological activities (see below). These include vasostatins (VS-1 and VS-2), which exert various effects in different model systems (see below), catestatin (CST), which has been shown to inhibit nicotine-evoked catecholamine release from chromaffin cells, and WE14, a peptide with no known function.[20] As depicted in Fig. 1B (see the supplemental disk), the sequences of VS, WE14 and additional peptides named EL35[20] and its C-terminal part serpinin[13] were preserved during evolution, whereas the region encoding PST in mammals has no homologous sequence in the frog protein and that encoding catestatin is not well conserved in the amphibian species. Several peptides that derive from the C-terminus of CgB have also been isolated and characterized (Fig. 1C). However, apart from a 13-amino-acid peptide purified from the adrenal medulla that exerts an antibacterial effect and named secretolytin,[17] no biological activity was attributed to these peptides.

Sequence comparisons confirm that CgA and CgB have probably evolved from an ancestral common precursor because the N- and C-terminal regions of these proteins display 36 and 45% sequence identity,[1] respectively, as previously reported for the mammalian proteins.[20]

DISTRIBUTION AND REGULATION OF THE mRNAs

The tissue distribution of granins has been extensively studied in several mammalian species. The majority of endocrine and neuroendocrine cells express at least one member of this family of acidic proteins. Pituitary cells, C cells of the thyroid, parathyroid cells, chromaffin cells of the adrenal medulla, and neuroendocrine cells of the gastrointestinal and pulmonary tracts produce and store granins in their secretory granules. In the central and peripheral nervous systems, granins are widely expressed with highest concentrations occurring in certain brain structures such as the hypothalamus, hippocampus, amygdala, and cerebellum.[3] The relative abundance of granins varies in a tissue- and species-specific manner. For instance, SgII is highly expressed in gonadotrophs compared with other pituitary cells or in glucagon-producing alpha cells compared with the other pancreatic endocrine cell types. Human CgA is predominantly expressed in the adrenal medulla, followed by the pituitary and the gastrointestinal tract.[3]

Although granins or granin-like molecules have been detected by immunocytochemistry in various nonmammalian species including birds, fish, flies, and even a unicellular eukaryotic organism, the paramecia, a precise mapping of the sites of synthesis of these proteins has awaited their cloning in frog.[20] Thus, northern blot, reverse transcription-polymerase chain reaction and in situ hybridization analyses provide the first overall mapping of granins in a nonmammalian species.[1,2,27] These studies show that granins are also widely expressed in endocrine, neuroendocrine, and neuronal cells in a nonmammalian vertebrate. Equivalent high levels of SgII mRNA are found in the frog brain, pituitary, and spinal cord, and moderate levels are detected in the adrenal gland. No expression could be seen in the pancreas, stomach, intestine, and kidney using northern blot analysis.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

The CgA gene is more strongly expressed in the frog pituitary than in the brain, spinal cord, or adrenal. Finally, the CgB transcript is abundantly expressed in various organs such as the brain, spinal cord, pituitary, adrenal, pancreas, and heart. In the frog brain, all three granins exhibit a widespread distribution (Fig. 2). In situ hybridization has shown that SgII expression is prominent in the pallium, the amygdaloid complex, and the hypothalamus. CgA mRNA is intensely expressed in thalamic and hypothalamic regions, whereas strong expression of CgB is observed in the lateral pallium, the dorsal hypothalamus, and the anteroventral tegmental area (Fig. 2A and B). Overall, the tissue-distribution studies in frog reveal that SgII is more highly expressed in neuronal tissues, that CgA is strongly expressed in the pituitary compared with all other tissues and that CgB exhibits a more diffuse expression.

Within the frog pituitary, CgA and SgII are present in both the distal and the neurointermediate lobes, whereas CgB only occurs in the pars distalis (Fig. 2B). In amphibians, the intermediate lobe of the pituitary is responsible for the synthesis of melanotropic peptides that induce darkening of the skin, allowing the animals to adapt to the color of the environment and therefore to hide from predators. Melanotrophs of the pars intermedia represent a valuable model in which the neuroendocrine regulation of hormone synthesis and release can be studied in physiological conditions. Thus, the biosynthesis of melanotropic peptides in these cells is tightly regulated through the control of the transcriptional activity of the proopiomelanocortin (POMC) gene, mainly by hypothalamic input.[30] Both SgII and CgA mRNA levels[28] are upregulated in parallel with those of POMC in the intermediate lobe after adaptation to a dark background, and conversely, the levels of these transcripts are downregulated when the animals are placed on a white background. We have observed that CgA and SgII are differentially expressed and processed in frog melanotrophs depending on the status of the secretory activity of these cells: although both SgII and CgA are elevated *in vivo* in dark background-adapted animals, the two proteins could play rather different roles in the regulated secretory pathway in melanotrophs. Thus, CgA expression and processing may be related to hormone storage in secretory granules, whereas SgII production and processing could be part of the active process of hormone release from melanotrophs. Further studies using this model are warranted to better understand the coordinate regulation of the SgII and CgA genes with the POMC gene during the neuroendocrine reflex of skin color adaptation in amphibians.

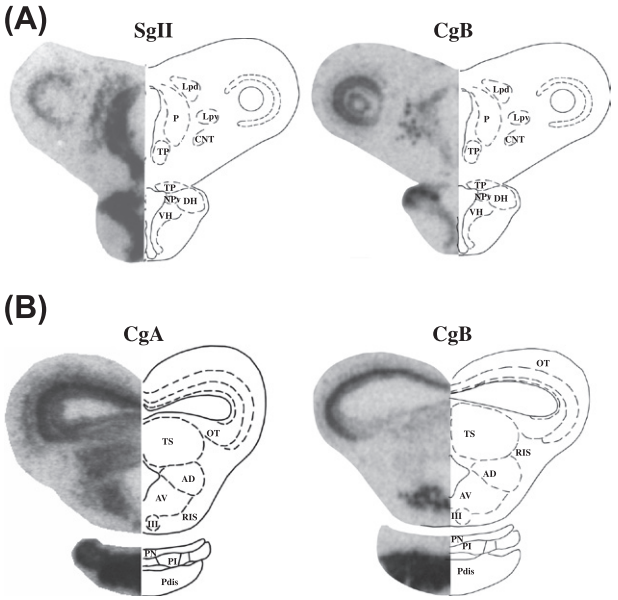

FIGURE 2 In situ hybridization histochemistry of granin mRNA in the brain and the pituitary of the frog *Rana ridibunda*. The left hemisections show autoradiograms obtained from frontal frog brain slices at the level of the diencephalon (A) and mesencephalon (B), hybridized with the CgA, CgB, and SgII antisense probes. The right hemisections designate the anatomical structures. Abbreviations: AD, anterodorsal tegmental nucleus; AV, anteroventral tegmental nucleus; CNT, central thalamic nucleus; DH, dorsal hypothalamic nucleus; Lpd, lateral thalamic nucleus, posterodorsal division; Lpv, lateral thalamic nucleus, posteroventral division; III, oculomotor and trochlear nuclei; NPv, nucleus of the periventricular organ; OT, optic tectum; P, posterior thalamic nucleus; Pdis, pars distalis; PI, pars intermedia; PN, pars nervosa; RIS, nucleus reticularis isthmi; TP, posterior tuberculum; TS, torus semicircularis; VH, ventral hypothalamic nucleus.

BIOLOGICAL ACTIONS

The search for the roles of granins in mammals has focused on their intracellular implication in the packaging of hormones and the formation of secretory granules, and on their extracellular activities as precursors of several peptides that could be released to exert hormonal effects in autocrine, paracrine, and endocrine manners.[3]

Intracellular Functions

Because granins are localized in secretory granules of virtually all neuroendocrine cells and because several studies have shown that these proteins aggregate in intravesicular conditions of acidic pH and high calcium, it has been proposed that they may play a fundamental role in granulogenesis.[6] Direct evidence in support of this hypothesis was lacking for several years until the demonstration by Kim et al.[12] of a pivotal role of CgA in the biogenesis of secretory vesicles in neuroendocrine cells. Inhibition of the expression of CgA in PC12 cells leads to a marked decrease in secretory granule formation and to impairment of the release of a transfected hormone. Subsequent studies revealed that CgB[11] and SgII[4] are also efficient in inducing the formation of secretory granule-like structures in non-neuroendocrine cells that are normally devoid of a regulated

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

pathway of secretion, suggesting that granins may play a crucial role in the generation of secretory vesicles. In addition, stored SgII could be released in a regulated manner from transfected, constitutively secreting cells.[4] Interestingly, the expression of frog CgA also induced secretory granule-like structures in nonneuroendocrine COS7 cells and the deletion of the conserved terminal domains of fCgA strikingly reduced its granulogenic activity (Fig. 3),[21] suggesting that CgA, through its N- and C-terminal domains could play an intracellular role in secretory granule formation in different vertebrates. In addition, the high content of acidic amino acids in frog CgA, alone or in combination with the conserved N- and C-terminal regions, is probably also required to confer the aggregating properties of this granin. Because all granins contain a high proportion of acidic amino acids in all species studied to date, this structural feature may well represent a critical requirement for the granulogenic effect of these proteins.

Several studies have proposed additional intracellular roles for certain members of the granin family. For instance, CgA and CgB are involved in intracellular calcium (Ca^{2+}) mobilization because these granins bind to the inositol 1,4,5-trisphosphate (IP_3) receptor that is present on the membranes of secretory granules and facilitate Ca^{2+} release in response to IP_3.[33] Finally, a clear intracellular function has been established for the granin-like protein 7B2, which binds and activates PC2 through two domains that have been highly conserved in various species, including the toad *Xenopus laevis*.[16] Most of the functional characteristics of 7B2 have been deduced from initial studies performed in Xenopus melanotroph cells in which this protein is also regulated in concert with POMC during background color adaptation.[16] The introduction of 7B2-knockout mice models has allowed confirmation and extention of these earlier studies.[23] Knockout models for the granins CgA and CgB firmly show the involvement of these proteins in intracellular events associated with hormone and neurotransmitter release.[15,22] Homozygous double mutant CgA/CgB mice are still capable of generating secretory vesicles but with impaired capacity to concentrate catecholamines in chromaffin cells.[8] As SgII has also been shown to play a role in granulogenesis,[7] the generation of a knockout model for SgII will allow elucidation of whether this granin may compensate somehow for CgA and CgB function in secretory vesicle biogenesis.

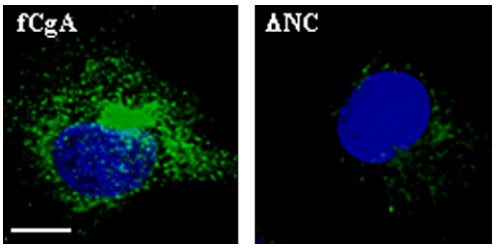

FIGURE 3 Granulogenic activity of frog CgA. COS7 cells transfected with the cDNA encoding full-length CgA (fCgA) or CgA deleted in its N- and C-terminal parts (ΔNC) were incubated with a rabbit antiserum directed against frog CgA ($CgA_{107–234}$) and examined for fCgA immunoreactivity using confocal microscopy. Scale bars, 10 μm. See color plate 14.

Extracellular Functions

The notion that granins may serve as precursors to biologically active peptides has received much attention since the first demonstration that the CgA-derived peptide PST exerts a potent inhibitory effect on insulin release from pancreatic cells.[20] Proteolytic processing of CgA, CgB, and SgII at both monobasic and dibasic residues gives rise to a wide spectrum of peptides, some of which exert biological actions, in particular inhibitory effects on hormone secretion from different endocrine glands.[3] In the context of this review, we will focus our attention only on peptides whose sequence has been conserved between frog and mammals (Table 2), which could be relevant to amphibian physiology. Among the peptides that could act in amphibians based on the remarkable preservation of their sequence, VS inhibits vasoconstriction of arteries in mammalian species.[20] Interestingly, VS and VS-derived peptides may exert cardioregulatory actions in frog.[20] VS-derived peptides promote fibroblast adhesion,[9] affect human colonic motility *in vitro*, trigger neuronal apoptosis, are involved in nociceptive responses in the rat,[3] and regulate tumor neovascularisation.[31] Further, the N-terminal peptides of CgA also exert potent antibacterial and antifungal activities.[17] Besides, a large polypeptide that derives from the highly conserved C-terminus of CgA has been previously isolated and named parastatin in consideration of its effect on parathyroid hormone secretion from parathyroid chief cells.[20] However, no results are currently available on the occurrence of this peptide and its actions in amphibian species. Nevertheless, a C-terminal peptide named EL35 is present in both frog and mammalian CgA and is produced in rat and human tissues,[18,27] suggesting that the processing of the C-terminal region of this granin may give rise to a ubiquitous peptide that may exert biological activities. A peptide encompassed in EL35 sequence (AL26) and named serpinin is secreted from endocrine cells to control granule biogenesis through the regulation of the protease nexin-1.[13]

Although peptides derived from the N and C termini of CgB have also been identified, there are few functional studies using these peptides. In particular, several C-terminal peptides have been isolated from various tissues such as GAWK and CCB, which have been purified from the human pituitary gland, a pyroglutamyl peptide named BAM-1745 that has been identified in bovine adrenochromaffin cells, and an 11-amino-acid peptide named PE-11 that has been characterized in the rat and human brain, but the activity of all these peptides remains unknown.[3] One exception is the

TABLE 2 Functions of Granin-Derived Peptides Conserved between Frog and Mammals

Chromogranin A-derived peptides	Biological activity of the peptide
Vasostatin-1 (bCgA$_{1–76}$)	Inhibits vasoconstriction; inhibits cardiac performance; promotes fibroblast adhesion; inhibits parathyroid hormone secretion; triggers microglial-cell-mediated neuronal apoptosis; exerts bacteriolytic and antifungal effects; regulates tumor neovascularization.
Parastatin (pCgA$_{347–419}$)	Inhibits parathyroid hormone secretion from parathyroid chief cells.
Serpinin (bCgA$_{403–428}$)	Upregulates the expression of the protease nexin-1 and granule biogenesis in endocrine cells.
Chromogranin B-derived peptides	
Secretolytin (bCgB$_{614–626}$)	Exerts bacteriolytic effects.
Secretogranin II-derived peptides	
Secretoneurin (rSgII$_{154–186}$)	Stimulates luteinizing hormone release from gonadotroph cells and dopamine release from central striatal neurons; promotes chemotactic attraction of monocytes, eosinophils, and fibroblasts; stimulates proliferation and migration of vascular smooth muscle; stimulates migration and inhibits proliferation of endothelial cells; stimulates transendothelial migration of monocytes; activates endothelial cells for neutrophil adherence; facilitates endothelium-dependent relaxation; promotes neurite outgrowth in cerebellar granule cells and neuronal cell survival.

bCgA, bovine chromogranin A; pCgA, porcine chromogranin A; rSgII, rat secretogranin II; bCgB, bovine chromogranin B.

peptide secretolytin, which exerts antibacterial activity.[17] The sequence of the majority of these peptides is highly conserved in the frog protein, but their occurrence as free entities and their function in this species have not been studied.

The SgII-derived peptide SN, initially isolated from the frog brain,[29] has been extensively studied during the last decade.[10] SN has emerged mainly as a peptide that links the nervous and the immune systems. Thus, SN attracts monocytes, eosinophils, and endothelial cells at sites of injury, facilitates endothelium-dependent relaxation, and acts as an angiogenic factor.[5,24] In addition, SN stimulates dopamine release from rat striatal slices, influences neurite outgrowth in cerebellar granule cells,[10] and promotes neuronal survival and plasticity.[26] Signaling mechanisms involved in the effects of SN have been proposed and include activation of phosphoinositide 3-kinase, protein kinase C, and antiapoptotic proteins Bcl-2 and Bcl-xL through the Jak2/Stat3 pathway, as well as blockade of caspase-3 activation.[13,26] Finally, SN exerts stimulatory effects on pituitary luteinizing hormone release from goldfish pituitary and mouse LβT2 gonadotroph cells, which suggests an important role played by SN in reproduction.[34] Specific binding sites for SN have been found in human monocytes and may represent the putative functional plasma membrane receptor for SN, which has not been identified so far.[25] SN exhibits 82% sequence identity between frogs and humans and is the most highly conserved region in SgII, indicating that SN may represent an authentic neuropeptide in various species.

Flanking SN at its C-terminus, the peptide EM66, which occurs in all species studied to date, including the frog *R. ridibunda*[32] [and unpublished observations], is also of potential interest. The concentration of EM66 is modulated by food deprivation in the jerboa hypothalamus, suggesting that this peptide may be involved in the control of food intake and/or the stress associated with fasting.[20]

The functions of the neuroendocrine proteins chromogranins and secretogranins have been intensively investigated during the last 45 years, at least for CgA and CgB, which were the first members of this family that were discovered. Although their physicochemical properties, localization, processing, and regulation are now well known, their function still remains incompletely understood. An intracellular role for these proteins has received strong support during the last few years, and some fundamental notions are now emerging that will probably enhance our understanding of the intracellular intervention of these proteins in hormone storage and release. Besides, the role of granins as precursors to neuropeptides and hormones is an attractive hypothesis that still needs to be substantiated. Several questions related to the mode of action of the derived peptides often remain unanswered. SN,V, and serpinin whose sequences have been preserved during evolution, are highly potent at regulating different systems but the issues of the concentrations used, the existence of specific receptors and the effects of these peptides *in vivo* should be clarified. Other biologically active peptides such as PST and CST may be relevant only in mammals because their sequences are either lacking or poorly conserved in certain vertebrates such as frog, suggesting that these peptides may have emerged late during evolution and/or their sequence has evolved rapidly. Thus, elucidation of the sequences and the properties of granins in frog, and the study of their expression in this model have

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

provided insights to help determine the physiological role of these proteins and to decipher the structure–activity relationships that may govern their function in all species.

Chapter 50

Dermaseptins

Pierre Nicolas and Ali Ladram

ABSTRACT

The dermaseptins belong to a superfamily of host defense peptides that are made in the skin of Hylidae frogs. These peptides are genetically related, with a remarkable identity in signal sequences and intervening sequences of their preproforms, but they have markedly diverged to yield several families of peptides that are structurally and functionally distinct. These include the dermaseptins (*stricto sensu*), the phylloseptins, the plasticins, the dermatoxins, the phylloxins, the raniseptins, the caerin-related peptides, the caerins, the fallaxidins, the frenatins, and the aureins. Most of these peptides are cidal against wall-less bacteria, Gram-negative and Gram-positive bacteria, fungi, protozoa, yeast, and enveloped viruses but are weakly toxic against mammalian cells. Their antimicrobial activity results from their capacity to bind to the bacterial plasma membrane, thereby triggering transient wormhole formation or membrane disruption. The dermaseptin superfamily also includes D-amino acid–containing opioid peptides (dermorphins, deltorphins), bradykinin-related peptides, myoactive peptides (hyposins/sauvatide, tryptophyllins), and Bowman–Birk-like trypsin inhibitors.

THE DERMASEPTIN SUPERFAMILY: A LIBRARY OF STRUCTURALLY AND FUNCTIONALLY DISPARATE PEPTIDES ORIGINATING FROM A SINGLE GENE FAMILY

Hylidae (tree frogs) are one of the largest families of frogs. There are about 51 genera that are arranged in three subfamilies: Pelodryadinae, Phyllomedusinae, and Hylinae. The first member of the dermaseptin superfamily, named dermaseptin-S1, was isolated from an extract of dried pieces of skin of *Phyllomedusa sauvagii* (subfamily: Phyllomedusinae) in the early 1990s.[26] This 34-residue peptide has lytic activity against Gram-positive and Gram-negative bacteria, yeast, and protozoa, without harmful effects against mammalian cells. It was the first gene-encoded eukaryotic peptide to show lethal effect against *Leishmania* promastigotes[16] and filamentous fungi that are responsible for opportunistic infections resulting from the immunodeficiency syndrome or the use of immunosuppressive agents. This discovery was followed by the isolation of adenoregulin (also named dermaseptin-B2) from *P. bicolor* skin, a peptide that interacts with the adenosine receptor,[11] and dermaseptin-B1.[27] These 2 peptides were thought to be unrelated until attempts to clone their precursor polypeptides revealed the presence of a common preproregion and 5′- and 3′-UTRs as well as extensive sequence identities with precursors of opioid peptides dermorphin, dermenkephalin, and deltorphins from *Phyllomedusa* skin.[2,3] Since then, additional members of the dermaseptin superfamily were rapidly identified in various species of South American Hylidae frogs and grouped to form distinct families on the basis of their structural characteristics: (1) the dermaseptins (*stricto sensu*) from *Agalychnis annae*, *A. callidryas*, *A. dacnicolor*, *A. lemur*, *A. spurrelli* (*litodryas*), *Phasmahyla jandai*, *Phyllomedusa bicolor*, *P. burmeisteri*, *P. distincta*, *P. hypochondrialis*, *P. oreades*, *P. sauvagii*, *P. tarsius*, *P. tomopterna*, and *P. trinitatis* (Table 1). Most of these peptides share a signature pattern consisting of a conserved Trp residue at position 3 and an AA(A/G)KAAL(G/N)A consensus motif in the midregion; (2) the dermatoxins from *Agalychnis annae*, *A. dacnicolor*, *Phasmahyla jandaia*, *Phyllomedusa bicolor*, *P. sauvagii*, and *P. tarsius* (Table 2); (3) the phylloxins from *Phyllomedusa bicolor* and *P. sauvagii* (Table 3); (4) the phylloseptins from *Agalychnis lemur*, *Phasmahyla jandaia*, *Phyllomedusa bicolor*, *P. burmeisteri*, *P. hypochondrialis*, *P. palliata*, *P. sauvagii*, *P. tarsius*, and *P. tomopterna* (Table 4); (5) the plasticins from *Agalychnis dacnicolor*, *A. annae A. callidryas*, *Phyllomedusa bicolor*, and *P. sauvagii*, which are rich in Gly and Leu residues arranged in regular 5-mer motifs GXXXG (where X is any amino acid residue) (Table 5); (6) the raniseptins from *Hypsiboas raniceps* (Table 6); (7) the caerin-related peptides from *Agalychnis annae* and *A. callidryas* (Table 7); and (8) the orphan peptides from *Agalychnis dacnicolor*, *Phyllomedusa hypochondrialis*, and *P. sauvagii*, which do not resemble any members of the other peptide families (Table 7). As shown in Tables 1–7, different species of hylid frogs are equipped with different sets of peptides

belonging to different families. Orthologous peptides and paralogous peptides have different amino acid sequences in different species and most often display differential activity against a range of microorganisms. This impressive divergence between and within species is such that the evolutionary relationships of these peptides would never have been apparent without the strong conservation of their biosynthetic precursor preproregions (Section 2). Australian hylid frogs belonging to the Pelodryadinae subfamily also produce in their skin several families of antimicrobial peptides (caerins, fallaxidins, frenatins, aureins) (see the chapter by Bowie and Tyler, in this Section of the book) that have no structural similarity with South American hylid peptides, but the signal peptide and intervening sequences of the precursors of the caerins, fallaxidins, frenatins, and aureins are highly similar to the corresponding regions of the precursors of the South American hylid antimicrobial peptides (Table 9). Similarly, numerous antimicrobial peptides from Eurasian and North American frogs (families: Ranidae and Dicroglossidae) that belong to the brevinin, esculentin, nigrocin, palustrin, ranacyclin, ranalexin, ranatuerin,

amolopin, temporin, and limnonectin[34] families have precursors whose preproregions strikingly resemble those of preprodermaseptins (Table 9) (see the chapter by Conlon in this Section). Frog skin secretions are also a rich source of biologically active neuropeptides and hormones that are very similar to mammalian peptides that are produced in the brain and the gastrointestinal tract. Most interestingly, preprodermaseptin-encoded peptides also include D-amino acid-containing opioid peptides belonging to the dermorphin/deltorphin family (see the chapter by Negri and Melchiorri in this Section), bradykinin-related peptides, the myoactive peptides hyposins and tryptophyllins, and Bowman–Birk-like trypsin inhibitors[32] (Tables 8 and 9). The discovery of the considerable extent of sequence identity between the neuropeptide and antimicrobial peptide precursors is unprecedented. Thus, although the two groups of peptides are genetically related and belong to the same gene superfamily, they have strongly diverged to yield families of peptides that are both structurally and functionally distinct.

