derivative molecules (termed TM602, TM604, etc.) have been produced to facilitate phenotyping and histological staining, and patient treatment. The door is now open for the use of other toxins in cancer diagnosis and treatment. BmKCT, which presents 68% amino acid sequence identity with chlorotoxin, also targets glioma *in vivo* and prevent its progression. Similarly, the nontoxic B subunit of the pathogen-produced Shiga toxin, known to bind to the glycosphingolipid Gb3 which is overexpressed in some tumors, specifically labels human colorectal carcinoma in nude mice.[33] Other technological applications are possible with toxins. The 12 amino acid peptide Tet1, derived from tetanus toxin, is an efficient vector for the delivery of plasmid DNA in complex to polyethylenimine.[22] A similar fragment of tetanus toxin, when placed in fusion to the reporter protein GFP, allows mapping of synaptic connections of the mammalian central nervous system.[17]

Most animal toxins hit cell surface receptors. This is by far the most straightforward means to interfere with signaling pathways for peptides as these molecular entities are sometimes considered unable to cross the cell plasma membrane. There are many exceptions to this belief, as some animal toxins target intracellular ion channel receptors. This occurs with toxins targeting the ryanodine receptor, an intracellular calcium channel that is located in the membrane of the endoplasmic reticulum and that controls cytosolic Ca^{2+} release. These toxins present intriguing peptide sequences that efficiently favor their entry into the cytoplasm. Ion channel recognition and cell permeation can easily be dissociated to retain the latter property. Also, cell penetration can be derived for the cell entry of other compounds of pharmaceutical or imaging interests. We illustrate this point extensively by reviewing the case of maurocalcine, the first cell-penetrating peptide of toxin origin to be discovered.

MAUROCALCINE, AN ANIMAL TOXIN THAT TARGETS AN INTRACELLULAR RECEPTOR

Maurocalcine is a scorpion toxin from *Scorpio maurus palmatus* that was discovered in 2000.[19] Based on its sequence homology with imperatoxin A from the scorpion *Pandinus imperator*, it was presumed to be active on the ryanodine receptor. This turned out to be indeed the case as maurocalcine (i) triggers Ca^{2+} release from purified sarcoplasmic reticulum,[12] (ii) induces both an increase in channel opening and the appearance of a long-lasting subconductance state,[7] and (iii) stimulates the binding of [^{3}H]-ryanodine on its binding site.[11] All these effects occur with an EC_{50} of 10–20 nM. Maurocalcine interaction with the ryanodine receptor is direct as shown by skeletal muscle ryanodine receptor pulldown by a biotinylated derivative of maurocalcine bound to streptavidin-coated beads.[1] Maurocalcine obviously belongs to a larger family of toxins with high sequence homology comprising opicalcine 1 and 2 from *Opistophthalmus carinatus* scorpion, hemicalcin from *Hemiscorpius lepturus* scorpion and hadrucalcin from *Hadrurus gertschi* scorpion (Figure 2). All these toxins similarly act on the ryanodine receptor with only minor functional differences. At the structural level, maurocalcine is a 33-mer peptide containing three disulfide bridges. The pairing motif has been assigned to Cys^1-Cys^4, Cys^2–Cys^5 and Cys^3–Cys^6 and the peptide folds according to an inhibitor cystine knot (ICK motif). Although ICK motifs have been found on other toxins acting on cell surface receptors, maurocalcine and its analogs all present interesting distinguishing features. A close examination of the 3D structure of maurocalcine reveals that (i) the peptide is heavily charged (one-third of amino acids are basic, net charge of +12) and (ii) the charge distribution of the peptide is strongly asymmetric creating an important dipole moment. One of the most amazing properties of the peptide is that on external application to skeletal muscle myotubes, the peptide triggers Ca^{2+} release from internal stores within only a few seconds.[11] A similar observation was made in 2010 on cardiac myotubes with imperatoxin A. This observation points to the fact that the peptide is able to reach its pharmacological target by rapid translocation through the plasma membrane rather than by endocytosis. Also, two pieces of evidence indicate that maurocalcine should accumulate into the cytoplasm to regulate the ryanodine receptor. First, maurocalcine regulates channel activity

from ryanodine receptors incorporated into artificial lipid bilayers only when applied to the cytoplasmic face of the channel.[12] Second, the maurocalcine binding site on the ryanodine receptor has been mapped to a domain that is localized within the cytoplasm according to the membrane topology of this receptor.[1]

Altogether, these findings led to the conclusion that maurocalcine rapidly crosses the plasma membrane and accumulates within the cytoplasm at concentrations >20 nM to effectively activate the ryanodine receptor. The possibility of indirectly imaging the cell penetration of maurocalcine by the release of internal Ca^{2+} is unique to the peptide world. Cell penetration of maurocalcine is not only limited to itself but also to cargoes attached to the peptide underscoring the huge technological potential of this uncommon toxin.

MAUROCALCINE IS A COMPETITIVE CELL-PENETRATING PEPTIDE

Investigation of the cell penetration properties of a peptide without labeling it is a tedious task. Therefore, the first evidence that maurocalcine may enter cells came from the use of a biotinylated analog. This analog coupled to fluorescent streptavidine enters into a variety of cell types.[10] This shows not only that maurocalcine enters into cells but also that it can be used as a peptide vector to facilitate the cell entry of a variety of cargoes, many of them being of a size in considerable excess than the vector itself. It was also the first report that a peptide toxin being a member of the growing family of cell-penetrating peptides (CPP). As expected, imperatoxin A was also shown later on to cross the plasma membrane along with a cargo. In parallel, crotamine, a 42 amino acid toxin from the rattlesnake *Crotalus durissus terrificus*, was shown to penetrate into dividing cells and to carry on plasmid DNA.[20] Reputed CPPs include Tat from the HIV-1 virus, the *Drosophila* transcription factor ANTP (encoded by the *antennapedia* gene), also called penetratin, and the herpes simplex virus type 1 (HSV-1) VP22 transcription vector. These peptides possess a number of common functional features in spite of impressive sequence divergences:

1. CPPs are generally small peptides that rarely exceed 20 amino acids. However, this issue is not mandatory because many CPP originate from larger proteins. The relationship between CPP size and cargo penetration efficacy is not known.
2. Many CPPs are enriched in basic amino acids. This led to the discovery that arginine-rich peptides are efficient CPPs.
3. CPPs lack clear cell selectivity although this issue is not well investigated. They can thus enter numerous cell types.
4. CPPs do not require specific membrane receptors for cell penetration. Indeed, optical CPP stereoisomers, made of D-amino acids instead of the natural L-amino acids, are at least as efficient as their L-counterparts in crossing the plasma membrane.[23] Nevertheless, CPPs do interact with cell surface components such as glycoaminoglycans (GAGs) and negatively charged lipids on the basis of electrostatic interactions.[8]
5. CPPs enter rapidly and efficiently into cells. Commonly, cell penetration occurs within a few minutes, although quantitatively saturation may take longer times. An important property hardly matched by other vectors is that CPPs can penetrate into 100% of a given cell type *in vitro*. We will see that *in vivo* this might not be the case.
6. True CPPs do not require metabolic energy for cell entry.[31] CCP cell entry should be preserved in cells maintained at 4°C or in the presence of metabolic inhibitors. This is however not always valid because for many peptides and depending of the cargo being transported, CPPs enter via endocytosis, which is an energy-consuming process.
7. CPPs trigger much interest for their ability to transport a great variety of cell-impermeable cargoes. The type of cargoes that have been coupled to CPPs and shown to enter into cells is astounding. So far, cell entry has been reported for DNA plasmids or mimics,[18] oligonucleotides, siRNA or shRNA,[14] peptide nucleic acids (PNA),[35] peptides, proteins,[5] drugs,[28] and nanoparticles.[32] The versatility in cargo that can be coupled to a given CPP opens an unprecedented number of applications that can't be matched by any other cell delivery system.

The discovery of new CPP sequences is steadily increasing, and there is enough choice now on the market to develop an application without worrying about the nature of the CPP. Why then would it be interesting to use maurocalcine as a CPP considering the fact that it is more complex (presence of disulfide bridges and difficulties for cargo grafting) and expensive (size) to synthesize than other CPPs? We summarize hereunder the advantage that maurocalcine has over other CPPs.

THE PHARMACOLOGICAL ACTIVITY OF MAUROCALCINE IS EASY TO NEUTRALIZE

Maurocalcine is notorious for its effects on the ryanodine receptor. Ca^{2+} release from the endoplasmic reticulum is a major signaling event that precludes the use of the original maurocalcine sequence as vector for the cell penetration of compounds of interest. Strategies had to be investigated to circumvent the bioactivity of the peptide. Four strategies turned out to be successful in that respect. They are all based on the observation that cell penetration of the peptide requires

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

less stringent structural integrity than pharmacology. First, the peptide can be mutated to lose its ability to bind and stimulate the ryanodine receptor. Arg^{23} and Arg^{24} turn out to be two positions that are critical for maurocalcine activity. Analogs mutated on any one of these positions yield efficient CPP devoid of pharmacological activity.[15] The alanine scan of maurocalcine also reveals other interesting amino acid positions where mutations can improve the pharmacology and/or the cell penetration. Mutation of Glu^{12} is particularly interesting in that respect. Second, maurocalcine can be produced in its D-diastereomer conformation with D-amino acids rather than L-amino acids. Interestingly, the peptide folds normally and produces its normal disulfide bridging pattern. It is also lacking recognition of the ryanodine receptor but, as expected, preserves intact its cell penetration efficacy because its affinity for the plasma membrane is not based on a receptor/ligand type interaction.[23] Obviously, this peptide is a very interesting lead compound because it has all the desired advantages as a CPP (protease resistance and efficacy). In the future, mutated D-maurocalcine peptides will be designed that further enhance the efficacy of cell penetration. Third, maurocalcine can be mutated in such a way that it lacks disulfide bridges. Disulfide bridging contributes to the acquisition of the 3D structure of maurocalcine. Therefore, a disulfide-less peptide is unable to fold and loses its ability to recognize the ryanodine receptor.[27] Nevertheless, this disulfide-less maurocalcine preserves good cell penetration properties albeit with a reduced efficacy. This altered potency can nevertheless be partially overcome by point mutations in the amino acid sequence. Needless to say, a similar disulfide-less maurocalcine can be prepared in the future by incorporating D-amino acids that may render it protease resistant and increase the half-life *in vivo*. Since in its nonfolded version, maurocalcine still acts as a CPP, our group is presently designing a number of mini-maurocalcine analogs with reduced peptide length. The preliminary results show that several analogs can be designed with significantly reduced lengths (9 amino acids). The completion of these four strategies has led to three benefits: (i) the in depth understanding of the structural determinants of maurocalcine that preside to pharmacology and cell penetration, (ii) the identification of essential factors that contribute to an efficient cell penetration of maurocalcine, and (iii) the production of several new maurocalcine analogs dedicated only to cell penetration.

MAUROCALCINE PRODUCES CELL DELIVERY INTO THE CYTOPLASM

The list of discovered CPPs is getting impressive. However, the definition of a CPP remains too tolerant. A peptide is considered as a CPP if it enters into cells. The problem is that any kind of peptide that binds to the external face of the plasma membrane is susceptible to enter into the cell merely by a process of endocytosis. Once this has occurred, organizing the escape of this peptide from the endosome is far from an easy endeavor. For most applications however, the delivery of the cargo in the cytoplasm is simply mandatory. In this registry, maurocalcine seems to be a particularly competitive peptide. The native peptide (unmodified and uncoupled to any cargo) presents the following distinguishing features: (i) the ability to follow its cytoplasmic accumulation on line (by the release of internal Ca^{2+}), (ii) a minimal cytoplasmic accumulation of 10–20 nM (to observe Ca^{2+} release), and (iii) a cytoplasmic accumulation against the concentration gradient (owing to the net positive charge of the peptide). The natural tendency of maurocalcine to accumulate into the cytoplasm ensures high cytoplasmic concentrations of the peptide. This tendency is greatly helped by its structural characteristics. The predominant orientation of basic residues on one face of the peptide, the presence of a dipole moment and the existence of a hydrophobic face ensure that maurocalcine can accumulate against its concentration gradient by electrochemical attraction in normally polarized cells. This would not be feasible if the peptide first accumulated within endosomes as the cytoplasmic accumulation factor would be kinetically limited by the endocytosis process itself and second by the endosomal escape. This being said, it would be inexact to state that maurocalcine does not also enter into cells by endocytosis. In fact, this is even the preferred route of entry when maurocalcine or one of its analogs is coupled to some cargoes. Macropinocytosis is the main route of entry with streptavidine as cargo[10] or when maurocalcine is coupled to nanoparticles covered with streptavidine molecules.[26] The nature and (or) size of the cargo therefore are susceptible to inhibit the normal balance in cell entry modes (translocation *versus* endocytosis) probably by increasing the residency time of the peptide at or within the plasma membrane. Obviously, smaller cargoes still allow a normal translocation process to occur as witnessed in the case of a fluorescent indicator[23] or a small drug such as doxorubicin.[4] This is also the case for a maurocalcine-maleimide-cys-nanoparticle complex, suggesting that in nanotechnology, size is not necessarily a limitation for cytoplasmic targeting.[27] In conclusion, although it may seem desirable to get rid of the pharmacological activity of maurocalcine, it may in the first instance represent an asset when it comes to evaluating the correct cytoplasmic targeting of the cargo transported. This is rendered possible since it was observed that N-terminal modification of the native maurocalcine (e.g., biotinylation and coupling to streptavidine) does not change dramatically its ability to interact with the ryanodine receptor.[10] Upon completion of this evaluation, it is then easy to turn toward maurocalcine analogs that structurally resemble maurocalcine itself but are mutated for their interaction with the ryanodine receptor.

MAUROCALCINE HAS AN EXCELLENT CELL ENTRY/TOXICITY RATIO

A drawback of many CPPs is their relative toxicity. This would not be a major problem if these CPPs entered into cells at doses much lower than their toxic concentration. Unfortunately, the concentration ratio between cell penetration efficiency and cell toxicity is often not that encouraging. For reasons that are unknown, maurocalcine is not toxic on intravenous injection in spite of its pharmacological activity. This is not the case for intracerebroventricular injections in mice. However, this issue is easily circumvented with the numerous pharmacologically inert maurocalcine analogs that are now available. These analogs have all been assessed for cell toxicity most often for long periods of time *in vitro* (24 hours) and on sensitive cells (neurons). It was systematically observed that there was an almost complete lack of toxicity at concentrations as high as 10 μM. By contrast, some efficient analogs show significant levels of cell penetration at 10 nM, suggesting that reaching a concentration ratio penetration/toxicity of 1,000 for maurocalcine analogs is feasible. Of course, these values are relevant for the maurocalcine vectors but ought to be reconsidered upon grafting a cargo on them. This favorable ratio stems from the observation that maurocalcine has been optimized by nature to invade cells with a minimal disturbance, which is not necessarily the case of other CPPs that originate most often as fragments of larger non–cell-penetrating proteins or are designed *de novo*. One additional feature that needs to be emphasized is the excellent concentration dependence of maurocalcine's cell penetration. In its folded conformation, the peptide enters at lower concentrations than the popular CPP (penetratin, Tat or poly-R). Further, optimizing these values seems as a reachable objective in spite of the fact that the cell membrane factors that contribute to the efficacy of cell penetration of CPP are ill defined. In an attempt to define these factors, it was found that maurocalcine binds with micromolar affinity onto cell surface glycoaminoglycans (GAG).[25] Interaction was evident with heparin, heparin sulfate, and chondroitin sulfate. Soluble GAG inhibits close to 80% of maurocalcine cell uptake because it screens maurocalcine positive charges required for cell entry and competes for its interaction with cell surface GAG. However, maurocalcine's cell penetration is well conserved (close to 50%) in GAG-deficient cells indicating that GAG mainly contributes to cell penetration at the quantitative level by acting as low-affinity reservoirs of CPPs. More importantly, maurocalcine interacts with several negatively charged lipids at suprananomolar affinities.[6] Maurocalcine interacts with gangliosides, such as GD3 (disialoganglioside NeuAcα2-8NeuAcα2-3 Galβ1-4Glcβ1-Cer), phosphatidylinositol (PtdIns)(3)P, PtdIns(4)P, and PtdIns(5)P), phosphatidic acid and sulfatide, and more weakly with lysophosphatidic acid, PtdIns(3,5)P2 and phosphatidylserine. It is difficult to envision that lipids are not directly concerned with the mechanism of membrane translocation of CPPs, while on the contrary GAG could be involved in endocytosis. The mutant maurocalcine analog Ala^{12} has improved cell penetration and lipid interaction. Conversely, the mutant analog Lys^{20} that has poor cell penetration has also limited lipid interaction. The problem is to identify which lipid is the most important for membrane translocation. Solving this question would tremendously help the design of better CPPs.

MAUROCALCINE IS A STABLE CPP VECTOR *IN VIVO*

Venom peptides have been designed by nature to be stable upon injection *in vivo*. The disulfide bridging and the compact fold is most likely also an advantage in that respect. We have investigated this question in the case of maurocalcine. A first analog was synthesized, tyr-maurocalcine, and iodinated with ^{125}I on the extra N-terminal tyrosine residue. Next, the peptide was incubated with mouse blood and its stability followed with time by HPLC. As shown in Figure 3, the folded maurocalcine analog with its disulfide bridges has excellent blood stability because one-third of the peptide is still not degraded after 24 hrs of incubation. A single metabolite is evident suggesting that maurocalcine can further be optimized in terms of *in vivo* stability. The same type of experiment was conducted with a similar analog but in which all cysteine residues were replaced by isosteric 2-aminobutyric acid residues. Such a peptide lacks disulfide bridges and also secondary structures. In that case, we found that the peptide has a two-fold reduced stability and also that more metabolites are present as well (not shown). This study illustrates that disulfide bridges bring in a significant competitive advantage in terms of peptide stability *in vivo*. For instance, Tat, a CPP that lacks disulfide bridges, degrades rapidly even in the extracellular culture medium of epithelial cells.

MAUROCALCINE PREFERENTIALLY TARGETS SOME CELL TYPES AND ORGANS *IN VIVO*

Although it is true that CPPs penetrate into all kinds of cell types, emerging evidence suggests that there are cell-specific differences in the efficiency of the penetration. We found for instance that maurocalcine penetrates better into glial cells than in neurons. Also, the snake venom CPP crotamine presents selective cell penetration into actively dividing cells. A close examination of FAM-D-maurocalcine distribution in human blood cells indicates that monocytes and lymphocytes NK are almost all invaded by maurocalcine, whereas a small

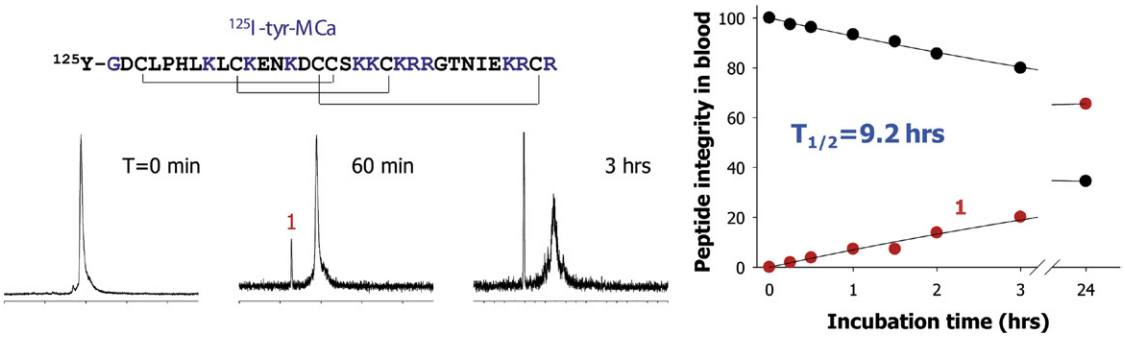

FIGURE 3 HPLC elution profile of iodinated Tyr-maurocalcine analog as a function of time of incubation in mice blood. The peptide was added at a concentration of 1mCi per milliliter of blood and incubated at 37°C. HPLC profile is from the protein-free plasma fraction. The half-life of maurocalcine exceeds 9 hours in these conditions.

percentage (<10%) of lymphocytes T and B take up maurocalcine. The reasons behind a selective cell-type cell penetration are unclear. One may assume that because CPPs have the ability to interact with different glycosaminoglycan species, changes in glycoaminoglycan patterns at the cell surface may explain differences in CPP cell selectivity.[8] It illustrates that CPP sequences may evolve in such a way to penetrate only into desired cell targets. After intravenous injection, 30% of iodinated Tyr-maurocalcine is associated to circulating cells, whereas 40% and 26% are associated to plasma and protein-free plasma, respectively. Combined nanoSPECT/CT imaging gives an indication of where the toxin accumulates *in vivo* (Figure 4). Additional organ quantification of the radioactively labeled peptide shows strong kidney accumulation and urine elimination. Other organs that light up quite well are stomach, spleen, skin, lung, liver, heart, and duodenum. No brain accumulation is evident even at longer periods of observation suggesting that the peptide does not cross the blood–brain barrier. These first observations give a hint to what organs would be best fitted for a therapy based on the use of maurocalcine sequence. It will be interesting to observe if cell and tissue selectivity can be altered by selective point mutations in maurocalcine sequence. If this could work, the door would be open for tissue-targeting cell-penetrating peptides for enhanced therapeutic potential.

CONCLUDING REMARKS

The existence of natural structural analogs of maurocalcine opens the route to new research programs aimed at discovering novel CPP molecules in the incredible rich sources of peptides that are venoms. The added benefit of increasing the number of known toxin-derived CPP is in their potential cell- and organ-specific targeting properties and in their usefulness for *in vivo* applications. Several discovery strategies may be pursued: (i) determining novel toxins active on intracellular ion channels by affinity column purification, (ii) screening for peptides that can enter into cells, and (iii) purifying peptides from venoms based on their basic or aliphatic nature. As for maurocalcine, these peptides will need optimization to remove any potential toxic or undesirable pharmacological effect. On the therapeutic side, what applications are best suited for maurocalcine or toxin-derived CPPs? The field of CPPs is blossoming with interesting and innovative applications at an exponential growth rate. Although most applications have focused on the cell entry of cargoes that are unable to enter into cells, there is also room for applications in which the CPP contributes not to the entry of a drug but to force it to stay into cells by limiting its passive diffusion or expulsion by multidrug resistance proteins for instance. Two such applications have been designed for maurocalcine. In one application, coupling maurocalcine to near-infrared emitting nanoparticles charged with MRI-detectable contrast agents allows for greater tissue retention time of the MRI signal in brain at the injection point, at least in much better proportions than the clinically used DOTAREM.[30] This kind of approach holds promises for theragnostic applications in which the therapeutic drug is combined to the imaging agent. In a second application, it was found that coupling maurocalcine to an antitumor agent, such as doxorubicin, a drug used for the treatment of solid tumors in clinics, finds useful applications for fighting chemoresistance.[2–4] Chemoresistance often occurs as the result of cancer cells that start overexpressing multidrug resistance proteins. Freely entering doxorubicin is readily expulsed by these cells, and tumors can then continue propagating. Increasing the therapeutic doses is not an option because of the secondary effects on healthy tissues, including neuropathies and cardiotoxicity. The coupling to maurocalcine turns a viable option, at least *in vitro* for the moment, as multidrug resistance proteins are no longer able to take into charge the complex molecule that keeps its antitumor activity. Coupled to cell-penetrating peptides that would be able to target cancer cells *in vivo*, such an application would hold great promises in the future. Now that maurocalcine is a proven and efficient CPP, it is on the track for biological, diagnostic, and technological applications.

Chapter 58

Hymenoptera Insect Peptides

Mario Sergio Palma

ABSTRACT

The venoms of the social Hymenoptera evolved as defensive tools to protect the colonies of these insects from the attacks of predators. Generally, they are not lethal but cause mainly inflammatory and/or immunological reactions in the victims of their stings. However, sometimes systemic effects, such as respiratory and kidney failure, may occur. The peptide components of venoms from Hymenoptera represent up to 70% of the weight of freeze-dried venoms. Most of these toxins are linear polycationic amphipatic peptides, with a high content of α-helices in their secondary structures. These peptides generally account for cell lysis, hemolysis, and antibiosis, and they sometimes promote the delivery of cellular activators/mediators through interaction with the G-protein receptor. Some of these peptides are also neurotoxins that target Na^+ and/or Ca^{2+} channels or even the nicotinic ACh receptor. This review summarizes the current knowledge about the biologically active Hymenoptera venoms.

INTRODUCTION

The dominance of insects and other Arthropods on land can be mainly attributed to the extraordinary diversity of their defense mechanisms coupled to chemical weaponry. In this regard, the development of venoms and its injection apparatus among the Insecta represent evolutionary attributes that contribute to the adaptation of insects to the many different terrestrial environments.[13] Those species that evolved in the direction of social behavior developed the formation of castes and established a hierarchical relationship among nest mates of different castes. Thus, different orders of the Insecta developed their self chemical arsenal, particularly the social Hymenoptera (bees, wasps, and ants), which evolved into their venoms and stinging apparatuses according to their biology and behavior. Social behavior is found in ants, which use their sting for defense and for killing their prey, and in some bees and wasps, which use their venoms only for defending themselves and the colony against intruders and predators of their colonies.[31] Within these insects, a particular activity is their stinging action, causing pain and local damage or even death (multiple stings) in vertebrates. These species evolved their venoms to prevent the presence of predators, keeping them far from the colonies; the venom of these species is not used to promote lethal actions but to produce mnemonical actions on the victims of their stinging resulting from the uncomfortable effects of venoms such as pain, local burning, edema, swelling, bradycardia, tachycardia, headache, and, sometimes, systemic effects such as respiratory and kidney failure.[30] The venoms of the social Hymenoptera consist of a complex mixture of proteins, peptides, and low molecular mass compounds. The enzymes are responsible for the injury caused to tissues and are frequently immunoreactive to specific IgE and are therefore involved in the allergy caused by these venoms in the victims of wasp and/or bee stings.[15,35] The most abundant components of the venoms from social wasps and bees consist of peptide toxins, which play many different functional roles during the victim's envenoming.

This chapter will summarize the current knowledge concerning the biochemical and pharmacological properties of the most representative peptide toxins from the social insects of the order Hymenoptera, which are now thoroughly characterized. It is not easy to comprehensively review the extensive literature on all the major components of these venoms in the available space. Therefore, for the interest of readers, the focus will be on the most relevant groups of biologically active peptides from Hymenoptera venoms, and the references mentioned will enable a more extensive search of the literature.

PEPTIDES FROM THE VENOMS OF SOCIAL HYMENOPTERA

The peptide components of venoms from social Hymenoptera are spread over the molar mass range of 1400–7000kDa and together compose up to 70% of the weight of freeze-dried Hymenoptera venoms.[13] Most of these peptides are polycationic, amphipatic molecules, presenting a high content of α-helices in their secondary structures; these peptides

Copyright Elsevier 2024

generally account for cell lysis, hemolysis, and antibiosis, and they sometimes promote the delivery of cellular activators/mediators. In addition to this, the Hymenopteran venoms also may contain a few neurotoxic peptides.

PEPTIDE TOXINS FROM HONEY BEE VENOM

Honey bee (*Apis mellifera*) venom contains well-known peptides such as melittin, apamin, tertiapin, secapin, and MCD peptide. Some of these peptides present a detergent-like action on plasma membranes,[7] causing cell lysis, whereas others are neurotoxins. Some aspects of the primary sequences, secondary structures, and the biological actions will be emphasized.

Melittin

Melittin is the major component of honey bee venom, representing approximately 50% of the total honey bee venom. It consists of 26 amino acid residues, mostly with hydrophobic or at least uncharged side chains, except for the C-terminal region. Melittin can aggregate into a tetrameric form in the venom reservoir, being apparently inactive under this condition.[4] This peptide lowers the surface tension of water at the level of the plasma membrane, acting mainly by its natural detergent-like effect on the plasma membrane, causing cell lysis (specially of mast cells), followed by histamine delivery. Because of this lytic effect on cell membranes, this peptide may be considered a venom diffusion factor, facilitating the entry of venom into the blood stream of the stung victims. X-ray crystallography of mellitin indicates that residues 1–10 and residues 13–26 form α-helices aligned approximately 120° to each other, while the proline residue at the position 14 could be the cause of a bend in the middle of the rod structure;[5,16] thus, a single polypeptide chain has the conformation of a bent α-helical cylinder (Fig. 1A).[5,7] When packed, the tetramer does so in a double planar layer. To achieve tight hydrophobic interactions, the hydrophobic residues of all four chains extend toward the center of the tetramer. Because of its surfactant properties, melittin is considered a direct hemolytic factor, acting synergistically with phospholipase A_2, activating this enzyme.[2,4,5]

Apamin

The honey bee venom also contains apamin, a peptide of 18 amino acid residues. The CD spectroscopy study of apamin in solution is consistent with a peptide presenting as an alpha-helix an showing a high degree of stability over a wide range of pH values.[4,16] This stability is a consequence of the rigidity imposed by two disulfide bridges. H^1-NMR studies of apamin in solution indicates a rigid, folded structure stabilized not only by the two disulfide bridges but also by at least seven intrachain hydrogen bonds. The structure of apamin has been studied by using a number of spectroscopic techniques, such as H^1-NMR, CD, Raman, FT-IR, and structure prediction algorithms of energy minimization with NMR and CD data. At first, the most suitable interpretation of the experimental results was the proposal of the coexistence of both an alpha-helix and beta-turns.[5,19] However, until now, the best structure for apamin remains controversial, with several available structural models.

Apamin is permeable to the blood–brain barrier, causing its effects on the CNS by several routes of administration. It causes neurotoxic effects in the spinal cord of mammals, producing hyperactivity and convulsions in rats.[5,10] When peripherically applied, apamin seems to selectively and

potently affect the potassium permeability of certain membranes, such as the smooth muscle of the gut. At very low levels, it seems that apamin treatment can convert the normal hyperpolarizing response to epinephrine into a calcium-dependent depolarization.[8,19] The peripheral effects of apamin suggest that the central action may also result from decreased potassium fluxes, since this would broadly reduce inhibitory tone and increase the excitability.

Mast Cell Degranulating Peptide (MCD)

The MCD peptide is a 22 residue toxin. Its secondary structure by CD and ^{1}H-NMR,[14] indicate a close resemblance to α-helical peptides from positions 13 to 19; it is stable over the pH range 2–8, stabilized by two disulfide bridges and six intrachain hydrogen bonds, which form a 28-atom ring structure, also observed in apamin.[4,16] This peptide may present two closely related conformations in solution, possibly differing by *cis-trans* isomerism involving the residues Pro^{12}His^{13}.

MCD produces cytolysis, thus being considered a potent mast cell degranulator, causing the release of histamine.[13,30] This peptide is a facilitator of the response of honey bee venom, responsible for the reddening, swelling, and locally occurring pain at the site of honey bee stinging, typical of histamine-mediated responses.