THE DERMASEPTIN SUPERFAMILY: GENE DUPLICATION, FOCAL HYPERMUTATION, AND DIVERSIFYING SELECTION

Peptides of the dermaseptin superfamily are synthesized in the multinucleated cells of the granular glands of the skin as prepropeptides that are processed by the removal of the signal peptide to the proform and then stored in the secretory granules of the glands. Glands may release their content onto the skin surface by a holocrine mechanism involving rupture of the plasma membrane and extrusion of the granules through a duct opening to the surface. Each peptide precursor results from transcription of a single genetic

locus that encodes a single mature peptide at the C-terminus of the precursor sequence (Table 9). The canonical precursor architecture comprises a common N-terminal preprosequence of approximately 50 residues that is remarkably well conserved both within and between species, while the C-terminal sequence corresponding to antimicrobial peptide or neuropeptide varies markedly.[30] The conserved region comprises a 22-residue signal peptide followed by an acidic intervening sequence that ends in a typical prohormone processing signal Lys-Arg. This conservation also extends into the 5′- and 3′-untranslated regions of the corresponding mRNAs. Preprodermaseptin mRNAs thus show a unique pattern of very high sequence conservation surrounding a region of very high sequence variability. The contrast between the strikingly conserved preproregion and the hyperdivergent mature peptides is one of the most extreme examples observed to date for homologous gene products within a single order of organisms. Moreover, the pattern of conserved and variable regions in skin antimicrobial peptide precursors is the opposite of that of conventional secreted peptides, suggesting that the conserved preproregion is important for the biology of the expressing cell.

The remarkable similarity of preproregions of precursors that give rise to very different end products in distantly related frogs suggests that all the corresponding genes came from a common ancestor in the ancestor of South American and Australian hylids and North American and Eurasian ranids before their divergence in the Mezozoic age 150 million years ago. A combination of phylogenetic reconstructions, analysis of mutation rates, and geophysical models for the sequence of fragmentation of Gondwana suggest that the impressive diversity of these peptides and the number of peptides per species reflect the combination of multiple duplications of the ancestral gene before and during radiation of these species and within individual species, focal hypermutations of the mature peptide domain, and subsequent actions of diversifying (positive) selection.[18,33] Targeted hypermutation of the C-terminal antimicrobial-coding region of preprodermaseptin genes might have evolved as a way of increasing genetic diversity, thus accelerating the adaptation of frogs to noxious microbial fauna.

binding to lipid bilayers.[21] They are cidal at micromolar doses against a wide spectrum of microorganisms, including wall-less bacteria (mollicutes), Gram-negative and Gram-positive bacteria, fungi, protozoa, yeast, and enveloped viruses, but each peptide has considerable variations in its antimicrobial activity.[28] All the dermaseptins, but DRS-S4, are not or weakly toxic against mammalian cells. The dermaseptins S exhibit synergy of action on combination, resulting in some cases in a 100-fold increase in antibiotic activity of the mixture over the activity of the peptides separately.[28] Shortening the peptide chain of DRS-S3 to DRS-S3-[1–16]–NH2 does not affect the potency of the peptide. Further reduction of the chain length yields derivatives gradually showing reduced activity, but analogs as short as 10–12 residues in length remain fully active against several bacterial strains.[29] [K^4]-DRS-S4-[1–16] has been investigated for antibacterial activity *in vivo*, using a peritonitis model of mice infected with *Pseudomonas aeruginosa*. Naive mice exhibited 75% mortality, compared with 18% mortality in mice that received a single i.p. injection (4.5mg/kg) of [K^4]-DRS-S4-.$^{1–16}$ Dermaseptins S1–S5 and DRS-H10 exhibit cidal activity against *Leishmania* in its promastigote form at micromolar doses,[9,16,28] and gold-labeled freeze-fracture microscopy shows that the peptides generate severe perturbations of the lipid bilayer, leading to the death of the parasites. DRS-S3 and derivatives of DRS-S4 selectively disrupt the plasma membrane of the intracellular parasite *Plasmodium falciparum* without harming that of the mammalian host cell.[12] The resulting antimalarial activity is allegedly exerted after the harmless peptide binding to the membrane of the host cell, followed by peptide translocation across a number of intracellular membrane systems and interaction with that of the intraerythrocytic parasite. Dermaseptin-O1, -DI1, and -DI2 show antiprotozoan activity against *Trypanosoma cruzi* in its tryptomastigote and epimastigote forms cultivated in both cell culture and blood media, without toxicity against mouse erythrocytes and white blood cells.[8] Dermaseptins S1–S5 display antiviral activity against herpes simplex virus type I and HIV-1 virus at micromolar doses.[22] The most potent peptide, DRS-S4, inhibits cell-free and cell-associated HIV-1 infection of D4-CCR5 indicator cells and human primary T lymphocytes. The peptide is effective against R5 and X4 primary isolates and laboratory-adapted strains of HIV-1. Its activity is directed against HIV-1 particles by disrupting the virion integrity.

Dermatoxins: The primary structures of dermatoxins are highly conserved exhibiting few chemically conservative amino acid substitutions (Table 2). DRT-B1 proved to be cidal toward mollicutes and Gram-positive bacteria and also, though to a lesser extent, toward Gram-negative bacteria. Measurement of the bacterial membrane potential revealed that the plasma membrane is the primary target of dermatoxin. Observation of bacterial cells by reflected light

fluorescence microscopy after DNA staining was consistent with a mechanism of cell killing based on the alteration of membrane permeability. In a liquid growth inhibition assay, DRT-B1 killed ≈50% of *Burkholderia cepacia*, a human pathogen that causes pneumonia in immunocompromised individuals with underlying lung disease (such as cystic fibrosis or chronic granulomatous disease). This showed that *B. cepacia* cell populations contain a mixture of dermatoxin-sensitive and dermatoxin-insensitive variants and that the liquid growth inhibition assay fails to reveal such a phenomenon.

Phylloxins: Two phylloxins from *Phyllomedusa* skin were identified, phylloxin-B1 from *P. bicolor* and phylloxin-S1 from *P. sauvagei* (Table 3). The primary structures of the two phylloxins are extremely conserved, exhibiting only one conservative amino acid substitution. Phylloxins have a narrow antimicrobial spectrum including the strains of the wall-less bacteria *Acholeplasma laidlawii* and *Spiroplasma melliferum*, the Gram-negative bacteria *Escherichia coli*, and the Gram-positive bacteria *Micrococcus luteus*. However, the Gram-negative bacteria *Pseudomonas aeruginosa*, *Sinorhizobium meliloti*, and *Salmonella typhimurium* and the Gram-positive bacteria *Staphylococcus aureus* and *Corynebacterium glutamicum* are resistant to PLX-B1. The antibiotic activity proved to be lethal for some of the sensitive strains, which were not capable of resuming growth on agar plates after a 2-h treatment with concentrations above the corresponding MICs.

Phylloseptins: The first member of the phylloseptin family, phylloseptin-B1, was discovered by cDNA cloning of preprodermaseptins from *P. bicolor*.[33] The common structural features of phylloseptins include a highly conserved sequence FLS[I,L]LI[L]P in the N-terminal region and C-terminal amidation[20] (Table 4). The antimicrobial activity spectrum of phylloseptins includes Gram-negative and Gram-positive bacteria, fungi, and protozoa: *Leishmania amazonensis* promastigotes; *Plasmodium falciparum* rings, trophozoites, and schizonts;[19] and *Trypanosoma cruzi* trypomastigotes.[20] PLS-H1 displays broad-spectrum activity against a range of planktonic organisms with a high potency (MIC = 5μM) against *Staphylococcus aureus*. In a specific bioassay with the same organism grown as a biofilm, the minimal biofilm eradication concentration was found to be of the same high potency.[35] No toxic effect was observed in an *in vitro* system and in an *in vivo* model with a concentration of PLS-H1 10-fold over that providing antimicrobial effect.

Plasticins: The plasticins, which are rich in Gly and Leu residues arranged in regular 5-mer motifs GXXXG (where X is any amino acid residue), have very similar amino acid sequences, hydrophobicities, and amphipathicities but differ markedly in their net charge, conformational plasticity, and activity spectra.[13,17] Plasticins are divided into two classes on the basis of their cytolytic activities. The strongly cationic peptides PTC-B1 and PTC-S1 that contain lysine residues are bactericidal against most of the tested microorganisms at micromolar concentrations and permeabilize the cytoplasmic membrane of *E. coli*, but the weakly cationic or neutral plasticins (PTC-A1, -C1, -C2, and -DA1) are hemolytic only. Plasticins display considerable conformational flexibility and polymorphism that modulate their ability to bind to and disrupt the bilayer membranes of prokaryotic and eukaryotic cells and/or to reach intracellular targets. For example, PTC-DA1 adopts a helical conformation when bound to anionic phospholipid vesicles but a β-sheet structure when bound to zwitterionic vesicles. All plasticins present a turn region that does not always result in folding into a β-hairpin-shaped conformation. However, a preformed β-hairpin in solution may act as a conformational lock that prevents the switch to α-helical structure. This lock lowers the antimicrobial efficiency and explains subtle differences in potencies of the most active antimicrobial plasticins.

Raniseptins: Raniseptins from *H. raniceps* display antimicrobial potential *in vitro* preferentially against Gram-negative bacteria and limited cytotoxicity against red blood cells. MALDI-IMS demonstrated that the mature raniseptins although stored inside the skin glands in their intact form within a defined glandular domain, undergo rapid proteolytic cleavage upon secretion. RSP-R1-(1–14) showed much lower or no antimicrobial action when compared with the intact RSP-R1. This contrasts with DRS-S1-$^{1–18}$ and shorter fragments of dermaseptin-S3 that still retain full potency against Gram-negative bacteria. Because RSP-R1-(1–14) possesses little or no antimicrobial activity, the raniseptin processing in Hylinae frogs presumably acts as a mechanism by which the protein and peptide content is altered to respond to different predatory attacks.

Caerin-related peptides: The 27-mer caerin-related peptides from *A. annae* and *A. callidryas* are most closely structurally related to caerins from Australian tree frogs—caerins 1.17 and 1.19 from *Litoria gracilenta*, and caerin 1.7 from *Litoria xanthomera* and *Litoria chloris*. This finding is not inconsistent with taxonomic suggestions and evidence that both Neotropical phyllomedusids and Australasian litorids are close phylogenetic relatives.[33]

Orphan peptides: Dermaseptin-S9 does not resemble any of the cationic and amphipathic antimicrobial peptides identified to date, having a highly hydrophobic core sequence flanked at either side by cationic termini. The peptide has broad-spectrum antibacterial activities and a low hemolytic activity, inhibiting the growth of Gram-positive and Gram-negative bacteria with minimal inhibitory concentrations in the micromolar range. DRS-S9 adopts a nonamphipathic α-helical conformation in trifluoroethanol, but it forms stable and ordered β-sheet aggregates in aqueous buffers or when bound to anionic or zwitterionic phospholipid vesicles. These structures slowly assemble into amyloid-like fibrils in aqueous environments via

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

spherical intermediates, as revealed by electron microscopy and Congo red staining.[6] DRS-S9 induced the directional migration of neutrophils, T lymphocytes, and monocytes. The antimicrobial and chemotactic activities of DRS-S9 are modulated by its amyloid-like properties. Although spherical oligomers of DRS-S9 exhibit antimicrobial activity, the soluble, weakly self-associated forms of DRS-S9 act on human leukocytes to promote chemotaxis and/or immunological response activation in the same range of concentration as amyloidogenic peptides Aβ-(1–42) and the prion peptide PrP-(106–126).

MECHANISMS OF MICROBICIDAL ACTIVITY

The mode of antimicrobial action of most of the preprodermaseptin-derived peptides is believed to be the permeation/disruption of the lipid plasma membrane of the target cells through an interfacial location of amphipathic antimicrobial peptides inducing positive curvature of the bilayer and/or clustering of anionic lipids.[14,21] The high content of anionic lipids in prokaryotic membranes and their absence from the neutral matrix of erythrocytes account for the preferential binding of cationic peptides to the outer leaflet of bacterial bilayers through long-range electrostatic interactions. Accordingly, cationic peptides initially bind onto the negatively charged surface of the target membrane and cover it in a carpet-like manner. The four steps proposed to be involved in the model are as follows: (i) binding of the cationic peptide to the phospholipid head groups, with subsequent formation of an amphipathic peptide helix, (ii) alignment of the helical peptides on the surface of the membrane, (iii) rotation of the helical peptides leading to reorientation of the hydrophobic residues toward the hydrophobic core of the membrane. The resulting spatial segregation of polar and apolar amino acids on opposing faces along the long axis of the helix permits the insertion of a well-defined hydrophobic sector into the acyl core of the lipid bilayer, and (iv) disintegration of the peptide-coated membrane by disrupting the bilayer curvature. As peptides cover the cell surface, transient mixed peptide-lipid holes may be formed. They may enable the passage of low molecular weight molecules before membrane lysis.

THE DERMASEPTINS: MULTIFUNCTIONAL HOST DEFENSE PEPTIDES

Most of the peptides belonging to the dermaseptin superfamily have been identified primarily by their antimicrobial activity. However, additional biological functions have been recognized that may or may not be directly associated with pathogen clearance. For instance, adenoregulin (DRS-B2) was first isolated by Daly et al. as a peptide able to stimulate binding of agonists to A1 adenosine receptors.[11] Adenoregulin was further shown to enhance the binding of agonists to several G-protein–coupled receptors in rat brain membranes through an enhancement of guanyl nucleotide exchange at G-proteins. DRS-B4, PLS-L2, and FSIP, a DRS-B4 related peptide from *A. spurrelli,* significantly stimulate insulin release in acute incubations with glucose-responsive BRIN-BD11 cells or BRIN-BD11 clonal β-cell line.[1,23,24] In addition to their role as endogenous antibiotics, antimicrobial peptides participate in multiple aspects of immunity (inflammation, wound repair, and regulation of the adaptive immune system). For instance, DRS-S1 stimulates microbicidal activities of polymorphonuclear leukocytes.[5] Treatment of polymorphonuclear leukocytes with DRS-S1 (10–100nM) stimulates the production of reactive oxygen species and release of myeloperoxidase. In addition, low peptide concentrations (1–10nM) prime the stimulation of respiratory burst induced by zymosan particles. The induced burst is inhibited by selective protein kinase inhibitors, and is associated with early signaling events such as a rapid and transient elevation of cytosolic-free calcium concentration and phospholipase D activity. DRS-DA4 is a potent chemoattractant for human leukocytes and is devoid of hemolytic activity.[7] On the other hand, the orphan peptide dermaseptin DRP-PD-3-7 exhibits no antibacterial activity but has an inherent propensity to self-assembles into amyloid fibrils in a reversible pH-controlled fashion.[15] Above pH 5, the amyloid fibrils disassemble in a cooperative manner. At neutral pH, this process proceeds instantaneously to the soluble form. Within the transition interval (pH 5–6.5), however, "backward" granular aggregates, 10–500nm in size, are formed. Such metastable amorphous aggregates, which are quickly released from an amyloid depot by a shift in pH, can mediate a strong cytotoxic effect.

Chapter 51

Insulin-Releasing Peptides

Opeolu O. Ojo, Peter R Flatt, Yasser H.A. Abdel-Wahab
and J. Michael Conlon

ABSTRACT

Peptides with the ability to stimulate the release of insulin from BRIN-BD11 rat clonal β-cells at low concentrations that are not cytotoxic to the cells have been isolated from skin secretions and/or skin extracts from several frogs belonging to the families Bombinatoride, Dicroglossidae, Hylidae, Leptodactylidae, Pipidae, and Ranidae. In addition, tigerinin-1R from *Hoplobatrachus rugulosus*, brevinin-2GUb from *Hylarana güntheri*, phylloseptin-L2 from *Hylomantis lemur*, and brevinin-2-related peptide (B2RP) from *Lithobates septentrionalis* have been shown to be active *in vivo*, increasing plasma insulin concentrations and improving glucose tolerance in mice. Nontoxic analogs of B2RP and psuedin-2 from *Pseudis paradoxa* with more potent insulin-releasing activities than the naturally occurring peptides have been developed that show therapeutic potential for the treatment of type-2 diabetes.

INTRODUCTION

The incidence of type 2 diabetes mellitus is increasing dramatically in all regions of the world. The current pandemic affects approximately 285 million people worldwide, and this number is expected to double by 2025.[17] New approaches to treatment and management are urgently required. Natural products, including biologically active peptides from both vertebrate and invertebrate species and from plants, are being examined for their glucose-lowering properties. One such approach to treatment is the use of agents based on physiological incretins. An incretin is a factor released by the gut in response to nutrients that facilitates the uptake of glucose by peripheral tissues by stimulating secretion of insulin. Peptides based on the structure of the endogenous insulin-releasing peptide, glucagon-like peptide-1 (GLP-1), and on exendin-4, an agonist at the GLP-1 receptor that was isolated from the venom of a lizard, the Gila monster *Heloderma suspectum*, show promise as effective treatments to improve glycemic control in patients with type-2 diabetes.[15]

The skins of many, although by no means all, species of Anura (frogs and toads) synthesize peptides with the ability to inhibit the growth of pathogenic bacteria and fungi.[10] The peptides are released into skin secretions, often in very high concentrations, in response to stress or infection and constitute a component of the animal's system of innate immunity. However, studies have shown that several frog skin peptides that were first identified on the basis of their ability to inhibit the growth of bacteria also stimulate insulin release *in vitro* from BRIN-BD11 rat clonal β-cells at low concentrations that are not cytotoxic to the cells. The BRIN-BD11 cell line is a well-established and convenient model to study insulin secretion in response to a range of nutrients, hormones, neurotransmitters, and drugs.[26] This chapter summarizes the primary structures and properties of the insulinotropic peptides that have been isolated from species belonging to genera within the families Bombinatoride, Dicroglossidae, Hylidae, Leptodactylidae, Pipidae, and Ranidae. The species names and taxonomic recommendations of Frost[16] and recent guidelines for antimicrobial peptide nomenclature[6,8,9] are followed. The primary structures of these peptides are shown in Tables 1 and 2.