Other Peptides

Secapin represents approximately 0.5% of total honey bee venom; it is a 25 amino acid residue peptide, containing a single disulfide bridge and high proline content. Apparently, this peptide has no known physiological and/or pharmacological activity, probably because it was not sufficiently tested so far.[4]

Tertiapin, which composes approximately 0.1% of total honey bee venom, is a 21 amino acid residue peptide containing a single disulfide bridge and a C-terminal residue in an amidated form. This peptide is not particularly toxic after intravenous injection; it degranulates mast cells with low potency. It has been compared pharmacologically to prostaglandins under the same conditions.[7] Tertiapin has been proposed to have both α-helical and β-sheet tendencies along the length of its sequence, raising the question of which conformational state the molecule is likely to be in. Considering the positions of both disulfide bridge and its CD spectrum that has no indication of a β-sheet, the structure of tertiapin is probably analogous to that of the MCD peptide.[5]

Adolapin, a basic polypeptide isolated from bee venom, shows potent anti-inflammatory and antinociceptive properties.[32] Its action involves the inhibition of both prostaglandin synthase and lipoxygenase in human platelets.[27] Like other nonsteroidal analgesics, this peptide also has antipyretic effects and inhibits the increase in mean body temperature.[11]

PEPTIDE TOXINS FROM BUMBLEBEE VENOMS

Bombolitins

The bombolitins are a family of heptadecapeptides isolated from the venom of the bumblebee *Megabombus pennsyluanicus*.[3,4] These peptides are able to form amphiphilic α-helical structures either by self-association or by interaction with amphiphilic matrices, such as micelles or vesicles. The biological activity of these peptides seems then to be directly correlated to their capability to form an amphiphilic order structure (α-helix) that allows them to associate and penetrate cellular membranes. They are capable of lysing erythrocytes and liposomes, in addition to increasing the activity of the enzyme phospholipase A_2. In more general terms, the bombolitins share common biological properties with other "toxin" peptides such as melittin, crabrolin, and mastoparans.

PEPTIDE TOXINS FROM SOCIAL WASP VENOMS

The venoms of social wasps contain a series of polycationic amphipathic peptides, such as mastoparans, chemotactic peptides, wasp kinins, and crabrolins, the group of compact peptides containing disulfide bridges, and the group of very short linear peptides. These toxins present a series of multifunctional pharmacological actions, which generally contribute to the occurrence of intense inflammatory processes.

Mastoparans

The most abundant peptide component from Vespid venoms is represented by the mastoparans, which involves a histamine-releasing principle. Mastoparans are generally polycationic, linear tetradecapeptide amides, rich in hydrophobic residues such as leucine, isoleucine, and alanine. The most representative molecules of species endemic from regions with a cold climate show characteristic lysine residues in positions 4, 11, and 12,[13] but novel peptide sequences showing a different pattern of lysine distribution have been identified recently in wasp species endemic from the tropical regions.[28,29] Mastoparans are randomly coiled in water, whereas in methanolic solution and/or in the presence of lipid vesicles, they are generally alpha helical peptides (Fig. 1B), causing their effects by interacting with plasma membranes because of their amphipaticity.[30] According to their mode of action, these peptides may be classified into two groups: (i) those acting by cell lysis from pore formation on cell membranes[1,13] (ii) and those acting by interaction with G-protein–coupled receptors, leading to the activation of degranulation mecha-

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

nisms and resulting in many different types of secretions depending on the type of target cell.[20,21] In any situation, the final action will be the delivery of histamine from mast cells, serotonin from platelets, or even insulin from pancreatic β-cells. In addition to the interaction with membrane components, mastoparans also activate phospholipases A.[1] Antibacterial activities have been described for these peptides.[16,17]

The amphiphilic nature of these peptides make them interact with different types of cell membranes through different mechanisms, depending on their primary sequences. Nonlytic mastoparans may present the ability to interact with different types of cell strains, causing a minimal membrane deorganization but interact with cell membrane receptors, especially those coupled to G-proteins. The high affinity of these receptors make the mastoparans molecules very attractive lead compounds to develop a new generation of drugs to modulate the activity of G-proteins–coupled cell signaling system.[33]

Mastoparan stimulate insulin secretion from βTC3 and INS-1 cells. Preincubation of β-TC3 cells with either toxin B (from *Clostridium difficille*), which inactivates Rho, Cdc42 and Rac, or with *C. sordellii* toxin (which inactivates Ras, Rap, and Rac), attenuates mastoparan-induced insulin secretion, implicating Rac in this phenomenon. Mastoparan-stimulated insulin secretion is resistant to specific inhibitors of geranylation of Rho G-proteins (e.g., Rac), suggesting that these peptides induce the direct activation of Rac via GTP/GDP exchange. However, glucose-induced insulin secretion from these cells is abolished by toxin B, suggesting that the geranyl-geranylation step is critical for glucose-stimulated secretion. Mastoparan increases the translocation of cytosolic Rac and Cdc42 to the membrane fraction. Further, stable expression of a dominant negative (N17Rac) form of Rac into INS-1 cells resulted in a significant reduction in mastoparan-stimulated insulin secretion from these cells. Taken together, these findings implicate Rho G-proteins, specifically Rac, in mastoparan-induced insulin release.[1]

Mastoparans are capable of directly stimulating the guanine nucleotide exchange reaction of the α-subunit of animal heterotrimeric G-protein–coupled receptors, leading to a myriad of downstream events including the activation of mitogen-activated protein kinases (MAPKs). Because of these properties, mastoparans are considered as important peptide ligands of G-protein–coupled receptors and are being used as tools to dissect the signal transduction mechanisms for different cell strains, associated with different diseases.

In addition to be ligands of G-protein–coupled receptors, there are mastoparans that interact directly with cell membranes, perturbing the phospholipid organization and causing cell lysis or cell/vesicle fusion.[34] This type of peptide has attracted attention because of the possible biotechnological applications developed from them, as follows:

(a) These peptides are potent facilitators of mitochondrial permeability transition and may thus be used as an antitumor agents; for this purpose, they are encapsulated in a selective tumor delivery system. Transferrin-modified liposomes carrying pH-sensitive fusogenic mastoparans may be used to deliver chemotherapeutical drugs into the cytosol of sick cells for cancer therapy.[22,34]

(b) ome Mastoparans are potent antimicrobial peptides (AMPs) with the potential to be used in the treatment of multiple drug-resistant infections. These peptides exist in solution as unstructured monomers, folding into predominantly α-helical structures upon membrane binding with their long helical axis parallel to the bilayer surface. Studies with model membranes have shown that these peptides intercalate into the lipid bilayer just below the level of the phospholipids glycerol backbone, in a location requiring expansion of the outer leaflet of the bilayer. Evidence from a variety of experimental approaches indicates that expansion and thinning of the bilayer are common characteristics during the early stages of AMP–membrane interactions. Subsequent disruption of the membrane permeability barrier may occur through a variety of mechanisms, leading ultimately to the loss of cytoplasmic membrane integrity and cell death. These AMPs constitute part of the "innate" arm of host resistance, serving as the first line of defense against infection in the insects. Importantly, AMPs are believed to have a mechanism of action entirely distinct from those of current clinically used antibiotics, and so there is great interest in their development for treatment of drug-resistant infections.[17]

Crabrolin

This is a 13 amino acid residue polycationic peptide present in the venom of the hornet *Vespa crabro*, presenting a helical conformation.[29] This peptide produces potent hemolytic and antibacterial activity; however, it is a weak mast cell degranulator, with <20% the activity of mastoparan. Crabrolin is four times less active than mastoparan in guinea pig erythrocytes[2,3] and shows no effect in rat erythrocytes.

Chemotactic Peptides

The second most important group of peptides among the Vespid are the chemotactic peptides, which generally are trideca-polycationic peptides, with primary sequences resembling the mastoparans in regards to the richness of hydrophobic amino acid residues and the amidation of the C-terminal residue.[13] These peptides induce chemotaxis in polymorphonuclear leukocytes and macrophages[6] and

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

sometimes also release histamine from mast cells. The result of such chemotactic activity is the development of a mild edema, accompanied by an inflammatory exudate around the site of stinging, containing mainly polymorphonuclear leucocytes. Thus, the chemotactic peptides do not cause pain directly, but they play an important role enhancing the inflammatory effect of wasp stings. A novel type of chemotactic peptide was reported in which the acetylation of the N-terminal residue seems to play a part in the modulation of polymorphonuclear leukocyte attraction.[13]

Kinin-Related Peptides (Wasp Kinins)

A third group of peptides biologically important among the Vespid toxins are the wasp kinins, which generally are known as pain-producing peptides. These peptides consist of bradykinin molecules elongated at the N-terminus with some extra amino acid residues. Sometimes, there is also an elongation from the original bradykinin C-terminal residue.[13] The general pharmacological properties are similar to those presented by human bradykinin; however, the effects of Vespidae kinins are much more pronounced and long lasting. These effects may be summarized as follows: When injected intravenously, they cause hypertension in rats, dogs rabbis, and cats; hypotension in chickens; brochoconstriction in guinea pigs; contraction of most isolated smooth muscle preparations; and relaxation of rat duodenum.[14,24]

Compact Peptides Presenting Disulfide Bridges

A fourth group of amphipathic polycationic peptides from Vespide venoms has been described, but few characterized are up to now; these peptides contain from 21 to 25 amino acid residues in their primary sequences, presenting a single disulfide bridge, constituting the first example of this type of structure among the Vespid peptide toxins. These peptides are mast cell degranulators, without known hemolytic activity, which apparently also inhibit the insulin secretion by β-cells.[14]

Very Short Peptides

The venoms of social Hymenoptera also contain a series of short peptides, not well studied up to now, which apparently induce chemotaxis of PMNLs and act as modulators of the classical chemotactic peptides.[6]

PEPTIDES FROM ANT VENOMS

Most of the ants only present traces of proteins/peptides in their venoms; however, in those species producing peptides as components of their venoms, these toxins follow the same general pattern already observed for peptides from wasps and bees venoms, that is, short and linear polycationic peptides, presenting a high content of α-helices, which are responsible for cell lysis, hemolysis, histamine release from mast cells, and antimicrobial actions. A few neurotoxins are also known.

"Myr p" Peptides and Pilosulin

The venom of the Australian ant *Myrmecia pilosula* seems to contain a complex mixture of allergenic peptides, some of them forming heterodimers, apparently maintained by disulfide bridges. From this complex was identified Myr p 1, the major expressed allergenic product being a 56 residue peptide, whereas Myr p 2 is a 27 residue peptide; these peptides may dissociate, or are cleaved to minor fragments, such as those previously identified as pilosulin-1 and pilosulin-2, characterized as the fragments 57–112 from Myr p1 and 49–75 from Myr p2.[5] Pilosulin-1 is a α-helical peptide with potent and broad spectrum of antimicrobial activity, both against standard and multidrug-resistant Gram-positive and Gram-negative bacteria, and *Candida albicans*.[29] Other pilosulins have been identified and characterized as hemolysins and histamine release peptides.[12,18,25]

Poneratoxins

Poneratoxin is a neuropeptide found in the venom of the ant *Paraponera clavata*. A peptide containing 25 amino acid residues, it affects voltage-dependent sodium channels and blocks synaptic transmission in the insect central nervous system in a concentration-dependent manner. Its NMR structure is in the form of two α-helices connected by a β-turn (Fig. 1C); the helices have quite different characteristics from each other: One of them is apolar, whereas the second contains polar and charged amino acids. This will result in different interactions with cell membranes. The extremely hydrophobic N-terminal helix may interact with uncharged lipid bilayers, while the C-terminal helix, slightly positively charged and terminating with arginine, will be able to attach to negatively charged cell surfaces as previously found for other membrane interacting peptides. Such a toxin can thus use two different complementary modes of interaction to attain its target, cellular membranes.[18,23]

Ponericins

Ponericins constitute a group of peptides isolated from the venom of the predatory ant *Pachycondyla goeldii*, exhibiting hemolysis, insecticidal activity against cricket larvae, and antimicrobial action against Gram-positive and Gram-negative bacteria. According to their primary structure similarities, they can be classified into three families: ponericin G, W, and L. Ponericins share high sequence similarities with

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

known peptides: ponericins G with cecropin-like peptides, ponericins W with gaegurins and melittin, and ponericins L with dermaseptins. The comparison of the structural features of ponericins with those of well-studied peptides suggests that the ponericins may adopt an amphipathic α-helical structure in polar environments, such as cell membranes.[13]

Ectatomin

This peptide is a neurotoxin isolated from the venom of the *Ectatomma tuberculatum* ant and contains two highly homologous peptide chains (consisting of 37 and 34 amino acid residues) linked to each other by disulfide bonds.[25] Each chain consists of two alpha-helices and a hinge region of four residues forming a hairpin structure that is stabilized by disulfide bridges; the hinge regions of the two chains are connected together by a third disulfide bridge (Fig. 1D). Thus, ectatomin forms a four-alpha-helical bundle structure.[18] Ectatomin is a potent inhibitor of calcium currents after a latency of a few seconds in rat ventricular myocites.[25]

PATHOPHYSIOLOGY OF HYMENOPTERAN PEPTIDE TOXINS

The large group of Hymenopteran venom consists of biologically active peptides that are responsible for the main pathophysiological actions occurring during the envenoming processes. Among the different groups of social Hymenoptera (wasps, bees, and ants), there are a series of different families of peptides, characteristic of each group of insect: melittin, apamin, and MCD peptides are typical of honeybees, whereas mastoparans, chemotactic peptides, and kinins are characteristic of wasps; the group of ants is biologically much more diversified than wasps and bees, and consequently, ant peptides are also more diversified than the previous ones. It is important to emphasize that only a few groups of ants present venoms containing proteins and peptides; pilosulins are characteristic of Myrmicinae, Poneratoxins, and ponericins are typical of Ponerinae, whereas ectatomin is characteristic of the Ectatomminae ants.

Despite the large structural differences among the wide variety of Hymenopteran venom toxins, some of these families of peptides share common pathophysiological actions. Thus, as an example: mastoparans, crabrolins, bombolitins, MCD peptide, and melittin cause mast cell degranulation, cell lysis, and hemolysis, with the consequent occurrence of inflammation, pain, myonecrosis, and ischemia, which all together promote a cascade of actions that in turn result in hemoglobinuria, rhabdomyolysis, and renal failure. Neurotoxins such as apamin, poneratoxins, and ectatomin act at the level of the nervous system blocking different subtypes of glutamate receptors, which in turn may affect differently the functioning of calcium channels.[5,6,23,28] The excessive chemotaxis of polymorphonucleated leukocytes (PMNLs) induced by the chemotactic peptides may cause a massive delivery of oxygen peroxide around the site of stinging, causing hyperoxidation of the surrounding tissues, followed by their consequent cellular death. The kinin analogs cause hypotension and bronchoconstriction, whereas the short peptides apparently are involved with the chemotaxis of PMNLs and the inhibition of the release of catecholamines from chromaffin cells.[24] Figure 2 summarizes the general scheme of the pathophysiology of the Hymenopteran peptide toxins occurring during the envenomation process.

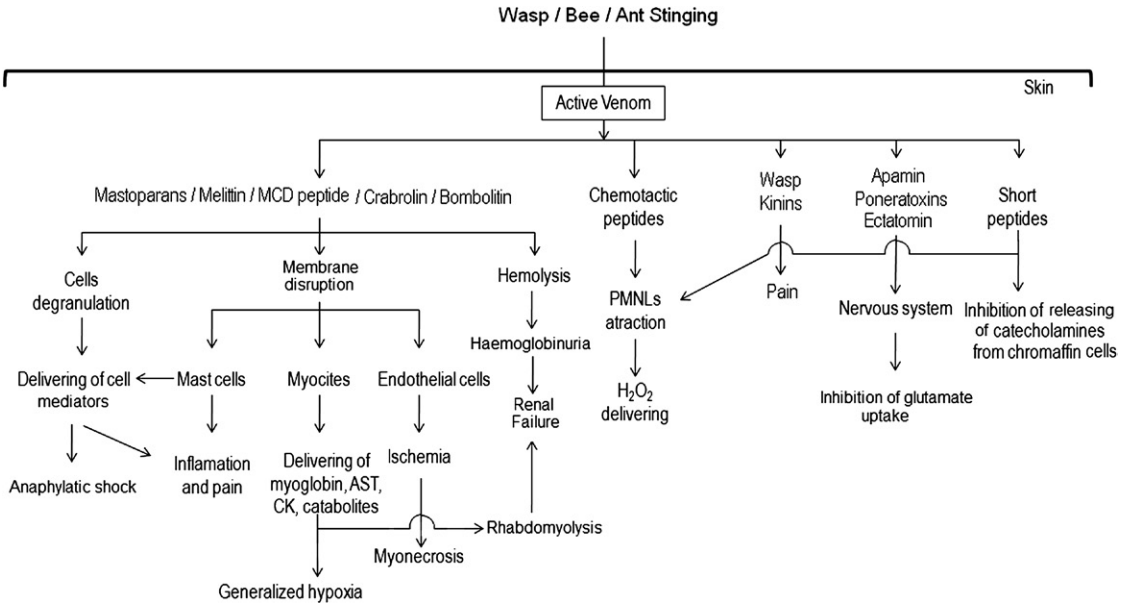

FIGURE 2 General mechanism of envenoming pathogenesis of the peptide toxins from the venoms of the social Hymenoptera.

Chapter 59

Scorpion Peptides

Ricardo C. Rodríguez de la Vega, Nicolas Vidal and Lourival D. Possani

ABSTRACT

Scorpion venoms are arsenal-like mixtures that provide the producing organism with the ability to kill their prey or deter possible competitors or predators. When the first edition of this book was published, most of the known scorpion venom components were encompassed into a single structural class dubbed as the Cystine-Stabilized α/β scaffold; their functions as ion channel modulators are now relatively well known and understood. However, mining on scorpion venoms using high-throughput techniques has revealed a large prevalence of noncanonical components that actually outnumber the typical toxin class. This chapter highlights the documented molecular diversity contained in scorpion venoms and reviews the known structural and functional classes. The biotechnological and pharmacological prospects of some scorpion venom peptides are also briefly covered.

INTRODUCTION

Scorpions rely on their venoms both for foraging and defending themselves against competitors or predators; they have been doing so over their 400 million years of evolution on land. Like many other toxic secretions from venomous animals, scorpion venoms are arsenal-like mixtures consisting of dozens of different compounds, including salts, organic molecules, and a wide diversity of proteins, ranging from short linear peptides to high molecular weight enzymes. Scorpion toxins are the venom components responsible for the envenomation caused by scorpion stings, whether in a trophic or a defensive context. Once injected, scorpion toxins gain access and bind directly to the victim's molecules prompting a cascade of physiological effects that can lead to death of susceptible animals; neurotoxic effects on mammals, for example, are triggered by the direct modulation of K^+ and Na^+ channels by scorpion toxins. Most of the research on scorpion venoms has been fueled by the medical interest in the toxins responsible for human envenomation and, later, by the use of some scorpion venom components as molecular tools for the study of ion channel function. By 2010, the sequences of >1000 scorpion venoms proteins were known.[12] Most of these components are peptidic ion channel modulators that belong to a single structural class built around the sequence signature of the Cystine-Stabilized α/β (CS-α/β) motif. Various studies aiming at cataloging the whole molecular diversity present in scorpion venoms have revealed, however, that within scorpion venoms CS-α/β proteins are actually outnumbered by proteins not belonging to this structural class, many of which display unprecedented biological functions.

This chapter deals with the molecular diversity documented in scorpion venoms and the molecular targets and mechanisms of action of well-known and not-so-well-known scorpion venom peptides. The biotechnological and pharmacological prospects of some of these are only briefly outlined as the chapters by Chandy and Beraud and by DeWaard and Sabatier present a deeper discussion. Important aspects of scorpion venom research, such as how venoms have attained their remarkable complexity through evolution and the puzzling effects that whole venoms exert on the immune response of affected mammals, are outside the scope of this chapter. The systematic characterization of scorpion venom components is expected to provide both a better understanding on how scorpion venoms accomplish their "native" functions and novel bioactive peptides that could be used to study many biological phenomena.

MINING ON SCORPION VENOMS

When the first edition of the Handbook of Biologically Active Peptides was published, sequence information of nearly 400 scorpion venom peptides and proteins was known, thanks to the painstaking job of dozens of laboratories around the world; the advent of high-throughput protein identification techniques by Mass Spectrometry and large-scale DNA sequencing have more than tripled that number in the last few years.

Comprehensive "venom proteomes" of twelve scorpion species have been published, including nine belonging to the Buthidae family (six *Tityus* species,[2] two *Androctonus* species,[4,20] and *Mesobuthus tamulus*[19]), two Liochelidae (*Liocheles australasie*[15] and *Opistacanthus cayaporum*[28]) and one Scorpionidae (*Heterometrus petersii*[14]). The number of identified components varies between 72 (*A. mauritanicus*

mauritanicus) and >600 (*M. tamulus*). In general, the largest group corresponds to peptides with rather low molecular masses (≤1500 Da), for which virtually nothing is known about their function or structures (see below). Proteins with molecular weights >7501 Da are scarce among these scorpion venom proteomes, accounting for about 10% of all identified masses. The best-known scorpion venom peptides, the CS-α/β peptides active on K^+ or Na^+ channels, fall in the 3001- to 4500-Da and 6001- to 7500-Da ranges and collectively account for approximately 30% of all identified masses, with a significantly larger contribution of Buthidae scorpions (up to 78% of all identified masses in *A. mauritanicus mauritanicus*). A number of other studies reporting the overall composition of scorpion venoms determined by MS have been published, but the component lists are not available;[17] nonetheless, the composition of the venoms studied is in agreement for the most part with the trends outlined above.

More than two-thirds of unassigned molecular masses in all these scorpion venom proteomic studies demand alternative methods to establish their molecular identity; cDNA sequencing is helping to fill this gap. A handful of studies surveying the transcriptional profiles of scorpion venom glands have been published over the last few years, including the Caraboctonidae *Hadrurus gertschi*,[27] the Euscorpiidae *Scorpiops jendeki*,[13] the Liochelidae *O. cayaporum*,[29] the Scorpionidae *H. petersii*,[14] and three Buthidae (*T. discrepans*,[5] *Lychas mucronatus*,[35] and *Hottentota judaicus*[16]). Taken together, these studies provided sequence information for >600 previously unknown scorpion venom gland proteins. The largest sequence diversity (~50% of the unique sequences) reported in these studies could be assigned to comparatively low expressing proteins (<30% of the total reads), which would participate in the cellular processes of the venom gland. Somehow unexpectedly, transcripts encoding common toxin types, that is, CS-α/β peptides active on K^+ or Na^+ channels and Inhibitory Cystine Knot (ICK) peptides active on Ca^{2+} channels, constitute a relatively small proportion of both the total reads and the number of unique sequences in all but one of these transcriptomes: around 10% on average (*T. discrepans* not taken into consideration) with as low as 3% of the total unique sequences in *S. jendeki*. In comparison, secretory proteins rarely reported or altogether unprecedented in scorpion venoms constitute a twice as large proportion of the molecular diversity (averaging 20% of the unique sequences). On the other side of this spectrum, 50% of the total reads of a randomly sequenced *T. discrepans* cDNA library encode for typical toxin precursors. The overlap between the expected molecular weight of the translated sequences identified in these studies and the molecular masses determined by proteomic studies remains rather low (for instance only nine sequences *O. cayaporum* fall within the mass range 3001–4500 Da, from which 28 unique masses were identified in the proteomic study). The combined approach used to analyze *H. petersii* venom and venom gland is remarkable in that sense: the random sequencing of venom gland transcripts allowed the authors to assign to which toxin "family" belong >110 unique masses identified in their proteomic study of tryptic digested venom.[14]

Most of these analyses have been performed on pooled samples, without distinction of the ontological state of the specimens, the gender or the geographical source of the scorpions from which the venom has been extracted. It should be stressed that variations in venom composition or transcriptional profile have been documented for several scorpions,[18,19,35] thus posing a cautionary mark on the extent the compendia outlined above reflect the actual molecular diversity present in scorpion venoms. Further research should take into consideration this variability. In spite of these limitations, proteomic and transcriptomic analyses of scorpion venoms and venom glands are revealing the large contribution of peptides considered atypical or completely ignored for many years (see below).

DOCUMENTED MOLECULAR DIVERSITY

By the time the first edition of the Handbook of Biologically Active Peptides was in production, the search for all the sequence information about scorpion venom peptides was a rather laborious enterprise. Most data were not deposited in publicly available databases, and extensive literature search was mandatory. Fortunately, this panorama has changed thanks to current publication policies—which now ask for submission to public databases of virtually every piece of sequence data—and to the emergence of dedicated annotation initiatives.[12] The Animal Toxin Annotation Program of UniProt (www.uniprot.org/program/Toxins) provides manually curated protein entries for approximately 750 scorpion venom proteins, almost twice as many translated sequences are also available from the query form. Among the 91 scorpion species covered, Buthidae scorpions largely surpass all the rest with 74 species; nine Scorpionidae, four Liochelidae, two Caraboctonidae, and two Chactidae complete the list. The number of sequences from each family shows an even more biased pattern: Buthidae 88%, Liochelidae 5%, Scorpionidae 3%, and approximately 1% for the other two families. Although in recent years more articles on neglected scorpion families have been published, scorpion biodiversity is still poorly covered (<5% of the almost 2000 extant species). The gravity of the situation is even more striking for the estimated number of different molecular components of scorpion venoms; these sequences would represent not >1% of the estimated 300,000 different peptides in all scorpion venoms (taking the conservative number of 150 peptides per venom proteome).

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

If the scorpion biodiversity is scantly sampled, the representation of the different types of venom components in sequence databases is only slightly better. For many years, CS-α/β peptides dominated the sequences available from scorpion venoms; by the time of the first edition of this book, almost 80% of the approximately 320 scorpion entries in UniProt with "evidence at the protein level" were classified as CS-α/β peptides. A small decrease of this proportion, to 70%, over the last few years has been prompted by the number of newly characterized peptides that do not belong to this group almost matching the number of novel CS-α/β peptides; although still moderately, these numbers speak about a shift in scorpion venom research toward the characterization of previously neglected venom components. Molecular diversity is even more obvious if translated sequences from scorpion venom glands are also taken into consideration;[23] the proportion of non CS-α/β scorpion venom peptides already reached 40% and is growing faster than CS-α/β peptides (see above).

STRUCTURAL AND FUNCTIONAL TYPES

According to proteomic studies, the largest group of scorpion venom peptides corresponds to the short peptides (<3001 Da), which dominate in most venom proteomes reported to date. The molecular identity of most of them remains to be uncovered and some could even be fragments of larger proteins, as suggested by the impressive finding that almost one-third of the masses within this range found in *T. serrulatus* are actually fragments of larger proteins;[24] remarkably, some fragments could be biologically active by themselves, thus adding to the functional complexity of scorpion venoms.[9] A wide range of linear peptides fall within this mass range, among the most abundant in sequence databases are α-helical peptides similar to the antimicrobial IsCT, which have been found in several species (Fig. 1): two Liochelidae (*Opisthacanthus madagascariensis*, where they were first reported, and *O. cayaporum*), the Scorpionidae *H. petersii* and four Buthidae (*H. judaica*, *Mesobuthus eupeus*, and *M. martensii*). Several other linear scorpion venom peptides have been reported in the literature, including some therapeutically promising ones highly active against antibiotic resistant bacteria (Fig. 1); a common membrane disrupting mechanism is assumed to explain both the antibiotic and cytolytic activities of these peptides.

Apart from the ubiquitous CS-α/β peptides from scorpion venoms, other types of disulfide rich peptides are also found in several species. Peptides folding into an ICK structural motif have been found in three Buthidae (*H. judaica*, *L. mucronatus*, and *M. martensii*), the Caraboctonidae *H. gertschi*, the Euscorpiidae *S. jendeki*, and four Scorpionidae (*H. petersii*, *Opistophtalmus carinatus*, *Pandinus imperator*, and *Scorpio maurus*). This structural motif is defined by a triple stranded beta sheet crosslinked by three disulfide bridges (although variations exist); it dominates among *Conus* and spider venom peptides, where it has been implicated in a true cornucopia of different biological actions (see the chapters by Nicholson and Olivera). In scorpions, the ICK peptides (Fig. 1), also called calcins or calcines, are invariably associated with agonistic activity on intracellular calcium release channels (the so-called Ryanodine Receptors, RyR); the ability of these peptide to crossmembranes without lysis of the cells, even with large cargoes, offers a promising perspective for intracellular drug delivery.[10,22] Interestingly, a peptide found in two *Liocheles* species displays the predicted two disulfide pattern and three-dimensional folding of the long forecasted Disulfide Directed Hairpin (Fig. 1), a putatively ancestral fold out of which ICK peptides would have evolved.[11,30] Other cysteine-rich peptides have been identified in scorpion venom gland transcriptomes, some of which show high similarity with biologically active peptides found in other venomous organisms (e.g., Kunitz protease inhibitors and Cysteine-Rich Secretory Proteins[8]), but their structures and functions remain to be determined. The most abundant component of *L. australasiae* venom illustrates our ignorance about disulfide rich peptides in scorpion venoms: La1 is a four disulfide bridged peptide[15] that makes up to 11% of total protein content in *L. australasiae* venom (Miyashita, personal communication) but no function for it or its homologs in *O. cayaporum*, *M. martensii*, and *H. judaica* has been reported yet. Other components with enzymatic activity have been patchily reported in scorpion venoms, including hyaluronidases (partial sequence information from *H. judaica*, *M. martensii*, and *T. serrulatus* as well as evidence for their presence in several others), phospholipases (three Buthidae; two Scorpionidae; and one each in Caraboctonidae, Chactidae, and Liochelidae), metalloproteases (in the Buthidae *H. judaica*, *M. eupeus*, and *T. serrulatus*[7]) and a sphingomyelinase homolog in the Liochelidae *Hemiscorpious lepturus*;[3] all of them are known to be important components of other venomous organisms.[8]

The CS-α/β peptides are the most thoroughly studied scorpion venom peptides and are still the ones receiving the largest attention (Fig. 1). The Cystine-Stabilized α/β scaffold consists of an α-helix joined by disulfide bridges to the last strand of a double- or triple-stranded β sheet. The CS-α/β scaffold is accompanied by a four-cysteine sequence signature ($C_i xxx C_{i+4} \ldots C_j x C_{j+2}$) forming two completely conserved disulfide bridges (C_i–C_j, C_{i+4}–C_{j+2}). Traditionally, scorpion venom CS-α/β peptides have been distinguished according to their length in short-chain (<45 residues long) and long-chain (55 residues long or more) peptides. This distinction is somehow mirrored by the pharmacological action of these peptides, with short-chain peptides being potassium channel blockers and long-chain peptides displaying different sodium channel modulation activities.

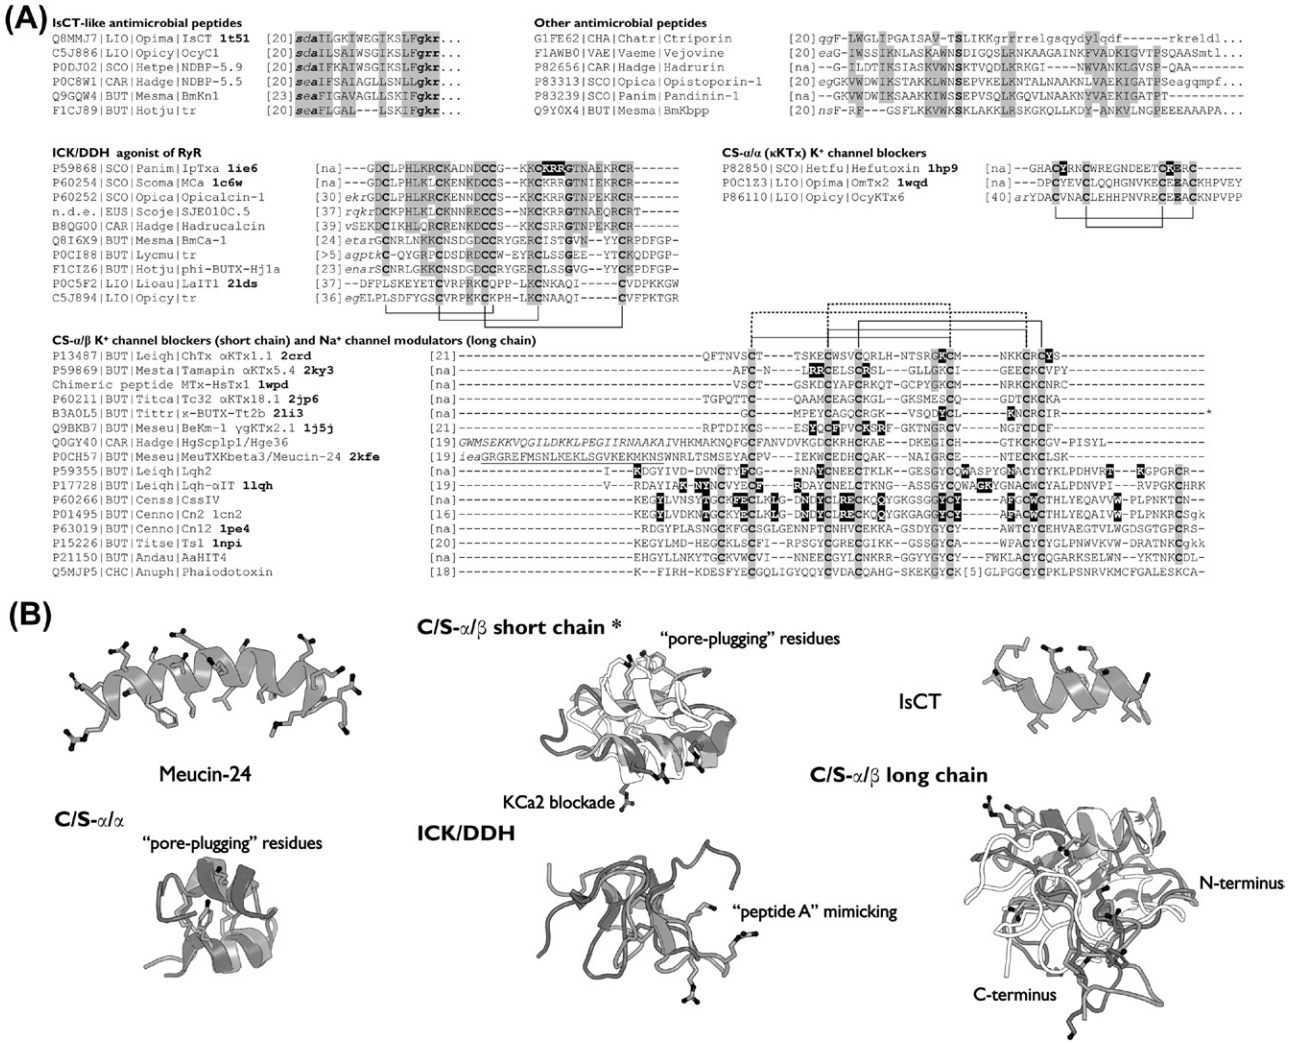

FIGURE 1 Structural and functional types of scorpion venom peptides. (A) Multiple sequence alignment of selected members of each class was performed with TCoffee (www.tcoffee.org/apps/tcoffee/play?name=regular). Sequences are labeled with UniProt accession numbers, followed by a two-letter code of the taxonomic family, a five-letter abbreviation of the species name, the name given in the original publications and PDB codes where available (bold). Conserved residues are highlighted in gray. Numbers between brackets denote N-terminal residues that are not shown. Lower case residues indicate that these are not present in the mature forms. Lines below the ICK/DDH and CSα/α and above CSα/β alignments specify the disulfide bridges. Broken lines indicate the two alternative disulfide bridges of the helix-loop-helix peptide κ-BUTX-Tt2b (*). The antimicrobial native fragment of MeuTXKbeta3, Meucin24, is underlined. The processed N-terminus of HgScplp1 not present in Hge36 is shown in italics (see Q0GY40). The residues important for the functions and highlighted in panel b and Fig. 2 are indicated on a black background. Family abbreviations: BUT, Buthidae; CAR, Caraboctonidae; CHA, Chaerelidae; CHC, Chactidae; EUS, Euscorpiidae; LIO, Liochelidae; SCO, Scorpionidae; VAE, Vaejovidae. (B) Three-dimensional structures and structural superimposition of selected scorpion venom peptides. Structural alignments were performed with TopMatch (topmatch.services.came.sbg.ac.at/TopMatchFlex.php) and the structures displayed with PyMOL (www.pymol.org). Residues considered important for the function are displayed as balls and sticks (see database entries for further reference): IsCT and Meucin24, amphipathic clustering of charged (top) and hydrophobic (bottom) residues; Hefutoxin, Kv channel "pore-plugging" residues Tyr5 and Lys21; IpTxa, basic loop (Lys22-Arg23-Arg24) mimicking the "peptide A" off the cognate RyR partner (the dihydropyridine receptor); ChTx, Kv channel "pore-plugging" residues Lys27 and Tyr36; Tamapin, basic residues in the region important for KCa2 channel blockade; κ-BUTX-Tt2b, putative "functional dyad" Tyr19 and Lys21; Cn2, conserved functional residues identified in CssIV; LqhαIT, residues important for toxicity and receptor binding (see P17728). Overlaid structures are CSα/α, Hefutoxin (light gray) and OmTx2 (dark gray); CSα/β short chain, ChTx (light gray), Tamapin (dark gray) and the helix-loop-helix κ-BUTX-Tt2b (white); CSα/β long-chain, αNaScTx LqhαIT (dark gray), βNaScTx Cn2 (light gray) and uNaScTx Cn12 (white); ICK/DDH, IpTxa (light gray) and LaIT1 (dark gray). Side chain heteroatoms are depicted in black. PDB codes are indicated in panel a.

The Protein Data Bank (www.rcsb.org/pdb/home/home.do) contains 135 structures for some 85 unique scorpion venom peptides from 22 species (67 from 17 Buthidae, 11 from 4 Scorpionidae, and 4 from 1 Liochelidae); 75 of them fold into the CS-α/β pattern. Although the permissiveness of the CS-α/β scaffold to different disulfide patterns has been known for some time, recently two peptides with helix-loop-helix structures and the same cysteine pattern

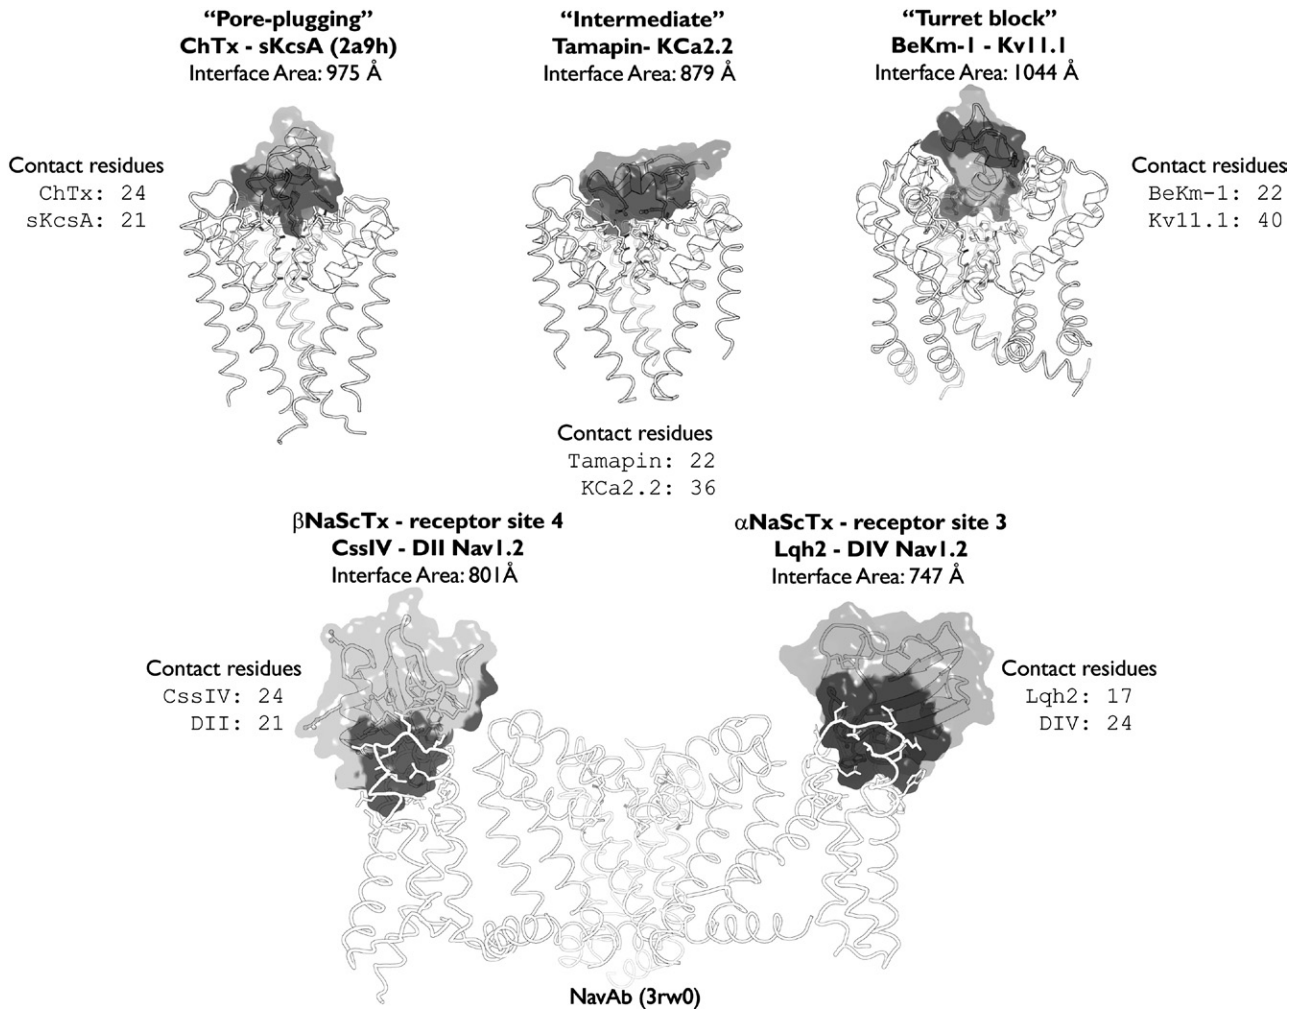

FIGURE 2 Molecular recognition between scorpion venom peptides and ion channels. Models taken from the original publications were displayed with PyMOL and analyzed with PISA (www.ebi.ac.uk/msd-srv/prot_int/pisastart.html). Channels are depicted as cartoon models, side chains are shown for residues making contacts with the scorpion venom peptides (any atom within 5 Å). The peptides are shown as semitransparent surface with embedded cartoon models; side chains of peptide residues important for the interaction are also displayed (Fig. 1), and the interacting area on surface is colored accordingly. Notice that several residues identified as important for NaScTx function are not in contact with the channel in the docking models. Interface details as evaluated in PISA are indicated for each model. ChTx–sKcsA structure was taken from the PDB (2a9h[33]), Tamapin– KCa2.2 model was rebuilt on the basis of the one published in Ref. 1, BeKm-1 – Kv11.1 from Ref. 31, Lqh2 – Domain IV voltage sensor of Nav1.2 from Ref. 32 and CssIV – Domain II voltage sensor of Nav1.2 from Ref. 34 The NaScTx – voltage sensor models were overlaid on NavAb channel structure.[21] The subunits closest to the viewer were removed for the sake of clarity. Templates for the channel modeling were KCa2.2, KcsA (1bl8); Kv11.1, KvAP in an open conformation (1ors); DII voltage sensor Nav1.2 model was based on a closed state model of Kv1.2[34]; DIV voltage sensor Nav1.2, Kv2.1-Kv1.2 chimera (3lut).

but shifted disulfides (Fig. 1) highlight an unforeseen structural versatility of this type of disulfide rich peptides.[26]

One of the main reasons for the large attention received by scorpion venom CS-α/β peptides is the exquisite specificity some could attain against closely related targets; thus, the great interest on defining the molecular basis of their target recognition.[6] For potassium channel blockers, also known as KTx, at least three different modes of interaction have been documented (Fig. 2): (a) in the "pore-plugging mode," ion conduction through the selectivity filter of Kv1, KCa1, and KCa3 channels is blocked by a pharmacophore consisting of a Lys residue assisted by an aromatic side chain located some 7 Å apart, other residues facing the channel vestibule also contribute to the binding[33]; (b) in KCa2 channel blockers, a patch of basic residues makes contacts with the vestibule in the so-called "intermediate" mode, although KTx binding is stabilized by contacts with a negatively charged extracellular loop of the channel,[1] and; (c) the unusual topology of Kv11 channels, the *ether-à-go-go* related gene homologs, are targeted by γKTx toward their binding to an extracellular α-helix, defining the interaction mode called "turret block."[31] Remarkably, a single KTx could bear more than one pharmacophore, as evidenced by the complete structural segregation of the molecular determinants

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

for Kv1.1/Kv1.3 and KCa2.1 blockade in a chimeric peptide based on the Kv1.1/Kv1.3-blocking HsTx1 and the KCa2.1-blocking MTx.[25] In spite of the detailed knowledge about potassium channel recognition by KTx, the large structural diversity of scorpion venom peptides that are active on this type of channels suggests that novel interaction modes are yet to be discovered. On the other hand, recent years have witnessed a great advance in our understanding of the molecular basis of scorpion venom peptides active on sodium channels (NaScTx), which have been now finely dissected to the point of generating structural models of the interaction.[32,34] On the basis of their receptor sites and pharmacology, two classes of NaScTx have been described: the α-type binds to receptor site 3, mainly composed by domain IV voltage sensor, provoking an abnormally slow inactivation, and β-type binds to the receptor site 4, largely defined by domain II voltage sensor, which are trapped in their preactivated configuration, thus causing an hyperpolarization shift on the activation potential. The structural models shown in Fig. 2 represent a long waited improvement in our understanding of classical αNaScTx and βNaScTx. However, in these models, not all the residues identified as important for NaScTx function are in contact with the channel; thus, a complete picture of the molecular determinants of the interaction is still missing. Much less is known about the puzzling activities of NaScTx that cannot be classified in α or β classes such as, among several examples, AaHIT4 (binds to both receptor sites), Cn12 (sequence resembles βNaScTx but displays an α-like effect) and the only non Buthidae NaScTx characterized to date Phaiadotoxin (which slightly affects both activation and inactivation of insect channels). Further research will certainly benefit from the more recently solved three-dimensional structure of a voltage-gated sodium channel.[21]

CONCLUDING REMARKS

In spite of the great increase in the number of known scorpion venom peptides, the vast majority of those which have been functionally characterized at any detail fall into two large categories: ion channel modulators and/or membranolytic peptides. The large diversity of novel peptides revealed by proteomic and transcriptomic analyses should lead to the discovery of other interesting functions in the near future. Moreover, it is expected that a much needed larger sampling of scorpion biological diversity and the use of high-throughput functional assays will greatly expand the number and types of scorpion venom peptides for which some biological activity is known. However, it should be kept in mind that the search for biologically active peptides is seldom performed in ecologically relevant models, such as natural prey or predators. Forthcoming research would benefit from a deeper knowledge of the natural context in which the venom evolved and is now used, in such a way that potential targets could be suggested. A combination of large-scale screenings and biologically informed searching would prove critical if we are to understand how venoms have achieved their remarkable complexity.

Chapter 60

Sea Anemone Peptides

Raymond S. Norton

ABSTRACT

Sea anemone venoms continue to afford a range of interesting new peptides directed against a range of biological targets. The first complete genome of a sea anemone was described recently, and its complement of toxins has been subject to various analyses. Concurrently, expressed sequence tag analyses of other anemones have identified many putative peptide toxins, while transcriptomic analyses may be expected to identify even more in the near future. Venom proteomic analyses are also revealing novel peptide toxins. Of those peptides that have been isolated, synthesized, or expressed, and then characterized functionally, the majority interact with sodium or potassium channels, although peptides binding to other targets are beginning to emerge, including one that modulates TRPV1 activity. Some of these peptides, in particular those capable of selectively blocking certain potassium channels, are being developed as new therapeutic leads.

INTRODUCTION

Since the publication in 2006 of the first edition of the *Handbook of Biologically Active Peptides*, sea anemones have continued to yield interesting new peptides with a range of biological activities, while genomic analyses have identified an ever-expanding array of candidate peptides. This chapter documents these new findings and comments on other exciting developments relevant to sea anemone peptides.

Cytolysins of the actinoporin family were described in the corresponding chapter of the first edition[18] but will not be further elaborated upon here. Significant progress has been made in understanding the structure and function of these toxins[11] although the molecular details of the mechanism by which they so potently form pores in target membranes remain elusive. Homologs of the actinoporins have been found in other organisms, predominantly fish,[11] and another related protein was found more recently in the foot muscle of a brackish-water clam, where it is unlikely to function as a toxin for prey capture. An intriguing aspect of these cytolysins that has come to light is their similarity to components of some pore-forming complexes in higher organisms.

SEA ANEMONE GENOME

The first genome of a sea anemone, the starlet one *Nematostella vectensis*, published in 2007;[23] showed extensive conservation in gene content, structure, and organization between this eumetazoan and vertebrates and has further established it as a useful model organism for developmental and evolutionary biology. An analysis by Anctil[1] reveals numerous orthologs of enzymes and nicotinic receptors associated with cholinergic function, an even larger number of genes encoding enzymes, receptors and transporters for glutamatergic, GABAergic and aminergic transmission, two orthologs of purinergic receptors, four adenosine-like receptors and one nitric oxide synthase. No muscarinic acetylcholine receptors were identified and a large number of melatonin-related, but not serotonin, orthologs were found. Genes encoding prepropeptides and receptors related to RFamide, tachykinin, galanin, gonadotropin-releasing hormones, vasopressin/oxytocin, melanocortins, insulin-like peptides, glycoprotein hormones, and uniquely cnidarian peptide families were also identified. Matching the unique cnidarian peptides with their receptors will be a challenging but rewarding undertaking.

The genome of *N. vectensis* has also provided the opportunity to analyze gene families encoding peptide toxins. Surprisingly, this genome contains 13 putative genes encoding the same peptide, Nv1,[14] which belongs to the Type-1 sea anemone class of neurotoxins;[17] each of these genes consists of two exons separated by an intron, with the first exon encoding a leader sequence and a portion of the pro region and the second encoding the remaining pro region and the mature peptide. Nv1 was expressed in *Escherichia coli* and, as expected for this class of toxin, it inhibits the inactivation of voltage-gated sodium channels (VGSCs).[16] Nv1 shows high specificity for insect over mammalian VGSCs, suggesting that it may act on VGSCs in marine arthropods. Some residues functionally

important in Av2 (aka ATX II) from *Anemonia viridis* (formerly known as *Anemonia sulcata*) are not present in Nv1,[16] although some of the key residues in Type-I anemone toxins[17] are conserved in Nv1.

Transcript analysis indicate that multiple Nv1 loci are transcribed at all developmental stages of *N. vectensis*, but transcripts are spliced only in the polyp stage,[16] making it unlikely that the embryo and planula stages produce Nv1 and providing a rare example of intron retention in the early developmental stages of this cnidarian.

The genome of *N. vectensis* also codes for four peptide domains with clear sequence similarity (28–41% identity) to the potassium channel blocker ShK toxin.[14] None of these sequences contains the KY functional dyad known to be important for K^+-channel blockade;[18,19] although similar elements are evident (QY, KW, TY, RF). The targets of these peptides have not yet been identified. Numerous ShK-like domains are found in nature, both as stand-alone peptides and domains within larger proteins,[24] and the functions of most of them remain to be clarified. As with the peptides encoded by the *N. vectensis* genome, many of the ShK-like domains found in other organisms lack the KY dyad. In common with many toxin folds, the ShK structure is clearly a robust scaffold on which a diverse range of functional epitopes can be displayed.

OTHER GENOMICS ANALYSES

Although *N. vectensis* is the only sea anemone for which the genome has been fully documented, useful insights are emerging from focused sequence comparisons in other species. For example, although the amino acid sequences of Av2 and AP-A (from *Anthopleura xanthogrammica*, and *A. elegantissima*) are highly similar,[17] Moran et al.[15] noted that their signal peptides differ, with that of AP-A being very similar to those of other Type-I toxins, whereas that of Av2 is closely related to the signal peptide of Av7, a Type-III toxin. They propose that the ancestor gene of Av2 and AP-A contains a signal peptide similar to those of AP-A and other Type-I toxins, and that subsequently the ancestor gene of Av2 lost this signal peptide sequence and acquired the signal peptide of Av7 in a lineage-specific manner. The fact that Av7 has a more complex gene structure than that of Av2 provides further support to the suggestion that a Type-III neurotoxin gene might have been the donor of the 5′-UTR and the region encoding the signal peptide of Type-1 neurotoxins in *A.viridis*.

Expressed sequence tags or ESTs are short segments of cDNA sequences that effectively provide a snapshot of the transcriptome of a particular tissue at a given time. Kozlov and Grishin[10] describe the use of single residue distribution analysis (SRDA) to identify polypeptide toxins in the EST database of the symbiotic anemone *Anemonia viridis*.[25] Searches of nearly 40,000 ESTs were undertaken using motifs based on key Cys residues and other motifs targeting the actinoporin family. New sequences and sequences with high homology to the already described toxins were identified and the precursor sequences were determined for two known toxins. Homologous peptides that differ by single or multiple amino acid substitutions were also found, as expected for venom components. In addition to 23 previously reported peptide toxins, 43 novel sequences were discovered, including short peptides with regulatory neuronal function and several groups of toxin-like polypeptides. As an example of the weaknesses and strengths of EST analyses, the known K^+-channel blocker kaliseptin (AsK) is not found in the library, although 11 similar peptides are.[10]

Shiomi et al.[31] used molecular cloning to elucidate the primary structures of Type-1 K^+-channel toxins, based on the sequences of cDNAs encoding representative K^+-channel toxins from the families Stichodactylidae and Actiniidae (Type-2 K^+-channel toxins are related to the Kunitz-type protease inhibitors and Type-3 toxins include the shorter BDS family,[8] as illustrated in Fig. 1). Twenty-one species of sea anemones were screened for Kv1 toxins by competitive inhibition of the binding of ^{125}I-α-dendrotoxin to rat synaptosomal membranes, with 11 species (two Actiniidae, one Hormathiidae, five Stichodactylidae, and three Thalassianthidae) found to be positive. Full-length cDNAs from three species of Stichodactylidae and three species of Thalassianthidae were cloned by a combination of RT-PCR and 3′- and 5′-RACE. The six toxins identified share > 90% sequence identity with one another and with ShK (Fig. 1). Putative signal and prosequences were also determined, the latter ending with a Lys-Arg pair.

By using a functional assay to guide the selection of species for cDNA analysis,[31] this study partially addressed one of the major issues associated with genomic analyses, namely, whether a peptide encoded by the genome is expressed at significant levels, and, if so, where and when in the life cycle of that species. An additional challenge is the identification of posttranslational modification, although this seems to be much less important for sea anemone peptides than for their counterparts in cone snails. For example, among the peptide sequences documented in Fig. 1, the only posttranslational modification identified is hydroxylation of Pro residues, and even that occurs in only three of those peptides, and only once in each. As a complement to genomic analyses, in-depth proteomic analyses of venoms are required to confirm the presence of particular peptides, while binding, electrophysiological, and other functional assays are required on naturally occurring, synthetic or recombinant peptides to characterize their targets and actions.

FIGURE 1 Representative K^+-channel toxin sequences from sea anemones.[4,19,29,31] UniProt accession numbers and entry names are given. Of the Type-1 toxins, ShK is from *Stichodactyla* (formerly *Stoichactis*) *helianthus*, HmK from *Heteractis* (formerly *Radianthus*) *magnifica*, CaK from *Cryptodendrum adhaesivum*, TaK from *Thalassianthus* aster, AETX K from *Anemonia erythraea*, AeK from *Actinia equina* and BgK from *Bunodosoma granulifera*. The KY functional dyad is underlined in the Type-1 toxins. The Type-2 toxin AsKC 1 is from *Anemonia sulcata* (now *Anemonia viridis*) and APEKTx1 from *Anthopleura elegantissima*. The Type-3 toxins illustrated are BDS-I and -II from *Anemonia sulcata*, APETx1 from *Anthopleura elegantissima* and Am II from *Antheopsis maculata*. Am II contains a Gly-Arg extension at the C-terminus that is believed to be removed from the precursor protein during processing. The entry for Am II is boxed to highlight the fact that the target channel for this toxin has not yet been identified,[29] even though its sequence (and presumably structural) similarity to the other Type 3 K^+-channel toxins shown here suggests that its target may be one of the specialist K^+-channels affected by those toxins. Of the Type-4 toxins, SHTX I and II are from *Stichodactyla haddoni*, Bcg III from *Bunodosoma cangicum* and Am I from *Antheopsis maculata*. Unidentified N-terminal residues for SHTX I and II and hydroxyPro for position 6 of SHTX I and Am I are denoted by 'X' and 'O', respectively.[7] The amino acid sequence shown for Bcg III is that deposited in UniProt (P86467; TX234_BUNCN); this differs slightly in the C-terminal region from the sequence for Bcg 23.41 shown in Figure 2 of Zaharenko et al.[33] The effects of Bcg 23.41 on crab leg nerve compound action potentials are similar to those of the Type-1 K^+-channel blocker ShK, although Bcg 23.41 is much less potent.[33] The entry for Am I is boxed to highlight that it probably acts on Na^+- rather than K^+-channels; it is lethal to crabs (LD_{50} 830 μg/kg) although much less potently than other anemone Na^+-channel toxins. The amino acid sequence shown here for Am I is taken from Figure 2 of Honma et al.[7]

NEW PEPTIDES FROM ANEMONES

The family tree of peptide toxins from sea anemones is dominated by those acting on Na^+-channels, including VGSC and ASIC channels.[3,8,19,30] Fewer K^+-channel toxins have been identified, although the number is increasing rapidly.[4,31] Honma and Shiomi[8] categorize the K^+-channel toxins as Type-1, exemplified by ShK (Fig. 1), Type-2, which are structural homologs of the Kunitz-type protease inhibitors and often retain protease inhibitory activity, and Type-3, represented by BDS-I and -II and APETx1, with 41 or 42 residues. To avoid confusion with sea anemone-derived Na^+-channel toxins and other anemone venom peptides, this nomenclature could perhaps be modified to Types K1, K2, and K3, but the original designations will be retained in this chapter. In any case, this classification has been extended already to Type-4[4] to accommodate two homologous peptides, SHTX I and II, from *S. haddoni*, which have 28 residues and two disulfide bridges (Fig. 1)[7] and one from *Bunodosoma cangicum*.[33] SHTX I and II are not lethal to crabs at 1000 μg/kg, although SHTX II inhibits the binding of ^{125}I-α-dendrotoxin to synaptosomal membranes, albeit weakly, and was therefore classified as a K^+-channel toxin.[7]

Shiomi et al. reported the isolation and cDNA cloning of a Type-1 K^+-channel toxin (AETX K) from *Anemonia erythraea*.[6] AETX K is an interesting member of the family Actiniidae, with a sequence much more similar to those of ShK and HmK (i.e., lacking the four-residue insert after the second Cys) than other representatives from this family, such as AeK and BgK (Fig. 1).

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

As shown in Fig. 1, Type-1 K^+-channel toxins lacking the four-residue insert come mostly from anemones of the families Stichodactylidae and Thalassianthidae, while other representatives from the Actiniidae family include this insert.[6,31]

A new Type-2 K^+-channel blocker has been reported by Tytgat et al.[22] APEKTx1 from *Anthopleura elegantissima*, containing 63 residues and three disulfide bridges (Fig. 1), selectively blocks Kv1.1 channels with an IC_{50} of 0.9 nM, as well as inhibiting trypsin with a K_d of 124 nM. It is not clear whether the trypsin inhibitory activity of APEKTx1 (or any of the other Type-2 K^+-channel toxins) is physiologically important, but its selectivity for Kv1.1 over a wide range of other K^+-channels tested is intriguing.

APETx1, which acts on voltage-gated human ether-a-go-go-related gene (hERG) K^+-channels, was first isolated from *Anthopleura elegantissima* about a decade ago, but more recently, its mechanism of action and binding site have been characterized further.[35] Its effects are similar to those of known gating modifier toxins (e.g., hanatoxin) on the Kv2.1 channel, shifting the voltage-dependence of hERG activation in the positive direction and suppressing current amplitudes elicited by strong depolarizing pulses that maximally activate the channels. Its binding site is distinctly different from that of pore-blocking toxins; APETx1 seems to interact with the hERG channel in the vicinity of the S3b-S4 region of the channel.

BcIV, a new paralyzing peptide obtained from *Bunodosoma caissarum*,[21] contains six Cys residues that presumably form three disulfide bonds. BcIV has 45 and 48% identity to APETx1 and APETx2, respectively, from *Anthopleura elegantissima* and 42% with Am II and BDS-I and -II from *Antheopsis maculata* and *Anemonia sulcata*, respectively. The target is yet to be identified but is proposed to be a Na^+-channel. Despite its sequence similarity to K^+-channel toxins, BcIV does not seem to act via these channels although further assays are clearly warranted to resolve this.

A detailed investigation has been undertaken subsequently into the effects of Bc III, also from *Bunodosoma caissarum*, on sodium currents in rat dorsal root ganglia;[27] as expected, increases are observed in the sodium current inactivation time course and current peak amplitude. Evidence was also found for this and two related anemone toxins that the binding affinity may be reduced in a voltage-dependent manner, as observed for scorpion α-toxins.

Several new Na^+-channel toxins have also been characterized. Four Type-II Na^+-channel toxins have been described from three species of sea anemones (*Cryptodendrum adhaesivum*, *Heterodactyla hemprichii*, and *Thalassianthus aster*) belonging to the family Thalassianthidae.[12] Extracts of all three species exhibit potent lethality to crabs, and all of the isolated toxins show this activity. These toxins were named according to the systematic nomenclature proposed by King et al.,[9] as follows: δ-TLTX-Ca1a, δ-TLTX-Hh1a and δ-TLTX-Ta1a.

AP-C (ApC) is by no means a new peptide, having been described first in 1981,[17] but its effects on neuronal sodium currents have now been documented.[26] As expected, AP-C delays Na^+-channel inactivation, but with an IC_{50} of 1.25±0.9 μM on mammalian neurons, making it more potent than other Type-I Na^+-channel toxins (e.g., ATX II (AsII) 9.6 μM, BgII 4.1 μM and BgIII 11.9 μM).

Proteomics has been applied to the neurotoxic fraction from *Bunodosoma cangicum*, with peptides being fractionated by RP-HPLC, identified by ESI and MALDI-TOF mass spectrometry, and, in some cases, sequenced by Edman methods.[33] Of those sequenced partially or completely, three are Type-I Na^+-channel toxins, three are Type 3 K^+-channel toxins, and three have masses around 3kDa and show no sequence similarity to known anemone toxins. Although these peptides show clear sequence homology to one another, the numbers and locations of their Cys residues vary, with two of the peptides containing two putative disulfides and the third just one. Testing of one of these on crab leg nerve compound action potentials gives results suggestive of K^+-channel blockade, but further studies are clearly required to clarify the activity and classification of these peptides.

Oliveira et al.[20] investigated the selectivity of three Type-I Na^+-channel toxins (ATX II, AFT II from *Anthopleura fuscoviridis* and Bc III from *Bunodosoma caissarum*) on $Na_V1.1$ to $Na_V1.6$ channels expressed in HEK293 cells. The detailed electrophysiological characterization provides a useful guide for choosing which toxin to use to study a given Na_V1 subtype, and highlights the importance of individual residues in this family of toxins, with the substitution of Lys36 in ATX II for Ala in AFT II having significant effects on some aspects of the channel response but not others.

A similar approach was taken to characterize cangitoxin II (CGTX II) and two new Na^+-channel toxins, δ-AITX-Bcg1a and δ-AITX-Bcg1b, all from *Bunodosoma cangicum*.[34] The selectivity of these toxins is the highest for $Na_V1.5$, followed by that of $Na_V1.6$ and 1.1. The authors also speculate that the binding site for these toxins is not restricted to the putative site 3, which lies between segments S3 and S4 of domain IV of the Na^+-channel.