INSULINOTROPIC PEPTIDES FROM RANIDAE

The taxonomy of frogs belonging to the extensive family Ranidae has undergone a series of major revisions in recent years, but many issues remain to be resolved. Analyses based primarily on molecular criteria have resulted in the reclassification of many well-known species. Current recommendations by Frost[16] divide the 347 species in the family Ranidae into 16 genera with the genus *Rana* being retained for a more restricted group of 48 species from Eurasia and North America. It must be pointed out, however, that other established taxonomists have claimed that this assignment of species is both arbitrary and premature, and it has been proposed that the genus *Rana* should be retained for all North American members of the family Ranidae. A recent phylogenetic analysis based on maximum likelihood analysis of two mitochondrial and three nuclear genes has divided the Ranidae into four monophyletic genera: *Amolops*, *Huia*, *Rana*, and *Staurois* with all North American frogs placed in the genus *Rana*.[31]

Xenopus amieti	Xenopsin-AM2	<EGRRPWIL	Zahid et al.[32]

A 24 amino acid peptide with insulin-releasing activities belonging to the brevinin-1 family was purified from electrically stimulated skin secretions the Northern leopard frog *Lithobates pipiens* (formerly *Rana pipiens*).[21] This peptide, termed brevinin-1Pa, is identical to pipinin-1, previously identified in this species on the basis of its histamine-releasing activity, and it produces a 1.8-fold increase in insulin release from BRIN-BD11 cells compared with that of 5.6 mM glucose only. The insulinotropic effect of brevinin-1Pa is reminiscent of that of histamine-releasing peptide mastoparan, isolated from hornet and wasp venom (see the chapter on Hymenoptera Insect Peptides in the Venom Peptides section of the book). Mastoparan stimulates insulin release through the activation of Rho G proteins, specifically Rac.[7] Analysis of skin secretions from the pickerel frog *Lithobates palustris* (formerly *Rana palustris*) by reversed-phase HPLC led to the isolation and structural characterization of an insulinotropic peptide that is identical to the previously described palustrin-1c.[19] The potency and mechanism of action of this peptide were not determined. A peptide of the brevinin-1 family (termed "gaegurin-6" in the publication) from the Korean frog *Glandirana emeljanovi* (formerly *Rana rugosa*) stimulates insulin release from rat RINm5F insulinoma-derived cells and increases intracellular calcium concentrations.[18]

Multiple peptides with insulinotropic activities but low cytotoxicities are present in skin secretions of the Sahara frog *Pelophylax saharicus* (formerly *Rana saharica*).[23] Structural characterization showed that the peptides are

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

identical to brevinin-1E, brevinin-2Ec, esculentin-1, and esculentin-1b previously isolated from *Rana esculenta* (now reclassified as a hybrid between *Pelophylax lessonae* and *Pelophylax ridibundus*). Preliminary mechanistic studies indicate that protein kinase A- and protein kinase C-dependent pathways may be involved in the insulinotropic effects of the esculentin-1 peptides. A previously undescribed insulinotropic peptide with structural similarity to the C-terminal domain of peptides of the brevinin-2 family was also isolated from *P. saharicus* secretions.[22]

The temporin family of antimicrobial peptides is widely distributed in both North American and Eurasian species belonging to genera *Rana* and *Lithobates* (see the chapter on this peptide in this section of the book). The insulin-releasing effects of synthetic replicates of seven temporins (temporin-Va, -Vb, and -Vc from *Lithobates virgatipes*, temporin-DRa and -DRb from *Rana draytonii*, temporin-Oe from *Rana ornativentris*, and temporin-TGb from *R. tagoi*) have been assessed.[1] Temporin-Oe, -Vb, -DRb, and -TGa stimulate *in vitro* insulin release from BRIN-BD11 in the concentration range 10^{-8}–10^{-6} M but do not stimulate the release of the cytosolic enzyme lactate dehydrogenase (LDH) indicating that the integrity of the plasma membrane is maintained. At a concentration of 10^{-6} M, temporin-Va and temporin-Vc also stimulate insulin release but are cytotoxic to the cells. Temporin-DRa was not insulinotropic. The component with maximum stimulatory ability (2.6-fold greater than the rate of release produced by 5.6 M glucose only) is temporin-Oe, which has the lowest cationicity of the peptides tested. Preliminary mechanistic studies show that temporins at 10^{-7} M do not increase intracellular calcium concentration suggesting that they may exert their effects via a K_{ATP} channel-independent pathway.

With a combination of reversed-phase HPLC and electrospray mass spectrometry, peptidomic analysis of norepinephrine-stimulated skin secretions of the American bullfrog *Lithobates catesbeianus* (formerly *Rana catesbeiana*) led to the identification and characterization of seven peptides with *in vitro* insulin-releasing activity (brevinin-1CBb, ranatuerin-1CBa, ranatuerin-2CBc, ranatuerin-2CBd, palustrin-2CBa, temporin-CBa, and temporin-CBf[27]). Ranatuerin-2CBd is the most potent peptide producing a significant stimulation of insulin release (119% of basal rate) from BRIN-BD11 cells at a concentration of 30 nM, with a maximum response (236% of basal rate) at a concentration of 3 μM. Ranatuerin-2CBd does not stimulate the release of LDH at concentrations up to 3 μM indicating low cytotoxicity. Brevinin-1CBb produces the maximum stimulation of insulin release (285% of basal rate at 3 μM) but the peptide is cytotoxic at this concentration.

The most potent insulin-releasing peptide identified in an extract of the skin of the Asian frog *Hylarana guentheri* (formerly *Rana guentheri*) belongs to the brevinin-2 family and is termed brevinin-2GUb.[13] The peptide lacks cytotoxic activity and produces stimulation of insulin release (139% of basal rate) at a concentration of 0.1 μM with a maximum response (373% of basal rate) at a concentration of 3 μM. Administration of brevinin-2GUb (75 nmol/kg of body weight) into healthy mice improves glucose tolerance following a intraperitoneal injection of glucose. The antimicrobial peptide B2RP (brevinin-2-related peptide), first isolated from skin secretions of the mink frog *Lithobates septentrionalis*, shows sequence similarity to antimicrobial peptides belonging to the brevinin-2 family but lacks the C-terminal cyclic heptapeptide domain (Cys-Lys-Xaa_4-Cys). Synthetic B2RP produces a stimulation of insulin release from BRIN-BD11 cells (148% of basal rate at a concentration of 1 μM with a maximum response of 222% of basal rate at a concentration of 3 μM) without increasing the rate of release of LDH.[3]

INSULINOTROPIC PEPTIDES FROM HYLIDAE

The extensive and widely distributed family Hylidae is divided into the subfamilies Phyllomedusinae (58 species), Pelodryadinae (197 species), and Hylinae (646 species).[16] The Central and South American tree frogs, particularly species in the genera *Agalychnis*, *Hylomantis*, *Pachymedusa*, and *Phyllomedusa* in the subfamily Phyllomedusinae, and the Australian tree frogs in the genus *Litoria* in the subfamily Pelodryadinae have proved to be a rich source of biological peptides (see the dermaseptins and the caeruleins chapters in this section of the book).

Peptides with significant insulinotropic effects have been isolated and characterized from four frog species in the subfamily Phyllomedusinae, notably *Phyllomedusa trinitatis*,[24] *Agalychnis calcarifer*,[2] *Agalychnis litodryas*,[25] and *Hylomantis lemur*.[4] Fractionation by HPLC of electrically stimulated skin secretions from *P. trinatatis* led to the isolation of a 28 amino acid peptide with insulin-releasing properties that were identical to dermaseptin B4 from *Phyllomedusa bicolor*.[24] A structurally similar insulin-releasing peptide belonging to the dermaseptin family was also isolated from the skin secretions of *A. litodryas*.[25] The potencies or mechanisms of action of these peptides were not determined. A 13 amino acid peptide, termed RK-13, with structural similarity to the N-terminal region of the proline–arginine-rich antimicrobial peptide PR-39 is present in skin secretions of *A. calcarifer*.[2] This peptide lacks antimicrobial activity but stimulates insulin release from BRIN-BD11 cells by a mechanism that may involve protein kinase A but is independent of pertussis-toxin-sensitive G proteins.

A peptide with the ability to release insulin from BRIN-BD11 cells was isolated from norepinephrine-stimulated skin secretions of the Lemur leaf frog *H. lemur*.[4] Structural characterization demonstrated that the peptide belongs to

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

the phylloseptin family whose members have previously been identified in other Phyllomedusinae species (see the chapter on the dermaseptins in this section of the book). The 15 amino acid peptide, termed phylloseptin-L2, produces a stimulation of insulin release from BRIN-BD11 cells (134% of basal rate at a concentration of 30 nM, with a maximum response of 301% of basal rate at a concentration of 3 μM) without increasing the rate of release of LDH. The stimulatory action is maintained in the absence of extracellular Ca^{2+} and in the presence of verapamil (50 μM) and diazoxide (300 μM) suggesting that the mechanism of action of the peptide does not involve influx of Ca^{2+} or closure of ATP-sensitive K^+ channels. Administration of phylloseptin-L2 (50 nmol/kg of body weight) into healthy mice increases total release of insulin and improves glucose tolerance during the 60-min period after intraperitoneal injection of glucose.

Synthesis of antimicrobial and other biologically active peptides in the skin of species belonging to the subfamily Hylinae is sporadic.[10] Four structurally related peptides, termed pseudin 1–4, were isolated from an extract of the skin of the South American paradoxical frog *Pseudis paradoxa* (Hylinae) although these peptides were not detected in norepinephrine-stimulated skin secretions.[29] Pseudin-2 shows the highest antimicrobial potency particularly against Gram-negative bacteria and has very low hemolytic activity. Pseudin-2 at concentrations of 10^{-7} and 10^{-6} M stimulates insulin release from BRIN-BD11 and is without β-cell cytotoxicity.[5] Activity was retained in the absence of extracellular calcium and in the presence of known antagonist of insulin release (diazoxide and verapamil) suggesting that that the action of the peptide was mediated through a calcium-independent pathway.

INSULINOTROPIC PEPTIDES FROM BOMBINATORIDAE

The family Bombinatoridae family comprises two genera *Barbourula* and *Bombina*.[16] The six species of fire-bellied toads of the genus *Bombina* are widely distributed in Eurasia and have been a rich source of antimicrobial and other biologically active peptides (see the chapters on bombesin-like peptides, bombinins, and Bv8 peptides in this section of the book). Fractionation of electrically stimulated skin secretions of *B. variegata* by reversed-phase HPLC led to the identification of bombesin and two bombesin-related peptides with the ability to stimulate insulin release from BRIN-BD11 cells.[20] In addition, two novel noncytotoxic insulinotropic peptides termed GM-14 and IN-21 were isolated and characterized structurally, but their potencies were not determined. Preliminary results suggested the involvement of a protein kinase A-dependent pathway in the insulin-releasing action of these peptides.

INSULINOTROPIC PEPTIDES FROM LEPTODACTYLIDAE

The family Leptodactylidae (currently 100 species) has been divided into four genera: *Hydrolaetare*, *Leptodactylus*, *Paratelmatobius*, and *Scythrophrys*, but both morphological and molecular investigations have indicated that the Leptodactylidae probably is probably not monophyletic.[16] Antimicrobial peptides with relatively low potency against bacteria and low cytotoxicity against mammalian cells have been isolated from the skin secretions of several species belonging to the genus *Leptodactylus* (reviewed in Ref. 10). A glycine–leucine-rich peptide is present in the skin secretions of the Sante Frog *Leptodactylus laticeps* that contain the $(GXXXG)_3$ motif found in the plasticins, previously identified only in phyllomedusid frogs of the family Hylidae (see the dermaseptins chapter in this section of the book).[11] Like the plasticins, the peptide from *L. laticeps* (termed plasticin-L1) adopts a random coil conformation in water, a β-sheet structure in methanol, and an α-helical conformation in 50% trifluoroethanol water. Plasticin-L1 does not inhibit the growth of bacteria or lyse human erythrocytes but, at relatively high concentrations (≥1 μM), the peptide produces a modest (139% of basal rate at 3 μM), increase in the rate of glucose-induced release of insulin from BRIN-BD11 cells without increasing the rate of release of LDH. A peptide, termed ocellatin-L2 is also present in *L. laticeps* skin secretions, which is identical to the previously described ocellatin-L1 except for the substitution $Asn^{23} \rightarrow Asp$.[11] Ocellatin-L2 is devoid of antimicrobial and hemolytic actions but shows modest activity in stimulating insulin release from BRIN-BD11 cells (181% of basal rate at 3 μM).

INSULINOTROPIC PEPTIDES FROM DICROGLOSSIDAE

The Asian frog *Hoplobatrachus rugulosus* (formerly *Rana rugulosa*) is classified with three other species in the genus *Hoplobatrachus* in the extensive family Dicroglossidae (149 species).[16] A cyclic, C-terminally amidated dodecapeptide, termed tigerinin-1R, was isolated from an extract of the skin of *H. rugulosus*.[28] The tigerinin family of peptides was first identified in the Indian frog *Hoplobatrachus tigerinus* (formerly classified as *Rana tigerina*) on the basis of antimicrobial activity.[30] Tigerinin-1R lacks cytotoxic and hemolytic activities but stimulates the rate of release of insulin from BRIN-BD11 cells at concentrations ≥0.1 nM. The maximum response is 405% of the basal rate at 5.6 mM ambient glucose concentration and 290% of basal rate at 16.7 mM glucose. The magnitude of this effect is greater than that produced under the same experimental conditions by the antidiabetic drug, tolbutamide and the well-characterized insulinotropic peptides, GLP-1 and GIP. C-terminal α-amidation is necessary for high potency and a

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

possible mechanism of action of the peptide involves membrane depolarization and an increase in intracellular Ca^{2+} concentration. Administration of tigerinin-1R (75 nmol/kg of body weight) to mice fed a high fat diet to induce insulin resistance and obesity enhances total insulin release and improves glucose tolerance during the 60-min period after an intraperitoneal glucose load.

INSULINOTROPIC PEPTIDES FROM PIPIDAE

The clawed frogs of the family Pipidae comprise five genera. *Pipa* is found in South America with the other four genera *Hymenochirus*, *Pseudhymenochirus*, *Silurana*, and *Xenopus* in sub-Saharan Africa.[16] S*ilurana* and *Xenopus* are united in the subfamily Xenopodinae but the cytogenetics and evolutionary history of this taxon is complex. A series of allopolyploidization events have generated tetraploid, octoploid, and dodecaploid species with only *Silurana tropicalis* retaining diploid status.[14]

Caerulein-B1 from the tetraploid frog *Xenopus borealis* stimulates the rate of insulin secretion from BRIN-BD11 cells at concentrations ≥30 nM compared with basal rate in the presence of 5.6 mM glucose only.[32] The maximum response (360% of basal rate, $P<0.05$) occurs with 3 μM. The peptide (1 μM) also produces a significant (128%, $P<0.05$) stimulation of the rate of insulin release in the presence of 16.7 mM glucose. Unfortunately, the therapeutic potential of caerulein-B1 may be limited by the observation that repeated intraperitoneal injections of caerulein into rats and mice produce acute edematous pancreatitis with cellular necrosis.

Xenopsin and xenopsin-AM2 from the octoploid frog *Xenopus amieti* stimulate the rate of insulin secretion from BRIN-BD11 cells at concentrations ≥30 nM compared with basal rate in the presence of 5.6 mM glucose only, but the peptides produce a significantly lower maximum response than caerulein-B1 (198% of basal rate for xenopsin and 207% of basal rate for xenopsin-AM2 at a concentration of 3 μM).[32] High dose infusions of xenopsin in dogs produce hyperglycemia resulting from a pronounced stimulation of glucagon and cortisol release, so that it seems improbable that either xenopsin or xenopsin-AM2 has potential for development into antidiabetic agents.

ANALOGS WITH INCREASED INSULIN-RELEASING ACTIVITY

The therapeutic potential of peptide-based pharmaceutical agents, particularly for systemic use, is limited by their short half lives in the circulation, possible immunogenicity, and toxicities toward human cells. Appreciable success has been achieved in transforming cytotoxic frog skin antimicrobial peptides with relatively low potency against microorganisms into promising antiinfective agents by designing analogs with substitutions of appropriate amino acids by either L- or D-lysine.[12] Increasing the cationicity of psuedin-2 from +2 to +3 by the substitution $Asn^{18} \rightarrow Lys$ increases the insulin-releasing potency and maximum response of the naturally occurring peptide. This analog produces a 46% increase in the rate of insulin release from BRIN-BD11 cells at 10^{-9} M and a 215% increase in insulin release at 10^{-6} M. However, increasing the molecular charge on the peptide to +6 in [N3K,Q10K, E14K]pseudin-2 and to +7 in [N3K,Q10K, E14K,N21K]pseudin-2 produces peptides that had no significant stimulatory effect on insulin release. Increasing the hydrophobicity of the peptide by the substitution $Ile^{16} \rightarrow Phe$ generates an analog that retains insulinotropic action but has increased hemolytic activity.[5]

Increasing cationicity of B2RP while maintaining amphipathicity by the substitution $Asp^{4} \rightarrow Lys$ enhances the insulin-releasing potency (137% of basal rate at a concentration of 0.3 μM) with no stimulation of LDH release. By contrast, the L18K and D4K,L18K analogs are toxic to the cells and the K16A analog, with increased amphipathicity and hydrophobicity, shows reduced potency. Administration of [D4K]B2RP (100 nmol/kg body weight) to mice fed a high fat diet to induce obesity and insulin resistance enhances total insulin release and improves glucose tolerance during the 60-min period after an intraperitoneal glucose load (18 mmol/kg of body weight).[3]

CONCLUSIONS

Naturally occurring nontoxic compounds with the ability to stimulate insulin release from pancreatic beta cells ("incretins") show promise as antidiabetic drugs. Many peptides present in the skin secretions of several frog species, including several that were first identified by their broad-spectrum antibacterial and antifungal activities, are able to stimulate the release of insulin from BRIN-BD11 clonal beta cells at concentrations that are not toxic to the cells and also improve glucose tolerance in mice. Such peptides represent candidates for development in drugs to treat patients with Type 2 diabetes.

Chapter 52

Neurohypophysial Peptides

Sunny K. Boyd

ABSTRACT

The amphibian neurohypophysis releases primarily two peptides—arginine vasotocin (AVT) and mesotocin (MT). Both are nonapeptides synthesized in multiple brain areas. Four specific receptor subtypes have been identified. The VT1aR is specific for AVT, found in the brain and kidney, and is coupled to a protein kinase C-mediated pathway. The VT1bR differs only in restricted expression exclusively in the brain and pituitary. The VT2R has a high affinity for AVT and hydrins and is found primarily in the skin and bladder, where it uses the cAMP signaling pathway. The MTR is specific for MT, couples to a protein kinase C–linked pathway, and is found in the brain and peripheral tissues. Biological actions of AVT include control of osmoregulation, behavior, reproductive tract contractions, and the cardiovascular system. Actions of MT are poorly understood. Finally, the amphibian neurohypophysis produces hydrins, which are extended forms of AVT with specific osmoregulatory effects on the skin and urinary bladder.

DISCOVERY

The class Amphibia contains three orders: the Anurans (frogs and toads), the Urodeles (salamanders and newts), and the Gymnophionans (caecilians). In the early 1900s, it was already recognized that the neurohypophysis (posterior pituitary) of frogs contained "active principles" that altered blood pressure. The structure of these principles was first elucidated in an anuran amphibian for arginine vasotocin (AVT) and mesotocin (MT) in the 1960s.[2] Characterization of AVT and MT structure in caecilians and urodeles, however, has only occurred within the last 15 years.[16,27] In all amphibians investigated, AVT and MT have been found, with the exception of *Bufo regularis* and *Plethodon shermani* in which mesotocin is replaced by [Ser5,Ile8]-oxytocin (seritocin) or [Val4]-mesotocin, respectively (Table 1[2,27]). Finally, anuran amphibians also possess unique closely related neurohypophysial peptides called hydrins.

PEPTIDE STRUCTURE AND PROCESSING OF PRECURSOR mRNAs

The nonapeptides AVT and MT are part of a conserved family of neurohypophysial hormones. Representative species from all vertebrate classes examined to date possess AVT, and it is thus considered the evolutionary precursor peptide in this family.[2] AVT is replaced by arginine vasopressin (AVP) in most mammals. Birds and reptiles also possess MT, in common with amphibians. Isotocin replaces MT in most fish and oxytocin (OT) is the mammalian homolog. All have a nine-amino acid peptide backbone with a disulfide bridge between conserved cysteine residues at positions 1 and 6. All possess an NH_2-blocked C-terminal glycine.

The nucleotide sequences coding for AVT and MT precursors have been reported for only four species of amphibians: the toad *Bufo japonicus*, two urodeles (*Taricha granulosa* and *Plethodon shermani*) and the caecilian, *Typhlonectes natans* (reviewed in Ref. 27). After a hydrophobic signal sequence, the amino acids of AVT or MT are represented. Next, a tripeptide is found which may facilitate processing or become incorporated into hydrin. This tripeptide is followed by a 93-amino acid neurophysin domain and a 36- or 37-amino acid glycoprotein domain. Although these domains result in the production of two peptides in mammals, this is not the case in amphibians where a single large neurophysin is produced.[2] In the MT precursor, a 93- or 94-amino acid peptide neurophysin also follows, but a glycoprotein is not present.

DISTRIBUTION OF AVT AND MT

Amphibian neurohypophysial peptides are synthesized in a variety of brain nuclei.[17,28] In all three amphibian orders, the most prominent cell group is in the magnocellular preoptic area. It is likely that these cells are the primary source of AVT and MT released from the neurohypophysis. AVT cell bodies can also be found in the pallium, bed nucleus of the stria terminalis, ventral thalamus, suprachiasmatic nucleus, hypothalamic nucleus, and midbrain tegmentum. On the other hand, MT cells are restricted primarily to diencephalic regions. Fibers are widespread, and these peptides likely function as neuromodulators. There can be significant variation in the location of AVT cell populations across species, especially outside the diencephalic regions. AVT concentrations in some brain areas are sexually dimorphic

Dashes indicate residues identical to those of vasotocin.

and steroid sensitive.[6,7,28] Current evidence indicates this primarily results from the effects of androgens.

RECEPTOR STRUCTURE AND DISTRIBUTION

The MT receptor (MTR) and three subtypes of AVT receptor have been cloned in representative species of anuran and urodele amphibians.[1,4,15,18,26] All four belong to the G protein-coupled receptor family, with typical seven transmembrane domains. One AVT receptor subtype closely resembles the mammalian AVP receptor subtype V1a. The cDNA for this receptor (VT1aR) encodes a protein of 418 or 419 amino acids. The potency of ligands for this receptor is AVT>OT >AVP ≈ MT in an anuran and AVT>AVP>MT ≈ OT in a urodele amphibian. The VT1aR preferentially couples to the protein kinase C-mediated signaling pathway. The second AVT receptor subtype (VT2R) is more similar to the mammalian V2R. The receptor protein is 363 or 367 amino acids. The potency of ligands for this receptor is AVT=hydrin 1 > hydrin 2=AVP>MT=OT. The VT2R likely uses the adenylate cyclase-cAMP signaling pathway. The third subtype of AVT receptor has only been recently characterized in a newt.[15] This subtype VT1bR shares high sequence identity with the mammalian V1b receptor. Finally, the cDNA for the MTR encodes a receptor of 384–393 amino acids that shares significant homology with the OT receptor. The sensitivity of the MTR for ligands in this peptide family is MT>OT>AVT≥AVP or MT>AVT=OT>AVP > hydrin 1=isotocin=hydrin 2, depending on species. The frog MTR probably couples exclusively to the protein kinase C-linked signaling pathway.