There are some discrepancies in the activities reported for the cangitoxin family. These are discussed in the report by Zaharenko et al.[32] that describes the isolation and characterization of cangitoxins II and III, which differ from one another in an Arg to His substitution at position 14, and from cangitoxin itself by an Asn to Asp substitution

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

at position 16. In view of the nearly identical sequences of cangitoxin and cangitoxins II and III, it seems highly unlikely that cangitoxin could have a different biological activity profile from cangitoxins II and III.

Grishin et al.[2] identified a potentially interesting peptide in *Heteractis crispa* collected from the Seychelles islands. APHC1 is a 56-residue peptide with high sequence similarity to the Kunitz-type protease inhibitor family, which includes not only bovine pancreatic trypsin inhibitor and anemone-derived serine protease inhibitors but also dendrotoxin-α and Type-2 K^+-channel blockers from sea anemones such as kalicludine. APHC1 is a modulator of TRPV1 channels, causing partial antagonism of capsaicin-induced currents (32% inhibition) with an EC_{50} of 54 nM (capsaicin being a selective agonist of the TRPV1 receptor). *In vivo*, APHC1 at 0.1 mg/kg significantly prolongs tail-flick latency and reduces capsaicin-induced acute pain. Thus, APHC1 should be a useful tool for further studies of TRPV1, particularly if mutants could be found that blocked more of the current.

Finally, we draw attention to the two new peptide toxins from the acrorhagi of *Actinia equina*[8] These organs, which are found in anemones from the family Actiniidae, form a ring around the base of the tentacles and are used not for defense or the capture of prey but rather in intra-specific aggression. By following crab toxicity, Honma et al. isolated acrorhagins I and II (50 and 44 residues, respectively) and determined their amino acid sequences from their cDNA. Acrorhagin I shows no sequence homology with any known toxins, whereas acrorhagin II shows limited similarity with hainantoxin-I from the Chinese bird spider *Selenocosmia hainana*, ω-conotoxin MVIIB from the cone snail *Conus magus* and Tx 3-2 from the Brazilian armed spider *Phoneutria nigriventer*, although the locations of the six Cys residues are not fully conserved between acrorhagin II and the other three toxins. Thus, the acrorhagi may represent a new source of potentially interesting peptide toxins although it is clear already that not all species with acrorhagi contain toxins.[29] Several protease inhibitors have also been isolated from acrorhagi of *Actinia equina*, *Anthopleura xanthogrammica*, and *Anthopleura fuscoviridis*.[29]

STRUCTURES

The solution structure has been determined for CgNa, a 47 residue toxin from the giant Caribbean anemone *Condylactis gigantea*.[28] The structure displays significant homology with both Type-I and Type-II anemone toxins,[17,19] although several unique residues create negatively charged surface patches that disrupt a surface-exposed cluster of hydrophobic residues present in other anemone-derived toxins described to date. CgNa delays the inactivation of tetrodotoxin-sensitive VGSCs.

The Type-III Na^+-channel toxins PaTX, Da I and II (from *Dofleinia armata*) and Er I (from *Entacmaea ramsayi*) all have eight Cys residues, and presumably four disulfide bridges,[8] whereas ATX III (As III, Av3) has only three disulfides, even though there is clear sequence similarity between it and the other four peptides. There is ample precedent for the inclusion of a fourth disulfide without modifying the structural scaffold determined by the first three disulfides. The structure of one of the four disulfide members of this family is eagerly awaited for comparison with the structure already determined for ATX III.[19]

As noted previously,[19] the structures of BDS-I, APETx1, and APETx2 are similar to those of the Na^+-channel toxins such as AP-A but quite different from the ShK/BgK family of K^+-channel toxins. Sea anemones are capable of using a common structural scaffold to create blockers of distinct targets (AP-A, APETx1 and APETx2 act on VGSC, HERG, and ASIC channels, respectively), while also using different scaffolds (all-β in APETx1 vs all-α in ShK) to block similar channels (HERG and Kv1, respectively).

The recent crystal structure of a bacterial sodium channel provides hope that structures will follow for VGSCs from higher organisms, as has proven to be the case for potassium channels. The availability of these structures, or at the very least of improved models based on crystal structures from lower organisms, will pave the way for a detailed understanding of the sites of interaction of sea anemone toxins with mammalian VGSCs. Complementary mutagenesis studies, where the effects of concerted mutations of residues on both the toxin and the channel are quantified, will also clarify the energetic contributions of pairwise interactions to the free energy of binding. Studies of this sort will provide an excellent basis for understanding the vast body of knowledge on the roles of individual residues in the Type-I and Type-II Na^+-channel toxins that has accumulated over several decades from amino acid sequence comparisons, chemical modification studies, and, most recently, site-directed mutation of recombinantly expressed peptides.[3,13,17,30]

THERAPEUTIC APPLICATIONS

The exciting prospects for development of ShK and synthetic analogs as selective immunosuppressants for the treatment of autoimmune diseases such as multiple sclerosis, rheumatoid arthritis, and type-1 diabetes mellitus have been reviewed.[5] The basis for this activity is that $CCR7^-$ effector memory T (T_{EM}) cells express Kv1.3 channels that play a major role in their activation, and blocking these channels preferentially inhibits the activation of these cells, with little or no effects on $CCR7^+$ naïve and central memory T cells. ShK, a 35-residue peptide isolated from the Caribbean sea anemone *Stichodactyla*

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

helianthus (Fig. 1), blocks Kv1.3 channels at pM concentrations, albeit with little selectivity for Kv1.3 over closely related Kv1 channels. Extensive mutagenesis studies combined with elucidation of the structure of ShK forms the basis for models of ShK docked with Kv1.3, which leads in turn to the development of new analogs with improved selectivity and increasing stability. One of these analogs, ShK-186, is scheduled to begin first-in-man phase-1 trials.

The actinoporins have been evaluated as the toxic warheads of immunotoxins directed against tumor cells and in various other biomedical applications.[11] The initial promise of the anthopleurins and related Type-I Na^+-channel toxins in the cardiovascular field has not been fulfilled, in part because of arhythmogenic activity in the heart.

To date, there is a paucity of examples of therapeutic or biomedical applications of sea anemone venom peptides. Moreover, the diversity of peptides found in these venoms does not match with those of cone snails or spiders. However, as pointed out by Honma and Shiomi,[8] only some 40 of the >800 recorded species of sea anemones have been investigated in any detail. The number of species investigated has increased since then, but there is every reason for optimism that the remaining 90% of species will provide interesting new peptides, some of which will no doubt have therapeutic potential. The application of state-of-the-art transcriptomics and the availability of complete genome sequences for other species of sea anemones will greatly accelerate the identification of such peptides, and continual improvements in the efficiency of peptide synthesis and recombinant expression will facilitate the production of such peptides for biological evaluation, although the challenge will remain to define the native disulfide connectivities for novel sequences containing multiple cysteine residues.

ACKNOWLEDGMENTS

The author dedicates this chapter to colleagues Laszlo Béress and Ted Norton, whose enthusiasm for sea anemone toxins helped stimulate the author's enduring interest in this field.

Chapter 61

Snail Peptides

Baldomero M. Olivera, Julita S. Imperial and Gisela P. Concepcion

ABSTRACT

The venoms of the 500–700 species of cone snails (genus *Conus*) each contain approximately 100 relatively small (10–30 AA), disulfide-rich peptides, often with unusual posttranslationally modified amino acids (e.g. γ-carboxyglutamate, 6-bromotryptophan, D-phenylalanine). Most pharmacologically characterized *Conus* peptides selectively target a specific ion channel or receptor isoform in the nervous system. Conopeptides are widely used for basic neuroscience research; a few have reached human clinical trials, and one is an approved drug for intractable pain. Cone snails have only a minor fraction of venomous marine molluscan biodiversity. Biochemical characterization or transcriptome analysis of venoms from four other conoidean lineages shows the same remarkable complexity of peptides as in *Conus* venoms. Because an interdisciplinary approach ("concerted discovery") for the discovery of molluscan venom peptides with novel targeting selectivity has been established, these should become increasingly important pharmacological research tools in neuroscience.

BIODIVERSITY OF VENOMOUS MOLLUSCS AND DISCOVERY OF THEIR VENOM PEPTIDES

Marine snails are not the first group of venomous animals that come to mind when venoms are discussed. However, the total number of species of venomous marine gastropod snails is surprisingly large; in fact, the most biodiverse of all molluscan lineages is probably the superfamily Conoidea (or suborder Toxoglossa, "toxoglossates"). These are venomous predators comprising many thousands of described species (with probably an even larger number still undescribed). Toxoglossates are believed to have originated in the Cretaceous; several toxoglossan stem groups can be confidently identified from fossil beds of this geologic period. However, the major adaptive radiations of toxoglossates took place in the Cenozoic, giving rise to the major living lineages.

Traditionally, the superfamily Conoidea has been subdivided into three groups, the cone snails (family Conidae), augers (family Terebridae), and turrids (family Turridae, *sensu lato*). Of these, the turrids are the least well characterized and most heterogeneous. Present estimates suggest that there are 500–700 cone snail species, 300–500 auger species, and very probably >10,000 turrids (broadly defined). In a systematic biodiversity survey in New Caledonia, Bouchet and coworkers found only 51 *Conus* species but >1500 "turrid" species, most not yet named.[4] If this were the true ratio for locations in the tropics, because both terebrids and cone snails are largely tropical groups (only turrids have adapted to cold-water environments), the estimate of >10,000 turrid species may very well be a conservative one. In some respects, turrids were defined by exclusion, that is, a toxoglossate that is neither a cone snail nor a terebrid (the last two groups have shells with easily recognizable morphology, see Fig. 1). Primarily based on new molecular phylogenetic data, it has been proposed that the species assigned to the classical family Turridae be split into 12 newly designated family groups.[3]

The current information about peptides from molluscan venoms is highly skewed and not at all aligned to the actual number of species in each venomous snail lineage. The peptide toxins characterized from toxoglossan venoms to date are almost exclusively from cone snails; as a consequence, this review largely focuses on conopeptides ("conotoxins") from *Conus* venoms. However, peptide toxins from other molluscan venoms are beginning to be investigated, and because of their great pharmacological potential (which remains almost totally untapped at the present time), an overview of peptides from these other groups of venomous molluscans is presented for the very first time in this chapter. The neglect of other venomous molluscs except for cone snails in the past resulted, in part, from the inaccessibility of sufficient venom for conventional biochemical analysis. The larger size of *Conus* species, and the relative abundance of some cone snails in shallow water marine habitats made *Conus* venoms much more accessible for standard purification and peptide characterization. However, newer interdisciplinary methods for the discovery of peptides have made it more feasible to access the peptides from the neglected groups of venomous molluscs. In particular, the "concerted discovery" platform developed[23] for *Conus* peptide discovery can easily be adapted for other groups of venomous

molluscs. Instead of requiring venom from hundreds of specimens of a particular species, peptide discovery can, in principle, be performed using a single specimen of a venomous snail, even one that is tiny. This radically changes the range of venomous molluscan biodiversity that can be realistically investigated.

However, the efficient application of the concerted discovery platform requires knowledge of both the molecular phylogeny of the family of venomous snails being analyzed, and basic information regarding the peptide superfamilies expressed in the venom ducts of species in the family. With this framework, a transcriptomic analysis of venom ducts, coupled with chemical synthesis and/or expression of the predicted peptides makes it possible to produce the individual venom peptides for further functional characterization. As discussed in the following sections, a particular family of venom peptides expressed in a group of related molluscans targets a corresponding family of ion channels, receptors or transporters. Consequently, the successful characterization of any individual member of a widely expressed venom peptide family becomes a beacon for the further pharmacological characterization of all other peptides in the family. Thus, for effective discovery, molecular phylogeny, identification of venom peptide gene superfamilies, transcriptomics, peptides synthesis and the functional characterization of individual peptides need to be seamlessly integrated together.

DISCOVERY OF CONOTOXINS

The first conotoxins were purified and characterized from the venom of *Conus geographus*, a dangerous species of *Conus* that has caused human fatality. The first peptides investigated caused paralysis in either fish or mice and were shown to target ion channels that are important for neuromuscular transmission.[21] The discovery by Craig Clark, then a 19-year-old student at the University of Utah that the different components of *C. geographus* venom elicited different behavioral phenotypes when injected into the central nervous system of mice led to the characterization of a larger group of *Conus* peptides, mostly from the venoms of fish-hunting cone snails. These had biological activity on mammalian neurons,[22] and some were subsequently developed for direct therapeutic application. One peptide from *Conus magus*, ω-conotoxin MVIIA, was purified because it caused tremors in mice; it was approved as a drug for severe pain in December 2004 (commercial name Prialt).[19,34]

Initially, the discovery of each new conotoxin required biochemical purification from venom. Unusual posttranslationally modified amino acids were identified in the first group of conotoxins characterized.[7] As more cDNA clones encoding conotoxins were elucidated, a molecular cloning/PCR approach for identifying novel conotoxins became feasible; the first venom peptide characterized solely on the basis of the predicted sequence from a cDNA clone was ω-conotoxin MVIIC.[12] However, a problem with this approach is that if the conotoxin is posttranslationally modified, knowing the encoding DNA sequence does not necessarily permit an accurate prediction of which amino acids are posttranslationally modified.

As detailed below, it is highly probable that there are well >50,000 different peptides in the venoms of living cone snails, with an ever accelerating rate of discovery of new peptides. At this time, there are probably amino acid sequences of >2500 *Conus* peptides available, but of these, only a small minority have been biochemically characterized, and the mechanism of action of a miniscule fraction of those has been elucidated.

PRECURSOR STRUCTURE, EXPRESSION, AND PROCESSING: CONOTOXIN SUPERFAMILIES

The *Conus* peptides characterized over the last 25 years provide an overview framework for all conoidean venoms. The great majority of biologically active *Conus* venom components are peptides, initially synthesized through ribosomal translation as polypeptide precursors, and posttranslationally processed to yield the mature, biologically active venom peptides. *Conus* venoms are unusually complex; every *Conus* species can express its own repertoire of approximately 100–200 different peptide toxins in the venom duct. Because there is virtually no molecular overlap between the peptides found in the different *Conus* species, there are >50,000 different peptides in living cone snail venoms. The number of different venom peptides evolved by all species in the superfamily Conoidea is likely to greatly exceed 10^6.

The molecular genetic work done on *Conus* peptides provides a simplifying framework; the majority of the 100–200 peptides in an individual conoidean venom are generally encoded by a few gene superfamilies, with all peptides that belong to the same superfamily having a number of

FIGURE 1 Shells of venomous marine snails from which peptides have been characterized. As described in the text, four classes of venom peptides have been characterized. Best known are **conopeptides** ("conotoxins") that come from the venoms of cone snails such as the geography cone, *Conus geographus* (A) and the magician's cone, *Conus magus* (B). Other classes of venom peptides include **clathurellipeptides** from clathurellid conoideans such as the recently described *Lienardia totopotens*, Rosenberg, 2011(C); **crassipeptides** from crassispirid snails such as *Crassispira cerithina* (D); **turripeptides**, from the family Turridae such as *Gemmula speciosa* (E), *Gemmula diomedea* (F); *Gemmula kieneri* (G), *Gemmula sogodensis* (H), and *Lophiotoma olangoensis* (I), **augerpeptides** from species in the family Terebridae such as *Hastula impages* (J), and *Terebra subulata* (K). See color plate 17.

shared characteristics [for a review, see Ref. 31]. is now well established that the genes encoding *Conus* peptide toxins are expressed in the epithelial cells of cone snail venom ducts and initially translated as prepropeptide precursors, with an N-terminal signal sequence, an intervening "pro" region and at the C-terminal end, the mature toxin in single copy. All members of a particular *Conus* peptide superfamily share a remarkable degree of sequence identity in their signal sequences. This is highly unusual, because in most gene families encoding secreted polypeptides, the signal sequences are the least conserved elements.

Like most peptidic toxins in animal venoms, *Conus* peptides are generally disulfide-rich. However, three characteristics differentiate conotoxins from other venom polypeptides. The mature toxins from *Conus* venoms are unusually small, typically 10–30 amino acids. The fully processed gene products of some major *Conus* peptide gene superfamilies are among the smallest biologically active gene products known; although many thousands of peptides in *Conus* venoms are probably between 10 and 20 amino acids, the great majority of these will be conformationally rigid because of the multiple disulfide crosslinks.

Another unusual feature is the presence, sometimes at high density, of posttranslationally modified amino acids. *Conus* peptides are first translated as longer precursors, and proteolytic processing and the formation of disulfide linkages are the required steps in maturation. Other posttranslational events that may occur at the ends of a mature *Conus* peptide toxin are C-terminal amidation and the cyclization of glutamine to pyroglutamate at the N-terminus, well-characterized modifications that occur in many other peptides.

However, many *Conus* peptides have nonstandard amino acids that are derived from a standard amino acid by the action of a modification enzyme. Table 1 shows the diverse set of posttranslationally modified amino acids discovered in *Conus* peptides so far; the presence of these unusual amino acids is one hallmark of peptide toxins from this group of venomous animals. The posttranslational modification of conotoxins has been reviewed.[5,7] The reader is referred to these more comprehensive reviews for a discussion of mechanisms of posttranslational modification, and the probable function of individual posttranslationally modified amino acids.

Another characteristic of *Conus* peptides is that a large diversity of "peptide folds" is found in each venom. In many animal venoms, polypeptide toxins have a dominant structural motif (e.g. the "three finger" motif of snake venom toxins). The characteristic arrangements of cysteine residues in the primary sequence of the mature *Conus* peptide toxins ("Cys patterns") reflect the patterns of the disulfide cross-links, and therefore an overall structural framework. All peptides belonging to the same conotoxin superfamily will typically have one major "Cys pattern"; additional minor Cys patterns may be observed in some superfamilies. These different Cys patterns reflect different structured folds in peptides encoded by the different conopeptide gene superfamilies. Thus, in *Conus* venoms, a greater diversity of peptide "folds" are found than is the case for most other animal venoms. The vast majority of *Conus* venom peptides are small, disulfide-rich and conformationally rigid. A small minority of *Conus* peptides lack disulfide crosslinks and are presumably much more flexible. There are preliminary indications that other conoidean groups may have a higher proportion of venom peptides that lack multiple disulfide crosslinks.

Examples of two different superfamilies, the O- and the A-conotoxin gene superfamilies, are shown in Tables 2 and 3. All peptides that belong to the A-superfamily have a highly conserved signal sequence different from that of the peptides of the O-superfamily. The arrangement of Cys residues differs between the two superfamilies: in the O-superfamily, only one major Cys pattern (-C-C-CC-C-C--) is found, reflecting an ICK (inhibitory cys knot) structural motif. A different major Cys pattern (-CC-C-C-) occurs in most peptides of the A-superfamily, but one with 3-disulfides (-CC-C-C--C-C-) is also found in a minority of the A-superfamily peptides.[26] The Cys patterns of the different conotoxin superfamilies were reviewed by Terlau and Olivera,[31] and an updated tally of all *Conus* peptide frameworks is maintained at the Conoserver website.[16]

There may be multiple peptides (>20) that belong to a single *Conus* peptide superfamily expressed in an individual venom duct. The major conotoxin gene superfamilies are widely distributed over the 500–700 different species in the genus. Some conotoxin superfamilies have been intensively investigated by molecular methods; thus, >500 different sequences are known that belong to the A-conotoxin superfamily at the present time, even though only a small minority of *Conus* species have been examined. A website with all conotoxin sequences that have been published, with appropriate references to the primary literature, is now available;[16] the reader is referred to this website to access the primary literature for individual peptide sequences discussed in this review.

A salient feature of *Conus* peptide gene superfamilies is that they undergo an unprecedented rate of accelerated evolution—as a result, there is essentially no molecular overlap between the venom peptides found in two different species of cone snails. The preliminary evidence is that this will be generally valid for all toxoglossan venom peptide genes.

It has been suggested that this rapid gene hypermutation can be anticipated for a wider class of genes, to which the genes that encode all toxoglossan venom peptides belong. This class of genes are the exogenes;[20] the products of exogenes act exogenously, not within the organism that produced

them. Because the spectrum of biotic interactions changes as species diverge, it has been postulated that these are the genes that must encode gene products that diverge functionally at the species level.

DEFINITION OF CONOTOXIN FAMILIES, RECEPTOR TARGETS, AND STRUCTURES

As described in the previous section, peptides from a given conotoxin superfamily with the same Cys pattern are believed, to a first approximation, to have generally similar three-dimensional structures. Disulfide crosslinks are a dominant determinant of how the polypeptide backbones will fold; consequently, peptides sharing a Cys pattern will generally have similar folds. Thus, all peptides in a conotoxin superfamily probably have similar overall conformations. Several conotoxin structures have been published.[8,9]

Conus peptide superfamilies are subdivided into discrete families. The salient feature that distinguishes different conotoxin families belonging to the same superfamily is pharmacological: to which family of ion channels, receptors or transporters are the peptides targeted. In general, all the peptides in a particular family have the same class of receptor targets; peptides in different families, but in the same superfamily, will have divergent targeting specificity (even though they may be similar structurally). Thus, in the M-superfamily, Ψ-conotoxin family peptides inhibit nicotinic acetylcholine receptors, μ-conotoxin family peptides block voltage-gated sodium channels, and κM-conotoxin family peptides are voltage-gated potassium channel antagonists (Tables 2 and 3). Two different conotoxin families may target the same class of receptors; these invariably belong to different gene superfamilies. Thus, both the Ψ-conotoxin and the α-conotoxin families are nicotinic acetylcholine receptor antagonists[18] but belong to the M- and A-conotoxin superfamilies, respectively, and are structurally unrelated (in this particular case, peptides from the two families probably bind to different sites on the nicotinic acetylcholine receptor complex).

Some conotoxin families are widely distributed over the entire genus *Conus*; examples of these are the α-conotoxins that target nicotinic acetylcholine receptors and the δ-conotoxins that target voltage-gated Na channels. By contrast, other conotoxin families seem to be very restricted in their phylogenetic distribution within *Conus* and are found only in a small group of closely related *Conus* species; this

appears to be particularly true of those conotoxin families that target voltage-gated K channels.

Based on their major prey, the 500–700 species of cone snails are usually divided into fish-hunting, worm-hunting, and snail-hunting species.[25] However, it has become apparent that these are not monophyletic groups, with each derived from a single common ancestor. Rather, there are distinct groups of fish-hunting cone snails and an even greater number of divergent groups of worm-hunting *Conus* species.

The subgeneric group to which a cone snail species belongs is strongly predictive of the conotoxins to be found

in its venom. For example, different groups of fish-hunting cone snails appear to have different specialized toxin families to target the neuromuscular nicotinic acetylcholine receptor. Although predicting which conotoxins will be found in the venom of a particular *Conus* species is far from a precise science, the assignment of a species to a particular taxonomic subdivision within the genus *Conus* has proven to be the most reliable indicator of the peptide toxin families likely to be present. This has made the molecular phylogeny of *Conus* a powerful catalyst for accelerating discovery. However, individual species often have evolved idiosyncratic venom components not found at all even in very closely related *Conus* species. This is why purification and characterization of peptides from venoms should

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

continue to reveal peptides with unexpected pharmacological targets.

BIOLOGICAL MECHANISMS: THERAPEUTIC APPLICATIONS

The biological effects of a particular conoidean venom are a function of the physiological targets of individual toxins expressed in that venom. The known receptor targets of molluscan venom peptides have been elucidated only for a small fraction of *Conus* peptides. Presently, these fall into three broad classes: (I) ligand-gated ion channels; (2) voltage-gated ion channels; and (3) targets other than those that belong to the two large groups of ion channels above. We discuss conotoxins specific for these target classes, and examples are provided for individual conotoxins with receptor targets in each of the three classes.

A large number of conotoxins that inhibit members of the ligand-gated ion channel superfamily have been identified; the largest group is nicotinic acetylcholine receptor antagonists. A surprisingly wide range of structural variation is seen for conotoxins that inhibit nicotinic receptors. The α-conotoxins comprise one well-characterized family;[2,26] these are competitive antagonists of various nicotinic acetylcholine receptor subtypes. Other classes of toxins that antagonize nicotinic receptors are the αA-conotoxins that have a different disulfide bonding framework (but also belong to the A-superfamily), and the αS-conotoxins, which are large, genetically unrelated toxins.[30] The last are more closely related to the σ-conotoxins, which target another class of ligand-gated ion channels, the serotonin (5HT3) receptor. In addition, many venom peptides target ion channels in the glutamate receptor superfamily. Peptides in the conantokin family target NMDA receptors, a major class of glutamate receptors. The structure of these unusual peptides is stabilized by a posttranslationally modified amino acid, γ-carboxyglutamate, rather than by disulfide crosslinks (which are generally absent in the conantokins). The presence of the γ-carboxyglutamate side chains in every three or four amino acids confers a stable helical structure to these peptides in the presence of Ca^{2+}. Some examples of these classes of *Conus* peptides are shown in Table 2.

Conotoxins that target various voltage-gated ion channels are shown in Table 3. The most widely used conotoxins for basic neurobiological research are the ω-conotoxins that block specific voltage-gated Ca channel subtypes. Conotoxins that target Na channels either inhibit conductance (such as the μ- and μO-conotoxins) or inhibit channel inactivation (the δ-conotoxins). Toxins with differential specificity for certain Na channel subtypes have been described.[35] Conotoxins that target voltage-gated K channels are particularly diverse structurally: three different groups of fish-hunting cone snails have different conotoxin families, all targeted to a single subfamily of K channels, the Shaker (or Kvl) channels.[13]

Although most established targets of conotoxins are either voltage-gated or ligand-gated ion channel, a spectrum of *Conus* peptides with other molecular targets have been identified; examples are given in Table 4. Several *Conus* peptides are known to affect the function of G-protein-coupled receptors (GPCRs). The *Conus* peptides shown to target GPCRS are from a diverse set of families and no major family of *Conus* peptides that targets diverse GPCRS has been identified so far. In addition, *Conus* peptides may target catecholamine transporters.[28]

Mechanisms of individual conotoxins provide the most reductionist insights required to understand the physiological activity of the whole venom. It has become clear that groups of peptides in the venom act together to more efficiently achieve a desired physiological end point. Thus, cone snails have evolved a pharmacological strategy similar to the combination drug therapy favored by the modern pharmaceutical industry for treating AIDS or cancer. To paralyze the prey and interfere with neuromuscular transmission, cone snails simultaneously target presynaptic calcium channels, postsynaptic nicotinic receptors, and voltage-gated sodium channels on the muscle membrane of the prey. These combinations of *Conus* peptides have been termed "toxin cabals"; the combination interfering with neuromuscular transmission is called the "motor cabal." In the venoms of many fish-hunting cone snails, a different toxin combination causes an extremely rapid excitotoxic immobilization of prey,[32] resulting in tetanic paralysis (the "lightning-strike cabal"). An alternative strategy of a different set of fish-hunting cone snail species is to make the potential prey quiescent and sedated (the "nirvana cabal").

The conotoxins that belong to a toxin cabal typically have high potency and specificity for their individual receptor targets. As a consequence of their potency and target selectivity, an increasing number of conotoxins are finding both diagnostic and therapeutic application.[10,17] It should be noted that aquarium observations of how each particular species of fish-hunting *Conus* approaches and captures its prey reveals whether it uses the "lightning-strike cabal" or the "nirvana cabal"; thus, *in vivo* behavioral observations can facilitate peptide discovery. In effect, peptides evolved for a deadly purpose such as killing prey in the natural context may be benign and useful when applied in an entirely different biological context.

OVERVIEW OF PEPTIDES FROM OTHER VENOMOUS MARINE SNAILS

As described in the Introduction, there were traditionally three groups of venomous marine snails recognized, the cone snails (family Conidae), the auger snails (family Terebridae) and the turrids (family Turridae). It has been proposed that the >10,000 species in the last group, which has been shown to be polyphyletic, be assigned to 12 newly defined family groups.[3]

Venom peptides from the auger snails (family Terebridae) have been biochemically characterized. Of the 12 proposed family-level turrid groups, three have been investigated, the turrids (a term now restricted to the newly redefined, more narrowly delineated family Turridae), the crassispirids and the clathurellids. The peptides characterized to date are summarized in Table 5; most of these are known only by their sequences, obtained through molecular cloning.

Augerpeptides: Venom Peptides from the Family Terebridae

The auger snails (family Terebridae) are a distinctive group of highly specialized sand dwelling tropical molluscs believed to feed on polychaete worms. They are among the most well-known marine snails (Fig. 1), with distinctive long, narrow, multiple whorled shells, well adapted for the sand dwelling lifestyle. Several species of auger snails have secondarily lost their venom glands. The venom peptides from this conoidean lineage are known as augerpeptides.

Augerpeptides have been elucidated from two species of Terebridae. In the first study,[15] *Terebra subulata* venom peptides that were purified proved to have structural frameworks similar to well-known conopeptide superfamilies; two peptides had a typical O-superfamily cys pattern, with precursors having a typical conopeptide precursor organization. However, there was no detectable homology between the signal sequences of augerpeptide precursors and the O-superfamily peptides from *Conus*.

A much more extensive analysis using both direct purification from venom and cDNA cloning was carried out on a species in a different branch of the Terebridae, *Hastula hectica*.[14] Peptide sequences were determined both by direct purification from venom and through the analysis of cDNA clones. Even though some of the cysteine frameworks found in the *H. hectica* augerpeptide precursors predicted by cDNA clones were similar to the *Conus* O- and P-peptide superfamilies, no homologous signal sequences were found. Thus, there seem to be no overlapping superfamilies between the conopeptides and augerpeptides characterized to date. The absence of unusual posttranslationally modified amino acids in venom peptides purified from Terebridae was another notable feature.

Turripeptides: Evidence for Conopeptide-Like Gene Superfamilies

The most extensive group of non-*Conus* venom peptides elucidated from the superfamily Conoidea are the turripeptides. As noted above, the family Turridae used to encompass all conoidean species referred to as turrids (the term turrids is still widely used in this broad sense), but there is an emerging consensus to restrict the family Turridae to the monophyletic branch of Conoidea that includes the type species of the genus *Turris*, *Turris babylonia*. We define turripeptides using this narrower definition, as venom peptides from several well-known genera: *Turris*, *Gemmula*, *Lophiotoma*, *Unedogemmula*, *Polystira*, and *Turridrupa*. Presently, the sequences of venom peptides from several Turrids species have been elucidated, including: *Polystira albida*, *Gemmula diomedea*, *Gemmula kieneri*, *Gemmula sogodensis*, *Gemmula speciosa*, and *Lophiotoma* (*Xenuroturris*) *olangoensis* (Fig. 1, Table 5).

*Amidated C-terminus.

Two peptides are purified directly from *G. speciosa* venom (gsp9a and gsp9b). These peptides are notable in that they contain two posttranslationally modified amino acids also found in conopeptides, 4-hydroxyproline and γ-carboxyglutamate. Further, the two purified peptides were homologous to each other, with significant sequence similarity, and the same framework of cys residues. This framework was similar to that of the P-conopeptide superfamily, but cDNA cloning from *G. speciosa* venom demonstrated that there is no apparent sequence homology between the signal sequences of the *G. speciosa* peptide precursors and the P-conopeptide superfamily. It was suggested that this superfamily of turripeptides be called the Pg-superfamily (G for the genus *Gemmula*). When standard PCR was carried out on other *Gemmula* species, additional homologous peptides were obtained from three other *Gemmula* species, *G. sogodensis*, *G. diomedea*, and *G. kieneri*. The Pg-superfamily sequences fell into two groups, suggesting that these may act on two different but homologous molecular targets.

The analysis of venom peptides using cDNA cloning from *Lophiotoma* (*Xenuroturris*) *olangoensis* also suggested turripeptide superfamilies; one superfamily encoded peptides with 16 cysteine residues, a set of venom components significantly larger than encoded by any *Conus* peptide superfamily. Another unusual aspect of the venoms of Turridae is venom peptides with no cysteine residues and very unusual amino acid compositions. Thus, both methionine-rich and leucine-rich peptides (see López-Vera et al. *Toxicon* 2004), quite unlike any conopeptides characterized, have been identified from turrid venoms (Table 5).

Crassipeptides: Venom Peptides from Crassispirid Snails

The crassispirids belong to a large group of species once assigned to the family Turridae. Recent molecular phylogenetic data[6,24] have established that these are a large biodiverse group of venomous snails that comprise a different

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

branch from the turrids; the phylogenetic evidence suggests that they are closer to the family Drillidae. The correct taxonomic designation of this group (family Crassispiridae or Pseudomelatomidae) is still unsettled; we will refer to this branch of Conoidea as the crassispirids, and the venom peptides as crassipeptides. So far, the venom of only one species of crassispirid has been investigated, *Crassispira cerithina*.

A recent report described one crassipeptide, Cce9a, which has been chemically synthesized in a biologically active form.[6] The peptide, elicited novel symptomatology on injection into the mouse CNS that is developmentally dependent, suggesting that this crassipeptide may have a novel molecular target in the mouse CNS. More recently, an analysis of cDNA clones from *C. cerithina* has defined 7 different venom gene superfamilies, encoding peptides with between 1 and 4 disulfide linkages (Cabang et al., 2012, in preparation).

Clathurellipeptides: from Minute Venomous Conoideans

The clathurellids belong to one of the major groups of turrids recently raised to the family level (Clathurellidae) by Bouchet et al.[3] These are believed to be one of the more closely related of the turrid groups to *Conus*, and indeed, in one prior taxonomic scheme,[29] it was proposed that the clathurellids be included with *Conus* in the family Conidae. The emerging consensus is that this an extremely biodiverse group of small, deep-water venomous molluscs that is a well-defined monophyletic branch of Conoidea using conventional molecular phylogenetic data, and we therefore, refer to any peptides in venoms of the family Clathurellidae, H. Adams and A. Adams, 1858, as clathurellipeptides.

Enormous progress can be anticipated in elucidating clathurellipeptide sequences; the reason is that these previously inaccessible molluscs are now collected by a highly-specialized fishery called *lumun–lumun*[27] and using this technology (which was not developed for research purposes, but to supply the commercial need for very small seashells for the Japanese microscope hobbyist market), several dozen different species can be recovered in a single net, with entirely different species occurring at different localities. Because of the extremely small size of most clathurellids recovered through the *lumun-lumun* methods, relatively few have been analyzed to date. However, three sequences have been published, one of them a conventional conopeptide-like precursor, encoding a clathurellid peptide with two disulfide linkages. Many additional sequences have been determined in addition to the one already published (Seronay and Watkins, unpublished results). It is anticipated that the *lumun–lumun* fishery will provide a steady stream of new Clathurellidae and that as techniques improve for getting access to venom peptide sequences in micromolluscs, we can expect to uncover novel pharmacology from this extremely biodiverse group.

PERSPECTIVES

There are many major developments with respect to molluscan peptides that can be anticipated in the coming years. We conclude this chapter by presenting what are probably the most important of these. The rate of discovery of novel peptides from cone snail and other conoidean venoms is likely to be greatly accelerated, particularly for peptides highly selective for specific ion channel and receptor isoforms. The elucidation of new gene superfamilies that encode these peptides makes access to new sequences much more efficient; once the physiological function of a specific venom peptide in a gene superfamily has been elucidated, identifying other peptides that have a related molecular target becomes a much more organized and productive effort. The combination of knowing both the gene superfamily and the molecular phylogeny of each family of venomous snails makes a focused search for peptides with related molecular targets feasible, once the selectivity and specificity of the first peptide is established. The combination of having a framework for understanding gene superfamilies expressed in a lineage of venomous snails, as well as molecular phylogeny of the species that express venom peptides in these gene superfamilies is highly synergistic and makes the discovery process much more facile.

A second important development that can be anticipated is the increasing use of conopeptides (and other conoidean venom peptides) for distinguishing between closely related molecular isoforms of ion channel and receptor families expressed in nervous systems. As noted above, there has already been significant progress in characterizing peptides that can differentiate between subtypes of nicotinic acetylcholine receptors and sodium channels; it is becoming increasingly important in the understanding of the nervous system function to be able to distinguish between closely related subtypes of signaling molecules such as ion channels and receptors, at both the cellular and circuit levels. Thus, establishing an effective neuropharmacology for other ion channel and receptor families depends on discovering novel subtype-selective peptides. Molluscan venoms have proven to be a primary source of such target-specific peptides in the past, and there seems to be a good probability that these venoms will provide a major fraction of the novel pharmacological tools required for investigating the more complex ion channel/receptor families for which a functional characterization of individual molecular isoforms is lacking.

Finally, as mentioned in the Introduction to this chapter, venom peptides from other lineages in the superfamily Conoidea can now be accessed, at least in principle. For

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

most of the non-*Conus* toxoglossan species, because these are almost all very small and relatively rare,[4] there is additional expertise required to apply the "concerted discovery" platform described above in an effective manner. To effectively carry out a transcriptomic analysis, considerable anatomical dissection skill is required. Thus, the range of interdisciplinary expertise that is necessary encompasses an impressive range of fields: taxonomy and phylogeny, peptide biochemistry, neuroscience, molecular genetics, anatomy, and field biology (for collecting the biodiversity). However, the peptides present in these unexplored molluscan venoms represent a new frontier that can increasingly be productively mined to provide unique pharmacological tools in the years to come.

Chapter 62

Snake Peptides

Alan L. Harvey

ABSTRACT

Snake venoms are complex mixtures of small molecules, peptides, and proteins. Most of the biologically active toxins are peptides or enzymes. This chapter covers the nonenzymatically active peptides and toxins. The peptides belong to several structural classes, and they have many different biological actions. The best characterized peptides are the so-called three-finger toxins that have 60–70 amino acid residues in three peptide loops stabilized by four disulfide bridges. Despite their common 3D shape, these peptides can interfere selectively with different biological targets, including nicotinic and muscarinic acetylcholine receptors, acetylcholinesterase, ion channels, and cell membranes. Other small peptides can block K^+ or Ca^{2+} channels and are based on Kunitz serine proteinase inhibitors (~60 amino acid residues and three disulfide bonds), whereas other toxins have different molecular scaffolds and different pharmacological activities. Many snake venom peptides are useful pharmacological tools, whereas others are leads for drug development.

INTRODUCTION

Snake venoms have been long known to have potent biologically acting molecules that are proteins or peptides. Although much early work focused on enzymes, the fashion changed in the mid-1960s with the advent of gel filtration and ion-exchange chromatography to look at the chemical and biological properties of smaller peptides. This research has been incredibly productive in terms of understanding how peptide structure contributes to biological activity and also in revealing molecules with highly selective pharmacological actions. More recent research on venom peptides has been aided by the application of molecular biology techniques and proteomics.[1] New classes of peptides with novel pharmacological effects are still being discovered, with three new examples being included since the first edition of this publication. This chapter concentrates on nonenzymatically active peptides.

THREE-FINGER TOXINS

The first members of this group ("α-neurotoxins") were isolated from the venoms of cobras and sea snakes because of their potent muscle paralyzing activity. They have 60–74 amino acid residues in a single chain crosslinked by four or five disulfide bonds. They contain a central core stabilized by four S–S bridges and three protruding peptide loops (like three fingers of a hand). It was long apparent that another group of cobra venom toxins with a completely different biological activity (the "cardiotoxins" or "cytotoxins") had a molecular architecture similar to that of the α-neurotoxins. Since then, nearly 300 different examples of snake peptides with the three-finger motif have been described, and they are known to have several quite different pharmacological actions. This makes them extremely interesting in terms of structure–activity relationships and for an understanding of molecular evolution[8]

α-Neurotoxins

(1) Discovery: These are generally found in the venoms of snakes of the Elapidae (cobras, kraits, mambas, etc.) and Hydrophidae (sea snakes) families, although similar molecules occur in venoms of some Colubridae. The α-neurotoxins can be subdivided into "short" (60–62 residues; four disulfides), and "long" (66–74 residues; five disulfides), including the κ-neurotoxins (66 residues; five disufides) and "weak" neurotoxins and other homologs (63–66 residues; five disulfides).

(2) Structure of the precursor/gene; Distribution of the mRNA; Processing: The nucleotide sequence of a cDNA encoding erabutoxin a was derived from the material extracted from venom glands, and subsequently, the relevant genes encoding erabutoxins were cloned from a genomic library prepared from the sea snake *Laticauda semifasciata.* The gene for cobrotoxins from *Naja naja atra* has a similar organization to those for the erabutoxins, with three exons separated by two introns. However, the gene for denmotoxin from the colubrid snake *Boiga dendrophila* has four exons and three introns.[19] For a review on work on the gene structures of α-neurotoxins, see Ref. 34.

Clearly, the toxins are found in venom that is synthesized and stored in the venom glands of the snake. The control of toxin synthesis is not yet understood, although transcriptional regulation of toxin genes may be involved.

Copyright Elsevier 2024

(3) Receptors: The α-neurotoxins bind to nicotinic acetylcholine receptors. Most early work concentrated on the receptors at the neuromuscular junction or on electroplaques of electric fish. These "muscle-type" receptors are pentameric proteins with two α subunits and one each of β, γ, and ε(or δ), and such receptors are powerfully blocked by the high affinity binding of both short and long α-neurotoxins.

Venoms of *Bungarus multicinctus* and other kraits also contain κ-bungarotoxins that have little affinity for muscle-type nicotinic receptors but which bind to some neuronal isoforms (particularly the α3β2 subtype). More recently, long α-neurotoxins were found to bind not only to muscle-type nicotinic receptors but also to homo-oligomeric nicotinic receptors (comprising five α subunits) that are found on neurons.The so-called "weak" toxins can also bind with relatively high affinity to such neuronal nicotinic receptors.

(4) Conformation: The three-dimensional structures of the short chain toxin erabutoxin b, the long-chain α-bungarotoxin, and κ-bungarotoxin have been described. The overall shape is formed by a central core that is stabilized by four S–S bonds and three peptide loops protruding like fingers from a hand. More recently, a covalently linked dimeric form with α-neurotoxin properties has been characterized from the venom of the colubrid *Boiga irregularis*.[20]

(5) Biological activity: The short and long α-neurotoxins paralyze the skeletal muscle by blocking the ability of the neurotransmitter acetylcholine to bind to and activate the nicotinic receptors at the neuromuscular junction. These α-neurotoxins are among the most potent of venom constituents and presumably evolved to help elapid and hydrophid snakes catch their prey. The biological activities of the neurotoxins that bind to neuronal acetylcholine receptors are not clearly understood. A structurally homologous toxin named γ-bungarotoxin was isolated from the venom of *Bungarus multicinctus*. It is lethal on injection, presumably because it binds weakly to nicotinic cholinoceptors. γ-Bungarotoxin also inhibits platelet aggregation.

Muscarinic Toxins

(1) Discovery: The venom of mamba snakes had been reported to contain acetylcholine or a cholinomimetic compound. However, competition-binding studies with synaptosomal membranes led to the discovery of three-finger-type peptides that bound to some central muscarinic receptors (see Ref. 24 for a review). The first peptides to be characterized were named muscarinic toxin 1 (MTx1) and toxin-2, although their toxicity has not been established. These toxins are relatively selective for the m1 subtype of muscarinic receptor, and other toxins from mamba venoms have different selectivities. More recently, homologous peptides have been isolated from cobra venoms, and a larger peptide BM14 (82 amino acid residues including 10 cysteines) was found in *Bungarus multicinctus* venom that bound to m2 muscarinic receptors. γ-Bungarotoxin also binds to m2 receptors.

(2) Structure of the precursor/gene; Distribution of the mRNA; Processing: The cDNA encoding muscarinic toxin-2 was cloned, including that of m1-toxin 1. Although not a classical muscarinic toxin, the muscarinic receptor binding peptide BM14 from *Bungarus multicinctus* venom is coded by a gene that has a similar organization as α-neurotoxin and cardiotoxin genes.

(3) Receptors: Different muscarinic toxins have different binding affinities for different subtypes of muscarinic receptors (see Ref. 24 for a review). From green mamba (*Dendroaspis angusticeps*) venom, MTx1 is relatively selective for the m1 subtype; MTx3 is highly selective for the m4 subtype; and MTx7 (or m1-toxin) is extremely selective for the m1 subtype. MTα from black mamba (*Dendroaspis polylepis*) venom has nanomolar affinity for α_{2B}-adrenoceptors,[9] whereas MTx1 and 2 binds to α_1-adrenoceptors.

(4) Conformation: The solution structure of MTx2 was solved by NMR and shown to be three finger-like.

(5) Biological activity: MTx 1 and 2 from green mamba venoms seem to be very unusual for toxins in that they cause an allosteric activation of their receptor target rather than a block. When injected into the hippocampus of mice, these peptides can enhance learning and memory processes, whereas MTx3 (which blocks m4 muscarinic receptors) is inhibitory. MTx7 (or m1-toxin) blocks m1 muscarinic receptors virtually irreversibly. The contribution of the muscarinic toxins to the action of mamba venoms is unknown, although they may aid absorption of venom through actions on lymphatic vessels.

Anticholinesterases

(1) Discovery: The anticholinesterase activity of green mamba venom was revealed in the pharmacological experiments by Osman et al. in 1973 and predicted from the muscle fasciculations caused by the injection of venom fractions into mice. The isolated peptides with powerful inhibitory effects on acetylcholinesterase are called "fasciculins."

(2) Structure of the precursor/gene; Distribution of the mRNA; Processing: cDNA encoding fasciculin 1 has been cloned. The cDNA is organized similarly to that of α-neurotoxins, although the signal peptide sequence for fasciculin 1 lacks a cysteine residue generally encoded in structurally related toxin genes.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

(3) Receptors: Fasciculins bind tightly to a peripheral anionic site on acetylcholinesterases from most species but not from birds. They also have very little affinity for butyrylcholinesterases. The interaction of fasciculin with enzyme has been studied in great detail, and the complexity of enzyme and inhibitor has also been studied.
(4) Conformation: The structure of fasciculin 1 is similar to that of the other three-finger toxins.
(5) Biological activity: Fasciculins produce a long-lasting inhibition of acetylcholinesterase activity, thereby prolonging the action of the neurotransmitter acetylcholine. *In vivo*, this can lead to visible trembling ("fasciculations") of muscles under the skin. When combined with other toxins that are present in mamba venoms, the fasciculins can cause muscle paralysis by inducing a depolarization-type blockade resulting from prolonged activation of acetylcholine receptors at the neuromuscular junction.

Three-Finger, Disintegrin-Like Peptides from Mamba Venoms

(1) Discovery: Many components of snake venoms inhibit platelet aggregation. Most are enzymes, but some peptides that are in the three-finger structural class have also been found, first in mamba venoms (mambin) and then in krait venom (γ-bungarotoxin).
(2) Structure of the precursor/gene; Distribution of the mRNA; Processing: There have been no reports on the cloning of these antiplatelet peptides from venoms of mambas, but gene organization for γ-bungarotoxin is similar to those of α-neurotoxin and cardiotoxin genes.
(3) Receptors: Mambin (also known as dendroaspin) and γ-bungarotoxin contain the sequence RGD that is common to proteins that bind to the glycoprotein receptor IIb-IIIa on platelets. Homologous sequences were noted in thrombostatin and peptide S5C1, which are also from mamba venoms and assumed to be platelet inhibitors.
(4) Conformation: The conformation of γ-bungarotoxin and mambin is similar to that of other three-finger toxins in being predominantly β-sheet.
(5) Biological activity: These peptides prevent the aggregation of blood platelets.

Ca^{2+}-Channel Blockers

(1) Discovery: From the screening of components of black mamba venom for activity on isolated smooth muscle, a 60-residue peptide was isolated and named calciseptine. Earlier, a similar molecule named FS2 had been isolated, although its biological activity was not known. They are in the general three-finger class of toxins.
(2) Structure of the precursor/gene; Distribution of the mRNA; Processing: The genes for these peptides do not seem to have been cloned.
(3) Receptors: The peptides bind to L-type Ca^{2+} channels, probably via the recognition site for 1, 4-dihydropyridines. Calciseptine does not affect N-type or T-type Ca^{2+} channels.
(4) Conformation: The solution structure of FS2 by NMR experiments is similar to those of other three-finger toxins.
(5) Biological activity: Both calciseptine and FS2 block Ca^{2+} currents through L-type Ca^{2+} channels in cardiac and smooth muscle cells, although calciseptine acts as an agonist on L-type channels in skeletal muscles.[5] Both *in vivo* and *in vitro*, calciseptine and FS2 inhibit contractions of smooth muscle; because of this, the peptides have hypotensive effects.

Cardiotoxins

(1) Discovery: Cobra venoms were long known to have cardiovascular effects *in vivo* and to cause direct damage to isolated cardiac preparations. Protein fractions showing such activity were called "cardiotoxins." Such fractions could lyse cells, particularly erythrocytes, and they also became known as "cytotoxins." Purified cardiotoxins were shown to be homologous in size and structure to the short chain α-neurotoxins.
(2) Structure of the precursor/gene; Distribution of the mRNA; Processing: Genomic DNAs encoding several cardiotoxins were isolated from the liver of the Taiwan cobra *Naja naja atra.* Similarities to the genes for α-neurotoxins were noted. Several cDNAs for cardiotoxins have also been obtained from RNA isolated from cobra venom glands.
(3) Receptors: The mechanism of action of cardiotoxins remains obscure despite decades of research. They are generally thought to disrupt cell membranes, but whether or not through binding to a specific receptor is unknown. Cardiotoxins are very basic peptides, and they have been suggested to bind to negatively charged lipids on membranes. Certainly, Lys residues on the peptides are important for activity, but cardiotoxins affect some cells much more than others, implying some selective binding. More recently, evidence was found for sulfo-containing receptors on the membranes of neuronal and cardiac cells.[30]
(4) Conformation: The structure of a cardiotoxin has been determined by X-ray crystallography and by NMR spectroscopy. The differences in a projection from the tip of the third loop may correlate with activity.
(5) Biological activity: Cardiotoxins depolarize electrically excitable cells (neurones and muscles) in an irreversible manner, leading to sustained contraction of muscles.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Some cardiotoxins have hemolytic activity, although this is difficult to ascribe directly to the cardiotoxins because they act in a highly synergistic manner with very low amounts of venom phospholipase A_2. Cardiotoxins have been shown to induce apoptosis in various tumor cell lines. A noncytolytic homolog of cardiotoxins binds to αvβ3 integrin and can inhibit bone resorption *in vitro*.[31]

Synergistic Toxins

(1) Discovery: Fractions from mamba venoms were noted to have little lethality in mice until combined, leading to the isolation of several peptides with a three-finger structure that were named as "synergistic toxins." Some of these were subsequently shown to have anticholinesterase properties, but others act by still unknown mechanisms.
(2) Structure of the precursor/gene; Distribution of the mRNA; Processing: The cDNA coding for a likely synergistic toxin was cloned from RNA from the venom glands of a green mamba *Dendroaspis angusticeps.*
(3) Receptors: The binding sites are unknown.
(4) Conformation: It is assumed that the synergistic toxins have a conformation broadly similar to the other members of the three-finger class.
(5) Biological activity: Little is known about the biological activity, other than *in vivo* toxicity.

Adrenoceptor Antagonists

(1) Discovery: Screening of green mamba (*Dendroaspis angusticeps*) venom in binding assays with various G-protein–coupled receptors revealed components with affinity for α-adrenoceptors.[13] Two three-finger-type peptides were isolated: ρ-Da1a (or AdTx1) and ρ-Da1b, specific for α_{1A} and α_2 adrenoceptors, respectively. These peptides had 65 and 66 amino acid residues and four disulfide bridges.
(2) Receptors: ρ-Da1a has a Kd at α_{1A} adrenoceptors of 0.6nM. ρ-Da1b binds to all three subtypes of α_2 adrenoceptor, being most potent at α_{2A}.
(3) Biological activity: Both peptides act as antagonists at their target receptors. When tested on isolated rabbit prostatic smooth muscle preparations, ρ-Da1a acts as an irreversible antagonist. In functional assays on cells expressing cloned α_{2A} adrenoceptors, ρ-Da1b behaves as a competitive antagonist.

Homologs of Unknown Activity

Protein isolation and cDNA cloning have provided examples of several peptides that are homologous to the three-finger toxins but whose activities are not yet known. These so-called "orphan toxins" have been studied from a phylogenetic perspective, but this does not point to pharmacological classifications. Further work is required.

PROTEASE INHIBITOR HOMOLOGS

Enzyme Inhibitors

(1) Discovery: Proteinase inhibitors are very widespread throughout nature, so it is not surprising that they have been isolated from various snake venoms, including viperids and elapids. Most are in the Kunitz class of serine proteinase inhibitors. Serum of the snake *Trimeresurus mucrosquamatus* has a novel glycoprotein that inhibits the activity of zinc-dependent metalloproteinases but not serine proteases.
(2) Structure of the precursor/gene; Distribution of the mRNA; Processing: cDNA for trypsin and chymotrypsin inhibitors has been cloned from the venom glands of *Vipera ammodytes*, *Naja naja atra*, and *Bungarus multicinctus.* There is a shared gene structure across a wide range of homologs, including some with markedly different biological activities (see the following sections on dendrotoxins and Ca^{2+}-channel blocking toxins).
(3) Receptors: The peptides bind to serine proteinases, particularly to trypsin and chymotrypsin. However, their physiological targets are not known.
(4) Conformation: The peptides adopt the same conformation as bovine pancreatic trypsin inhibitor.
(5) Biological activity: The peptides inhibit the activity of various proteinases, but their purpose in venoms is obscure, although they may interfere with blood clotting by inhibiting enzymes involved in the clotting cascade. Protease inhibitor-like protein-1 (PILP-1) from *Bungarus multicinctus* venom downregulates a disintegrin and metalloprotease 17 (ADAM 17) and induces apoptosis of leukemia cells.[11]

Dendrotoxins

(1) Discovery: The Venom from the Eastern green mamba *Dendroaspis angusticeps* increases acetylcholine release from motor nerve endings, an effect subsequently correlated with block of some neuronal K^+ channels.[6] The peptides responsible (dendrotoxins) had been isolated and sequenced before their biological activity was known.
(2) Structure of the precursor/gene; Distribution of the mRNA; Processing: The gene for dendrotoxin K was cloned from a cDNA library made from the venom glands of black mamba *Dendroaspis polylepis.* Most dendrotoxins have a pyroglutamic acid residue at their N-terminus.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

(3) Receptors: α-Dendrotoxin from green mamba and dendrotoxin I from the black mamba block some cloned voltage-dependent K^+ channels (Kv1.1, Kv1.2 and Kv1.6) in the low nanomolar range; dendrotoxin K from the black mamba selectively blocks Kv1.1 channels at picomolar concentrations.[6] Interactions with channel proteins have been studied.
(4) Conformation: The solution structures of dendrotoxin I and K were determined by NMR, and the X-ray crystal structure of α-dendrotoxin was also solved. All are similar to bovine pancreatic trypsin inhibitor (BPTI).
(5) Biological activity: The first biological activity of the dendrotoxins to be noticed was the augmentation of twitch responses of skeletal muscle preparations in response to nerve stimulation. Although not very toxic on peripheral injection, dendrotoxins are potent toxins when injected centrally in mice, causing convulsions and death. These effects result from the peptides blocking some of the voltage-activated K^+ channels in neurons, leading to increased neuronal firing and excitability. Dendrotoxin K, which is highly selective for Kv1.1 potassium ion channels, reduces tumor formation in a mouse xenograft model.

Ca^{2+}-Channel Blockers

(1) Discovery: A BPTI homolog with blocking activity at L-type Ca^{2+} channels was isolated from green mamba venom and named calcicludine.
(2) Structure of the precursor/gene; Distribution of the mRNA; Processing: The gene for calcicludine has not been characterized.
(3) Receptors: Calcicludine blocks L-type Ca^{2+} channels in cerebellar granular cells and cardiac myocytes. The block of the α1C form of the L-type channels is partial but irreversible, while calcicludine can increase the activity of the α1A, B, and E subtypes.[25]
(4) Conformation: The NMR structure of calcicludine is similar to that of dendrotoxins.
(5) Biological activity: Calcicludine can reduce contractions of cardiac muscle.

CROTAMINE-LIKE MYOTOXINS

(1) Discovery: Rattlesnake venoms are known to cause damage to skeletal muscle, and several small peptides (42 residues with three disulfides) associated with that activity have been isolated. These include myotoxin A from the prairie rattlesnake *Crotalus viridis viridis* and crotamine from the South American rattlesnake *C. durissus terrificus*.
(2) Structure of the precursor/gene; Distribution of the mRNA; Processing: A 1.8kb gene Crt-p1 coding for crotamine was found in specimens of *C. durissus terrificus*.
(3) Receptors: Crotamine and homologous myotoxins can bind to Na^+ channels on skeletal muscle membranes and also to lipid membranes.
(4) Conformation: The NMR-derived structure of crotamine has a short N-terminal α-helical region and a small antiparallel triple stranded β-sheet area; overall, the folding has a resemblance to that of β-defensins, and crotamine has some antimicrobial properties.
(5) Biological activity: The crotamine-like myotoxins can depolarize skeletal muscles and cause myotoxic damage. Crotamine also has analgesic activity that is reversed by naloxone. Crotamine penetrates into dividing cells and localizes in the nucleus.[7]

SARAFOTOXINS

(1) Discovery: The venom of the burrowing asp *Atractaspis engaddensis* causes cardiac arrest. A family of toxins, the sarafotoxins, has been characterized. They have 21 amino acid residues in a single chain stabilized by two disulfide bonds.[4] A similar toxin, bibrotoxin, was found in the venom of *Atractaspis bibroni*. Longer homologs, with 24 residues, were discovered in the venom of *Atractaspis microlepidota microlepidota* and 25-residue homologs are found in another species, *Atractaspis irregularis*. All are homologs of the mammalian endothelins (see endothelin chapters in several sections of the book).
(2) Structure of the precursor/gene; Distribution of the mRNA; Processing: The gene encoding sarafotoxins from the burrowing asp is unusual in coding for five different isotoxins in a "rosary-type" organization. The mechanisms for processing the mature toxin peptides are unknown.
(3) Receptors: The sarafotoxins bind to endothelin receptors. There may be a different, as yet uncharacterized subtype that recognizes the "long" sarafotoxins.
(4) Conformation: The solution structure of a sarafotoxin has been solved using NMR techniques. The molecule is largely α-helical, with a very flexible C-terminal region.
(5) Biological activity: The principal activity is vasoconstriction mediated by actions on endothelin receptors. *In vivo*, death is caused by cardiac arrest.

CRISP FAMILY TOXINS

(1) Discovery: Cysteine-rich secretory proteins (CRISPs) are found in mammalian epididymis and the immune system, though their functions are unknown. They are widely distributed in snake venoms, with examples

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

being known from colubrid, elapid and viperid snakes.[33] Pseudechetoxin was discovered by screening a wide variety of venoms for activity on a particular ion channel.

(2) Structure of the precursor/gene; Distribution of the mRNA; Processing: cDNAs encoding ablomin, catrin, latisemin, ophanin, piscivorin, tigrin, and triflin have been cloned. They code for mature proteins of 221 residues including 16 cysteines.[33] Similar molecules with different pharmacological actions were cloned from Australian elapids: pseudechetoxin from *Pseudechis australis* and pseudecin from *Pseudechis porphyriacus*.[32] These gene products have 238 amino acid residues, including a 19-residue signal peptide. A further eight residues are thought to be cleaved enzymatically to give the mature peptide.

(3) Receptors: It is suggested that ablomin, catrin, latisemin, ophanin, piscivorin, and triflin may be L-type Ca^{2+}-channel blockers (they reduce contractions of arterial smooth muscle stimulated by K^{+}-induced depolarization with no effect on contractions stimulated by release of intracellular Ca^{2+} by caffeine).[33] Pseudechetoxin and pseudecin block channels in olfactory and retinal cells that are gated by cyclic nucleotides.[32]

(4) Conformation: A crystal structure of triflin has been obtained. It has a large globular portion linked to a rod-like cysteine-rich domain containing five disulfide bridges.

(5) Biological activity: The function of the CRISP proteins in snake venoms is unknown. Because they are so widely distributed in snakes of different families and in different geographical regions, perhaps they serve a common purpose such as aiding the spread of venom after a bite. A CRISP protein from *Bothrops alternatus* venom can induce angiogenesis and also improve healing in an experimental wound model.

NATRIURETIC PEPTIDES

(1) Discovery: A vasorelaxant peptide of 38 amino acid residues and with homology to atrial natriuretic peptide (ANP) was isolated from green mamba venom and named dendroaspis natriuretic peptide, DNP. Homologous peptides have been isolated from the venom of the inland taipan *Oxyuranus microlepidotus*.[27]

(2) Structure of the precursor/gene; Distribution of the mRNA; Processing: DNP is expressed in venom glands, but it is not known if it plays a signaling role elsewhere in the snake. DNP has been found in human tissues.[10] Several Asian and South American snakes contain genes for C-type natriuretic peptides, and cDNA for a natriuretic peptide precursor has been found from a venom gland cDNA library from king cobra, *Ophiophagus hannah.*

(3) Receptors: DNP activates ANP-A receptors rather than ANP-B receptors.

(4) Conformation: The overall conformation of DNP has not been described. It is assumed to have a disulphide bridge between residues 7 and 23.

(5) Biological activity: DNP acts on ANP-A receptors to activate guanylate cyclase and increase the levels of cyclic GMP, which cause vascular relaxation. DNP also causes natriuresis. It has been suggested that DNP may have a use in treating patients with congestive heart failure, either as the native peptide or as a chimeric molecule with C-type natriuretic peptide.

DISINTEGRINS

(1) Discovery: Many components of snake venoms interfere with blood coagulation through actions on platelets.[2] Disintegrins have a variety of peptide structures (including some three-finger-shaped molecules described earlier) but generally share a three-residue section of RGD. They have been divided into five groups according to the size and disulfide bonds. The largest also has enzymatic activity.

(2) Structure of the precursor/gene; Distribution of the mRNA; Processing: Several cDNA sequences have been cloned and found to be quite variable in length, although a common ancestor is likely.[2]

(3) Receptors: The peptides bind to various integrins, including $\alpha IIb\beta 3$, $\alpha 2\beta 3$, and $\alpha 5\beta 1$. A cardiotoxin homolog binds to $\alpha v\beta 3$ integrin.[31]

(4) Conformation: A crystal structure of schistatin from the saw-scaled viper *Echis carinatus* has been solved. This is a homomeric dimer formed by two disulfide bonds between monomers. Each monomer has three sets of antiparallel β-strands and four intramolecular disulfide bonds. The conformation of albolabrin has been defined by NMR measurements.

(5) Biological activity: The disintegrins prevent platelet aggregation. They may also have potential in reducing metastatic spread of cancer cells.

C-TYPE LECTINS AND LECTIN-LIKE PROTEINS

(1) Discovery: Lectins are complex proteins that bind to various sugars and have a variety of biological effects. C-type lectin-like proteins lack carbohydrate binding activity and have only been found in various snake venoms. Over 80 are known.[18] They affect platelet functions and/or coagulation factors and therefore disturb blood coagulation.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

(2) Structure of the precursor/gene; Distribution of the mRNA; Processing: Phylogenetic analysis of the A and B chains of the C-type lectins and the lectin-like proteins indicate that the C-type lectin-like proteins evolved separately from the lectins.[18]

(3) Receptors: Different C-type lectin-like proteins seem to bind to different receptors on platelets, including the integrins α2β1 and αIIβ3, glycoproteins in the leucine-rich repeat family GPIb-IX-V and the immunoglobulin superfamily GPIV, causing either inhibition or activation.[12,30] They can also bind to von Willebrand factor, collagen, and fibrinogen. Other C-type lectin-like proteins have anticoagulant activity through binding to different coagulation factors in blood.[16,18]

(4) Conformation: The C-type lectin-like proteins are made up of various combinations of homologous subunits (A and B chains, each of ~14kDa). The structures and structure–activity relationships are being actively studied.[12,14,16,18]

(5) Biological activity: Many of the proteins can both inhibit and activate platelets.[12] Overall, most seem to produce thrombocytopenia. Others have anticoagulant properties.[16]

WAGLERINS

(1) Discovery: Waglerins are small peptides from the venom of Wagler's pit viper, *Tropidolaemus (Trimeresurus) wagleri* that are lethal to mice.