The VT1aR mRNA is abundant in brain, anterior pituitary, heart, adrenal gland, kidney, and oviduct.[1] In the brain, the distribution of binding sites detected with 3H-AVP autoradiography is very similar to the distribution of the receptor mRNA.[1,6,15] Putative receptors are abundant in accumbens, pallium, striatum, lateral amygdala, preoptic area, magnocellular nucleus, hypothalamus, thalamus, and optic tectum. In the pituitary, VT1aR mRNA is found in the anterior pituitary and the intermediate lobe but not in the neurohypophysis.[1] Binding studies with 3H-AVP show receptors in the anterior pituitary but, in contrast, also show receptors in the neurohypophysis. This may reflect the presence of another subtype of AVT receptor in amphibians, not detected by the VT1aR probe. The presence of a VT1R subtype (either 1a or 1b) in amphibian kidney is also supported by autoradiographic and physiological evidence.[5,8,24] Binding sites for 3H-AVP or 125I-OVTA are found specifically located over the glomeruli and not renal tubules. These sites have ligand specificity more similar to mammalian V1 receptors than V2 receptors. The mRNA for the VT2R is expressed in the brain, heart, kidney, urinary bladder, and pelvic skin patch.[14,15,18] Lastly, the VT1b receptor is expressed almost exclusively in the brain and anterior pituitary in a newt.[15]

The MTR mRNA is abundant in the brain of anurans.[1,4,18] *In situ* hybridization shows highest levels in pallium, amygdala, ventral striatum, anterior preoptic area, nucleus of the periventricular organ, posterior tuberculum, ventral hypothalamic nucleus, thalamic nuclei, and optic tectum.[1] The MTR mRNA, like that for VT1aR, is found in the anterior pituitary and intermediate lobe but not in the neurohypophysis. The neural function of MT is unknown. The MTR mRNA is also found in several peripheral tissues, including the heart, adrenal gland, kidney, urinary bladder, skeletal muscle, fat body, and testis.[1,4,18] Importantly, the receptor is not found in the oviduct.[1] This suggests that, despite the structural similarities with the OT receptor, the MTR does not play a homologous role in reproductive tract smooth muscle contraction.

MAJOR BIOLOGICAL ACTIONS OF AVT AND MT

Osmoregulatory Effects

AVT control of osmoregulation in amphibians is complex and involves several different target organs—the kidneys,

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

the urinary bladder, and the skin. At the renal level, AVT causes antidiuresis first by constricting preglomerular arteries and causing a reduction in glomerular filtration rate by as much as 85%.[33] The glomerular action is supported by the location of receptors over the glomeruli and presence of VT1aR mRNA. Whether AVT alters tubule reabsorption in amphibians is more controversial. AVT can cause antidiuresis by acting directly on tubules in a few species.[33] In addition, anuran amphibian kidney possesses an AVT-dependent aquaporin water channel protein.[30,32] Binding sites for radioactively labeled AVT analogs have not been located over tubules, however, and it is clear in some species that AVT has no tubular effects.[5,8] Mesotocin increases glomerular filtration rate and is diuretic in amphibians.[13,32,33]

The anuran urinary bladder served as the archetypal tissue for research on the water permeability of membranes for decades. Anurans can store fluid equivalent to 50% of body weight in the bladder. AVT stimulates the movement of water from the bladder back into the vasculature and this probably occurs via the VT2R.[33] AVT increases cAMP levels and the expression and translocation of aquaporin proteins.[30,32] Interestingly, although mammals possess a single AVP-dependent aquaporin in the kidney, anuran amphibians have three AVT-dependent proteins—aquaporin forms unique for the kidney, urinary bladder, and ventral pelvic skin. The anuran bladder also shows AVT-modulated sodium and urea reabsorption.[19,32] Mesotocin has a limited ability to stimulate water and sodium uptake across the anuran bladder, and the MTR has been located in this tissue.[32]

The permeable skin of amphibians allows the unique movement of water across that surface. AVT increases water permeability of ventral pelvic skin and facilitates rehydration of anurans and urodeles.[33] The VT2 receptor mRNA and protein is expressed in the pelvic skin and AVT regulates expression of water channel aquaporins in this tissue.[23,30] Mesotocin has been reported to increase cutaneous water permeability; however, MTR mRNA has not been found here.[1,4,18] Neither AVT nor MT alters water permeability of the skin of a caecilian amphibian.[29] Finally, active sodium transport across skin is also facilitated by AVT and MT in some, but not all, species.[31,33]

Behavioral Effects

In recent decades, the behavioral effects of neurohypophysial peptides in amphibians have received the most attention.[7] In many anurans, AVT modulates the display of vocal behavior.[21,34] The peptide facilitates the advertisement call used to attract mates, while it inhibits the release call given by unreceptive females. In addition, AVT stimulates the attraction of female anurans to the calls of males and alters locomotor behaviors. AVT also alters reproductive behaviors of urodeles. AVT stimulates amplectic clasping, pheromone release, and egg-laying behavior.[21,34] Effects of AVT are probably occurring via action in the central nervous system, and there is extensive interaction between AVT, androgens, and corticosterone in the modulation of amphibian reproductive behaviors.[7]

Reproductive Tract Effects

As in other vertebrate classes, the amphibian oviduct shows robust smooth muscle contractions after exposure to neurohypophysial peptides.[11] Unexpectedly, however, the oxytocin homolog, MT, is not the most potent peptide. Instead, AVT causes oviduct contractions. Sex steroids increase the responsiveness of the oviduct to AVT. In an analogous fashion, AVT stimulates contractions of the male urodele Wolffian duct.[35]

Cardiovascular Effects

It has been known since 1904 that pituitary extracts alter the circulatory system of the frog; however, this has received little attention. AVT is a vasopressor and causes the constriction of vessels *in vitro*.[9] Further, although AVT causes bradycardia *in vivo*, when autonomic receptors are blocked, AVT increases the heart rate and contractile force. On the other hand, MT acts as a vasodepressor in amphibians.[9] Three receptor subtypes (VT1R, VT2R, and MTR) are found in the heart, but it is unknown as to which receptors are present in the vasculature.[1,4,18] It has been proposed that the cardiovascular effects of AVT are the most primitive and that these gave rise to the osmotic effects of the peptide in amphibians and other tetrapods.

Other Effects

In amphibians, the adrenal gland homolog is the interrenal gland, where chromaffin cells are intermingled with steroidogenic cells. AVT immunoreactivity is found in virtually all chromaffin granules and may serve in a paracrine role to stimulate secretion of steroids.[20] AVT causes a rapid increase in corticosterone and aldosterone output from the interrenal gland.[12] The rank order potency of ligands suggests that VT2R is responsible.[20] However, the effect is via phosphoinositide-specific phospholipase C, and VT2R mRNA has not been found in the interrenal gland.[1,4,18,20]

AVT stimulates hepatic glycogenolysis and increases glycogen phosphorylase *a* activity in representative anuran and urodele amphibians.[3] This effect differs significantly from the stimulation of glycogenolysis in mammalian liver by AVP, however, because it seems to work via a VT2 subtype receptor and coupling to adenylate cyclase. VT2R mRNA has not been reported in the liver, but the liver receptor subtype may differ from the bladder VT2R.[14,18]

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

STRUCTURE AND FUNCTION OF HYDRINS

Neurohypophysial extracts from anuran amphibians were first reported in 1961 to contain a third class of peptides. These peptides were sequenced and named "hydrins" in 1989 (Table 1[25]). Hydrin 2 is broadly distributed across anuran families. In *Xenopus laevis*, two variants of hydrin (termed hydrin 1 and 1′) are found instead. Hydrins have not been detected in any urodele or in any other vertebrate. Hydrins probably result from differential processing of the AVT preprohomone. The result is an extended peptide that is not amidated. Hydrins are as active as vasotocin in the anuran bladder, more active on anuran skin, but inactive in the kidney.[2,25] Given the high affinity of the VT2R for hydrins, it is probable that a receptor of this subtype is responsible for the biological actions of hydrins. Indeed, AVT, hydrin 1, and hydrin 2 have very similar effects on the translocation of aquaporin proteins in anuran ventral pelvic skin.[22] In addition to the effects on water reabsorption, hydrin 2 influences cutaneous ion transport.[10] Differences in physiological effects of AVT and hydrins on target tissues, however, suggest that two subtypes of VT2R may exist.

Chapter 53

Opioid and Bv8 Peptides

Lucia Negri, Pietro Melchiorri and Roberta Lattanzi

ABSTRACT

Amphibian opioids are small peptides found in the skin of South American hylid frogs Phyllomedusinae. Two subfamilies of opioid peptides have been distinguished according to their selectivity for the μ- and δ-opioid receptors: the dermorphin and deltorphin families.

The distinctive feature of opioid peptides is the presence of a D-amino acid in the N-terminal sequence, Tyr-D-Xaa-Phe, which restricts peptide conformation and confers resistance against enzymatic degradation. Bv8 is a small protein isolated from the skin secretion of the frog *Bombina variegata*. Orthologs of Bv8 have been found in snakes (MIT) and in mammals (Prokineticins). The striking characteristics of these proteins are the identical amino terminal sequence AVITG and the presence of ten cysteines with identical spacing. Bv8/Prokineticin proteins have been shown to modulate several physiological and pathological conditions including neurogenesis, angiogenesis, cancer progression, pain perception, immune response, and circadian rhythms. Disruption of the prokineticin system has been implicated in human Kallmann's syndrome and Hirschprung's disease.

OPIOID PEPTIDES

Although Vittorio Erspamer and his colleagues discovered the opioid peptides in Amazonian frogs only in the1980s,[5] the Matses tribe of the upper Amazonian basin unveiled the pharmacological properties of amphibian skin opiates long ago. For centuries, they had habitually applied the dried skin secretions of *Phyllomedusa bicolor*, called "sapo" (the Spanish word for toad), to cuts in their skin during shamanistic hunting rituals. The abundance of the opioid peptides in "sapo" probably caused analgesia and behavioral excitation in hunters.

Classical amphibian opiate peptides have been found only in the skin of South American hylid frogs belonging to the subfamily Phyllomedusinae (*Phyllomedusa*, *Agalychnis*, and *Pachymedusa* species). They are small peptides codified by different genes and secreted by the syncytial cells forming the luminal wall of serous holocrine glands in the frog integument. Electron microscopy reveals that the serous glands of Phyllomedusinae have morphological features, especially the secretory granules, which differ from those of the glands in other frogs. The biosynthesis and secretion of opioid peptides occur together with dermaseptins, antibiotic peptides. Although these peptides differ in their structure and activity, they derived from precursors that have very similar preproregions.[11]

New peptides endowed with opioid activity have been recently identified in the skin secretion of an Australian frog and in the brain of the Xenopus. In the skin secretion of Australian frogs of the genus Litoria, two major peptides (FPWL-NH_2 and FPWP-NH_2) have been identified that display opiod activity at micromolar concentrations. They are analogs to peptides first isolated from *Phyllomedusa rohdei* and called tryptophyllin. The sequences of these peptides resemble those of the human brain endomorphins (e.g., YPWF-NH_2).[7] These peptides are released in the skin secretion in milligram amounts.

Nonmammalian prodynorphin-derived peptide was discovered by analysis of a Xenopus brain cDNA library. The prepropeptide contains five potential opioid-like peptides, collectively named xendorphins. One of these, xendorphin B1 (Xen)PDYN-B sequence 96-111: YGGFIRKPDKYKFLNA), is a hexadecapeptide that displays nanomolar affinity for κ-opioid receptors in rat brain membranes and produces a long-lasting and dose-dependent antinociceptive effect in the *Rana pipiens*.[24]

A Brief History of the Amphibian Opioid Peptides

The first to be discovered were two dermorphins (N. 1 and N. 2 in the Table 1) identified in the skin of *Ph. sauvagei*, *Ph. rohdei*, and *Ph. burmeisteri*. The very high dermorphin content in the skin of these Phyllomedusinae, about 50–80μg/g of fresh skin, made it easy to purify and sequence the peptides. Until the discovery of mammalian endomorphins,

these peptides represented the most potent and selective μ-opiate receptor agonists identified in living organisms.[5]

The screening of a cDNA library prepared from the skin of *Ph. sauvagei* established the amino acid sequence of several dermorphin precursors. The sequence of one of these cDNAs indicated the existence of another peptide that contained methionine as the second amino acid. This peptide (N. 8 in Table 1) was subsequently isolated from the skin of *Ph. sauvagei* and proved to have higher affinity and selectivity for δ-opiate receptors than any other known natural compound. It has been given various names: deltorphin, D-Met-deltorphin, dermenkephalin, and deltorphin A. Subsequently, two additional peptides with an even higher affinity for the δ-opiate receptor were isolated from the skin of *Ph. bicolor*. Like dermorphin, these peptides contain D-alanine as the second amino acid. They have been termed D-Ala-deltorphin-I and D-Ala-deltorphin-II (N. 9 and 10 in Table 1). Screening of cDNA libraries from the skin of *Ph. bicolor* revealed the sequence of four precursors for D-Ala-deltorphin-I and -II. These precursors contain one copy of D-Ala-deltorphin-II and one, three, or no copies of D-Ala-deltorphin-I, respectively. The D-Ala-deltorphin precursors also contain three additional sequences related to dermorphins. As predicted by the absence of glycine at the carboxyl terminus of these peptides, the end products extracted from the skin contain a free α-carboxyl group at the C-terminus.[5,18] Alternative cleavage sites in the sequence of dermorphin can generate C-terminally elongated dermorphins: Two of these dermorphins have been isolated from *Ph. sauvage*i skin extracts (N. 6 and 7 in Table 1). In the Brazilian frog *Ph. burmeisteri*, a linear peptide of 17 amino acids with a D-Leu residue at position 2 has been identified and termed D-Leu-deltorphin-l7 (N. 11 in Table 1). During screening of cDNA libraries prepared from the skin of two additional species of Phyllomedusinae, the *Pachymedusa dacnicolor* and *Agalychnis annae*, using sequence information from cDNAs encoding dermorphin and deltorphin precursors from *Ph. sauvagei* and *Ph. bicolor*, we identified, in addition to four copies of dermorphin, a sequence that contains the genetic information for a novel peptide: Tyr-D-Ile-Phe-His-Leu-Met-Asp-NH_2 (N. 12 in Table 1). This peptide, an analog of D-Met-deltorphin, contains a D-Ile at the second position.[23]

Structure and Conformation

All amphibian opioid peptides contain the N-terminal sequence Tyr-D-Xaa-Phe, where the amino acids Tyr^1 and Phe^3 are of L-configuration, and D-Xaa^2 is a D-amino acid. The D-amino acid–containing opioid peptides arise from precursors showing a common preproregion (22-residue signal peptide and an 18–25-residue acidic prosequence) with precursors of the peptide antibiotics dermaseptins (24–34 residue polycationic and α-helical amphipathic peptides). The D-enantiomer is encoded, however, by the codon for the

L-isomer in the precursor cDNA. Thus, L-Xaa^2 must be converted to D-Xaa^2 by an unusual posttranslational reaction that presumably takes place in the precursor itself in the secretory granules. The specificity of isomerization depends on the presence of structural and/or conformational determinants in the peptide N-terminus surrounding the isomerization site.[1]

Because [L-Xaa^2]-containing peptides have never been found in amphibian skin extracts, the epimerization mechanism probably involves a quantitative inversion of the chirality of the α-carbon of the amino acid residue, rather than a racemization, which would yield an equimolar mixture of L- and D-isomers. Enzymes catalyzing the formation of D-amino acids are so far known only in yeast. From Bombina skin secretions, Kreil[8] purified a 52-kDa glycoprotein that catalyzes the reaction Ile-Ile-Gly to Ile-D-allo-Ile-Gly. The partial conversion of Ile to D-allo-Ile in peptide linkage proceeds without the addition of cofactors.

Similar to mammalian prohormones, all opioid peptides in amphibian skin precursors are flanked by paired dibasic amino acids (Lys–Arg). Moreover, the precursor sequence contains an additional Gly residue at its carboxyl terminus; this extra residue is required for the carboxamidation of the mature heptapeptide.

Despite the common N-terminal tripeptide (Tyr-D-Xaa-Phe), the two families of amphibian opioids differ widely in receptor selectivity but bind to their own receptors with similar affinity. The N-terminal domain contains the minimum sequence essential for opioid receptor binding, whereas the C-terminal domain contains the address requisites for receptor selectivity. The presence within the putative transmembrane domains II and III of the μ-receptor protein of negatively charged amino acid residues (Asp [114], Asp [147]) that contribute to ligand binding may explain why positively charged dermorphins have high μ-opioid receptor selectivity and why the amidation of their terminal carboxyl group increases their affinity and potency.

Similarly, the negatively charged C-terminal tetrapeptide of deltorphins enhances deltorphin selectivity for the δ-opioid receptor by electrostatic attraction to the positively charged binding site of the δ-receptor (Arg [292]) and electrostatic repulsion from the negatively charged μ-receptor site. Unlike the positively charged C-terminus of dermorphins, the negatively charged C-terminal tail of deltorphins (especially in D-Ala^2-deltorphin-II) comes into close contact with the positively charged N-terminal tripeptide of the molecule and folds the backbone, thus placing the Tyr^1 and Phe^3 aromatic rings in specific orientations best suited for δ-receptor docking.

Biological Actions

The pharmacology of amphibian opiates has been extensively described.[5,16,18,22,23]

Dermorphin has a high affinity and selectivity for μ-opioid receptors: Its opioid potency in guinea pig ileum (GPI) preparations is 100 times higher than that of morphine. The amidated analogs of *Ph. bicolor* dermorphins display a similar or slightly higher μ-opioid receptor affinity but a significantly higher (15–20 times) κ-opioid receptor affinity than dermorphin does (Table 2). Like μ-opiate agonists, dermorphins produce antinociception and also catalepsy, respiratory depression, constipation, tolerance, and dependence, although at a lower degree than morphine does. Dermorphin-induced antinociception takes place at both the supraspinal and spinal levels. The analgesic potency of dermorphin is about 280 times higher than that of morphine after intracerebroventricular (icv) injection but comparable to that of morphine after subcutaneous (sc) injection because of its low CNS permeability and bioavailability. [Lys^7]dermorphin and some synthetic analogs bearing a hydrophilic group (a basic amino acid or a glycosyl residue) at the C-terminal end of the molecule enter the CNS at a 7–10 times higher rate than dermorphin does, suggesting facilitated transport across the blood brain barrier by a carrier or endocytosis. The amphibian opioid with the highest analgesic potency and efficacy is [Lys^7]dermorphin (AD_{50}: 30pmol per rat, by the icv route; 0.22μmol/kg, by the sc route). Its antinociceptive effect lasts more than 3h and is never accompanied by catalepsy. By contrast, [Trp^4,Asn^7]dermorphin induces catalepsy at icv doses that do not modify the reaction time in the tail-flick test: The ratio of antinociceptive to cataleptic ED_{50} (AD_{50}/CD_{50}) is 40, a value 500 times higher than that calculated for [Lys^7]dermorphin ($AD_{50}/CD_{50}=0.073$). The ratio of antinociceptive to respiratory-depressant ED_{50} doses is 17 times lower for [Lys^7]dermorphin than for morphine. Indeed, [Lys^7]dermorphin, in the range of the analgesic doses (36–120pmol, icv; 0.12–4.7μmol/kg, sc) significantly increases respiratory frequency and minute volume of rats breathing air or hypoxic inspirates. The early onset ventilatory stimulation produced by [Lys^7]dermorphin, and ascribed to the intact peptide, is mediated by serotonergic descending excitatory pathways that stimulate neurons of the brain stem respiratory network.[22] In rats and mice, central or peripheral administration of the dermorphin-like peptides induces a significantly slower development of tolerance to the antinociceptive effect than morphine does. Withdrawal symptoms precipitated by naloxone are less intense in peptide-dependent than in morphine-dependent rats. Like morphine, dermorphin inhibits gastric acid secretion, delays gastric emptying, and slows down intestinal and colonic propulsion. Compared with dermorphin, [Lys^7]dermorphin is slightly (3–5 times) more potent in both reducing acid gastric secretion and gastric emptying. By contrast [Trp^4,Asn^7]dermorphin is 20–50 times less potent than dermorphin in inhibiting gastric acid secretion but is 100–1000 times less potent in delaying gastric emptying. In spite of comparable μ-opioid receptor affinity, the two dermorphins from *Ph. bicolor*, [Lys^7]dermorphin and [Trp^4,Asn^7]dermorphin, differ in biological effects, underling distinct functional roles of the μ-opioid receptors.

The discovery of deltorphins provided the tools for the functional characterization of the δ-opiate system. Although D-Ala^2-deltorphins have δ-binding affinity similar to D-Met^2-deltorphin, they consistently have the highest δ-opioid selectivity (Table 2). The rank order of selectivity ($K_{i\delta}/K_{i\mu}$) is D-Ala^2-deltorphin-I = D-Ala^2-deltorphin-II > D-Met^2-deltorphin >> D-Ile^2-deltorphin >> D-Leu^2-deltorphin heptadecapeptide or its N-terminal decapeptide fragment. Both D-Met^2-deltorphin and D-Ala^2-deltorphins are highly resistant to enzyme degradation. D-Ala^2-deltorphin-I and -II cross the blood–brain barrier *in vivo* and *in vitro*: D-Ala^2-deltorphin-II is a transport substrate of organic anion transporting polypeptides (Oatp/OATP), a family of polyspecific membrane transporters, strongly expressed in the rat and human blood–brain barrier.