(2) Structure of the precursor/gene; Distribution of the mRNA; Processing: The peptides have 22 or 24 amino acid residues, including seven proline residues and one disulfide bond. The genes for waglerins do not seem to have been cloned, but the peptides can be readily synthesized.

(3) Receptors: Waglerins bind to muscle-type nicotinic acetylcholine receptors containing the ε-, but not the γ-subunit.[15] Waglerin-1 also binds to sites on different forms of $GABA_A$ receptors.

(4) Conformation: The 3D conformation of waglerin-1 has been resolved by NMR studies. There is a short, rigid loop formed by the S–S bond and two extended and flexible tails.

(5) Biological activity: When injected into mice, waglerins cause respiratory failure because of blockade of acetylcholine receptors at the neuromuscular junction. Rats are insensitive to the toxins.

BRADYKININ-POTENTIATING PEPTIDES

(1) Discovery: The venom of the Brazilian snake *Bothrops jararaca* was found to potentiate the effects of bradykinin *in vitro* and *in vivo*.[3] Several small peptides of 5–14 residues with that activity were isolated, and other examples have been found in other venoms of *Bothrops* and *Crotalus* snakes. Because these act by inhibiting the activity of angiotensin-converting enzyme (ACE), they led the way to the discovery and development of clinically useful ACE inhibitor drugs.[3]

(2) Structure of the precursor/gene; Distribution of the mRNA; Processing: Several genes have been cloned from a cDNA library of venom glands of *Bothrops jararaca* that code for the precursor of bradykinin-potentiating peptides along with C-type natriuretic peptide. Similar genes were found in the venom glands of three Asian snakes: *Trimeresurus flavoviridis*, *Trimeresurus gramineus*, and *Agkistrodon halys blomhoffi.* The control of expression and the modification to give the pyroglutamic residue found in the active peptides are not known. However, similar mRNA was detected in various brain regions in the snakes, suggesting that the peptides may have a signaling role within the snake.

(3) Receptors: Bradykinin-potentiating peptides interact with the active sites on ACE. Some also can activate argininosuccinate synthase to lead to increased production of nitric oxide.[3] A homologous peptide, blomhotin from *Agkistrodon halys blomhoffii*, causes contractions of rat stomach preparations in a manner consistent with there being specific receptors for the peptide; these have not yet been identified. More recent work indicates that bradykinin-potentiating peptides from *Bothrops jararaca* can activate m1 muscarinic receptors and B2 bradykinin receptors.

(4) Conformation: The conformation of bradykinin-potentiating peptide F from *Agkistrodon piscivorus piscivorus* was studied by NMR. Two major forms were found (stretched and folded), and it was speculated that one was associated with the activity on ACE and the other with potentiating responses to bradykinin.

(5) Biological activity: The peptides enhance the contractile activity of bradykinin on smooth muscle, although potency does not necessarily correlate with the ability to inhibit ACE activity.[3]

AVIT PEPTIDES

(1) Discovery: Among several peptides isolated from black mamba venom and then sequenced were protein A and A′ that had 81 amino acid residues, including 10 cysteines and which were not homologous to any known peptide group. A very similar peptide was later found to cause contractions of intestinal smooth muscle preparations and was called "mamba intestinal toxin" (MIT1).

(2) Structure of the precursor/gene; Distribution of the mRNA; Processing: Although MIT1 does not seem to have been cloned, mammalian homologs have been found. These are known as prokineticins, and they are expressed in the gastrointestinal tract, brain, and other tissues.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

(3) Receptors: Schweitz et al. noted that radiolabeled MIT1 bound to ileal and brain membranes with very high affinity, and there was pharmacological evidence that prokineticins act on G-protein–coupled receptors. Two such receptors have been cloned.
(4) Conformation: MIT1 is unusual in the arrangement of its five disulfide bonds, and, from NMR experiments, it was found to have an overall homology with colipase. In addition to the mammalian prokineticins, there are homologs in amphibian skin. All share a conserved N-terminal sequence of AVIT, hence the proposed name of "AVIT protein family."
(5) Biological activity: MIT1 powerfully contracts smooth muscle in sections of the gastrointestinal tract. The peptide also can sensitize pain receptors. However, its contribution to the overall effects of mamba venom is not known.

CYSTATINS

(1) Discovery: These were originally found in several different snake venoms (*Bitis arietans*, *Naja naja atra*, *Notechis scutatus*) because of their ability to inhibit cysteine protease activity. Recent studies indicate that cystatins are widely distributed in snake venoms.[23]
(2) Structure of the precursor/gene; Distribution of the mRNA; Processing: The cDNA for a cystatin from *Bitis gabonica* has been reported, and 12 cystatin cDNA sequences were obtained from venom glands of several species of elapid snakes.[23] There is a common sequence for a 26 amino acid residue propeptide.
(3) Receptors: Cystatins bind to and inhibit the activity of the C1 family of cysteine proteases, including cathepsin L and papain.
(4) Conformation: The snake venom cystatins have about 140 amino acid residues and two intrachain disulfide bridges. Their three-dimensional structure has not been directly determined, but homology modeling indicates structural similarities with ovocystatin.[23]
(5) Biological activity: The biological function of cystatins in snake venoms is unknown. However, one of them has been shown to reduce metastatic spread of cancer cells in an experimental animal model.

CATHELICIDINS

(1) Discovery: Peptides with antimicrobial properties are widespread in animals, plants, and microbes. Some snake venom peptides are structurally related to defensins. Another family of antimicrobial peptide, the cathelicidins, has been found in venoms of some cobras and kraits.[35]
(2) Structure of the precursor/gene; Distribution of the mRNA; Processing: Three cDNA sequences coding for elapid cathelicidins have been studied. They code for a 22-amino acid residue signal peptide, a 135-amino acid residue cathelin domain, and a mature antimicrobial peptide of 34 residues.
(3) Receptors: The molecular mechanism of action is unknown, but they may disrupt membranes in susceptible cells.
(4) Conformation: They are linear peptides of 34 residues. CD experiments indicate a random coil conformation with the possibility of forming α-helices.
(5) Biological activity: The peptide that has been tested, cathelicidin from *Bungarus fasciatus*, has a broad spectrum of antibacterial activity with minimum inhibitory concentrations (MICs) of <1μM, although strains of *Staphylococcus aureus* were more resistant. The peptide was also active against different species of fungus but had little cytotoxicity against mammalian cells and was not hemolytic.[29]

WAPRINS

(1) Discovery: By fractionating venom of the cobra *Naja nigricollis* and using mass spectrometry to detect peptides with masses different from known classes of toxin, a novel 51 amino acid residue peptide was isolated and characterized.[26] It is homologous to whey acidic proteins (WAPs), and the cobra-derived peptide was named nawaprin. A similar peptide named omwaprin has been isolated from the venom of the inland taipan *Oxyuranus microlepidotus*.[17]
(2) Structure of the precursor/gene; Distribution of the mRNA; Processing: This is not known, although a synthetic gene for omwaprin has been expressed in *E. coli*.[17]
(3) Receptors: Nawprin is homologous to the elastase inhibitor elafin, but it does not inhibit elastase. Omwaprin is able to disrupt membranes of some Gram-positive bacterial cells.[17]
(4) Biological activity: This is not known for nawaprin. Omwaprin has selective antibacterial effects of some species of Gram-positive bacteria, and it is not hemolytic against human erythrocytes.[17]

MISCELLANEOUS PEPTIDES

In the late 1960s, the advances in protein purification and analysis techniques gave rise to information about the structures of many venom components whose activity was unknown. Often, it took many years before a biological activity could be ascribed to such peptides. Recently, a similar phenomenon is appearing because of the use of

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

proteomics to reveal the presence of more and more peptides in venoms (see Ref. 1 for a review). Many of these peptides may have biological activity, but that remains to be determined. Other peptides have been ascribed a biological activity because of similarities to other better characterized molecules, but their significance in snake venom is still unknown. Some current examples follow.

Vascular endothelial growth factors are proteins that stimulate angiogenesis. Several examples have been found in snake venoms (e.g. *Bothrops* and *Vipera* species), and it is suggested that they may act to enhance distribution of venom after a bite by increasing vascular permeability.

A small protein of 107 residues was isolated from the venom of the king cobra (*Ophiophagus hannah*) and named ohanin.[21] It is different from other snake venom proteins, but it has homology with SPRY domain proteins. It is not lethal in mice, but it decreases locomotor activity and sensitizes responses to painful stimuli. Its mechanism of action is unknown.

Low molecular weight (1.3–2.4kDa) peptides have been isolated from *Dendroaspis angusticeps* venom.[22] They are unusual because of their high number of proline residues and because they are glycosylated. No biological activity is known.

Chapter 63

Spider Peptides

Graham M. Nicholson

ABSTRACT

Spider peptide and protein toxins are recognized as highly potent and specific molecular tools that modulate signaling in excitable cells via interaction with a variety of ion channels, receptors, and transporters in vertebrates and invertebrates. By a process of natural selection, spider venoms have evolved as complex preoptimized combinatorial peptide libraries, displaying extremely diverse pharmacology with a wide range of molecular targets, designed to subdue or kill their prey or predators. The discovery that these disulfide-rich proteins and peptides bind to their cognate receptors with high affinity, and in many cases with outstanding selectivity, means that spider venoms are now being investigated as sources of molecular tools for probing ion channel and synaptic neurotransmission, for validating novel insecticide targets, and as lead compounds in therapeutic and biopesticide discovery pipelines.

INTRODUCTION

Spiders are the most speciose venomous animals and the most successful terrestrial predators, with >42,000 extant species described to date.[22] Because they rely completely on predation as a trophic strategy for survival, spiders have developed during evolution a complex preoptimized combinatorial library of enzymes, neurotoxins, and antimicrobial and cytolytic peptides in their venom glands.[27] These comprise mainly of three groups delineated by their molecular mass: (i) low molecular mass acylpolyamines (<1 kDa), (ii) disulfide-rich neurotoxins and linear cytolytic peptides (1–10 kDa), and (iii) high molecular mass proteins (>30 kDa) – mainly enzymes and neurotoxins. Given the focus of this book, this review will center on the peptide neurotoxins and cytolytic peptides, particularly as high molecular mass spider venom neurotoxins and enzymes were already described in the first edition of this book.

Since the publication of the first edition of the *Handbook of Biologically Active Peptides* in 2006, some 380 additional new spider peptides have been formally reported. To date, around 800 peptide toxins from 78 spider species have been described. These are from the venom of 20 of the 110 extant spider families, including representative families from the two major suborders—aranemorph ("modern") and mygalomorph ("primitive") spiders (Fig. 1A). These venoms comprise mainly of 3 to 9 kDa peptide toxins, mainly focused on 3 to 5 kDa peptides and also with some larger proteins in the 30- to 40 kDa (sphingomyelinases D involved in loxoscelism; Fig. 5) and 130 kDa range (latrotoxins, latroinsectotoxins and latrocrustatoxins). In the recent years, it has become clear that these spider venom libraries are considerably more complex than previously appreciated, comprising >1000 distinct peptides.[8] If one uses a conservative estimate of 100,000 species and 200 peptides per venom, then spider venoms probably contain at least 10 million bioactive peptides. Consequently, <0.01% of the potential proteomic diversity of spider venoms has been tapped to date.

There has been an exponential increase in the number of spider toxins that have been reported in the literature.[15] This has resulted from the advent of high-throughput modern analytical techniques especially involving proteomic, transcriptomic and genomic approaches. As a result of the explosion in the number of new peptide toxins being discovered and characterized a rational nomenclature system based on a Greek letter 'activity prefix' together with a toxin name based on the family, genus and species of the spider has been proposed and adopted by UniProtKB.[15] In addition, a curated spider toxin peptide and protein database (ArachnoServer Spider Toxin Database; www.arachnoserver.org) has also been developed.[12] This review will use this new nomenclature to facilitate the identification of orthologs and paralogs and will also provide original names of the toxin. In addition, the readers are directed to relevant entries in the ArachnoServer database for original literature references, biological activity, molecular targets, sequence and 3D structure (where known).

Spiders use their venoms to paralyze and/or kill prey or predators as rapidly as possible. Therefore, their venoms are particularly rich in neurotoxins that rapidly modify ion conductance (ion channel toxins) and to a lesser extent affect neurotransmitter exocytosis (presynaptic toxins). Like scorpion toxins, however, they lack significant numbers of toxins that block the action of neurotransmitters (postsynaptic toxins) particularly common in snakes and,

Bars in dark gray indicate peptide toxins from mygalomorph spiders, whereas light gray bars are from araneomorph spiders. (B) Mass distribution of extant spider toxins. Masses represent the monoisotopic oxidized mass sorted into 500 Da bins. The overlaid curve shows the cumulative total number of peptides. Dark gray columns show mass range dominated by sphingomyelinase D (SMase D), latrotoxins (LTX), latroinsectoxins (LIT), and latrocrustatoxins (LCT). *Data were collated from the ArachnoServer Spider Toxin Database (*www.arachnoserver.org [12]*) on November 25, 2011.*

to a lesser extent, marine cone snail venoms. Many of these spider peptide toxins are selectively insecticidal or modulate the activity of various targets in vertebrates, including humans. In particular, insect-selective toxins have been patented for their possible use as bioinsecticidal agents for the control of phytophagous pests or insect vectors of new and re-emerging diseases.[13] Other neurotoxins have been invaluable molecular tools for the identification and characterization of ion channel subtypes and for unraveling the process of neurotransmitter exocytosis. Yet others, have already been patented as antiarrhythmic and analgesics.[17,18] Indeed, in addition to their well known neurotoxic actions spider peptide toxins have been identified with an extensive range of other biological activities including antimicrobial, antiparasitic, cytolytic/haemolytic, as well as enzyme activity and protease inhibition (Fig. 2A). The focus of this review is the discovery, processing, structure, and function of spider venom peptides. In particular, it will detail the site and mechanism of their action, the molecular determinants for their pharmacology, and discuss the application of these peptides in the fields of pharmacology and neuroscience and the development of novel insecticides.

METHODOLOGICAL APPROACHES IN THE ISOLATION OF SPIDER VENOM PEPTIDES

Several different methodological approaches have led to the isolation of novel spider peptide toxins. The most commonly used approach has been the use of insect and mammalian bioassays to drive venom fractionation using acute toxicity testing via injection assays or isolated organ bath screening. The weakness with this approach is that numerous toxins remain uncharacterized in terms of target

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

and mode of action. Indeed in the ArachnoServer Spider Toxin Database (www.arachnoserver.org), there are currently >400 peptides with an unknown target (those designated with a 'U' prefix), representing a little over 50% of all spider peptides toxins so far reported (Fig. 2B). Also the potential array of targets for a novel toxin is too vast to be comprehensively screened. Another approach has been to study all the components of a single venom, or venoms of closely related species, and characterize their mode of action in target-oriented bioassays. This has been the approach taken with the hexatoxins (HXTXs; formerly atracotoxins) and theraphotoxins (TRTXs) where several families of toxins that modulate voltage-activated Na^+ (Na_V), Ca^{2+} (Ca_V), and K^+ (K_V) channels have been described. The limitation of this approach is that it does not always yield the most active toxin for a specific target and again many toxins remain uncharacterized. Currently, a number of groups are using a systematic approach employing screening assays using cloned ion channels expressed in *Xenopus* oocytes or other cells, or well-characterized channels in clonal cell lines or native cells. Such electrophysiological, ELISA, radioligand binding or absorbance/fluorescence-based methods have revealed high-affinity and often highly selective ligands that block or modulate ion channel subtypes for which there were no previous pharmacological tools (e.g. π-TRTX-Pc1a, τ-TRTX-Pc1c and purotoxin-1; see below). Unfortunately, this approach is limited if a potential therapeutic or insecticidal target has not been previously validated or if the target has not yet been cloned. This restricts the discovery of ligands to only those with affinity for known target subtypes. Accordingly, methodologies centered on a combination of the last two approaches are likely to be the most successful.

STRUCTURE OF THE PRECURSOR SPIDER VENOM PEPTIDE AND POSTTRANSLATIONAL PROCESSING

The expression of spider venom peptides, like those from marine cone snails and sea anemones, are translated mostly as prepropeptides that undergo posttranslational modification to yield the mature toxin.[27] These prepropeptide precursors typically are composed of an N-terminal signal peptide that precedes a propeptide region rich in acidic residues and of highly variable length, which is followed by the mature toxin sequence. It seems that during evolution, families of toxins within spider venoms underwent hypermutation in the mature peptide region while conserving the basic disulfide framework. This cystine framework seems to be associated with a specific signal sequence. However, the signal peptide was conserved because its role was, most likely, to direct the precursor to a specific secretory pathway thereby to ensure correct peptide folding. The specific role(s) of the propeptide region, however, is still not understood but most likely involved in the proteolytic processing and posttranslational modifications such as N-terminal pyroglutamine formation, isomerization, palmitoylation, and C-terminal trimming and amidation (Fig. 3B). In the case of the MIT-like U_1-HXTX-Hv1a (formerly ACTX-Hvf17) and high molecular mass latrotoxins, this N-terminal propeptide is absent.

LINEAR PEPTIDES

Membrane-acting Antimicrobial Peptides and Cytolytic Peptide Toxins

To date, several groups of cytolytic peptides with antimicrobial activity have been discovered in araneomorph spider venoms, especially from the members of the araneomorph spider families Ctenidae (ctenitoxins, CNTXs), Lycosidae (lycotoxins, LCTX), Oxyopidae (oxotoxins, OXTXs), and Zodariidae (zodatoxins, ZDTXs). These have been classified as membrane-acting antimicrobial peptides (MAMPs with the activity prefix 'M'). For a review of the structure and biological activities of cytolytic peptides from spider venom see Ref. 28.

These cytolytic peptides are short (<50 residues) linear, highly cationic, amphipathic peptides lacking cysteine residues and have isoelectric points >10 (Fig. 5). They are characterized by being highly basic peptides because of the high proportion of lysine residues, often with few arginine residues. In addition, they often possess an amidated C-terminus. In solution, these peptides are disordered; however, their secondary structure acquires an α-helical conformation, typical of antimicrobial pore-forming peptides, upon contact with membranes. The amphipathic motif is characterized by a right-handed ribbon of positively charged lysine and polar residues winding around the α-helix. The cytoplasmic membrane therefore serves as a target for MAMP action. The positive charge of MAMPs provides for electrostatic binding to the membrane surface, while their amphiphilic nature allows the peptides to incorporate into the bilayer resulting in the disturbance of the bilayer integrity and subsequent cell death. Several models have been proposed to explain the mechanism of pore formation including 'barrel stave,' 'carpet,' and 'toroidal' models or a combination of these, but no one model fits all spider venom peptide actions.[28] These peptides are highly active against Gram-negative and Gram-positive bacteria with minimal inhibitory concentrations in the low micromolar range. Furthermore, many MAMPs display fungicidal (against *Candida* spp.) and antitrypanosomal activity. The insecticidal effect of MAMPs on insects has been reported but is negligible, with very high LD_{50} values (5–10 nmol/g). However, coinjection of the neurotoxin ω-OXTX-Ol1a (formerly oxytoxin) with the MAMP M-OXTX-Ot1a (formerly oxyopinin 1)

into insect larvae resulted in a significant increase in the paralytic and lethal activity of the neurotoxin. Electrophysiological studies showed that M-oxotoxins reduce cell membrane resistance by opening nonselective ion channels. Unfortunately, these peptides also exhibit a hemolytic effect on human erythrocytes that is dependent on the content of phosphatidylcholine. Synthetic N- and C-terminal truncates of M-CNTX-Cs1d (formerly cupiennin 1d) showed that the residues involved in the cytolytic activity are located in the hydrophobic N-terminal chain segment. Removal of the first six N-terminal residues totally abrogated cytolytic activity, while the polar C-terminal region seems to modulate the peptide association at negatively charged cell surfaces to reduce activity. This may be because many MAMPs are amidated at the C-terminus to protect the peptide against proteolytic cleavage.

In addition to these short MAMPs, the venom of *Lachesana tarabaevi* also contains a family of long, linear M-ZDTX-Lt toxins (cyto-insectotoxins) with insecticidal, cytolytic, and antimicrobial activity. These are more than twice the length of typical MAMPs and possess very high charge at neutral pH. They still retain the α-helical motif but seem to be composed of two short MAMPs joined together in a 'head-to-tail' configuration by a short four-residue linker. The major difference between cyto-insectotoxins and conventional MAMPs is that the former seem to possess much high insecticidal activity.[29]

Several groups have speculated as to the role of these antimicrobial and cytolytic peptides in the venom of various spiders. They may play several roles; first to protect the spider from potentially infectious organisms arising from prey ingestion, second to assist in external digestion via cytolytic degradation of prey membranes, or, more probable, functioning as membrane disrupting agent in a cooperative fashion with disulfide-rich neurotoxins in the prey capture strategy by facilitating absorption and distribution of the neurotoxins.

DISULFIDE-RICH PEPTIDES

Structural Organization of Disulfide-Rich Peptides: Variations on an Ancestral Fold

Around 90% of spider venom peptides are compact globular proteins possessing several disulfide bridges. The number of disulfide bonds range from one to seven, but nearly 60% of all toxins have three disulfides bridges (Fig. 3C). In addition, several have modified N-termini, such as formation of pyroglutamate, or most commonly C-terminal amidation (Fig. 3B) that increase their *in vivo* stability. These peptides, predominantly targeting voltage-activated ion channels, often contain a 'disulfide pseudoknot' which places them in a class of toxins and inhibitory polypeptides with an 'inhibitory cystine-knot' (ICK) motif.[20] This structural motif is normally exemplified by a triple-stranded, antiparallel β-sheet stabilized by disulfide bridges. Because not all ICK peptides exhibit the N-terminal β-sheet (β1 in Fig. 4Cb), a modified definition composed of 'an antiparallel β-hairpin stabilized by a cystine-knot' without a mandatory third β-sheet has been proposed. The three disulfide bridges and intervening backbone form a pseudoknot consisting of a ring (C_I–C_{IV}, C_{II}–C_V) penetrated by a third disulfide bridge (C_{III}–C_{VI}) (Fig. 4Db). However, within this fold-class, the biological activities of spider ICK toxins are quite diverse with activity at Na_v, Ca_v, K_V, acid-sensing channels, transient receptor potential, and mechanosensitive channels (see below). This highlights the observation that different biological functions are often grafted onto the same, or similar, structural scaffolds. Another structural fold has been defined for spider toxins. The disulfide-directed β-hairpin (DDH) fold lacks the disulfide knot and is composed of a double-stranded antiparallel β-hairpin stabilized by two mandatory disulfide bridges with a current consensus sequence of $–CX_{4–19}–CX_2$[G or P]$X_2–CX_{4–19}$–C– where X is any amino acid (Fig. 4A–B). The ICK motif seems to have evolved from this simpler canonical ancestral fold.[32] This DDH fold has been observed in a range of toxins with unknown targets such as MIT-like U_1-HXTX-Hv1a,[33] U_1-TRTX-Hh1 toxins, U_1-TRTX-Asp1f and -Asp1g, and U_1-TRTX-Lp1a and -Lp1b.[7] The ICK fold creates hyperstable miniproteins with tremendous chemical, thermal, and biological stability. ICK toxins are typically resistant to extremes of pH, organic solvents, and high temperatures.[4] However, from a therapeutic perspective, their most important property is their resistance to proteases. Specific differences in the DDH and ICK structural folds, determined by the spacing between cysteine residues and their connectivity, is critical for the presentation of key functional residues to the target, thus generating a vast array of peptides acting on distinct biological systems. This together with their protease resistance and compact nature provides an effective scaffold for the design of molecular tools and therapeutics.[20]

Voltage-Activated Sodium Channels: Blockers and Gating Modifiers

Na_v channels are responsible for the initiation and propagation of the action potential in excitable cells. To date, nine mammalian Na_v channels (Na_V1.1–1.9) have been cloned, and in all cases, except for Na_V1.9, they are functionally expressed and extensively characterized. Interestingly, much of their structure and function has been elucidated by the use of various plant and animal toxins. These molecular probes bind with seven identified targets, referred to as neurotoxin receptor sites 1–7 of which four sites bind spider peptide toxins.[2] Spider venoms are becoming an interesting source of peptide toxins that modulate Na_V channel conductance and/or gating.

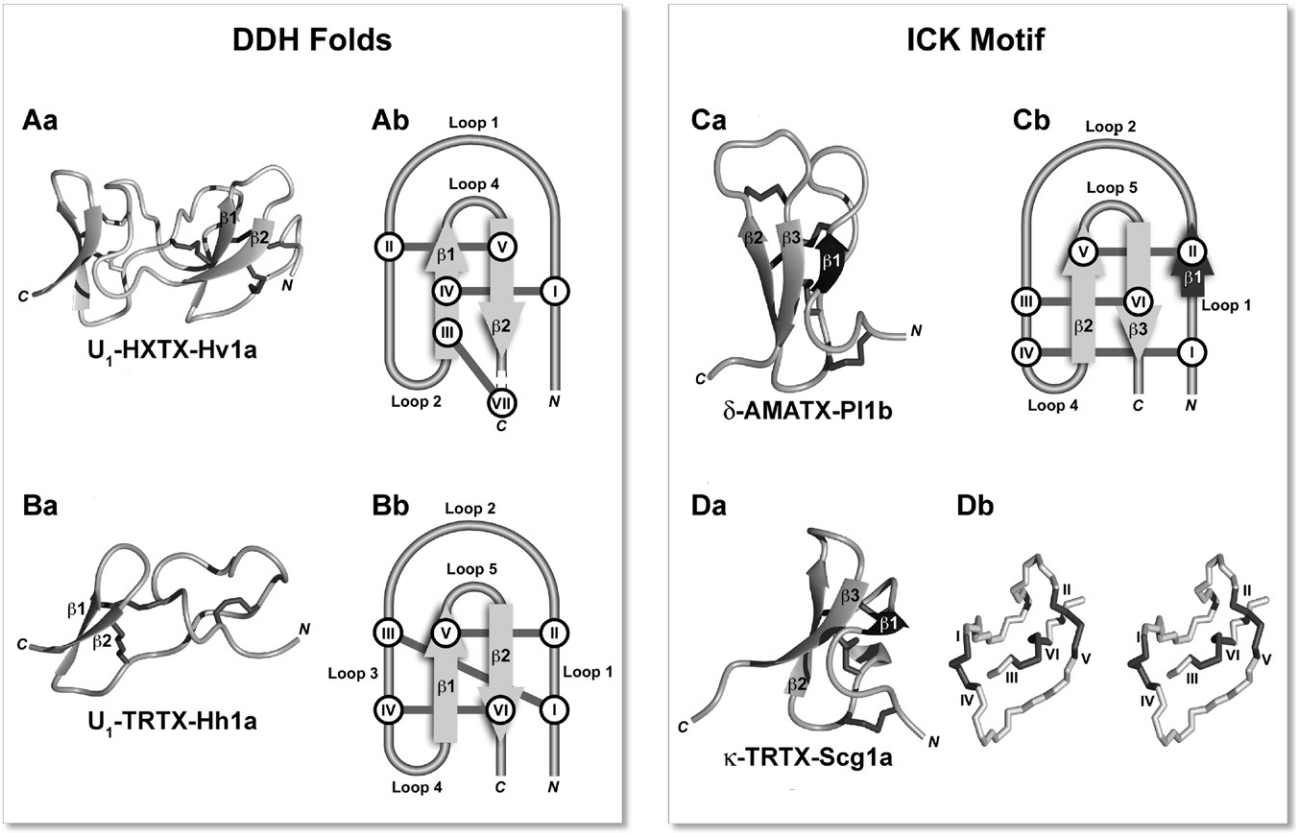

FIGURE 4 Evolution of DDH-related folds (A,B) into the ICK structural motif (C,D). Left-hand panels (Aa-Da) show a schematic view of the 3D structures of typical representatives of the two structural motifs. (Aa) MIT-like U_1-HXTX-Hv1a from *Hadronyche versuta* modeled on the structure of MIT1 from the black mamba snake *Dendroaspis p. polylepis*, (Ba) U_1-TRTX-Hh1a (formerly HWTX-II; PDB 1I25), (Ca) δ-AMATX-Pl1b (PDB 1V91) and (Da) κ-TRTX-Scg1a (formerly SGTx1; PDB 1LA4). Right-hand panels (Ab-Cb) show schematic representations of the structural motifs depicting the formation of the cystine knot and possible addition of the third β-sheet. The dark arrow (β1) in panel Cb represents the additional β-sheet not always present in ICK spider toxins. (Db) Stereoview of the pseudoknot of κ-TRTX-Scg1a. In all panels, β-sheets are shown as gray arrows, and disulfide bridges connecting cysteine residues are shown as dark gray lines with roman numerals.

Several spider toxins have been found to block Na^+ conductance such as μ-CNTX-Pn1a (formerly PNTx1) from *Phoneutria nigriventer*, μ-TRTX-Hh2a (formerly huwentoxin-4) from the venom of *Haplopelma huwenum* and the structurally related μ-TRTX-Hhn1a, -Hhn1b, and -Hhn2a (formerly hainantoxin III–V) from *Haplopelma hainanum*. This action most probably occurs via an interaction with site 1 of the Na_V channel. Interestingly, an ortholog, μ-TRTX-Hhn2b (formerly hainantoxin-I), also has a similar action but displays a 15-fold increase in selectivity for insect vs. mammalian Na_v channels. Therefore, these peptides represent the first family of spider toxins to selectively block Na^+ conductance and, in the case of μ-TRTX-Hhn2b, the first insect-selective toxin to block the Na_v channel.

Spider δ-toxins from funnel-web (*Hadronyche* and *Atrax* spp.) and eastern mouse spiders (*Missulena bradleyi*) are lethal toxins, responsible for the major symptoms of human envenomation (e.g. δ-HXTX-Ar1a; Fig. 5). Together with δ-HXTX-Mg1a (formerly Magi-4) from *Macrothele gigas*, δ-TRTX-Cj1a (formerly jingzhaotoxin-I) from *Chilobrachys jingzhao* and δ-CNTX-Pn2a (formerly PnTx2-6) from *Phoneutria nigriventer*, this family of 33–43 residue peptides has been shown to target the Na_V channel.[14,35] Electrophysiological studies have identified that the lethal δ-HXTXs alter neuronal excitability in both insect and mammalian neurons by causing a prolongation of action potential duration resulting in the appearance of plateau potentials, accompanied by spontaneous repetitive firing. These actions result mainly from a slowing of Na_V channel inactivation. Radiolabel binding experiments reveal that this results from an interaction with site 3 on both mammalian and insect Na_V channels in a comparable manner with the scorpion α-toxins.[2]

Other excitatory toxins interact with Na_V channel site 4 by acting as 'gating modifiers' of activation. δ-Amaurobitoxins (δ-AMATX-Pl1 toxins; formerly δ-paluITs) from the spider *Pireneitega luctuosus* are a family of four insect-selective peptides that act by slowing down insect Na_v channel inactivation, similar to site 3 scorpion neurotoxins such as LqhαIT. Despite this, δ-AMATX-Pl1a (Fig. 4Ca) has been shown to

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

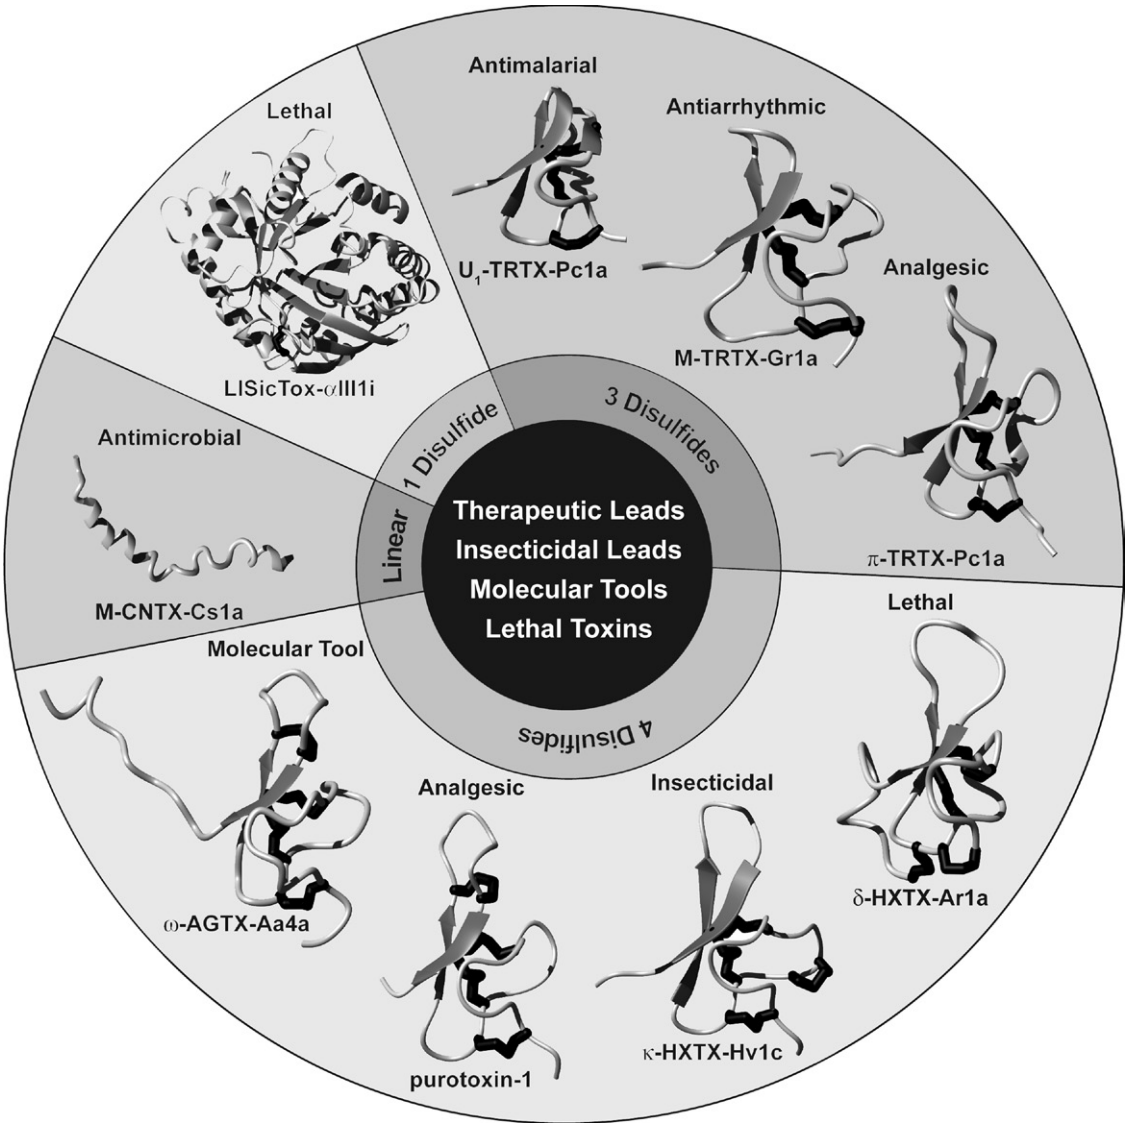

FIGURE 5 Spider venom peptides being investigated as therapeutic or insecticidal leads, together with toxins that are used as molecular tools or have been identified as the causative agent in lethal envenomation. Schematic view of NMR 3D structures showing the location of β-strands (dark gray arrows) and α-helices (light and dark gray helices). Disulfide bridges are shown as thick black tubes. LlSicTox-aIII1i is the X-ray crystal structure of the sphingomyelinase D from *Loxosceles laeta* (PDB 1XX1) responsible for clinical cases of loxoscelism. This toxin has a single disulfide bond Cys^{51}–Cys^{57}.

displace the site 4 excitatory scorpion β-toxin, Bj-xtrIT, from cockroach neuronal membranes and fail to displace LqhαIT binding. Thus, δ-AMATX-Pl1 toxins reveal that the modulation of Na_v channel inactivation can be achieved by binding to a site thought to be associated with the effects on channel activation. In support, the μ-agatoxins from *Agelenopsis* and *Hololena* spp. and β-HXTX-Mg1a (formerly Magi-5) also seem to share this activity.[1] This provides further support for the hypothesis that the insect site 4 is a macrosite, which may be allosterically linked to channel inactivation.

Perhaps the most important discovery in this area is that spider venoms may be excellent sources of Na_V channel subtype specific toxins that could be developed as novel analgesics. Previously, $Na_V1.3$, $Na_V1.7$ or $Na_V1.8$ channels have been identified to be involved in pain signaling, particularly the $Na_V1.7$ subtype. Presently, three spider toxins show $Na_V1.7$ channel subtype selectivity. Of these, the most potent and selective was β-TRTX-Tp2a (formerly protoxin II) a 30-residue ICK peptide from the Green velvet tarantula *Thrixopelma pruriens*. Unfortunately, despite its 100-fold selectivity for $Na_V1.7$ compared with the other Na_V channel subtypes tested, β-TRTX-Tp2a still has relatively high potency against $Na_V1.2$ and $Na_V1.5$ resulting in severe toxicity in rats.[25] In contrast, a highly homologous toxin, β-TRTX-Gr1b (formerly GsAF I), from the Chilean rose tarantula

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Grammostola rosea failed to produce signs of toxicity at analgesic doses.[17] At present, the Na_V subtype selectivity of β-TRTX-Gr1b is unknown, but structure function studies using β-TRTX-Gr1b and β-TRTX-Tp2a should provide key information for the rational design of novel analgesics.

Voltage-Activated Potassium Channels

Voltage-activated K^+ channels are the most abundant ion channels and play important roles in excitable cells such as controlling neuronal excitability, resting membrane potential, and neurotransmitter release. Although there are many voltage-activated K^+ channel families, two are of particular importance to this discussion. First, the outward-rectifying K^+ (K_V) channels are classified into four groups K_V1-K_V4 and, second, Ca^{2+}-activated K_V (K_{Ca}) channels. Spider toxins have been instrumental in the structural and pharmacological characterization of the K_v2 and K_v4 channels particularly those isolated from "tarantula" spider venoms.[7] κ-Sparatoxins-1 toxins (κ-SPRTX-1; formerly heteropodatoxins 1–3) from *Heteropoda venatoria* (Sparassidae) are a family of toxins that prolong the duration of the cardiac action potential via a voltage-dependent block of $K_V4.2$, but not $K_V1.4$, channels. Moreover, the toxins slowed the time course of channel activation and inactivation and caused a depolarizing shift in the voltage-dependence of activation. Thus, κ-SPRTX-Hv1 toxins represent pharmacological tools with which to study transient outward K_V currents in cardiac tissue. Other $K_v4.2$ channel blockers include κ-TRTX-Ps1a and -Ps1b (formerly phrixotoxin-1 and -2) from the venom of *Paraphysa scrofa* and κ-TRTX-Gr1a and -1b (formerly hanatoxins-1 and -2), from *Grammostola rosea*. κ-TRTX-Sc1a (formerly stromatoxin-1), from *Stromatopelma calceatum* blocks $K_V4.2$, but in addition it inhibits $K_V2.2$, and to a lesser extent, $K_V2.1$ and $K_V2.1/K_V9.3$ subtypes. By contrast, κ-TRTX-Hm1a and -Hm2a (formerly heteroscodratoxin-1 and -2), from *Heteroscodra maculata* venom, bind to the voltage sensor and inhibit K_V channels. κ-TRTX-Hm2a seems to be specific for K_V2 channels, whereas κ-TRTX-Hm1a also inhibits $K_V4.1$.[7]

Of interest has been the discovery of a family of insect-selective neurotoxins from the Australian funnel-web spider *Hadronyche versuta* and *Eucratoscelus constrictus*. κ-HXTX-Hv1c (formerly Janus-faced atracotoxin-Hv1c) and κ-TRTX-Ec1 toxins both target K_{Ca} channels in cockroach neurons.[11,34] The most remarkable feature of κ-HXTX-Hv1c is a vicinal disulfide bridge between the sidechains of Cys^{13} and Cys^{14} (Fig. 5). Vicinal disulfide bridges are exceptionally rare in peptides and proteins. By alanine-scanning mutagenesis, the vicinal disulfide as well as Arg^8, Pro,[9] and Tyr^{31}, were determined to form the binding epitope (pharmacophore). Intriguingly, the functionally critical Arg^8 and Tyr^{31} residues in κ-HXTX-Hv1c align extremely well with the Lys–Phe/Tyr diad that is conserved across structurally dissimilar K_{Ca} channel blockers such as BgK, agitoxin2, and charybdotoxin.[11]

Voltage-Activated Calcium Channels

A variety of Ca_V channels are classified into low-voltage-activated (LVA) channels that inactivate rapidly, and high-voltage-activated (HVA) channels that show no inactivation. HVA Ca_V channels are further subdivided according to their pharmacological and biophysical characteristics into $Ca_V1.1$–1.4 (L-type), and $Ca_V2.1$ (P/Q-type), $Ca_V2.2$ (N-type), and $Ca_V2.3$ (R-type). LVA Ca_V channels comprise $Ca_V3.1$–3.3 subtypes (T-type). In the heart and CNS, the $Ca_V2.x$ and $Ca_V3.x$ channels (non-L type) are inhibited by many peptide toxins from animal venoms including a number of spider toxins. Given the role of these Ca_V channel subtypes in neurotransmission, selective toxins could therefore have potential as lead compounds for the development of neuroprotective and analgesic agents. Undoubtedly, the best characterized Ca_V channel blockers are the ω-agatoxins (ω-AGTXs) from *Agelenopsis* spp. spider venom that inhibit release of a variety of neurotransmitters.[1] ω-Agatoxins vary from 5–10 kDa in length and are classified according to their sequence homology and spectrum of activity against insect and vertebrate Ca_v channels. Type- I and Type- II ω-AGTXs are selective blockers of insect Ca_V channels. Type- III ω-AGTXs are inactive in insects but block the binding of the $Ca_V2.2$ channel ligand [^{125}I]ω-conotoxin GVIA to vertebrate membranes, as do toxins from group I. They bind in a voltage-dependent manner to all Ca_V1 and Ca_V2, but not Ca_V3, channels in mammalian neurons. Type- IV toxins such as ω-agatoxin-Aa4a (Fig. 5; formerly ω-Aga IVA) are not toxic at the fly neuromuscular junction but do block Ca_V channels in insect central neurons and block $Ca_V2.1$ channels in mammals. This results from a depolarizing shift in the voltage dependence of activation. ω-Agatoxin-Aa4a has therefore become the defining pharmacology for $Ca_V2.1$ channels. Recently, ω-LCTX-Gsp2671a (formerly ω-Lsp-IA) from a *Geolycosa sp*. has been found to also inhibit $Ca_V2.1$ channels. This toxin decelerates activation kinetics and partially inhibits the amplitude of P-currents in rat cerebellar Purkinje neurons. It also competes with ω-agatoxin-Aa4a for binding to $Ca_V2.1$ channels in hippocampal neurons.[23] A selective $Ca_V2.2$ blocker ω-TRTX-Hh1a (formerly huwentoxin-10) from *Haplopelma huwenum* has also been described, which is likely to be useful as a therapeutic lead for the treatment of pain.[19]

Phoneutria nigriventer and *reidyi* venom also contain several toxins targeting a variety of Ca_v channel subtypes including: ω-CNTX-Pn2a ($Ca_V2.1$ and $Ca_V2.3$), ω-CNTX-Pn3a (Ca_V1 and $Ca_V2.2$), ω-CNTX-Pn1a (Ca_V1), ω-CNTX-Pn4a ($Ca_V2.1$), and ω-CNTX-Pr1a (Ca_V1, $Ca_V2.1$ and $Ca_V2.3$).[9,30] Other spider toxins that target various Ca_V channel subtypes have also been isolated

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

and characterized from mygalomorph (ω-TRTX-Gr1a and ω-TRTX-Hg1a) and araneomorph (ω-CNTX-Cs1a, ω-SGTX-Sf1a, ω-FLTX-Kh1a, ω-PLTX-Pt1a) spiders. Unfortunately, Ca_V subtype selectivity was not always clearly established for many of these latter toxins.

Several insect-selective Ca_v channel blockers have been discovered in various spider venoms. ω-Hexatoxins from the venom Australian funnel-web spiders from *Atrax* and *Hadronyche* spp. in particular have undergone extensive characterization. These peptides are lethal neurotoxins with ω-HXTX-Hv1a (Fig. 5; formerly ω-atracotoxin-Hv1a) one of the most potent insecticidal peptide toxins discovered to date. ω-HXTX-Hv1a binds to orthopteran Ca_V channels at low nanomolar concentrations, whereas it has no effect on cloned human $Ca_V2.1$, $Ca_V2.2$, or $Ca_V1.2$ channels. ω-HXTX-Hv2a, a 45 residue insect-selective toxin, inhibits insect Ca_v channels but with a vastly different 3D structure.[14] Recently, several toxins have been partially characterized from other spider venoms. Perhaps the best characterized is ω-TRTX-Hh2a (formerly huwentoxin-5) from *Haplopelma huwenum*. This peptide is an insecticidal toxin that blocks HVA but not LVA Ca_V channels in adult cockroach DUM neurons but lacks activity on vertebrate neurons. It also lacks activity on insect Na_V or K_V channels. The toxin reversibly paralyzes locusts and cockroaches and causes death at high doses, but it has no effect on mice by intraabdominal or intracerebroventicular injection.[6] Other toxins that have been less well characterized in terms of their target or activity include the ω-oxotoxins (formerly oxytoxin 1 and 2) from *Oxyopes* spp. that are insecticidal but with weak activity on vertebrate HVA Ca_V1 and Ca_V2 channels. ω-oxotoxin-Ol1a was shown to be lethal at high dose to lepidopteran larvae, while being nontoxic to mice at modest doses.[31] ω-TRTX-Ba1a is another insecticidal toxin that is lethal to crickets but causes no adverse effects when injected either intracranially or intraperitoneally into mice at modest doses. The molecular target of the toxin has not been experimentally determined, but it has no effect on insect Para/tipE Na_V channels or mammalian $Na_V1.2$ and $Na_V1.5$ channels. The toxin shows strong sequence homologies to ω-TRTX-Asp1g from the related spider *Aphonopelma sp.* that is known to be insecticidal and which is assumed to inhibit Ca_V channels.[5] Finally, ω-PLTX-Pt1a is assumed to be insecticidal as it seems to block presynaptic Ca_V2 channel currents in *Drosophila* nerve terminals but not synaptic transmission at the frog neuromuscular junction. Interestingly, it contains a unique posttranslational modification, namely a C-terminal *O*-palmitoyl threonine amide residue, which is essential for toxin activity.[16]

Acid-Sensing Ion Channels

An exciting development has been the discovery of a spider toxin targeting novel acid-sensitive ion channels (ASIC) belonging to the epithelial sodium channel/degenerin (ENaC/DEG) superfamily. These proton-gated sodium channels are associated with nociception, taste transduction, and perception of extracellular pH changes in the brain and sensory ganglia and may also contribute to synaptic plasticity, learning, and memory. The ASIC1a subunit, the most abundant ASIC subunit in the CNS, has been implicated as a novel therapeutic target in pain, ischemic stroke, depression, and autoimmune and neurodegenerative diseases such as multiple sclerosis, and Huntington's and Parkinson's Disease. π-TRTX-Pc1a (Fig. 5; formerly psalmotoxin 1), isolated from the venom of *Psalmopoeus cambridgei*, has been found to selectively inhibit homomultimeric ASIC1a channels, but not other ASIC subtypes. The mechanism of ASIC1a inhibition by π-TRTX-Pc1a is not yet understood, however, given that gating of ASIC channels by protons is likely to be different from that of the voltage-activated channel family, this may be via a novel mechanism. So far this is the only selective ligand with which to study the functional role and pathophysiology of ASIC channels. π-TRTX-Pc1a is efficacious as an analgesic in rat models of acute pain and as a neuroprotectant in a model of ischemic stroke. Docking models of the π-TRTX-Pc1a–ASIC1a complex are now offering new insights into the mechanism by which π-TRTX-Pc1a modulates the activity of ASIC1a.[24]

Mechanosensitive Ion Channels

Mechanosensitive channels (MSCs) potentially transduce many external (sound, vibration, and touch) and internal stimuli (local blood flow control, cell volume regulation, and dilation-induced heart rate changes). The only well-characterized MSCs cloned from eukaryotes are a subset of the K^+ selective 2P family. However, the physiological role of these channels is only just starting to be explored after the discovery of M-TRTX-Gr1a (Fig. 5; formerly GsMTx4) as a specific ligand.[21] This peptide was isolated from the venom of *Grammostola rosea* and produces a complete and specific block of MSCs in astrocytes and kidney cells. However, this seems to result from a perturbation of the channel-bilayer boundary, which no doubt underlies its antimicrobial activity (hence 'M' prefix). M-TRTX-Gr1a also blocks MSCs in atrial tissue, suggesting it could also be a new lead compound for the development of antiarrhythmics and drugs to treat atrial fibrillation, spinal cord damage, muscular dystrophy, and gliomas. Several spider toxins, which block cation-selective MSCs with additional actions on voltage-activated ion channels, have been isolated from *G. rosea* venom. These include κ-TRTX-Gr2c (formerly GsAF II) that has been patented as an antiarrhythmic and analgesic peptide[17,18] as well as κ-TRTX-Gr2a (formerly GsMTx-2) and the identical peptide κ-TRTX-Ps1b from *Paraphysa scrofa* that have only weak affinity with MSCs.

Purinergic (P2X) Receptors

$P2X_1$–$P2X_7$ purinergic receptors are ATP-gated cation-selective ion channels, of which some subtypes are associated with the transmission of nociception. In particular, $P2X_3$ receptors are involved in a wide range of pain states. Purotoxin-1 from *Geolycosa* sp. is the first potent and selective modulator of $P2X_3$ receptors from spider venom (Fig. 5). This 35-residue ICK peptide produces potent analgesic effects in the low nanomolar range in a variety of inflammatory pain models. This involves a complex mechanism of action to prolong the rate of recovery from $P2X_3$ channel desensitization.[10] Thus, purotoxin-1 represents a promising lead compound for the development of analgesics targeting $P2X_3$ receptors.

Transient Receptor Potential (TRP) Channels

Transient receptor potential (TRP) channels are a superfamily of cation channels that are also the target of spider peptides. TRPV1 is a nonselective cation channel that is preferentially expressed on Aδ and C pain fibers and in sensory neurons in pain pathways. τ-TRTX-Pc1c (formerly vanillotoxin 3), and to a lesser extent τ-TRTX-Pc1b (formerly vanillotoxin 2), are potent and selective members of a family of toxins from *Psalmopoeus cambridgei* that activate TRPV1 channels.[26] Another toxin τ/κ-TRTX-Pc1a (formerly vanillotoxin 1) also inhibits $K_V2.1$ channels, supporting potential similarities between TRP and voltage-gated channel structures. TRP channels can now be included among the targets of peptide toxins, showing that spiders, like plants (e.g. capsaicin from chilli plants), deter predators by activating TRP channels on sensory nerve fibers to elicit pain and inflammation.

Glutamate Receptors or Transporters

Arguably, the most important excitatory neurotransmitter in the mammalian CNS and insect peripheral nervous system is L-glutamate. Although there have been a wide range of glutamate receptor antagonists found in spider venoms, these are mostly acylpolyamines (in particular α-agatoxins [1]). The only peptide toxin from spider venom known to interact with glutamate receptors is Γ-CNTX-Pn1a (formerly PnTx4(5–5)) from *Phoneutria nigriventer*, an insecticidal toxin that also reversibly inhibits ionic currents mediated through NMDA receptors in rat hippocampal neurons.[9] However, δ-CNTX-Pn1b (formerly PnTx4-3) from the same venom also inhibits glutamate uptake in rat cortical synaptosomes. ω-CNTX-Pn3a (formerly PnTx3-4) decreases glutamate release from synaptosomes via a block of glutamate transporters in synaptosomes in addition to its activity to block $Ca_V2.x$ channels. These toxins therefore provide *P. nigriventer* spiders with the means to disrupt specific aspects of insect glutamate neurotransmission.

Antimalarial Toxins

The ability of spider venom peptides to produce selective toxicity against various microorganisms also encompasses the malaria parasite *Plasmodium falciparum*. Two unrelated ICK peptides, U_1-TRTX-Pc1a (Fig. 5; formerly psalmopeotoxin I) and U_2-TRTX-Pc1a (formerly psalmopeotoxin II) both from *Psalmopoeus cambridgei* inhibit the intraerythrocyte stage of *Plasmodium falciparum*.[3] Importantly, neither peptide has significant hemolytic, antifungal or antibacterial activity or displayed overt neurotoxicity. Presently, the mechanism underlying the antimalarial action is unknown but may involve new permeability pathways that are established in the erythrocyte membrane following parasite invasion. Thus, in addition to being useful therapeutic leads, these peptide toxins might help validate a new antimalarial drug target.

CONCLUSIONS AND FUTURE DIRECTIONS

Using several molecular mechanisms, spiders have developed a combinatorial peptide library strategy to vary their toxin pool.[27] New pharmacologies have been produced by hypermutation of the mature toxin sequence resulting in a rich diversity of neurotoxins with high potency and selectivity for multiple cellular targets built onto a stable protease-resistant peptide backbone. This confers an evolutionary advantage for the spider, enabling them to efficiently immobilize a wide variety of prey. As pharmacologists, we can take advantage of this preoptimized peptide library as a diversified source of molecular probes for identifying subtype differences in specific targets and as leads for novel therapeutics such as analgesics, antimalarials, antiarrhythmics, neuroprotectants, and antimicrobials.

Given that spiders rely upon their venom to immobilize or kill their prey, it is not surprising that they also contain a wide variety of insect-selective toxins that may provide the basis for the development of biopesticides. Interestingly, a large number of these phyla-specific toxins target voltage-activated ion channels. These represent suitable targets for the future development of insecticides because they are ubiquitous among insects. This may lead to the development of more efficacious and more selective insecticidal toxins.

To date, very few studies have investigated the actions of spider toxins on transmitter-gated ion channels, G protein-coupled receptors or transporters. Given the important role these structures play in homeostasis in invertebrates and vertebrates, and the increasing use of target-based high-throughput assays, future research should lead to discovery of additional spider toxin pharmacologies beyond those already discussed in this review. This should also provide leads for the development of new therapeutics and bioinsecticides and validate novel drug and insecticide targets.

Chapter 64

Targets and Therapeutic Properties

Christine Beeton

ABSTRACT

A large number of animals produce venoms to defend themselves from predators or to catch, eat, and digest prey. When injected into humans, these venoms can induce unpleasant effects, from mild itching to death within minutes. However, these venoms also have the potential for development into drugs useful for human health. Each venom contains as many potential drugs as the compound library of a medium to large pharmaceutical company. Some of these peptides may even have more than one potential therapeutic use. Such peptides are identified almost daily, but most are yet to be studied in detail for their potential usefulness. Venoms therefore still remain a largely untapped source for therapeutics. This chapter reviews the relatively few venom peptides that have been identified to date and are at different stages of development into potential therapeutics.

The ability of animals to kill with tiny amounts of powerful venom has inspired both fascination and fear in humans around the world since the dawn of civilization. Snakes and scorpions were worshipped as deities in many ancient religions in Egypt, Greece, India, China, and Mesoamerica. In the Biblical Garden of Eden, the snake tempted Eve into tasting the forbidden fruit, forcing her and Adam into exile in an impermanent world. The Aztec deity Quetzalcoatl was a feathered snake and in Greek mythology, Medusa's head of writhing snakes inspired terror. More recently, French author Antoine de Saint-Exupéry used the venomous bite of a snake "fast as lightening" to send the Little Prince back to his planet and his very special rose.

In spite of all this bad press, venomous animals have also long been associated with healing and in early Babylon the symbol of two intertwined snakes represented fertility, wisdom, and healing. Asclepius, the Greek god of medicine, carried a staff with a sacred snake coiled around it, which has become and remained the Caduceus, the symbol of Western medical science. Ancient and modern medicine both use venom as a rich source of compounds with a wide range of useful pharmacological activities. For example, traditional Chinese medicine uses venom, extracts, or whole scorpions to treat a variety of conditions, including rheumatic diseases, pain, meningitis, epilepsy, or stroke.

This chapter focuses on recent scientific advances in the exploitation of venom, an extensive and still largely untapped pharmacopoeia, for the development of therapeutics. It was organized by disease targets, and for each target, peptides of interest are grouped by their animal source. Some peptides, such as mellitin from the venom of the European honey bee, *Apis Mellifera*, have >1 potential therapeutic target and are therefore listed more than once in this chapter.

CARDIOVASCULAR DISEASES

Anticoagulants and Thrombolytic Agents

Venomous creatures are an abundant source of anticoagulants and thrombolytic agents that are widely used in the management and diagnosis of cardiovascular diseases. These include disintegrins, direct thrombin inhibitors, fibrinolytic compounds and plasminogen activators.[27]

Snake Venoms

Snake venoms contain a variety of disintegrins that affect both the platelet aggregation and adhesion. Two of these have already been approved for preventing and treating thrombotic complications in patients undergoing percutaneous coronary intervention (such as stenting or angioplasty) and in patients with acute coronary syndrome.[27] These drugs are Eptifibatide/Integrilin® (barbourin, eptifibatide), a cyclic heptapeptide from the venom of the Pygmy rattlesnake (Sistrurus miliarus barbouri), and Tirofiban/Aggrastat®, a peptidomimetic of echistatin from the venom of *Echis carinatus*. They inhibit platelet aggregation by binding with high affinity to the fibrinogen receptor (a.k.a integrin αIIbβ3) via a Lys-Gly-Asp recognition sequence.

Other disintegrins isolated from snake venom use the more common Arg-Gly-Asp recognition sequence to interact with their target receptor.[27] The list is extensive—rhodostomin and Ancrod/Viprinex™ from the Malaysian pit viper (*Calloselasma rhodostoma*) developed to treat acute ischemic stroke, Batroxobin/Defibrase® from *Botrox atrox moojeni*, salmosin from the Siberian pit viper (*Agkistrodon halys brevicaudus*), echistatin from the African saw-scaled viper (*E. carinatus*), dendroaspin (mambin) from Jameson's Mamba (*Dendroaspis jamesoni kaimose*), and crotavirin from the Western Rattlesnake (*Crotalus viridis*). Although disintegrins have similar functions, they have different structures.

Fibrolase from the Southern Copperhead snake is an enzyme that cleaves fibrin. It consists of 203 amino acids, has a molecular weight of approximately 23kDa, is held together by three disulfide bonds, and belongs to the class of nonglycosylated metalloproteinases known as metzincins or alpha-fibrinogenases.[32] Alfimeprase, a recombinant fibrinolytic enzyme derived from fibrolase, was evaluated in clinical trials. It unfortunately failed to meet the primary endpoint in phase-III clinical trials and was therefore suspended.

Ximelagatran/Exanta®, from cobra venom, was the first oral anticoagulant to follow warfarin, a vitamin K antagonist. However, it causes severe hepatotoxicity and was thus removed from the market.[27]

Medicinal Leech Venom

Hirudin exemplifies antithrombin anticoagulants.[5] It is a peptide of 65 amino acids with three disulfide bonds and is derived from the saliva of the medicinal leech. Hirudin forms a biomolecular complex with thrombin via its acidic C-terminus and thereby prevents the activity of thrombin. Hirudin has been produced synthetically and used in the treatment of deep vein thrombosis and for coronary angioplasty reparation. A topical cream manufactured from hirudin is used to shrink hematomas caused by musculoskeletal injuries. Desirudin, a recombinant form of hirudin, is effective in the treatment of heparin-induced thrombocytopenia. A number of derivatives of hirudin are available, including hirugen, a synthetic C-terminal peptide fragment of hirudin, hirulog (bivalirudin; 20 amino acid peptide), a derivative of hirugen, and Argatroban (heterocyclic peptidomimetic).

Vampire Bat Venom

Desmoteplase, a salivary plasminogen activator from the vampire bat *Desmodus rotundus* (DSPA alpha 1) exhibits 85% sequence similarity with human tissue plasminogen activator. It was shown >40 years ago to be a potent plasminogen activator and is currently undergoing clinical trials for use in acute ischemic stroke with encouraging results.[9]

Tick Venoms

Contact phase inhibitor, a protein from the tick *Ixodes ricinus* saliva, inhibits human kallikrein and factors Xia and XIIa in the coagulation cascade. It reduces venous and arterial thrombi and protects against embolic events in rodents.[5]

Ixolaris, from the saliva of the tick *Ixodes scapularis*, blocks coagulation factors X and Xa and decreases the formation of venous thrombi in rodents.[5]

A protein isolated from the tick *Ornithodoros moubata* that inhibits coagulation factor Xa has been used in experimental femoral artery balloon angioplasty in rabbits.[5]

Procoagulant Drugs

Haemocoagulase® is a mixture of two proteinases isolated from the venom of the snake *Botrox atrox*.[27] They have a thromboplastin-like and a thrombin-like activity. One activates factor X in the coagulation cascade, whereas the other cleaves off fibrinopeptide A, leading to coagulation of fibrinogen. Haemocoagulase® is indicated for the prevention and treatment of hemorrhages by accelerating platelet aggregation and shortening coagulation time and thus loss of blood.

Diagnosis of Coagulopathies

Many snake venom-derived peptides are used as diagnostic tools for coagulation disorders.[27]

ACC-C/Protac® is a serine proteinase from *Agkistrodon contortix* venom that potently and rapidly activates protein C through a thrombomodulin-independent mechanism.[27] It is used to diagnose protein C and protein S deficiencies or defects in the protein C anticoagulant pathway.

RVV-V is a serine proteinase from *Daboia russelli* venom that activates factor V by cleaving it at Arg1545 and is not inhibited by antithrombin.[27] It is used to test for blood levels of factor V and for identifying the resistance of factor V to inactivation by activated protein C caused by the coagulation factor V Leiden mutation. One of the commercial tests (Pefakit®) also includes a group D prothrombin activator, noscarin from *Notechis scutatus*.

RVV-X is a factor X activator from *D. russelli* venom used in several clotting tests for assaying blood levels and deficiencies in factor X in the coagulation cascade, and in lupus anticoagulant assays.[27]

Ecarin is a selective group A prothrombin activator from *E. carinatus* venom.[27] The Ecarin clotting time is a laboratory test for monitoring prothrombin levels in patients undergoing anticoagulant therapy with Hirudin (described above in section Anticoagulants and Thrombolytic Agents). It is also used for diagnosing disseminated intravascular coagulation and for preparing meizothrombin.

Botrocetin® is a C-type lectin-like protein isolated from the venom of *Bothropps jararaca*. It aggregates platelets by

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

inducing the von Willebrand factor to bind to the platelet GPIb receptor. It is used to determine the concentration of von Willebrand factor in plasma and for detecting disorders such as von Willebrand and Bernard–Soulier diseases.