In mice, D-Ala^2-deltorphin II, by the icv route (EC_{50} = 2.1 nmol per mouse) is half as potent as morphine and the δ-selective antagonist, naltrindole, antagonizes its analgesic effect. Repeated injections of D-Ala^2-deltorphin-II induce tolerance to the antinociceptive effect. Isobolographic analysis shows that the supraspinal antinociception induced by the δ-opioid agonist DPDPE and the spinal antinociception induced by D-Ala^2-deltorphin-II are synergistic in many nociceptive tests. In rats, intrathecal injections of D-Ala^2-deltorphin-II (from 0.6nmol per rat) produce a naltrindole-reversible inhibition of the tail-flick response by inhibiting the nociceptive neurons in the superficial and deeper dorsal horn of the medulla. Conversely, when injected icv in rats, D-Ala^2-deltorphin-II is a weak partial agonist (>30nmol per rat) and induces fleeting naloxone-sensitive antinociception. Both D-Ala^2-deltorphin-I and D-Met^2-deltorphin at doses between 6.5 and 52nmol per rat induce a naloxone-sensitive analgesia.

Results suggest that the δ-agonists play a predominantly modulatory role in antinociception rather than a primary role. In mice and in rats, the intensity of δ-opioid analgesia depends on the coactivation of μ-opiate receptors by endogenous or exogenous opioids. Accordingly, deltorphin-induced analgesia is weaker in homozygote mice with a disrupted μ-opiate receptor gene than in wild-type mice.

Injections of the deltorphins into the rat brain ventricles, ventral tegmental area, and nucleus accumbens at doses

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

10–100 times lower than those inducing analgesia (0.06–3.8nmol per rat) invariably increase locomotor activity and induce stereotyped behavior. The δ-selective antagonist, naltrindole, antagonizes deltorphin-induced motor activity. Repeated icv injections of D-Ala^2-deltorphin-II in naive rats induce tolerance to the stimulant effects. High doses (10–50nmol per rat) of all the D-Met^2-deltorphin analogs and His^4-substituted D-Ala^2-deltorphins induce nonopioid motor dysfunction that is completely blocked by the non-competitive NMDA antagonist, dextrorphan. Deltorphin improves memory consolidation in a passive avoidance test in mice. D-Ala^2-deltorphin-I, at low doses, stimulates respiratory activity in fetal lambs. D-Ala^2-deltorphin-II inhibits diarrhea induced by castor oil and colonic bead expulsion, but it leaves the rate of transit through the small intestine unchanged. By the sc route, D-Ala^2-deltorphin-I inhibits acidified alcohol-induced gastric mucosal lesions. It is involved in the control of ingestive behavior, stimulating food intake and angiotensin-mediated water consumption in rats.

The discovery of the amphibian opioid peptides confirms that the amphibian skin and its secretions offer an inexhaustible supply of biologically active peptides. The amphibian peptides isolated from methanol extracts of amphibian skin are of a small or relatively small molecular mass (700–4600Da). Proteins, externally secreted by syncytial cells forming the wall of the integument glands, can be obtained upon electrical stimulation of the skin of the living frog. By repetitive electrical stimulation at weekly intervals, several milligrams of bioactive proteins can be collected from a single frog, yielding an amount of biologically active proteins that is enough for pharmacological research. This is the case of the new Bv8/prokineticin family.

BV8/PROKINETICIN FAMILY (SWISS-PROT: Q9PW66)

A basic small peptide, containing 77 amino acids of which ten are cysteine, has been isolated from the skin secretion of discoglossid frogs *Bombina variegata* and *Bombina bombina*[17] and named Bv8, to indicate its origin (*Bombina variegata*) and its molecular mass (about 8kDa). The amino acid sequence was established by automated Edman degradation and analysis of proteolytic fragments as well as by cDNA cloning. Homologs of Bv8 have been predicted (but not yet isolated) in skin secretions of *Rana temporaria* and *Rana esculenta* and have been demonstrated in the skin secretion of *Bombina orientalis* (Bo8) and *Bombina maxima* (Bm8a). These proteins are derived from simple precursors composed of a putative 19-residue signal peptide and the mature protein. Bo8 and Bm8a show 96% and 92% sequence identity with Bv8. Moreover, the putative signal peptides in all three proproteins are 100% identical (Fig. 1). The primary sequence of Bv8 is similar to MIT (mamba intestinal toxin), a constituent of the venom of the snake black Mamba. The amphibian and snake proteins share the same pattern of cysteine distribution, and their overall identity is 58%. cDNA cloning showed the existence of mouse (mBv8) and human (hBv8) homologs of amphibian Bv8.[21] The striking characteristics of these proteins are the identical amino terminal sequence, AVITG, and the presence of ten cysteines with identical spacing (Fig. 1). A similar Cys-motif is also present in mammalian colipase and in the carboxy-terminal region of members of the Dickkopf family of extracellular signaling proteins. However, the frog protein does not stimulate the activity of pancreatic lipase, and it is also inactive in an assay for Dickkopf functions. Starting from the 3D-structure of mammalian colipase, a model was built for frog Bv8 in which the hydrophobic amino terminal sequence AVITG forms a sort "beak" exposed at the surface of the tightly folded rest of the protein.[9]

Two forms of mBv8 and hBv8 have been characterized in the mouse and human testis. These forms differ in an exon coding for 21 amino acids, the majority of which are basic (Fig. 1). The predominant site of Bv8 expression in both humans and mice is primary spermatocytes in the seminiferus tubules of the testis. The genomic structure of these murine and human Bv8 genes has been determined, and the chromosomal localization was identified near a synteny breakpoint of mouse chromosome 6 and human 3p21.[21] By searching the EST database using the predicted coding of Bv8, Zhou[15] identified two human EST sequences, one encoding the human protein already described and the other encoding a slightly different Bv8-like protein. The two proteins were named prokineticin 2 (PK2) and prokineticin 1 (PK1) (Fig. 1). The name prokineticin refers to the ability of these peptides to contract GPI, a property shared with amphibian Bv8.[15] By screening a library of human-secreted proteins for the ability to induce proliferation in capillary endothelial cells, Ferrara[14] identified a protein that induced proliferation, migration, and fenestration in the endothelial cells of steroid synthesizing glands (ovary, testis, adrenals) and named it endocrine-gland-derived vascular endothelial growth factor (EG-VEGF). EG-VEGF and PK1 are the same protein and have an overall identity of 58% and homology of 76% with human PK2 and murine Bv8 and 43% identity with amphibian Bv8. PK1/EG-VEGF has been isolated and sequenced also from bovine milk. Rat and human mRNAs for PK1 and PK2 have been cloned and their expression patterns reported in peripheral tissues and the central nervous system.[15] The distribution of murine Bv8-like proteins, PK1 and PK2, and their mRNAs has been reported in the brain (olfactory bulb, cerebral cortex, hippocampus, some thalamic and hypothalamic nuclei, Purkinje cells of the cerebellum, many nuclei of the brain stem), spinal cord, gastrointestinal tract, endocrine glands, and other peripheral organs.[21] The PK2 mRNA expression pattern in the suprachiasmatic nucleus (SCN) of mice[2] and of rats[20] is rhythmic

FIGURE 1 Amino acid sequences of Bv8-like proteins in the frog (Bv8, Bo8 and Bm8a) skin secretion compared with the snake venom protein (MIT) and the human prokineticins: PK1, PK2, and PK2L, the long form of PK2, containing a 21-amino acid insert.

(being the lowest in the dark phase) and is severely blunted in mutant mice deficient in Clock or cryptochrome genes. PK2/Bv8, constitutively expressed in cells and organs of myeloid origin, is dramatically upregulated by inflammatory processes.[6]

Receptors for PK1 and PK2 have been identified in humans, mice, and rats. These receptors, named prokineticin receptor 1 and 2 (PKR1 and PKR2), belong to the family of G protein-coupled receptors, share approximately 85% amino acid identity, and are about 80% identical to the previously described mouse orphan receptor gpr73. In a study aimed to map the expression of PKR1 and PKR2 in rat and mouse nervous system, we[21] and others[3] detected PKR2 mRNA in the brain (olfactory bulbs, SCN, hippocampus, paraventricular thalamic and hypothalamic nuclei, nucleus arcuatus, subfornical organ (SFO), amygdala, caudate putamen, and cortex) and in dorsal root ganglia (DRG). PKR1 is mainly expressed outside the mammalian central nervous system, with the highest density in the neurons of DRG. PKR1 is also expressed by murine macrophages. Mice lacking the PKR2 show a dramatic reduction in olfactory bulbs (OB) size, and they do not survive; mice lacking PKR1 are severely deficient in their responses to noxious thermal and chemical (capsaicin, protons) stimuli.[19,21]

Intensive investigation of the Bv8/prokineticin system over the past decade has revealed a dazzling array of physiological functions including the regulation of circadian rhythms, metabolism, angiogenesis, neurogenesis, muscle contractility, hematopoiesis, immune response, reproduction, and pain perception. In addition, the disruption of prokineticin system has been implicated in several pathological conditions, including cancer, immunological response, mood disorder (anxiety/depression),[10] cardiomyopathy, and persistent pain. Point mutations in the genes encoding for prokineticins and/or prokineticin receptors are involved in human Kallmann's syndrome and Hirschprung's disease.[19] The isolation of an adequate amount of the amphibian Bv8 protein has provided valuable research tools for characterizing the prokineticin pharmacology.

On cultured cerebellar granular cells, Bv8 reduces the extent of apoptotic death induced by switching the concentration of K^+ in the growing medium from 25 to 5mM. In cell-based assays, Bv8 and EG-VEGF/PK1 induce proliferation, migration, and survival of primary adrenal cortical capillary endothelial (ACE) cells. Delivery of Bv8 or EG-VEGF to the mouse testis results in a potent angiogenic response resulting from activation of PKRs on vascular endothelial cells within the interstitial space.[13,14]

Injections of Bv8 (from 0.25 to 60pmol) into the lateral ventricles of the rat brain suppress diurnal, nocturnal, deprivation-induced, and neuropeptide Y-stimulated feeding. Bv8 injected icv also stimulates drinking in a dose-dependent manner. We showed that Bv8 stimulates drinking through its receptors in the SFO and inhibits feeding after injection into the arcuate nucleus. Rat sensitivity to the Bv8-induced anorexogenic response increases significantly during the dark phase of the circadian cycle,[20] in accordance with the physiological role of Bv8/PK2 in controlling circadian rhythm from the SCN.[2]

In rats, icv and sc injections of Bv8 induce antidiuresis dependent on vasopressin release. Bv8 injected sc also induces the release of oxytocin and corticosterone.[21]

In rodents, subcutaneous, intrathecal, intraplantar (Fig. 2), and intrabrain administration of amphibian Bv8 induces hyperalgesia activating the prokineticin receptors that are present on peripheral nociceptors and in regions of the central nervous system associated with pain.[19,21]

We showed that amphibian Bv8 binding on PKR1 and PKR2 in dorsal root ganglion neurons produces $[Ca^{++}]_i$ mobilization, PKCε translocation, and sensitization of the vanilloid receptor TRPV1, hence decreasing the nociceptive threshold to mechanical and thermal stimuli.[19] Amphibian Bv8 injected into the periaqueductal gray (PAG) exerts a pronociceptive action by increasing the intrinsic GABAergic tone which, in turn, is responsible for the inhibition of PAG antinociceptive output neurons demonstrating that the Bv8/PKR system may also intervene in modulating central pain mechanisms.[4]

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

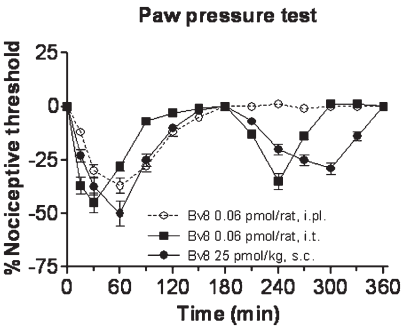

FIGURE 2 Time course of hyperalgesia induced in rats by subcutaneous (s.c.), intrathecal (i.t.), and intraplantar (i.pl.) injections of Bv8. Hyperalgesia is expressed as the percent decrease of the basal nociceptive threshold.

We have shown that amphibian Bv8 activates macrophages to migrate and to produce proinflammatory cytokines. It is also able to affect the T lymphocyte population, because the administration *in vitro* and *in vivo* of amphibian Bv8 skews the Th1/Th2 balance toward a Th1 response. All these effects depend on the activation of PKR1 because they lack in the lymphocytes and macrophages from PKR1-KO mice.[19]

Endogenous Bv8/PK2 is overexpressed in inflamed tissues and in animal and human neoplastic tissue, predominantly in infiltrating neutrophils. These cells can secrete it, since the sequence of the precursors contains the typical signal peptide for secretion.[19] Ferrara's group showed that Bv8 regulates myeloid-cell-dependent tumor angiogenesis. We showed that Bv8 has a crucial role in neutrophil-dependent inflammatory hypernociception.[6]

To develop PKR antagonists as novel analgesic and anti-inflammatory drugs, structural determinants required for the biological activity of Bv8 must be identified.

Studies from our group suggested that AVITGA family members could interact with PKR1/PKR2 by orienting the protein region that comprises the AVITGA sequence and the conserved tryptophan residue in position 24. The N-terminal deletion of the first two amino acids in amphibian Bv8 molecule (dAV-Bv8) yield an analog lacking any biological activity but still able to bind the receptors. dAV-Bv8 is a short acting antagonist *in vivo*. Substituting Trp with Ala in position 24 yields a molecule, A-24, that preferentially binds and activates PKR2. It displays weak affinity and efficacy on PKR, acting as an antagonist. A-24 has an extraordinary, long-lasting antihyperalgasic effect in animal models of postsurgical and inflammatory pain.[12]

Some nonpeptide molecules, triazine-guanidine derivatives, seem very promising. Local or systemic injection of the lead compound, PC1, abolishes the hyperalgesia in animal models of inflammatory[6] and postsurgical pain and speeds up the paw healing being, on a molar base, about a thousand times more potent than indomethacin (unpublished). Our results also show an important role for the Bv8/PKR in neuropathic pain at least in rodents. If this role is confirmed in humans, reducing Bv8 levels in damaged tissues or antagonizing PKRs might be an innovative strategy to control persistent, invalidating pain.

Chapter 54

Sodefrin and Related Pheromones

Sakae Kikuyama, Fumiyo Toyoda, Kazutoshi Yamamoto, Takeo Iwata, Tomoaki Nakada and Itaru Hasunuma

ABSTRACT

This chapter describes the current state of understanding of sodefrin, a peptide pheromone from the newt *Cynops pyrrhogaster*, and [Leu^3,Gln^8] sodefrin (silefrin) from the congeneric species, *C. ensicauda*. Both pheromones consist of 10 amino acids and were isolated from the abdominal glands of male newts. They exhibit a potent female-attracting activity only to the conspecific females, suggesting a contribution of the pheromones to maintaining the reproductive isolation of the species.

Both pheromones are generated from 20-kDa precursor molecules. They are emitted through the cloaca of the male and are directed toward the female partner's snout during courtship to act primarily on the lateral nasal sinus cells. Hormone dependency of secretion of and response to the pheromones has been observed.

DISCOVERY

It is well recognized that courting male red-bellied newts, *C. pyrrhogaster*, attract their partners by sending water from around the cloaca toward the female's snout by vibrating their tail and that during courtship they project numerous minute tubules that are connected to the abdominal gland, from the cloaca. This suggests that the male newts emit female-attracting pheromones through the cloaca.[8,16] We found that the water in which sexually active male newts are kept attracts conspecific females. The attractant was believed to be secreted by the abdominal gland of the cloaca because the water in which abdominal gland-ablated males had been kept did not attract females. Thus, an attempt was made to isolate and characterize the active component. Female-attracting activity was monitored by a preference test.[17]

An aqueous extract of the abdominal glands of sexually developed male red-bellied newts exhibits female-attracting activity. The minimum effective amount of the extract in a sponge block that attracts a female placed in a container filled with 3000ml of water is the equivalent of 0.1% of the abdominal gland content. When the water-soluble fraction of the abdominal gland is subjected to gel-filtration column chromatography, the most potent female-attracting activity elutes with a relative molecular mass <5000. Incubation of this fraction with pronase results in the loss of its female-attracting activity, indicating that the active substance is a peptide.

To isolate the active peptide from the crude fraction, two purification cycles of reversed-phase HPLC were used. The final product was subjected to direct sequencing by a pulsed gas-liquid phase protein sequencer, and the active substance was identified as a decapeptide with the amino acid sequence SIPSKDALLK. COOH-terminal analysis by carboxypeptidase-P digestion shows that a free (nonamidated) Lys residue is present at the COOH terminus. The relative molecular mass of 1071.2 estimated from fast atom bombardment mass spectrometry corresponds to that calculated from the amino acid sequence. Ten nanograms of the final product absorbed in a block of sponge is enough to attract female newts placed in a container filled with 3000ml of water. The synthetic version exhibits female-attracting activity similar to that of the natural material. The peptide shows no sequence similarity with any known peptide. Thus, the novel peptide is designated sodefrin (derived from the ancient Japanese word "sodefri," meaning "soliciting").[9]

To study the localization of sodefrin in the abdominal gland and to develop a specific radioimmunoassay (RIA) system for the measurement of the peptide, an antiserum against sodefrin was generated. Frozen sections of abdominal glands stained with the antiserum against sodefrin show that the apical region of the epithelial cells are positive for sodefrin[22] (Fig. 1). Immunoelectron microscopy of the abdominal gland reveals that the sodefrin-immunoreactive substance is localized mainly in the secretory granules[18] (Fig. 2). This clearly indicates that sodefrin is secreted by the epithelial cells of the abdominal gland.

To ascertain whether the abdominal gland of a congeneric species, *C. ensicauda* (the sword-tailed newt) synthesizes molecules that immunoreact with the sodefrin antiserum,

an aqueous extract of the abdominal gland was subjected to a sodefrin RIA. This extract showed no crossreactivity in this RIA system, whereas a water extract from the abdominal gland of *C. pyrrhogaster* showed an inhibition curve parallel to the sodefrin standard.[22] On the assumption that *C. ensicauda* abdominal glands contain a molecule possessing a female-attracting activity that is different from sodefrin, purification of putative *C. ensicauda* pheromone was performed. The pheromone was isolated from the abdominal glands by gel-filtration chromatography and reversed-phase HPLC. The final product consists of the 10 amino acid sequence SILSKDAQLK and a molecular mass of 1102.3 as estimated by electrospray mass spectrometry. This peptide is designated silefrin, a combination of the first three N-terminal amino acids, SIL and -efrin, derived from sodefrin.[23] The sequence of this peptide differs from that of sodefrin by two amino acids, with substitutions of Leu for Pro and Gln for Leu at positions 3 and 8, respectively. Both native and synthetic silefrin are equipotent in attracting conspecific females, 10ng being the minimum effective amount. Localization of silefrin in the abdominal gland of *C. ensicauda* shows an intense immunofluorescence on the apical side of the epithelial cells in the cryosections incubated with the antiserum.

STRUCTURE OF THE PRECURSOR mRNA/GENE

A sodefrin precursor cDNA, isolated from a cDNA library constructed from *C. pyrrhogaster* abdominal gland mRNA, contains 1364bp with an open reading frame of 567bp and encodes a sodefrin precursor polypeptide of 189 amino acids. The precursor polypeptide includes a predicted signal peptide and, in a region close to the C-terminus, the sodefrin molecule. The molecular mass of the sodefrin precursor deduced from its sequence is approximately 20kDa (Fig. 3A). Likewise, a cDNA clone encoding a silefrin precursor protein isolated from a *C. ensicauda* abdominal gland cDNA library consists of 1339bp; it contains a predicted open reading frame of 576bp encoding a precursor polypeptide of 192 amino acids, including a domain rich in hydrophobic amino acids that was presumed to be a signal peptide. Its nucleotide sequence shows 82% sequence identity with preprosodefrin from *C. pyrrhogaster*[3] (Fig. 3B).

A partial sodefrin precursor gene structure was identified by genomic PCR by the use of genome DNA purified from the liver of male newts captured in Niigata. At least one intron is inserted between nucleotide position 569 and 570 of sodefrin precursor cDNA. In addition, we

FIGURE 3 Nucleotide and deduced amino acid sequences of the cDNA clone encoding sodefrin (A) and silefrin (B). The predicted amino acids are shown below the nucleotide sequence. The amino acids comprising sodefrin and silefrin molecules are circled. The asterisk indicates the termination codon, and the polyadenylation signal (AATAAA) is underlined. *From Ref.* 16 *Copyright 2000 by the Zoological Society of Japan.*

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

confirmed the existence of the two kinds of genes that have different lengths of intron, one having a 2020-bp intron and the other having a 1535-bp intron. The sequence of the exon of the former encodes sodefrin and that of the latter encodes [Asn[10]] sodefrin (see a later section of this chapter).[2]

DISTRIBUTION OF THE mRNA

Northern blot analysis of sodefrin mRNA in the abdominal gland indicates a size of about 1.5kb and that sodefrin mRNA is expressed in the abdominal gland but not in other organs such as tail, liver, kidney, testis, and brain. Similarly, the expression of the silefrin precursor mRNA of *C. ensicauda* was also analyzed with silefrin precursor cDNA as a probe. A single band showing positive hybridization corresponding to approximately 1.5kb is found exclusively in the abdominal gland.[3] Localization of mRNA by in situ hybridization with ^{35}S-labeled silefrin precursor cDNA as a probe shows intense specific signals in the epithelial cells of the abdominal gland[5] (Fig. 4).

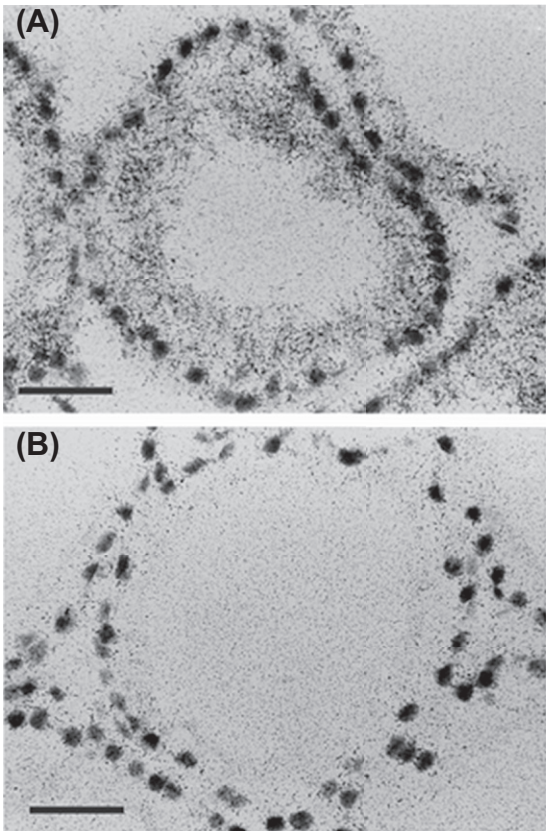

FIGURE 4 Micrographs of the signals for silefrin precursor mRNA in the abdominal gland of the newt, *C. ensicauda*. In situ hybridization was performed with a specific ^{35}S-labeled probe (A) and with a ^{35}S-labeled probe containing an excess of nonlabeled silefrin precursor cDNA (B). Bars represent 50 μm. *From Ref.* 5 *Copyright 2000 the Society for the Study of Reproduction.*

PROCESSING OF THE PRECURSORS

Sequence analysis of the cDNAs encoding sodefrin and silefrin reveals that both peptides are generated from precursor proteins. Both molecules are sandwiched between monobasic amino acids (Arg and Lys).[3] It is well known that most peptide hormones are derived from precursor proteins as a result of posttranslational processing (see Peptide Biosynthesis/Processing section of this book). The peptide hormone sequence is flanked by pairs of dibasic amino acids that are subjected to cleavage by enzymes such as the prohormone convertases PC1 and PC2. The absence of such dibasic amino acids flanking the sodefrin and silefrin molecules suggests that the mode of processing of these peptide pheromones are different from that of most peptide hormones.

Synthetic sodefrin C-terminally extended by Ile-Ser-Ala (the C-terminal portion of sodefrin precursor consisting of 13 amino acids) does not attract the females, indicating that these three amino acids must be removed from the C-terminus of this molecule for acquisition of biological activity.

To show the presence in the abdominal gland of enzymes that cleave the amino acids at the C- and N-termini of sodefrin, an assay for enzyme activity was developed with *t*-butoxycarbonyl (Boc)-LGR-methylcoumaryl-7-amide (MCA) and Boc-LLK-MCA as synthetic substrates. These substrates were designed on the basis of the predicted amino acid sequence of the C-terminal region of the sodefrin precursor protein (…LGRSIPSKDALLKISA). A *C. pyrrhogaster* abdominal gland extract hydrolyzed both Boc-LGR-MCA and Boc-LLK-MCA to liberate 7-amino-methyl-4-courain (AMC), suggesting that enzymes that generate sodefrin from its precursor molecule exist in the abdominal gland. The activity in the extract for cleaving Boc-LGK is optimal at PH 9.0 and 45°C and for Boc-LGK at PH 9.0 and 40 °C. The enzyme preparation loses activity when it is boiled or when proteinase inhibitors are present during incubation. The effects of a range of specific protease inhibitors on activities in the extract suggest an involvement of enzymes belonging to the serine protease family. The enzymatic activity in an extract of the abdominal glands of sexually developed males is significantly higher than that of sexually undeveloped ones.[13]

RECEPTORS

At present, no receptors for either sodefrin or silefrin have been identified. Bilateral, but not unilateral, nostril plugging in females with a cotton ball soaked in melted vaseline completely abolishes the female-attracting activity of sodefrin.[18] This strongly suggests that the action of sodefrin is mediated through the olfactory organ. This result concurs with the results of an electrophysiological study showing that sodefrin evokes a marked electro-olfactogram (EOG)

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

response when applied to the lateral nasal sinus. The lateral nasal sinus region is considered to be a primitive vomeronasal organ. The EOG response to sodefrin is markedly enhanced in the females when they are treated with gonadotropin or estrogen in combination with prolactin. In the male, however, the effects of the similar hormonal treatments on the EOG response to sodefrin are not apparent. Thus, it was concluded that there is a sex difference in the responsiveness of lateral nasal sinus to the hormones and/or the pheromone.[19]

Sodefrin, but not silefrin, increases $[Ca^{2+}]_i$ in dissociated lateral nasal sinus cells from the female *C. pyrrhogaster*. Species specificity in terms of the responsiveness to the pheromone occurs at the cellular level. The number of cells that respond to sodefrin increase concentration dependently. Relatively few cells in the lateral nasal cells from female newts in the nonbreeding season or from male newts respond to sodefrin compared with cells from reproductive females. There are at least two cell types in the lateral nasal cells that respond to sodefrin by elevating $[Ca^{2+}]_i$. One increases $[Ca^{2+}]_i$ through the phospholipase C (PLC)-inositol 1, 4, 5-triphosphate pathway and the other increases $[Ca^{2+}]_i$ through the PLC-diacylglycerol-phosphokinase C pathway.[6]

STRUCTURE–ACTIVITY RELATIONSHIPS

In addition to sodefrin, several peptides related to sodefrin (SIPSKDALLK) have been identified. Minute amounts of peptides such as SKDALLK and DALLK were obtained during purification of sodefrin. These peptides, possibly degradation products of sodefrin, were subjected to the preference test. SKDALLK retains the ability to attract sexually developed female newts, whereas DALLK exhibits no activity. This indicates that the sequence Ser^4-Lys^5 in the sodefrin molecule is indispensable for mediating the female-attracting activity. From an extract of the abdominal glands of male red-bellied newts captured 5 months before the onset of the breeding season, a COOH-terminally extended form of sodefrin (SIPSKDALLKISA) was obtained. This peptide is biologically inactive, suggesting that activation of a protease that cleaves at the Lys–Ile bond to generate the active pheromone must occur by the time of onset of reproductive behavior. Another biologically inactive peptide isolated is a COOH-terminally extended form of [Asn^{10}] sodefrin (SIPSKDALLNISA). The presence of this sodefrin variant raises the possibility of the expression of multiple genes encoding preprosodefrin. Analyses of PCR products derived from total RNAs from the abdominal gland of individual newts collected from three different regions (Chiba, Niigata, and Nara) of Japan confirm the existence of multiple genes encoding sodefrin and its variants. Their expressions varied according to the individuals and the regions. Among them, mRNA encoding the sodefrin variant, SIPSKDAVLKICA ([Val^8] sodefrin. ICA) is expressed exclusively in the animals from Nara, whereas genes encoding sodefrin are expressed in all the specimens sampled.[7] [Val^8] sodefrin and sodefrin were isolated from the abdominal gland of the male newts inhabiting the Nara region. [Val^8] sodefrin is slightly more potent than sodefrin when tested with Nara females. A full-length cDNA encoding [Val^8] sodefrin precursor was cloned and characterized. The deduced amino acid sequence of prepro[Val^8] sodefrin shows 86% identity with that of the sodefrin precursor. The region-specific pheromone is designated aonirin ("aoni" derived from "aoni-yoshi," the conventional epithet of Nara and "rin" from sodefrin). Aonirin exhibits a potent female-attracting activity toward females belonging to the same population but no or much less activity to the females captured in different regions.[14] The occurrence of geographical variation in the courtship pheromone and of differences in the responsiveness toward the variant pheromone among the females inhabiting different regions might cause reproductive isolation and finally lead to the differentiation into separate species.

BIOLOGICAL ACTIONS

The biological test for female-attracting activity is performed according to the method established by Toyoda et al.[17] This preference test reveals that 10ng of both native and synthetic sodefrin adsorbed by a sponge block is enough to attract female newts and that the minimum effective concentration lies within the range 0.1–1.0pM.[9]

Both native and synthetic silefrin attract *C. ensicauda* females, the minimum effective amount absorbed in a sponge block being 10ng as in the case of sodefrin. Silefrin attracts only *C. ensicauda* females but not *C. pyrrhogaster* females. Likewise, sodefrin attracts only *C. pyrrhogaster* females.

A combination of prolactin and androgen produces the structural development of various male organs related to reproduction, including the abdominal gland.[10] The combination of both hormones elevates sodefrin precursor mRNA levels[4] and increases the content of immunoassayable sodefrin.[23] Likewise, silefrin precursor mRNA and silefrin content in the abdominal gland of *C. ensicauda* are increased by treatment with prolactin and androgen.[5] Both prolactin and androgen receptors exist in the epithelial cells of the abdominal gland.[11,12]

Arginine vasotocin (AVT) is considered to be a candidate hormone for regulating discharge of the pheromone. The water in which AVT-treated *C. pyrrhogaster* males are kept shows considerable female-attracting activity as compared with the water in which saline-injected males are kept. In addition, the sodefrin content in the abdominal gland is

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

decreased by the hormonal treatment. The effect of another neurohypophyseal hormone, mesotocin, is less pronounced in this respect. AVT induces contraction of the excised gland concentration dependently. This AVT-induced contraction is blocked completely by a V1a receptor blocker. The expression of mRNA of V1a-type receptor has been confirmed in the abdominal gland of the newt *C. pyrrhogaster.*[1] Thus, AVT may serve as a hormone to induce the release of sodefrin, acting on a contractile structure of the abdominal gland through a V1a-type receptor.[20]

PHYSIOLOGICAL IMPLICATIONS

The existence of pheromones in the class Amphibia has long been postulated. Sodefrin is the first amphibian pheromone to be identified and the first peptide pheromone to be identified in a vertebrate. Since sexually mature newts lead an aquatic life, it is quite reasonable to expect a nonvolatile but water-soluble peptide as a pheromone in this animal.

A protein pheromone has been identified in a urodele *Plethodon jordani.*[15] In this species, courtship takes place on land, whereas courtship by *Cynops* is performed in water. In an anuran *Litoria splendida*, a female-attracting pheromone was shown to be a peptide consisting of 25 amino acids that is secreted by the male skin gland.[21] In this species mating, takes place in water. However, until the chemical nature of sex pheromones from various species of amphibians performing reproductive behavior in various environments has been elucidated, it may be premature to conclude that peptides are the dominant form of sex pheromone for amphibians in which courtship or mating takes place in water. Nevertheless, water-soluble peptide pheromones might be considered to be the ideal forms of species-specific reproductive pheromones for amphibians performing courtship or mating in aquatic environments where other species are liable to exist, since variant forms that may exert species-specific pheromonal activity can be generated by modification of the nucleotide sequence of the pheromone gene.

Chapter 55

Tachykinins

Cinzia Severini and Giovanna Improta

ABSTRACT

As many as 20 tachykinins (TKs) have been isolated from amphibian skin and 11 from amphibian gut or brain. Amphibian TKs exert their biological actions in mammals through the activation of the three classical TK receptors and, in their species of origin, through activation of receptors that resemble the structure of the mammalian TK receptors. This suggests a high degree of conservation of the receptor sequence among different vertebrate species. As the potencies of the amphibian TK are comparable to, or can exceed the potencies of their mammalian counterparts, amphibian TKs represent a widely used tool in the characterization of the TK functional roles.

DISCOVERY

The history of both nonmammalian and amphibian TKs began in 1947. In that year, Vittorio Erspamer, while investigating the occurrence of biogenic amines, especially serotonin, in the extracts of the posterior salivary glands of a Mediterranean octopod (*Eledone moschata*), discovered an unidentified substance that lowered the blood pressure in rabbits and dogs, stimulated isolated intestinal smooth muscle, and caused profuse salivation in dogs and rats. The new substance, called eledoisin (ELS), was structurally characterized in 1962. In the same year, from the skin of the South American leptodactylid frog *Physalaemus biligonigerus* (formerly *fuscumaculatus*), a new peptide with eledoisin-like activity and called physalaemin (PHYS), was extracted and isolated. The structural characterization of this first amphibian TK in 1964 led to the prediction of the primary structure of substance P (SP), already identified by bioassay in 1931 but sequenced only 40 years later, in 1971. Therefore, it became evident that the short peptides of nonmammalian origin, named TKs by Vittorio Erspamer, represented the phylogenetic precursors of SP and of the other mammalian TKs (neurokinin-A/NKA and neurokinin-B/NKB).[4]

During the following years, a systematic screening of the peptide content in the skins of as many as 600 amphibian species from all over the world resulted in the discovery and isolation of numerous families of neuropeptides, including that of TKs.[5] Despite the large amount of TKs isolated from extracts of frog skin, there are relatively few studies describing the isolation of TKs from amphibian brain or gut.

Although with some exceptions, the great majority of amphibian TKs have, like all vertebrate TKs, the classical C-terminal pentapeptide sequence Phe-X-Gly-Leu-Met-NH_2 essential but not sufficient for their biological activity. The minimum chain length required for activity is six residues. In addition, the Phe residue at position 5 from the C-terminus and amidation at their C-terminus are crucial for their biological activity. On the basis of their chemical structure and receptor affinities, both amphibian skin TKs and amphibian brain/gut TKs can be grouped into two subfamilies: "Aromatic TKs" (with the C-terminal pentapeptide Phe-Tyr(Phe)-Gly-Leu-Met-NH_2) and "Aliphatic TKs" (with the C-terminal pentapeptide Phe-Val(Ile)-Gly-Leu-Met-NH_2).[28]

Parallel bioassays on a number of isolated and *in situ* test systems, using the natural peptides and selective synthetic analogs alone or in the presence of selective antagonists, together with radioactive ligand binding studies, allow the receptor selectivity of amphibian TKs to be functionally characterized, mostly in mammals and to a lesser degree in the species of origin. The main monoreceptor systems used are the rabbit vena cava for NK1-, endothelium-removed rabbit pulmonary artery and hamster urinary bladder for NK2-, and rat portal vein for NK3 receptors.

"Aromatic TKs" preferentially interact with the mammalian NK1 receptor, whereas "Aliphatic TKs" mainly interact with the mammalian NK2/NK3 receptors.[24,25,27]

Table 1 summarizes the sequence and source of the 20 TKs extracted from amphibian skin. All these peptides have a nonneuronal origin, as they are synthesized in the syncytial cells lining the wall of the granular glands. These cells are capable of cosynthesizing, costoring, and cosecreting not only peptides belonging to different families but also amines and alkaloids of various classes and families. The occurrence of such a variety of substances and neuropeptides in amphibian skin may perhaps be explained by the common embryogenic origin of the integument and the nervous system from the primitive ectoderm.

The list of the 11 TKs extracted from frog gastrointestinal or nervous systems is shown in Table 2 and should be completed by authentic NKB found in the brain of *Rana esculenta*.

STRUCTURE OF THE PRECURSOR mRNA/GENE

The high degree of sequence similarity among amphibian and mammalian TKs, a C-terminal region completely identical in different species and crucial for TK biological activities, suggests that TK genes are phylogenetically ancient genes that have been highly conserved throughout the course of evolution. Therefore, our knowledge about the structure of the amphibian TK precursor mRNA/gene and its processing has been referred to information about mammalian TKs (for detailed information, see the Tachykinin chapter in the Brain Peptides section).

Only recently, the structures of amphibian preprotachykinins have been deduced from cDNAs cloned from the skin secretion library of two different amphibians, the Oriental ranid frog, *Odorrana grahami*[16] and the African hyperoliid frog, *Kassina senegalensis*.[34] From *O. grahami*, two cDNA sequences were characterized, encoding TK OG1 and ranamargarin, respectively. These precursors are composed of 61 amino acid (aa) residues including a signal peptide followed by an acidic spacer peptide and only one copy of mature TK-like peptide. Their overall structure is different from the structure of mammalian TK precursors such as preprotachykinin (TAC)-1 containing 143 aa including two kinds of TK peptides (SP and NKA), inserted at the middle of their precursor protein. Besides the obvious size difference, the only single copy of the mature TK-like peptides is at the end of the C-terminus of its precursor.[16]

Moreover, from *K. senegalensis* skin, two different cDNA sequences encoding kassinin and (Thr^2,Ile^9)-kassinin were determined. Each of these preprotachykinins consists of 80 aa residues encoding single copies of either kassinin or its analog and showed a different domain architecture from the *O. grahami* precursors. Indeed, a single TK-encoding domain, adjacent to the N-terminal putative signal peptide, characterizes each precursor. In conclusion, these findings suggest that the biosynthesis mode of TKs in amphibians is different from that of other animals.

PROCESSING OF THE PRECURSOR

Mammalian TKs, synthesized as large precursor proteins through alternative mRNA splicing, generate the distinct mature peptides (for detailed information, see the Tachykinin chapter in the Brain Peptides section). However, details of the biosynthesis of amphibian TKs remained unknown until the discovery of preprotachykinins from *Odorrana grahami* and *Kassina senegalensis* skin.

The *Odorrana grahami* precursors of OG1 and ranamargarin share an identical signal peptide and a highly conserved acidic peptide, while the regions of mature TK-like peptides are different. There is a dibasic processing site for trypsin-like proteases sited before the mature TK-like

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY
Copyright Elsevier 2024

peptide. At the end of the mature TK-like peptide, a glycine provides the amide for the C-terminal methionamide.

In the *Kassina senegalensis* precursors, a typical propeptide convertase-processing site occurs flanking the C-terminus of the TK that is preceded by a glycyl residue amide donor constituting the cleavage/amidation motif. This motif occurs at two additional sites, implying that upstream peptides could likewise be cleaved at these sites and C-terminal amidated.

DISTRIBUTION

Studies on TK-mRNA distribution in nonmammalian vertebrates are very few, but the available information about final peptide localization could be a predictor of the corresponding mRNA expression sites. Evidence for the presence of TKs in amphibian skin, brain, and gut was obtained through techniques of isolation and structural characterization of the original peptides from extracts of these tissues. The use of radioimmunological and immunohistochemical techniques revealed the presence of TK-like substances in different amphibian tissues and organs.

In amphibians, as in mammals and other vertebrates, TK-like immunoreactivity (TK-LI) is widely distributed throughout both the central and peripheral amphibian nervous system.[10]

In *Rana pipiens*, SP-LI is found in the brainstem with a distribution similar to that detected in amniotes, thus emphasizing the phylogenetic conservation of large amounts of the structure and possibly of functional activities in the old reticular formation. TK-LI is also present in the hypothalamic–hypophysial system of *Rana esculenta*, and in visual systems of the frogs *Rana pipiens* and *Xenopus laevis*, especially in the retina (amacrine cells) and in the optic tectum, with a distribution of SP-related peptides remarkably similar to that seen in the homologous regions of mammals. In *Rana esculenta*, *Rana catesbeiana*, and *Xenopus* spinal cord, a dense TK-LI is observed in the dorsal horn where the TK functional organization seems to be similar to that of mammals, as well as the colocalization of TK-LI with calcitonin gene-related peptide (CGRP) immunoreactivity restricted to primary afferent fibers.[10,26]

In the peripheral nervous systems of mammals, the main source of TKs is the enteric nervous system. The TKs in amphibian gut have a distribution similar to that occurring in mammals, as shown by the dense SP-LI and bufokinin-LI (BFK-LI) in the myenteric plexus and in the fibers innervating submucosal and mucosal structures, and conversely, by the moderate immunoreactivity detected in the circular muscle of the intestine of the toad *Bufo marinus*.[20]

In *Rana catesbeiana*, TK-LI is also found in the nerve fibers innervating the frog palate, the carotid labyrinth, the respiratory system (pharynx and lung in colocalization with CGRP), and the vasculature. Recently, BFK-LI was mapped in varicose fibers in the wall of many peripheral blood vessels in the toad. In *Rana ridibunda*, TK-LI (SP-, NKA-, and ranakinin/RNK-LI) is observed in peptidergic fibers innervating the adrenal gland, supporting functional data relating to TK control of corticosteroid release in amphibians.[15]

As well as neuronal distribution, TKs are also localized in nonneuronal structures. In amphibians, the most complex and richest nonneuronal localization is certainly represented by the skin, which may be considered a huge workshop producing bioactive peptides and a true endocrine system.

RECEPTORS AND SIGNALING CASCADES

The biological activity of vertebrate TKs depends on their interaction with three main types of Gq/G_{11} protein-coupled receptors, NK1, NK2, and NK3, which mediate their functional roles by activating phospholipase C (PLC), inositol–phosphate formation, and increasing intracellular calcium. Although mammalian TK receptors have received great attention (for detailed information, see Tachykinin chapter in the Brain Peptides section), the nonmammalian counterparts of these receptors have been poorly studied. Because mammalian and nonmammlian TKs have broadly similar actions in both mammalian and nonmammalian species, it is probable that the sequences of the TK receptors have been conserved across different vertebrate species.

The first amphibian TK receptor cloned and characterized was an SP receptor complementary DNA from the sympathetic ganglion of bullfrog *Rana catesbeiana*. It has a protein sequence with 69% identity to the mammalian NK1 receptor, with the highest degree of conservation seen in the transmembrane and intracellular loop regions. The endogenous ligands of this receptor, the ranatachykinins (RTKs), act as full agonists at this site, inhibiting the potassium current that causes alterations in neuronal excitability. However, NK1 antagonists, at concentrations that block mammalian NK1 receptors, had little or no effect on the responses to the bullfrog NK1-like receptor.[31]

Recently, three NK1-like receptor isoforms (bNK1-A, bNK1-B, and bNK1-C), differing only at the intracellular COOH terminus, were cloned from cane toad brain and intestine by Liu et al., suggesting that the alternative splicing of the NK1 receptor is a mechanism that has been physiologically conserved across different species and that each isoform could play a distinct physiological role. Two of these bufokinin receptors (bNK1-A and bNK1-B) are similar to the truncated and full-length forms of the mammalian NK1 receptor, whereas bNK1-C does not correspond to any previously described receptor. The three isoform transcripts are strongly expressed in the gut, lung, and skeletal muscle and in the spinal cord and brain.[19] BFK receptors were pharmacologically characterized in the gastrointestinal tract of *Bufo marinus* and show functional similarities to the NK1

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

mammalian receptor, although displaying very low affinity for the mammalian NK1 receptor–selective agonists and antagonists.[20] Moreover, in *X. laevis* gastrointestinal tract, two different TK receptors were functionally characterized, one an NK1-preferring form and the other an NK2-preferring receptor. Both may exist in the stomach, whereas the NK1-like receptor predominates in small intestine longitudinal muscle. However, no molecular evidence exists for the presence of either NK2 or NK3 receptor in amphibians. Additionally, as classical TK antagonists seem to interact differently with these amphibian receptors in comparison with mammalian receptors, the sequence of the "antagonist binding domain" of amphibian TK receptors is probably not well conserved.

Compared with the large amount of data about mammalian TK receptors, we have only limited knowledge about the signal transduction mechanisms of amphibian TK receptor activation.

Nevertheless, binding studies in toad intestinal smooth muscle membranes show the presence of a G protein–coupled TK receptor. Indeed, TK dose dependently increases the production of inositol phosphates in this tissue, suggesting that the mechanism of TKs in contracting toad intestine is via the inositol phospholipid hydrolysis pathway.[18] Similarly, in the frog adrenal gland, ranakinin enhances polyphosphoinositide hydrolysis, and this effect is mediated through the activation of a phospholipase-C positively coupled to a pertussis toxin-sensitive G protein.[14]

ACTIONS IN AMPHIBIANS

Amphibian TKs were available in pure form several years before the structures of mammalian TKs were elucidated and have been shown to have counterparts in mammalian tissues and to exert wide ranging biological actions mediated through the activation of the three classical TK receptors. Consequently, the earliest studies on the biological actions of TKs that involve the effects of amphibian TKs such as PHYS and KASS have contributed substantially to the explosive progress of the knowledge of the functional roles of TK system in mammalian species. Although the results obtained with KASS, an NK2/NK3 TK receptor agonist, do not exactly mimic results obtained with either NKA or NKB, the results obtained with PHYS, a selective NK1 agonist, are identical, with negligible quantitative differences, to those obtained later with SP, the mammalian selective NK1 receptor agonist. The availability in 1990 of PG-SPI and PG-KII, two highly selective and potent NK1 and NK3 TK receptor agonists, provided a further instrument to investigate the role of the TK system in mammals, in which amphibian TKs show a spectrum of biological actions that is usually identical with that of mammalian TKs.[30]

Conversely, although it has often been demonstrated that mammalian TKs are able to produce effects in nonmammalian species, the extent to which amphibian TKs mirror these effects in their species of origin is not clear, although some studies exist that indicate a number of similarities. In this chapter, we therefore summarize the main *in vitro* and *in vivo* actions of some amphibian TKs on different systems in both their species of origin and mammals.

ACTIONS OF AMPHIBIAN TKs IN THEIR SPECIES OF ORIGIN

PHYS exerts a strong excitatory action on motoneurons of bullfrog-isolated spinal cord. On a molar basis, PHYS was 1500 times more active than L-glutamate in depolarizing the motoneurones, suggesting that TKs are excitatory transmitters of primary sensory neurons in this animal species. PHYS and the other SP-like amphibian neuropeptides, RTKs and BFK, produce a potent and long-acting hypotensive effect without any reflex tachycardia in the anaesthetized cane toad *Bufo marinus*. The blood pressure depressant action of RTK is left unmodified by a nonpeptidic NK1 antagonist, indicating that the amphibian NK1 receptor mediating this effect differs from its mammalian counterpart. The occurrence of BFK-LI in varicose fibers of blood vessels of the toad suggests that the fall in systemic blood pressure is the consequence of a decrease in peripheral vascular resistance in this species. BFK may be released by antidromic stimulation of sensory nerves and may play a role in haemodynamic regulation in the toad. PHYS, KASS, RNK, and BFK are very potent and long-acting spasmogens in the toad intestine, and the presence of BFK-immunoreactive nerves in the myenteric plexus and *muscularis externa* supports this finding. The absence of BFK-LI in the intestinal mucosa suggests a minor role in regulating toad intestinal secretion.[21]

Among the *X. laevis* TK-like peptides, both the SP-like (structurally identical to BFK) and the NKA-like peptide induce an equipotent myotropic effect on isolated strips of circular smooth muscle from *Xenopus* stomach, whereas only the SP-like peptide acts as a spasmogen on intestinal musculature. The maximum response to *Xenopus* SP is lower than that to the NKA-like peptide, suggesting a more effective interaction of the NKA peptide with the TK receptors in *Xenopus* stomach. These findings confirm the presence of both NK1 and NK2 receptors in stomach and only of the NK1 subtype in intestine.[11]

Administration of PHYS in *Rana porosa porosa* has a positive effect on protein and mucous granule secretion from the lingual gland as detected by transmission electron microscopy. This reaction is very different from that observed in mammals, in which TKs stimulate only water secretions. In *Rana esculenta* skin, TKs stimulate ion transport (Na^+ absorption and Cl^- secretion, measured by short-circuit currents) by interacting with NK1-like receptors

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

and by involving prostanoid synthesis. The rank order of TK potency is as follows: PG-KI > UP > HYL > KASS> PHYLL >RTKA >PHYS> RNK. The skin of this frog does not produce TKs, and it is probably a target for TKs produced in other tissues, which, by promoting fluid secretion, may regulate the pain response.

Amphibian TKs, which are detected in frog adrenal gland extracts, stimulate corticosteroid secretion by frog adrenal slices through a prostaglandin-dependent mechanism. The rank order of their potency in comparison with mammalian TKs is as follows: NKA >RNK >SP >KASS > PHYS > NKB suggesting that TKs released by nerve fibers control neuroendocrine secretions in amphibians. RNK, the most potent amphibian TK in stimulating steroid secretion, causes the mobilization of calcium from adrenochromaffin cells through the activation of an NK1-like receptor linked to phospholipase C and pertussis toxin-sensitive G protein, which is different from the mammalian NK1 subtype.[14]

ACTIONS IN MAMMALS

Cardiovascular System

TKs can relax or contract *in vitro* vascular preparations. Relaxation results from the activation of NK1 receptors located in the endothelium, whereas contraction is caused by the activation of NK2 receptors located on the arterial smooth muscle. Likewise, in the rat portal vein (with intact endothelium), contraction elicited by KASS is brought about by NK3 receptors, presumably located on the smooth muscle membrane. In *in vivo* studies, the response of the vasculature to TKs is complex, depending on the animal species, density in the smooth muscle cells and in the endothelium of the various receptor subtypes, as well as on the TK administered or released. The NK1 receptor-preferring TK, PHYS produces a marked dose-dependent hypotension in dogs and rabbits, whereas the NK2/NK3 agonist KASS is 10–20 times less potent. Conversely, PHYS produces moderate hypotension with tachyphylaxis, hypotension/hypertension, or frank hypertension in cats, sheep, rats, and pigeons. PHYS is a very potent vasodilator of the dog coronary, skeletal muscle, and hepatic vascular bed and after intradermal injection, increases rat, guinea pig, and human capillary permeability. These findings suggest that the striking amphibian TK hypotensive effect is the consequence of intense vasodilatation in several peripheral vascular beds due to direct TK action on the blood vessel wall promoting the release of endogenous relaxing factors from the endothelium.

Gastrointestinal Tract (GIT)

(a) Motor Effects

TKs, so-called because they evoke a fast contraction of intestinal smooth muscle, represent one of the most active substances inducing a clear-cut stimulation of motility in all sections of the gut (from esophagus to the rectum, and in all muscle layers, including longitudinal muscle, circular muscle and *muscularis mucosae*) of all mammalian and submammalian vertebrates examined to date. The actions of mammalian TKs in the gut have been the subject of extensive and thorough investigation (for detailed information, see the chapter on Substance P in the Gastrointestinal Peptides section of this book). As far as effects of amphibian TKs on the GIT are concerned, we can summarize by saying that all these peptides, with few exceptions, provoke a contractile response in *in vitro* gut preparations, although the intensity and reproducibility of the response may be considerably different depending on animal species, gut section, and agonist receptor selectivity. Moreover, *in vivo* studies have shown that peripherally administered amphibian TKs induce complex, mainly stimulatory and also inhibitory effects in the GIT propulsion in several mammalian species (dog, cat, guinea pig, rat, sheep).

(b) Secretory Effects

Amphibian TKs exert a potent stimulatory effect on salivary secretion, which was recognized several years before the sialagogic factor in a bovine hypothalamic extract was identified as SP. The most sensitive animal species are dog, ferret, rat, and guinea pig. The rank order of potency (PHYS=UP>SP=PG-SPI>PG-KII = KASS >> NKA >>> NKB) in causing salivary secretion in rats after intravenous injection indicates that this TK effect is preferentially mediated by the NK1 receptor. The greater potency of PHYS and UP in comparison to SP may be explained by the considerably higher resistance to enzyme attack offered in the two first peptides by their N-terminal pGlu residue. PHYS generates vomiting, diarrhea, and profuse salivation in dogs. Exogenous TKs cause secretion of fluid and electrolytes from the intestinal mucosa, and it has been suggested that also endogenous TKs may play a messenger role in the intestinal secretory pathway. Also, an increased permeability of the capillaries could contribute to increased secretions. Moreover, there is increasing evidence that TKs participate in hypersecretory, vascular, and immunological disorders associated with infection and inflammatory bowel disease.[28]

PHYS displays a moderate, short-lasting stimulatory action on exocrine pancreatic secretion in the dog. In dispersed acinar cells from guinea-pig pancreas, both NK1 (PHYS) and NK3 (PG-KII) TK receptor agonists increase amylase release, whereas in rat acinar cells, only the NK1 agonist is active. These functional findings indicate a species-related difference in the TK regulation of exocrine pancreatic secretion, which has been confirmed by immunocytochemical studies.[17] In a secretagogue-induced model of acute pancreatitis in rats, NK1 receptor expression in

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

pancreatic acini is unchanged compared with normal pancreas, whereas NK3 receptors, which apparently have no physiological role in pancreatic secretion in rats, are overexpressed, become activated, alter cell function, and probably intervene in mediating acute pancreatitis.[2] PHYS is a potent stimulant of lachrymal secretion in the dog, while the rat is much less sensitive.

Airways System

In guinea pigs, KASS increases insufflation pressure, while PHYS, by activating receptors localized in the endothelial cells, increases the microvascular permeability to protein, indicating that both NK2 and NK1 receptors, respectively, are involved in the guinea-pig tracheobronchial tree response to TKs. In rats, KASS elicits a broncho-constrictor action that is much more potent than SP.[12]

Urinary Tract

TKs stimulate smooth muscle preparations of the urogenital tract, especially the urinary bladder, and display differences in their agonistic potency depending not only on the different animal species but also on the particular segment of the urinary tract, probably resulting from the involvement of different receptor types. Intravenous injection of TKs induces a phasic contraction of the urinary bladder (increase of internal pressure), and an activation of rhythmic contractions, with KASS being the most potent peptide. These different responses are mediated through different receptors and are brought about both by a direct effect on the bladder's smooth muscle and by an effect on intramural sensory nervous pathways ("micturition reflex").[22]

Central Nervous System

In the mammalian CNS, TKs occur in large amounts, particularly in areas involved in the central control of peripheral autonomic functions (blood pressure, respiration, micturition, gastrointestinal motility, and secretions), essential functions (e.g., drinking behavior), affective and emotional life (stereotyped behavior, motility, anxiety, aggressivity, pain), and higher cerebral functions (learning, memory). Therefore, systematic studies with intracerebroventricular administration of amphibian TKs that are selective for different receptor types allows the roles of these neuropeptides to be evaluated in the CNS control of several peripheral functions and the identification of the TK preferring receptor types involved.

(a) The NK2 receptor–preferring agonist KASS induces a dose-related delay in the gastric emptying of a liquid meal, whereas the activation of NK3 receptors by the highly selective NK3 agonist PG-KII mediates a colonic antipropulsive effect;[1]

(b) NK3 receptor activation by KASS and PG-KII mediates an inhibitory action on gastric acid secretion in pylorus-ligated rats;[7]

(c) NK2 receptors participate in the protection against gastric ulcers;[7]

(d) NK3 receptor activation via amphibian PG-KII exerts an antidipsogenic effect on angiotensin II-induced drinking behavior, an antidiuretic effect resulting from release of vasopressin, and a potent and long-lasting decrease in salt intake;[23]

(e) The NK3 receptor–preferring agonist PG-KII decreases ethanol intake in genetically alcohol-preferring rats;[23]

(f) The NK1 and NK3 receptor systems are involved in supraspinal analgesia in rats;[8]

(g) PHYS and other NK1 agonists do not affect the response of rat cerebellar granule neurons to the cytotoxic action of glutamate, whereas the NK2/NK3 receptor–preferring amphibian TKs, KASS, RKA, and PG-KII significantly increase glutamate excitotoxicity.[29]

PATHOLOGICAL IMPLICATIONS

Advances made during the past decade indicate that TKs, besides their physiological roles in both mammals and in amphibians, may play also significant roles under pathological conditions. An imbalance in the functionality of the mammalian TK system may contribute to several diseases, and so TK receptors could represent attractive target for novel agonist and antagonist therapeutic agents. In this regard, although results obtained with amphibian TKs are rather scanty, some representative studies both in experimental models and in human disorders show that these peptides, being more selective and more resistant to enzymatic degradation than mammalian TKs, may be helpful to clarify pathological implications.

PHYS administered through eye drops increases lachrymal secretion, ameliorates Sjögren's syndrome and other forms of keratoconjunctivitis sicca resulting from a deficit of lachrymal secretion.[3] In a screening study of new sialogogue agents that might be of use in the treatment of dry mouth in humans, PHYS is the most potent substance.[6] Central injection of PG-SPI (NK1 selective agonist) and PG-KII (NK3 selective agonist) in rats stimulate IL-1β production and increase granulocyte infiltration into the colon worsening experimental models of colitis, which are reminiscent of human inflammatory bowel disease (Crohn's disease and ulcerative colitis), thus providing further evidence of the central role of TKs in this gut pathology and of the potential usefulness of NK1 and NK3 TK receptor antagonists as therapeutic agents.[9] Fragment 25-35 of β-amyloid peptide, the primary constituent of senile plaques and cerebrovascular deposits in Alzheimer's disease and Down syndrome,

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

shows important sequence similarity with the C-terminal region of TKs. Interestingly, the neurotoxic response to β-amyloid (1–40) is completely reversed by SP and PHYS and partially by NKB and KASS, raising the possibility that β-amyloid may interact with TK receptors.[32] Furthermore, in neuroblastoma cells, the toxic effect induced by β-amyloid (1–40) is inhibited by the concurrent treatment of the cells with PHYS.[33] In turn, β-amyloid(1-40), which alone weakly activates the TK receptors, in the presence of glutamate strongly activates both TK receptors (especially the NK1 receptors) and phosphatidylinositol turnover.[13] Taken together, all studies on amphibian TKs reported here cannot merely be considered of academic interest, as they have substantially contributed to the progress of research in the field of mammalian TKs. These studies may lead to the discovery of new TKs and elucidation of their structures and subsequently provide easily available models for studying structure–activity relationships and identifying physiopathological implications in mammals, including humans.

Chapter 56

Temporins

Andrea C. Rinaldi and J. Michael Conlon

ABSTRACT

The temporins belong to a family of short (8–17 amino acids), hydrophobic, C-terminally α-amidated peptides with antibacterial and antifungal properties that are synthesized in the skins of a wide range of North American and Eurasian frogs of the Ranidae family. Temporins adopt an α-helical conformation in hydrophobic environments and have the ability to perturb the integrity of target cell membranes. Not all temporins are cationic, but the number of positively charged amino acids correlates with antimicrobial potency. Temporins are mostly effective against Gram-positive bacteria, but some are also active against Gram-negative bacteria. Temporins show potential for development into therapeutically valuable anti-infective agents, particularly for use against antibiotic-resistant Gram-positive bacteria such as methicillin-resistant *Staphylococcus aureus* (MRSA) and *Enterococcus faecalis*, against anaerobic pathogens such as *Clostridium difficile*, and against the protozoan parasite *Leishmania* spp. Although the clinical usefulness of naturally occurring temporins is limited by high hemolytic activity, noncytotoxic analogs have been designed.

DISCOVERY AND DISTRIBUTION

Frogs of the family *Ranidae* synthesize in granular glands in the skin a remarkably diverse range of antimicrobial peptides that are released into skin secretions, often in very high concentrations, in a holocrine manner on stress or injury as a result of contraction of myocytes surrounding the glands.[6] These peptides represent a component of the animal's system of innate immunity and serve to protect the frog against invasion by a variety of pathogenic microorganisms (see the chapters on the Dermaseptins and Bombinins in this section of the book). Included in this arsenal of defensive peptides are members of the temporin family. Consisting of between 8 and 17 (typically 13) amino acids, they are among the smallest antimicrobial peptides to be found in nature. Temporins were first identified in the skin of the Asian frog *Rana erythraea*[34] and the European frog *Rana esculenta* (reclassified as a hybrid between *Pelophylax ridibundus* and *P. lessonae*)[31] on the basis of their hemolytic activity. These hydrophobic, C-terminally α-amidated peptides were originally described as "*Vespa*-like" because of their structural similarity to the short (13–14 amino acids) peptides with chemotactic and histamine-releasing properties isolated from the venom of wasps of the genus *Vespa*. The term "temporin" was first used by Simmaco and coworkers to describe a family of 10 structurally related peptides (temporins A-L) with antibacterial and antifungal properties identified in the electrically stimulated skin secretions of the European common frog *Rana temporaria*.[32]

Subsequent work has shown that the temporin family is widely, but not universally, distributed in ranid frogs of both North American and Eurasian origin (Figs 1 and 2). Adopting the classification of new world ranid frogs proposed by Frost,[12] temporins have been isolated from the skin secretions and/or extract of several North American species belonging to the genera *Rana* and *Lithobates* (reviewed in Ref. 9) (Fig. 1). Among the Eurasian ranid frogs, temporins have been identified in the skins of the Japanese brown frogs *R. dybowskii*, *R. japonica, R. ornativentris*, *R. pirica*, *R. sakuraii*, *R. tagoi tagoi*, *R. tagoi okiensis*, and *R. tsuschimensis*, but not the Ryukyu brown frog *R. okinavana*, and in several species belonging to the genera *Amolops*, *Hylarana*, and *Pelophylax* (reviewed in Ref. 6) (Fig. 2). Temporin-SHf (FFFLSRIF.NH_2) from skin secretions of specimens of *Pelophylax saharicus* collected in Tunisia is the smallest natural linear antimicrobial peptide found to date and, despite its small size and hydrophobicity, has broad-spectrum microbicidal activity against Gram-positive and Gram-negative bacteria and yeasts, with no hemolytic activity.[1]

BIOSYNTHESIS

Screening of a cDNA library prepared from the skin of *R. temporaria* with an oligonucleotide probe derived from the signal peptide region of preproesculentin-1 from *R. esculenta* led to the identification and characterization of the biosynthetic precursors of temporin B (LLPIVGNLLKSLL.NH_2), temporin G (FFPVIGRILNGIL.NH_2), and temporin H (LSPNLLKSLL.NH_2).[32] The structural organization of the three preprotemporins is the same and is illustrated

schematically for preprotemporin B in Fig. 3. Molecular cloning studies have confirmed these findings for many other temporin biosynthetic precursors. A study of the expression of preprotemporin genes in the skin of Japanese mountain brown frog *R. ornativentris* found that although preprotemporin mRNAs were not detectable in the skins of tadpoles before the onset of metamorphosis, their levels increased markedly during metamorphosis, reaching a maximum at the stages of metamorphic climax.[25] This suggests a correlation with thyroid hormones, which "…may induce the expression of genes encoding preprotemporins in a coordinated fashion that is synchronized with the metamorphosis in tadpoles and with molting in adults to protect the skin surface from pathogens in the environment."[25]

The temporins conform to the general rule among the frog skin antimicrobial peptides that the signal peptide and acidic propeptide regions are very strongly conserved, even in the case of frogs belonging to different families, whereas the antimicrobial peptide domain at the C-terminus of the precursor is hypervariable (see the chapter on Dermaseptins

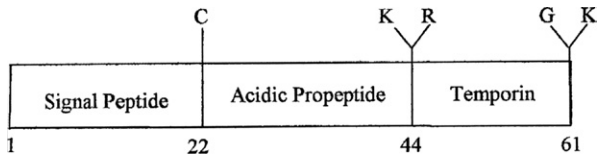

FIGURE 3 A schematic representation of the biosynthetic precursor of temporin B deduced from the nucleotide sequence of a cloned cDNA from the skin of *Rana temporaria*. Cys^{22} is the probable site of cleavage of the signal peptide, $Lys^{45}Arg^{46}$ is the site of cleavage of a prohormone convertase, and Gly^{60} acts as nitrogen donor for C-terminal α-amide formation.

in this section of the book). Thus, the Cys^{22} residue represents the site of cleavage of the signal peptide in the preprotemporins and in the preprodermaseptins and a range of other precursors. The mature temporin is generated by cleavage at a typical Lys-Arg prohormone processing site and the penultimate Gly residue in the propeptide acts as a substrate for peptidyl-glycine α-amidating monooxygenase to produce a C-terminal α-amidated residue in the secreted peptide (see the chapter on this enzyme in Peptide Biosynthesis/Processing section of the book).

Preprotemporin mRNAs are expressed at low levels in extradermal tissues of Tago's brown frog *R. tagoi tagoi*. cDNAs encoding temporin-TGa (FLPILGKLLSGIL.NH_2), previously isolated from an extract of the skin, were amplified and cloned from the stomach, liver, kidney, and skeletal muscle. However, a net insertion of 10 nucleotides results in the presence of a premature stop codon in the open reading frame that is not present in the corresponding region of preprotemporin-TGa from skin. The preprotemporin cDNA obtained from small intestine contains an additional 12 nucleotide insertion in the region that encodes the temporin sequence resulting in a novel peptide (FLPVILPVIG10KLLSGIL.NH_2), termed temporin-TGc. This cDNA also contains a premature stop codon in the open reading frame.[18] Nucleotide sequence analysis reveals marked polymorphism of preprotemporin genes among individual frogs. Twenty-seven distinct preprotemporin-Oe mRNAs have been identified in individual *R. ornativentris* specimens that contain synonymous substitutions in the antimicrobial peptide region and both synonymous and nonsynonymous substitutions in the signal peptide and intervening sequence regions. Up to eight preprotemporin-Oe mRNA variants are found within a single frog.[26]

The mRNA encoding temporin-CBa (FLPIASLLGKYL.NH_2) is detectable in the Harderian gland of the bullfrog *Lithobates catesbeianus*,[17] the first example of an AMP gene transcribed in such an organ. The Harderian gland is an orbital gland found in many vertebrates, where it is believed to play important roles such as lubrication of the eye and nictitating membrane, a source of pheromones and growth factors, as well as osmoregulatory, thermoregulatory, and immunoregulatory functions. By analogy with the situation in amphibian skin, the expression of AMP genes in the Harderian gland may be regulated by thyroid hormones.

MOLECULAR HETEROGENEITY

As shown in Figs 1 and 2, >90 members of the temporin family have been identified in the skins of Eurasian and North American ranids. The temporins are among the most highly variable of all antimicrobial peptides and no single residue in the peptide is invariant. Most temporins contain a single basic residue (generally Lys) giving a charge of +2 at physiological pH but several temporins, for example, temporin-Oe lack this structural feature. Conversely, temporin L from *R. temporaria*, temporin-Lb from *Rana luteiventris*, temporin-PRc from *Rana pretiosa*, temporin-CPa, from *Lithobates capito*, and temporins-DRa and -DRb from *Rana draytonii* contain two basic residues. All temporins isolated to date contain a preponderance of hydrophobic amino acids and are C-terminally α-amidated.

Structure–activity studies with temporin A have indicated that a hydrophobic N-terminal residue and bulky hydrophobic residues at positions 5 and 12 are important determinants of antibacterial activity.[33] Replacement of the Ile^5 and Ile^{12} residues by leucine resulted in an increase in antimicrobial potency but replacement by Ala abolished activity. The positively charged amino acid is usually located at position 7 or 11 to maintain the amphipathic character of the α-helix that is important for activity. Most temporins that lack a basic amino acid residue show very weak or no antimicrobial properties, the exception being temporin-1Od (FLPLLASLFSGLF.NH_2) from *R. ornativentris*, which is active against *Staphylococcus aureus*.

BIOPHYSICAL PROPERTIES AND INTERACTION WITH MEMBRANES

In common with the majority of frog skin antimicrobial peptides, the temporins exist in a random coil conformation in aqueous solution but have the propensity to form a stable amphiphathic α-helix in a membrane or when in hydrophobic environments, such as 50% trifluoroethanol/water. To gain deeper insight into conformation–activity relationships, temporin A and and temporin L from *R. temporaria* were selected to test the hypothesis that a significant correlation exists between the conformation adopted by the peptide in solution, that is, *before* its interaction with membranes, and its antimicrobial activity. Temporin A (FLPLIGRVLSGIL.NH_2) is preferentially active against Gram-positive bacteria and has a moderate hemolytic activity, whereas the strongly hemolytic temporin L (FVQWFSKFLGRIL.NH_2) displays the highest antimicrobial potency among temporins tested to date and has strong affinity for lipid membranes and for the lipopolysaccharide (LPS) component of the Gram-negative outer membrane.[15,16] A combination of molecular dynamics simulations, CD spectroscopy, and studies with model membranes revealed that temporin L possesses a higher, intrinsic propensity (negative free energy of folding)

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

to form an α-helix in water, existing basically in a "semi-folded" state characterized by a 4(5)-residue helix.[11,28] Thus, the greater antimicrobial and hemolytic activity exhibited by temporin L may be ascribed to its higher propensity to assume a folded conformation in aqueous solution, which would facilitate, both thermodynamically and kinetically, the peptide folding in the microbial membrane.

The all-D enantiomer of temporin A is equipotent with the native peptide against bacteria, indicating that effects on the cell membrane are mediated through nonchiral interactions.[33] Studies involving the use of liposomes of different composition indicate that the lytic activities of the temporins are not greatly influenced by composition or surface charge of the lipid membrane, suggesting that hydrophobic rather than ionic interactions are of primary importance.[22] It is proposed that the temporins produce bacterial cell death by formation of transmembrane pores ("toroid pore" mechanism) rather than by causing a detergent-like disruption of the cell membrane into peptide-coated vesicles ("carpet" mechanism) (see the Cationic Antimicrobial Peptides chapter in the Bacterial/Antibiotic Peptide section). However, the possibility that at least some of these peptides could interact with intracellular targets is not excluded.

One of the most interesting and potentially important properties of selected temporins—shared with a number of other cationic antimicrobial peptides—is their affinity toward LPS, the endotoxin, responsible for the systemic inflammatory response syndrome (SIRS) and the often fatal septic shock that follow Gram-negative infections.[16,21] Temporin L penetrates efficiently into *Escherichia coli* LPS monolayers and binds with strong affinity to purified *E. coli* LPS *in vitro*, as shown by a fluorescent probe displacement assay.[15] The effect of several temporins, alone and when combined with each other, in inhibiting secretion of LPS-induced proinflammatory cytokines by LPS-activated macrophages have been examined.[21] The effect of a mixture of temporin L and temporin A or B on antiendotoxin and antibacterial activities is significantly greater than the corresponding additive effect of the single peptides, thus showing synergism. An NMR study of the interaction of temporins with LPS micelles reveals that temporins L and B are able to interact in a way that impacts the oligomerization status of peptides when bound to LPS, leading to changes in the structure of LPS itself and disruption of the outer membrane.[3] In a broader context, this contributes to the concept that the presence of multiple forms of structurally related peptides in the same frog specimen offers extended protection from infections.

BIOLOGICAL ACTIVITIES

In general, the temporins show greater potencies against Gram-positive bacteria such as *S. aureus*, *Staphylococcus epidermidis*, *Enterococcus faecalis*, and S*treptococcus* spp. than against Gram-negative bacteria.[22] The exceptions are temporin L,[20,29] temporin-CPa,[10] and temporin-DRa,[7] which bear a net positive charge of +3 and are active against clinically relevant Gram-negative species such as *E. coli* and *Pseudomonas aeruginosa* and against the opportunistic yeast pathogen *Candida albicans*. The therapeutic potential of the many of the temporins is limited by their toxicities against mammalian cells. Temporin L is strongly hemolytic against human erythrocytes and also cytolytic toward several human tumor cell lines.[29] Temporin A and B, however, have relatively weak hemolytic activity but have been shown to severely damage the plasma membrane of the human parasitic protozoan, *Leishmania donovani* leading to cell death.[23] Temporin A also shows antiviral activity, by reducing the infectivity of channel catfish virus and frog virus 3,[5] and the peptide inhibits the growth of the chytrid fungus *Batrachochytrium dendrobatidis* that has been implicated in declines in amphibian populations worldwide.[30]

The biological properties of the temporins are not confined to cidal activities. As well as their antiendotoxin properties, temporins B and L enhance the ability of secretory phospholipase A_2 from bee venom and in human lacrimal fluid to hydrolyze anionic liposomes.[35] In common with the structurally related peptides from wasp venom, temporin A and temporin-CBb (ranatuerin-6; FISAIASMLGKFL.NH_2) from *L. catesbeianus* induce migration of monocytes, neutrophils, and macrophages, both *in vitro* and *in vivo*, by a mechanism that involves interaction with the formyl peptide receptor-like 1.[4] Temporin-Gb (SILPTIVSFLSKFL.NH_2) and temporin-Gd (FILPLIASFLSKFL.NH_2), isolated from *Lithobates grylio* skin, elicit concentration-dependent relaxations of preconstricted vascular rings from the rat thoracic aorta with EC_{50} values of approximately 2 μM but the physiological significance, if any, of this observation is unclear.[19] Temporin-Vb from *Lithobates virgatipes*, -Oe from *R. ornativentris*, -DRb from *R. draytonii*, and -TGb from *R. tagoi tagoi* in the concentration range 10^{-8}–10^{-6} M, produce significant and dose-dependent stimulatory effects on insulin secretion from clonal rat BRIN-BD11 β cells without cytotoxicity.[2]

POTENTIAL CLINICAL AND COMMERCIAL APPLICATIONS

The emergence of strains of pathogenic microorganisms with resistance to commonly used antibiotics constitutes a serious threat to public health that has necessitated a search for new types of antimicrobial agents. The temporins are promising candidates for development into clinically useful anti-infectives, particularly with regard to topical applications, such as treatment of *acne vulgaris* and infected foot ulcers in diabetic patients. Several temporins show high potency *in vitro* against nosocomial Gram-positive pathogens such as MRSA[7,13] and antibiotic-resistant strains of *E. faecalis*.[14]

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

The all D-isomer of temporin B is active against a range of anaerobic bacteria and is stable in a fecal milieu, suggesting the possibility of its use in the treatment of *Clostridium difficile* associated diarrhea.[24] Combination therapy with a conventional antibiotic, such as rifampicin, seems promising, as the temporin may increase the permeability of the bacterial plasma membrane facilitating the entry of the second bactericidal agent.[22] Infection of indwelling medical devices, such as central venous, urinary, and dialysis catheters and prosthetic heart valves, contributes significantly to mortality rates after surgery. In a subcutaneous pouch model in which rats are infected with drug-resistant clinical isolates of *S. epidermidis,* presoaking of a Dacron vascular graft in temporin A solution, either alone or in combination with vancomycin, markedly reduces the number of bacteria adhering to the graft.[13] Thus, temporins have potential as prophylactic agents in preventing vascular prosthetic graft infections.

The cytolytic properties of cationic α-helical peptides are determined by a complex interaction between cationicity, hydrophobicity, conformation, and amphipathicity[7,20] (Fig. 4). The dodecapeptide temporin-DRa (HFLGTLVNLAKKIL. NH_2) was first isolated from skin secretions of the California red-legged frog *R. draytonii* and shows potential for treatment of infections produced byMRSA.[7] Temporin-DRa shows high growth-inhibitory potency against clinical isolates of MRSA (MIC = 8 μM) and has the advantages of ease of synthesis and high solubility. Its therapeutic potency is limited by moderately high hemolytic activity (LC_{50} = 65 μM). However, the analog containing the amino acid substitution $Val^7 \rightarrow$ L-Lys and the analogs containing the helix-destabilizing substitutions $Thr^5 \rightarrow$ D-Lys and $Asn^8 \rightarrow$ D-Lys retain activity against MRSA (MIC in the range 8–16 μM) but have very low hemolytic activity (LC_{50} > 300 μM).[7] In addition to increasing cationicity, the substitution $Val^7 \rightarrow$ Lys decreases amphipathicity by increasing the polar angle θ (the angle subtended by the positively charged residues) from 100° to 140° thereby delocalizing the positive charge over a greater surface area of the molecule. Substitutions at Leu^9, Ile^{13}, and Leu^{14} by α-aminoisobutyric acid (Aib) produce analogs with decreased helicity and hydrophobicity that retain activity against microorganisms but show appreciably lower cytolytic activities against mammalian cells. In particular, the fourfold increase in therapeutic index [ratio of LC_{50} against erythrocytes to MIC against microorganisms] of [Aib^{13}]temporin-DRa identifies it as a compound with potential for development as a therapeutically valuable anti-infective agent.[8]

Related studies with temporin L show that the % helicity of analogs correlates directly with their hemolytic activities but not with their antimicrobial activities. The nature and position of basic residues (Lys and Arg) along the sequence significantly affects the biological properties of the analogs without changing their helicity, indicating different modes of interactions of positively charged side chains within the peptide's folded structure with anionic membranes. The analog [Pro^3,Orn^{11}]temporin L shows therapeutic potential displaying antimicrobial activity which is slightly lower than temporin L but the lowest hemolytic activity among the derivatives tested.[20]

The possibility of expressing genes that encode for an antimicrobial peptide to protect commercially important crops from bacterial and fungal diseases has excited interest within the agricultural biotechnology industry. Genetically engineered potatoes expressing the gene for temporin A have been grown successfully and are resistant to *Phytophthora infestans*, responsible for late blight, and to *Phytophthora erythroseptica*, responsible for pink rot. The transgenic tubers remained disease-free during prolonged storage.[27]

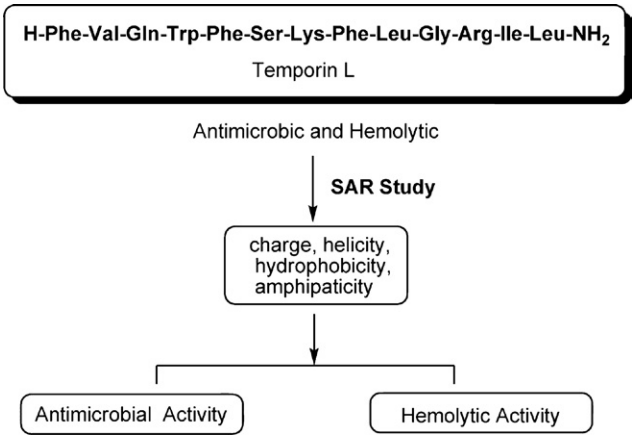

FIGURE 4 General strategy for the development of analogs of temporins (and other frog skin antimicrobial peptides) with a higher therapeutic index than the native peptide through structure-activity relationship (SAR) studies. Temporin L is presented as an example. Reproduced with permission from Ref. 20.

CONCLUSIONS

The small size and ease of synthesis of the temporins, especially temporin-L, -CPa, and -DRa that show broad-spectrum antibacterial and antifungal activities, make them promising candidates for development into therapeutically valuable anti-infective agents. The potent hemolytic activity of the naturally occurring temporins prevents their systemic use but analogs of temporin-L and -DRa have been designed that preserve high antimicrobial activity but show low cytotoxicity against mammalian cells.

Chapter 57

Animal Toxins

Jean-Marc Sabatier and Michel De Waard

ABSTRACT

Animal toxins are renowned for their ability to regulate ion channel activity and hence cell function. Therefore, they have been investigated as lead compounds for the development of analogs with toxic activity or conversely with therapeutic potential. Besides the pharmacological usefulness of animal toxins, there is a second emerging field in which toxins may soon reveal all their potential. The advent of modern biology witnesses the development of novel biotechnological applications of interest for which toxins present tremendous advantages. In this chapter, we illustrate how toxins can be derived to carry on novel functions that make them become tools of choice for diagnostic, imaging, and therapeutic applications. Among the examples developed, the case of maurocalcine will be detailed. This toxin, discovered for its activity on the ryanodine receptor, a calcium channel, is now entering a new phase of development for *in vivo* drug or imaging agent cell delivery.

ANIMAL TOXINS AS CANDIDATE DRUGS

Animal venoms represent an extremely rich source of pharmacological peptides. These peptides are generally of a length comprising between 10 and 70 amino acids and come with a variety of folds. Proteomic profiling of animal venoms with MALDI-TOF mass spectrometry techniques is increasingly used and provides important information regarding peptide mass, disulfide bridging, and minimum number of toxins within given venom. According to many pioneering studies, venoms should contain no fewer than 100 peptides on average. More precise information on the identity of the peptides can be gained when proteomic analyses are combined to transcriptomic studies based on the isolation of venom gland mRNA. In one such study, it has been estimated that spider venoms may well contain 1,000 different peptides.[9] Of course, many of these peptides could differ by simply differences in posttranslational modifications, but these numbers remain representative of the important biodiversity encountered in various species. Considering for instance that there are about 80,000 spider species and assuming the idea that one spider venom contains not <200 unique peptides, then one may estimate the biodiversity in peptides to close to 16 millions. Adding to this diversity, the ones encountered in cone snails, scorpions, and snakes, to name a few, provide an estimate of the richness of these natural biolibraries.

Besides the numbers in venom peptides, these are three advantages to consider when deriving a drug from a natural toxin. First, the natural biolibraries made by animal venoms contain exclusively bioactive drugs in contrast to libraries of drugs of most pharmaceutical industries. Peptide toxins are tailored for efficient bioactivity *in vivo* by targeting crucial receptors (generally cell surface ion channels and G protein-coupled receptors). Although some toxins are evidently toxic *in vivo*, many others, present in the same venom, may have beneficial effects. Second, venoms are generally injected subcutaneously and reach the blood stream for efficient dissemination *in vivo*. Some deleterious effects can take hours to come into play showing an encouraging half-life of the active peptides *in vivo*. Third, gene duplication, extensive splicing, and posttranslational modifications have ensured that venoms contain toxins with exquisite affinity and selectivity for their pharmacological targets. There is therefore no doubt whatsoever that animal venom constitute an infinite source of biologically active peptides of pharmaceutical interest and therefore an excellent basis for screening programs. Although the initial motivation in studying animal venoms was to identify active principles (at best) or active HPLC fractions (at worst) involved in toxicity, combined with the production of therapeutic sera for treating envenoming, current efforts are also now devoted to identifying pharmacological drugs for therapeutics or pesticides for industrial use. Although identifying drugs of interest from animal venom is technically eased by combined proteomic and transcriptomic approaches, once a peptide of interest has been isolated, one also needs to overcome the difficulties inherent to its synthetic production. This can be performed by using

recombinant techniques or by chemical synthesis, but this task is not always straightforward as the peptides need to undergo oxidative folding, a complex process in which the peptide acquires the correct disulfide bridge pairing pattern and adopts the right fold. Once this task is mastered however, access is gained to the possibility to create a large number of peptide analogs, overcoming the tedious task of toxin purification from natural sources that always come with limited availability and quantity. Analogs can be worked out to optimize certain characteristics, including greater affinity for a given target, improved selectivity or enhanced potency. In addition, the increasing development of bioinformatics has steadily improved the functional classification of the growing list of orphan toxins and their potential use in pharmacological applications.

With these considerations in mind, it is therefore not so surprising that several peptides, originating from animal venoms, made their way to the clinic and the drug market. Figure 1 illustrates a nonexhaustive list of peptides or analogs thereof that are in various clinical phases or already on the market. For instance, several *Conus* peptides, present in predatory cone snails, are now used for medication in clinics for pain (Ziconotide, the synthetic form of ω-conotoxin MVIIA, a Ca^{2+} channel N-type blocker, from Elan Pharmaceuticals), epilepsy, and other neuropathic disorders.[34] Natural peptides are therefore increasing the list of peptides (438 in total in 2009) being considered by the pharmaceutical industry in their development programs. Seventy-two of these 438 peptides reached phase III clinical trial and 48 were on the market. Four of them reached global sales over 500 millions $ each in 2007: Copaxane ($3.33 billion), Lupron ($1.88 billion), Byetta ($967 million), and Forteo ($709 million). The majority of these peptides target G protein–coupled receptors, although other targets are increasingly common such as ion channels. A complete report on the development of peptides as therapeutic drugs is available from http://www.peptidetherapeutics.org. Although the pharmacological potential of animal toxins is progressively unraveled and that exploitation of the natural resources for therapeutic aims is only in its infancy, this trend should not hide the fact that toxins are also increasingly used in biotechnological applications.

ANIMAL TOXINS IN BIOTECHNOLOGICAL APPLICATIONS

In 2004, the group of Wonnacott showed that the subcellular distribution of alpha7 nicotinic acetylcholine receptors can be investigated by coupling alpha bungarotoxin to gold nanoparticles.[13] In that respect, toxins seem as perfect tools to target anticancer agents directly to the site of tumor *in vivo* as far their targets are overexpressed in tumors. For instance, the G protein–coupled receptors (BBR1, BBR2, and BBR3) of bombesin, a 14 amino acid peptide from frog skin, are overexpressed in small cell carcinoma of lung, gastric cancer, neuroblastoma,[21] and human prostate cancer. This property has been used to prepare bombesin derivatives harboring lutetium-1777 for prostate cancer targeting, *in vivo* imaging and therapeutic intervention.[24] Another successful example for tumor applications includes chlorotoxin,[16,29] a 36-mer peptide with four disulfide bridges initially isolated from the venom of the Israeli scorpion *Leiurus quinquestriatus*. Although initially developed for the diagnosis and treatment of glioma, chlorotoxin specifically labels cancer cells from other solid tumors as well (melanoma, small cell lung carcinoma, neuroblastoma, medulloblastoma, Ewing's sarcoma, and pheochromacytoma). The identity of the biomarker on which it binds is still under debate (initially a chloride channel, then matrix metalloprotein 2, and now, which seems more probable, annexin 2A). Currently, a ^{131}iodinated version of the toxin from Eisai (TM601) has successfully ended clinical phase II for the treatment of recurrent glioma and has obtained FDA approval to go to phase III clinical trials. Besides, it has also obtained FDA approval to investigate the effect of TM601 on newly occurring glioma. TM601 is extremely stable, presents no immunogenicity and produces no toxicity in humans. Several

Name	Indication	Phase	Company
Prialt (ω-conotoxin MVIIA)	Pain	Market	Azur Pharma
Byetta (GLP 1)	Diabetes 2	Market	Eli Lilly
Capoten (mimetic)	Hypertension	Market	Bristol-Myers Squibb
Integrilin (mimetic)	Acute coronary syndrome	Market	Schering-Plough
Aggrastat (mimetic)	Acute coronary syndrome	Market	Merck
Chlorotoxin (TMI601)	Metastic tumor, glioma, solid tumor (prostate, lung, etc.)	Clinic III	Eisai
Viprinex (mimetic)	Ischemic stroke	Clinic III	Neurobiological Industries Inc.
Xen2174	Chronic pain/post operative pain	Clinic IIb	Xenome
OSK-1	Autoimmune disorders	Pre-clinical	Amgen