Alboaggregin-B, another C-type lectin-like protein, from *Trimeresurus albolabris* venom competes with the von Willebrand factor for binding to platelet GPIb receptor and has been used to quantitate von Willebrand factor on platelets.[27]

Batroxobin, a snake venom thrombin-like enzyme isolated from *Bothrops atrox* venom, plays a role in the Reptilase time test.[27] This assay is an alternative to the thrombin time clotting assay for samples containing heparin, a thrombin inhibitor. Ancrod/Viprinex™ can also be used in this assay in place of Batroxobin. The Reptilase time test is used to diagnose various fibrinogen polymerization diseases, low levels of fibrinogen, and the presence of fibrin degradation products. Batroxobin is also used for the preparation of desAA-fibrinogen (fibrinogen lacking fibrinopeptide A) for the assay of tissue plasminogen activator.

Antihypertensive Agents

Antihypertensive drugs have important and increasing medical uses because of the increase in chronic hypertension in developed countries.

Snake Venoms

The Brazilian arrowhead viper (*Bothrops jararaca*) produces peptide inhibitors (e.g. nonapeptide SQ 20,881 or teprotide) of angiotensin-converting enzyme (ACE), a hormone that cleaves angiotensin I to generate angiotensin II and causes vasoconstriction and increased blood pressure. These snake peptide inhibitors bind to the active site of ACE in the same manner as natural substrates and reduce blood pressure. Captopril was the first drug based on a protein derived from snake venom >30 years ago.[14]

Snake venoms, such as those from *Dendroaspis angusticeps*, *Micrurus corallines*, *B. jararaca*, *Trimeresurus flavoviridis*, *Trimeresurus gramineus*, or *Agkistrodon halys blomhoffii* (and many others), represent one of the major sources of exogenous natriuretic peptides. These peptides are potent body fluid volume regulators and therefore reduce blood pressure.

Frog Venoms

A number of neurotensin-like peptides identified from frog skin (e.g. margaratensin and ranatensin) are hypotensive in rats and have the potential for development into novel therapeutics.

Antiarrhythmic Agents

Atrial fibrillation can be acute or chronic and has potentially serious squeals, including stroke and death.

Spider Venom

The Venom from the South American tarantula (*Grammostola spatulata*) contains GsMtx-4, a small peptide belonging to the 'cysteine-knot' family that blocks cardiac stretch-activated ion channels in the mid-nanomolar range and suppresses atrial fibrillation in rabbits. Efforts are underway to develop therapeutics for atrial fibrillation based on GsMtx-4. This peptide also holds promise as an analgesic and for the treatment of Duchenne muscular dystrophy, as described later in this chapter.[3,5]

Heart Failure

Human natriuretic peptides, such as Neseritide and Carperitide, are used in the management of congestive heart failure, but several of their exogenous reptilian counterparts hold therapeutic value too.

Snake Venoms

A chimeric peptide (CD-NP) was formed by fusing the 15 residue C-terminal tail of the dendroaspis natruiretic peptide (isolated from the green mamba, *Dendroaspis angusticeps*) with the taipan natruiretic peptide c (isolated from the inland taipan, *Oxyuranus microlepidotus*). This chimeric peptide was well tolerated with minor side effects in healthy humans and is currently in phase-II clinical trials in acute decompensated heart failure and stable chronic heart failure.[34]

INFECTION, IMMUNITY, AND ONCOLOGY

Antimicrobial Peptides

The increasing resistance of pathogenic or opportunistic bacteria to antibiotics is a major health concern, especially with the emergence of nosocomial infections, and new antibacterial compounds need to be developed. Many venomous creatures produce one or more antimicrobial peptides, which could be developed into new classes of antibiotics or antimicotics.

Frog and Toad Venoms (see the Amphibian/Skin Peptides Section of the Book)

The first peptide with antimicrobial activity was isolated from the skin secretions of the African clawed frog, *Xenopus laevis* (Pipidae). Since then, several hundred more such antimicrobials have been identified in skin secretions or skin extracts from frogs and toads. Although not all frogs and toads produce antimicrobial peptides in their skin secretions, a large number across families do produce interesting antimicrobial compounds, from ancient Archaeobactrachia

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

to the more recent Neobatrachia.[8] These peptides can be grouped into families based on limited similarities in amino acid sequence, as listed below.

Within the Leiopelmatidae family, *Ascaphus truei* produce at least eight peptides (ascaphin 1–8) with broad-spectrum antimicrobial properties but greatest activity against Gram-negative bacteria. Ascaphin-8 is particularly interesting for development into an anti-infective agent.[8]

In the Alytidae family, *A. obstetricians* produces two families of structurally related antimicrobial peptides. Alyteserin-1 peptides display selective antibacterial effects against Gram-negative bacteria and also have low hemolytic activity against human erythrocytes.[8] Alyteserin-1c is especially interesting for its potency against multidrug-resistant strains of the nosocomial pathogen *Acinetobacter baumannii*. Alyteserin-2 peptides in contrast preferentially target Gram-positive bacteria, such as *Staphylococcus aureus* and also exhibit low hemolytic activity.[8]

Antimicrobial peptides have been discovered in the skin secretions of fire-bellied toads from Europe (*Bombina bombina* and *B. variegata*) and from Asia (*B. orientalis* and *B. maxima*), all members of the Bombinatoridae family. Bombinin has a strong hemolytic activity. Its analogs BLP-1 and BLP-3 have antimicrobial activity against both Gram-positive and Gram-negative bacteria, as well as against *Candida albicans*. Both have low hemolytic activity, making them interesting lead compounds for further clinical use. In contrast, bombinin H2 and H4 are more hemolytic and less potent against microorganisms and therefore less interesting as lead compounds for the development of new therapeutics.[8]

In the Pipidae family, *Xenopus laevis* produces magainin-1 and -2, peptide glycine-leucine amide (PGLa), and additional antimicrobial peptides with varying potencies and specificities.[8] A lysine-substituted analog of magainin-2 (Pexiganan) is a potent broad-spectrum antimicrobial with low toxicity against mammalian cells. It is being developed as a topical therapy for infected foot ulcers in patients with diabetes. Orthologs of magainin-1 and -2 were identified in the skin secretions of *X. borealis* and *X. amieti*. The skin secretion of *Silurana tropicalis* contains at least seven host-defense peptides.

Within the Myobatrachidae family, antimicrobial peptides have been found in the extracts of skin glands of species belonging to the *Uperoleia* and *Crinia* genera.[8] Uperins from the Australian frogs *U. mjoberii* and *U. inundata* are active against Gram-positive bacteria. *C. signifera* produces two highly homologous peptides, signiferin 2.1 and 2.2, also active against Gram-positive bacteria. A structurally related peptide, riparian 2.1, was isolated from *C. riparia*.[8]

The large Hylidae family is a rich source of antimicrobial peptides grouped into five families based on amino acid sequence similarities (dermaseptins, phylloseptins, plasticins, dermatoxins, and phylloxins) and a number of orphan peptides.[8]

Most frogs from the Leptodactylidae family and the genus *Leptodactylus* produce one or more structurally related peptides with antimicrobial activity.[8]

Within the African frogs of the Hyperoliidae family, antimicrobial peptides have to date only been identified in the skins of the running frogs from the genus *Kassina*. Kassinatuerin-1, from *K. senegalensis*, displays potent growth inhibitory activity against *Escherichia coli* and *Staphylococcus aureus*. However, it also displays strong hemolytic activity, which limits its attractiveness as a potential drug for clinical use.[8]

Four small peptides (11–12 amino acids) with broad-spectrum antimicrobial activity were identified in the skin of the Indian *Hoplobatrachus tigerinus*, from the Dicroglossidae family, and named tigerinins.[8]

Frogs from the Ranidae family produce very diverse antimicrobial peptides in their skin secretions. Temporins are small (8–21 residues) and easy to synthesize, they have therefore received attention for development into therapeutics.[8] Most temporins affect specifically Gram-positive bacteria, but temporin-L from *Rana temporaria* and temporin-1DRa from *R. darytoniii* are active against clinically relevant Gram-negative bacteria and *C. albicans*. Other antimicrobial peptides produced by Ranidae frogs include the following families: brevinin-1 and -2, esculentin-1 and -2, ranatuerin-1, palustrin-2, and nigrocin-2.

Ant Venoms

The jumper ant *Myrmecia pilosula* produces broad-spectrum antibacterial and antifungal peptides (the pilosulins) but, like many frog-derived antimicrobials, these peptides also exhibit significant hemolytic activity.[11] Modification of pilosulin-1 increased its antimicrobial activity while reducing its hemolytic activity, making it far attractive as a potential therapeutic.

Scorpion Venoms

Antimicrobial peptides have also been isolated from both the venoms and the hemolymph of scorpions. Most are small (15–22 amino acids), amphipathic, and positively charged. These peptides can be grouped into three different families, as detailed below.[26]

The first family consists of homologs of insect defensins.[26] These can eliminate both Gram-positive and Gram-negative bacteria, and also fungi, protozoans, and viruses.[4] Both insect and scorpion defensins are receiving great interest as lead compounds for the development of therapeutics.

The second group includes cysteine-free antimicrobial scorpion peptides. These include parabutoporine from *Parabuthus schlechteri*, pandinins 1 and 2 from *Pandinus imperator*, hadrurin from *Hadrurus aztecus*, Bmkbpp3 from *Buthus martensii*, and opistoporins 1 and 2 from *Opistophtalmus carinatus*.[26]

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

The third group consists of peptides that combine the properties of the first two families. It includes scorpine from *Pandinus imperator* and IsCT from *Opisthacanthus madagascariensis*.[26]

Spider Venoms

Antimicrobial peptides called oxyopinins (composed of 48 amino acid residues) were isolated from the wolf spider (*Oxyopes kitabensis*) and the lynx spider (*O. takobius*) and share sequence similarity with the frog dermaseptins.

GsMTX-4, isolated from the venom of the tarantula *Grammostola spatulata*, affects the growth of both Gram-positive and Gram-negative bacteria.[3]

Wasp, Hornet, and Bee Venoms

A 10-residue antimicrobial peptide called anoplin found in the venom of the solitary wasp *Anoplius samariensis*, and its synthetic analogs, exhibit broad-spectrum antimicrobial activity against both Gram-positive and Gram-negative bacteria, including *E. coli* and *S. aureus*.[19] Other antimicrobial peptides from wasp, hornet, and bee venoms include two peptides from the venom of the neotropical social wasp *Agelaia pallipes pallipes* called protonectin and agelaia, crabrolin, a 13-residue peptide present in the venom of the hornet *Vespa crabro*, mellitin, a 26-amino acid peptide from European honey bee venom, and bombolitins from the bumble bee (*Megabombus pennsylvanicus)*.

Snake Venoms

Peptides derived from a snake venom phospholipase A2 are effective as broad-spectrum bactericidal agents and also as antiendotoxic compounds.[28] Antifungal peptides have also been isolated from the venom of the Brazilian arrowhead viper (*Bothrops jararaca*). Crotamin, from the venom of *Crotalus durissus terrificus*, is a potent antimicrobial.[13]

Sea Squirt

Halocidin, a heterodimer antimicrobial peptide from the sea squirt tunicate (also known as sea peach) *Halocynthia aurantium*, consists of two subunits containing 18 and 15 amino acids, respectively. It is effective against methicillin-resistant *Staphylococcus aureus* and multidrug-resistant *Pseudomonas aeruginosa* and is therefore of special interest for the development of treatments against nosocomial infections.[12]

Centipede

Two peptides isolated from the Chinese red-headed centipede (*Scolopendra subspinipes mutilans*), scolopin 1 and 2, are antibacterial *in vitro*.[5]

Immunomodulatory Peptides

Venom-derived peptides from a number of sources are being evaluated as immunomodulators for the treatment of autoimmune or allergic diseases and the prevention of graft rejection.

Ant Venom

Venom from the tropical ant *Pseudomyrmex triplarinus* contains heterodimeric peptides called myrmexins that relieve pain and inflammation in patients with rheumatoid arthritis and inhibit inflammatory carragenin-induced edema in mice.[24]

Scorpion Venoms

The venoms of scorpions represent a rich source of peptides that block the Kv1.3 and KCa3.1 channel in human T and B lymphocytes. The most potent scorpion Kv1.3 channel blockers include OSK1 (from *Orthochirus scrobiculosus*), its analog OSK1-$K^{16}D^{20}$, margatoxin (from *Centruroides margaritatus*), kaliotoxin (from *Androctonus mauretanicus mauretanicus*), agitoxin-2 (from *Leiurus quinquestriatus*), hongotoxin-1 (from *Centruroides limbatus*), noxiustoxin (from *Centruroides noxius*), Pi1 (from *Pandinus imperator*), and anuroctoxin (from *Anuroctonus phaiodactylus*). Many more are discovered every year, and a large number are still probably unknown.[33] Several of these peptides showed efficacy in treating animal models of inflammation in rodents and pigs, such as delayed-type hypersensitivity, experimental autoimmune encephalomyelitis (an animal model for multiple sclerosis), and inflammatory bone resorption in experimental periodontal disease. Maurotoxin, from *Scorpio maurus*, is the most potent inhibitor of the human T and B lymphocyte KCa3.1 channel, whereas charybdotoxin, from *Leiurus quinquestriatus*, blocks both Kv1.3 and KCa3.1 channels at low nanomolar concentrations.[33]

Sea Anemone Venoms

Two peptides with 35 amino acids, ShK and BgK, were isolated from the Caribbean sea anemones *Stichodactyla heliantus* and *Bunadosoma granulifer*a, respectively.[6] These were later shown to block Kv1.3 channels. ShK blocks T and B lymphocyte Kv1.3 channels with an IC_{50} value of 11pM, and it also blocks the neuronal Kv1.1 channel at similar concentrations. Modification of ShK generated an analog, ShK-186, with high affinity and selectivity for Kv1.3 channels. It is an extremely stable compound, suppresses the proliferation of autoimmune associated disease-relevant effector memory cells at picomolar concentrations, is effective *in vivo* in preventing and treating animal models of delayed-type hypersensitivity, multiple sclerosis, and rheumatoid arthritis, and exhibits an excellent safety index

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

in rodents and nonhuman primates. ShK-186 is being developed as an injectable therapeutic for the treatment of autoimmune diseases.[6]

Snake Venoms

A derivative of cobratoxin from the Thailand cobra (*crotalus dirissus terrificus*), called CAM-NTX, prevents disease in a guinea pig model of the chronic inflammatory disease multiple sclerosis by reducing lymphocytic infiltration into the brain. Antibody titers to myelin basic protein (MBP), a major component of central nervous system myelin, are also reduced in treated animals. Its mechanism of action is yet to be defined.

Bee Venoms

Apitherapy (the use of bee products) has long been used in patients with the chronic inflammatory diseases such as rheumatoid arthritis and multiple sclerosis. Venom from the honey bee (*Apis mellifera*) is often injected at a traditional acupuncture point (Zusanli), and its analgesic and anti-inflammatory actions have been shown both in animal models and human trials of autoimmune arthritis and multiple sclerosis.[16] The anti-inflammatory effects of bee venom are at least in part mediated by melittin through the inhibition of the cyclooxygenase COX-2 and of the production of superoxide by neutrophils, both major players in the maintenance and amplification of inflammation in the joints during rheumatoid arthritis. However, mellitin also exhibits hemolytic and cytotoxic activities against mammalian cells and needs to be modified before it can be safely developed into a drug.

Bombolitins from the bumble bee *Megabombus pennsylvanicus* degranulate mast cells and induce the release of histamine and other bioactive compounds. It may therefore have therapeutic use.[1]

Frog Venoms

Tachykinins and their receptors are widely recognized as therapeutic targets for inflammatory diseases. Ranamargarin is one of more than 20 tachykinins isolated from frog skin and could serve as a template for a novel anti-inflammatory drugs.[17]

Antitumor Peptides

Venomous creatures are an abundant source of antiproliferative peptides, many of which are in clinical trials for the treatment of various types of cancer.

Scorpion Venoms

Chlorotoxin, a 36-amino acid basic peptide from the venom of the scorpion *Leiurus quinquestriatus*, blocks chloride channels expressed by glioma cells but not by normal glial cells.[31] Chlorotoxin binds *in vitro* to medulloblastomas, neuroblastomas, ganglioneuromas, melanomas, pheochromocytomas, and small cell lung carcinomas and to mice gliomas *in vivo*. ^{131}I-labeled chlorotoxin (^{131}I-TM-601) has been effective in targeted radiotherapy of gliomas in mice. ^{131}I-TM-601 was also evaluated in phase-I clinical trials and was deemed safe and tumor specific. Further clinical trials are under way.[31]

Bengalin, isolated from the Indian black scorpion (*Heterometrus Bengalis Koch*), is a large protein of 72kDa.[5] It induces apoptosis in human leukemic cells *in vitro*. Bengalin also shows efficacy in a rat model of osteoporosis but exhibits subacute cardiotoxicity.

Toad Venoms

Bombesin, a tetradecapeptide neurohormone isolated from the skin of the fire-bellied toad (*Bombina bombina*), binds to Bombesin receptors. These receptors are frequently expressed at high levels by a variety of tumors (such as breast, colon, lung, ovarian, urinary bladder, skin, and prostate). Bombesin is used to target cytotoxic drugs directly to these tumors. AN-152, a cytotoxic analog of bombesin containing doxorubicin, exhibited disease stabilization during phase-I clinical trials in ovarian and endometrial cancers. It is now undergoing phase-I or phase-II clinical trials in various cancers.[29]

Snake Venoms

Disintegrins from snake venom may have therapeutic use in suppressing tumor growth by inhibiting angiogenesis. Contortrostatin from the Broad Banded Copperhead snake (*Agkistrodon contortrix*) is a homodimeric disintegrin, each subunit having a molecular mass of 6750Da. Contortrostatin inhibits β1-integrin-mediated cell adhesion of human melanoma and blocks experimental metastasis of these tumors and breast cancers. Vicrostatin, a chimeric recombinant disintegrin generated through the fusion of the C-termini of echistatin and contortrostatin reduces breast cancer tumor growth in rodents and is well tolerated.[20] Jerdonin, another disintegrin from the venom of the Oriental pit viper (*Trimeresurus jerdonii*), improves the survival time of B16 tumor-bearing mice.

Crotamin, a neurotoxin isolated from the venom of *Crotalus durissus terrificus*, exerts antitumor activity against human lung adenocarcinoma through apoptosis induction.[13]

Venoms from Marine Sources

Didemnins, isolated from the Caribbean tunicate *Trididemnum solidum*, are a family of cyclic depsipeptides.[30] Didemnin B, the most potent didemnin in an antitumor screening assay, was tested in phase-I and phase-II clinical

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

studies but showed poor efficacy and was abandoned. Aplidin® (dehydrodidemnin B), a second generation didemnin isolated from the Mediterranean tunicate *Aplidium albicans*, was more effective than Didemnin B in preclinical trials. Phase-I clinical trials show that it is generally well tolerated, and it is currently being evaluated in phase-II clinical studies in solid tumors. It was also granted "orphan drug status" in the European Union for acute myeloblastic leukemia.

Dolastatins are antimitotic peptides originally identified in the sea hare (*Dolabella auricularia*).[30] The two most promising peptides of this family, dolastatin 10 and dolastatin 15 were selected for development and are currently undergoing phase-II clinical trials. These peptides also exhibit antifungal activity. However, the complexity of their synthesis and their poor water solubility are significant obstacles for their development in to marketable drugs. LU103793, a stable and water-soluble analog of dolastatin 15, showed moderate and dose-dependent toxicity in phase-I clinical studies. It is currently being evaluated in phase-II clinical studies for breast, lung, ovarian, prostate, and colon cancer patients.

Thiocoraline, isolated from Micromonospora marine, a marine microorganism located in the Mozambique Strait inhibits RNA synthesis.[30] It is currently being evaluated in clinical trials.

Kahalalides are peptides isolated from the Hawaiian mollusk (*Elysia rufescens*).[10] Seven of these are cyclic depsipeptides (kahalalides A-F and O) and three are linear (kahalalides G, H, and J). Kahalide F is in clinical trials in patients with advanced androgen refractory prostate cancer.[30]

NERVOUS SYSTEM

Analgesia

A number of antinociceptive agents have been derived from venomous sources and are at various stages of development for therapeutic use.

Marine Cone Snail Venoms

Ziconotide (Prialt®) was approved for the treatment of severe chronic pain by intrathecal infusion by the US Food and Drug Administration in 2004.[15] With morphine, it is the only treatment for intractable pain approved for intrethecal injection. It is a synthetic analog of ω-conopeptide MVIIA, isolated from the fish-hunting marine snail *Conus magus*. It blocks N-type voltage-sensitive calcium channels in mammalian pain-sensing neurons and is therefore potently antinociceptive in conditions where morphine is poorly or not active, making it the best studied intrathecal analgesic drug to date. Ziconotide has an excellent safety profile with no neurotoxicity, inflammation, teratogenicity, mutagenicity, or carcinogenicity, and low immunogenicity.[15]

Scorpion Venoms

Extracts from the scorpion *Buthus martensis Karsh* have long been used in China to treat neurological diseases such as apoplexy, epilepsy, and paralysis.[25] These effects have been partly attributed to the peptides *Bm*K dIT-AP, *Bm*K dIT-AP3, and *Bm*K AS1 that exhibit analgesic effects in mice and rats.[25] These are short 31 amino acid peptides with three disulfide bonds, but their tertiary fold differs from that of other scorpion toxins.

Frog Venoms

Caerulein a decapeptide from the skin of the Tree frog *Hyla caerula*, shares sequence similarity to the C-terminal octapeptide of cholecystokinin. Peptides related to Caerulein have been isolated from the skin of the Australian Blue Mountains tree frog *Litoria citropa*. Caerulin and its analogs exhibit antinociceptive activity and cause sedation, inhibition of water intake, and anticonvulsive effects.[35] However, caerulein induces acute pancreatitis.

Dermorphins and deltorphins are peptides isolated from the skin of South American frogs belonging to the subfamily Phyllomedusinae.[22] Dermorphins act like μ-opiate agonists and induce antinociception, catalepsy, rigidity, and sedation. Within this peptide family, [Lys^7] dermophin exhibits the highest analgesic potency. Ala-deltorphin-I is the most potent γ-opiate agonist within the family.

Snake Venoms

Snake toxins have antinociceptive effects in rodents. Crotamine (molecular mass ~5kDa) is a mild toxin derived from the venom of the Northeastern Brazilian rattlesnake (*Crotalus durissus terrificus*). It is about 30-fold more potent than morphine as an analgesic. Hannalgesin (a.k.a. Oh9-1) from the venom of the King Cobra (*Ophiophagus hannah*) and Cobrotoxin from the venom of the Chinese cobra (*Naja naja atra*) are also potent analgesics and do not cause neurological or muscular deficits. However, in a clinical trial, a modified version of cobrotoxin with oral bioavailability did not produce significant pain relief to patients suffering from the demyelinating disorder adrenomyeloneuropathy.[21] Interestingly, cobrotoxin has a similar structural fold as the disintegrin dendroaspin although they have very different activities.

Spider Venoms

Psalmotoxin 1, a 40 amino acid peptide from the South American tarantula (*Psalmopoeus Cambridgei*), inhibits the acid-sensing ion channel and may have use in reducing acid-induced pain.[5] Psalmotoxin 1 has an inhibitor cysteine knot (ICK) fold and is related to gating modifier toxins of voltage-gated ion channels.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

GsMTx-4, a peptide isolated from the Chinese rose tarantula (*Grammostola spatulata*) blocks pain reactions in rat experimental pain models.[3,5]

Spinal Cord Injury

Spinal cord injury is common after road or sports accidents. It most often leads to permanent disability. GsMTx-4 showed efficacy in stimulating *in vitro* neurite growth through a reduction of local calcium influx. This peptide may therefore have potential for the treatment of spinal cord injury.[3]

Anticonvulsants

Many conditions can cause seizures, from epilepsia to kidney or liver failure, brain injuries, high fevers, infections, or drug use. BmK AS, a sodium channel site 4-selective modulator isolated from the venom of the scorpion *Buthus martensi Karsh*, exhibits anticonvulsant activity in rodents and has the potential for being developed into a useful drug for human clinical use.[5]

METABOLIC AND OTHER DISEASES

Obesity

Obesity is a major and growing health problem. Centipede acidic protein, isolated from the Chinese red-headed centipede (*Scolopendra subspinipes mutilans*), lowers the levels of cholesterol, triglycerides, and low-density lipoprotein (LDL) in rodents and may help manage some aspects of obesity.[5]

Diabetes Mellitus

Diabetes mellitus wreaks a deadly toll on the human population.

Gila Monster Venom

The venom of the gila monster (*Heloderma suspectus*) contains exendin-3 and exendin-4, two peptides that stimulate insulin secretion in response to increases in glycemia and modulate gastric emptying to slow the entry of ingested sugars in the blood. The 39 amino acid peptide exendin-4 has been developed into an injectable drug (Exenatide), which was approved for the treatment of type-2 diabetes by the US Food and Drug Administration in 2005.[2]

Frog Venoms

Peptides with insulin-releasing activity have been isolated from the skin secretions of the frogs *Agalychnis litodryas* and *Hoplobatrachus rugulosus*. They may serve as templates for a novel class of insulin secretagogues.[18,23]

Liver Diseases

Liver failure leads to death rapidly, unless a liver transplant donor is available. New treatments for various liver disorders have the potential of reducing the need for liver transplants or at least increasing the waiting time for patients.

Snake Venom

A preparation of snake venom from the Chinese water mocassin (*Agkistrodon halys pallas*) has long been used in Chinese medicine to treat liver diseases. Its beneficial effect in a rat model of fibrotic/cirrhotic liver disease results from a combination of increased bile flow, improved hepatic microcirculation, altered expression of bile salt transporter, and fibrinolytic and antithrombotic effects. The active ingredient in the venom remains to be identified and could lead to a new class of therapeutics for liver diseases.

Bee Venom

Mellitin, a cationic peptide from the venom of the honey bee (*Apis mellifera*) protects hepatocytes against injury from transforming growth factor β1 (TGF-β1).

Duchenne Muscular Dystrophy

Duchenne muscular dystrophy is the most common form of dystrophies. It is also the first genetic disease for which the responsible gene was identified through positional cloning. However, there still is no cure for this devastating disease. By inhibiting the elevation in calcium concentrations in stretched muscle fibers, GsMTx-4, from the venom of the South American tarantula (*Grammostola spatulata*) may provide a new strategy to treat Duchenne muscular dystrophy.[3]

Cell-Penetrating Peptides for Drug Delivery

A number of cell-penetrating peptides have been identified in the last few years. These are short cationic peptides (also called nanomolecules) that can traverse cell membranes through covalent or noncovalent binding. Most are nontoxic and do not interfere with the function of the macromolecules they bring through the cell membranes. They include crotamine, from the venom of the snake *Crotalus durissus terrificus*[13] and dermaseptins from the skin of various frogs.[7]

Antioxidants

Oxidative stress has been involved in a large number of pathologies, including Alzheimer's disease and multiple sclerosis, and also in the normal but often disliked process of skin aging.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Scorpion Venom

Parabutoporin, a peptide from the venom of the scorpion Parabuthus schlechteri, has antioxidant properties through the inhibition of superoxide production.[26]

Bee Venom

Mellitin, from the venom of the honey bee *Apis mellifera*, also displays antioxidant properties by inhibiting the production of superoxide.

CONCLUSIONS

Peptides derived from venoms have already proven effective in treating several human diseases and many more are on the way to be developed into drugs. Venoms from insects, snakes, arachnids, amphibians, marine cones, and sea anemones are widely recognized sources of peptides with potential medical applications and new peptides are identified on an almost daily basis. However, only a very small number of venoms have been studied for potential therapeutic effects, and from these venoms only a few peptides have been studied in detail. Most certainly there are useful hidden venom peptides, as well as venomous animals, still awaiting discovery on dry land and in our oceans, lakes, and rivers.

ACKNOWLEDGMENTS

Grants from the National Institutes of Health (AI084981, AR059838, and NS073712) and the Department of defense (BC096018) have allowed the author to prepare this review.

Chapter 65

Worm Peptides

William R. Kem

ABSTRACT

There are at least 12 animal phyla that are worms. They have received little scientific attention except as they influence human affairs. Nevertheless, an investigation of the substances that worms use to attack or defend against other organisms provides useful probes for examining receptors, ion channels and even mechanisms of innate immunity toward infectious viruses, microbes, and parasites. Nemertines are carnivorous marine worms that produce a plethora of peptidic neurotoxins and cytolysins. The venom of the blood worm *Glycera*, a marine annelid, contains a very large protein that stimulates neurotransmitter release by targeting voltage-gated calcium channels in nerve terminals. Another marine annelid (*Arenicola*) and nematodes produce antimicrobial peptides with different structures. Finally, parasitic worms (liver flukes) secrete cytolytic peptides to aid in the digestion of host tissues. This chapter summarizes the current knowledge of the structures and modes of action of these worm peptides.

INTRODUCTION

Worms have relatively simple body plans that allow growth without having to undergo metamorphosis. Along their length, a basic anatomical–functional unit is repeated, whether the worm is externally segmented (as in annelids) or not. Worms within a given phylum vary in size from tiny meiofauna living between grains of sand to long (but thin) species whose length can exceed 30m (the nemertine *Lineus longissimus*). What a worm may lack in speed of movement is often made up for by an uncanny ability to hide in cracks between rocks, burrow in soil, or produce a toxic chemical defense against predators. These include venoms that can also efficiently immobilize their prey. Worms, like most living animals, also possess antimicrobial peptides that represent an innate immune mechanism against infectious organisms such as bacteria, fungi, and viruses. Examples of these different types of peptides will be considered in this chapter.

NEMERTINE NEUROTOXINS

Nemertines are a phylum of marine worms that use a large, eversible proboscis to capture their prey.[12] Most nemertines are relatively small, inconspicuous inhabitants of marine coastal waters. Thus, it is not surprising that fewer than a thousand species are known. The phylum has been subdivided into three main groups: hoplonemertines possessing a proboscis stylet (barb) capable of puncturing the skin of a prey animal, paleonemertines which are considered to represent the most primitive nemertines, and heteronemertines. Paleonemertines and heteronemertines apparently lack a means of injecting a venom into their prey. Although hoplonemertine toxins are used for offensive and defensive purposes, it is believed that the other two groups use their toxins to repel predators.

In 1936, the Belgian pharmacologist Bacq reported his serendipitous discovery of two different types of toxic activity in nemertines.[1] Homogenates of a hoplonemertine (*Amphiporus lactifloreus*) potently contracted isolated frog skeletal muscle and stimulated the cat cervical autonomic ganglion in a manner similar to nicotine. Because this biological activity survived highly alkaline conditions, it could not result from acetylcholine, the neurotransmitter that normally stimulates these synapses. Extracts of paleonemertines and heteronemertines contained a different type of neurotoxic activity that, rather than affecting nicotine-responsive cells, generated spiking (action potential) activity in crustacean nerves. These are, respectively, called "amphiporine" and "la nemertine," and both types of homogenates caused convulsions, paralysis, and death when injected into shore crabs. Although "amphiporine" activity readily passed across a dialysis membrane, "la nemertine" activity only passed across very slowly.

About 30 years had elapsed before nemertine toxins were reinvestigated. Fortunately, many new separation and analytical methods became available, facilitating the isolation of these natural products even in relatively small amounts. These methods included thin-layer and column chromatography (and later HPLC), as well as amino acid analysis and Edman sequencing methods for the analysis of peptides. The first toxin isolated was the hoplonemertine alkaloid anabaseine, a nicotinoid compound possessing a biological and chemical profile similar to Bacq's "amphiporine."[22] Related compounds, described elsewhere, were found in other hoplonemertines.[16,19] The pharmacological

properties of anabaseine and a variety of anabaseine derivatives have been assessed.[25] One of these derivatives, GTS-21 (also called DMXBA), selectively stimulates alpha7 nicotinic acetylcholine receptors that are involved in cognitive brain function and is currently undergoing clinical tests.[21,26] Heteronemertines, though lacking alkaloid toxins, possess peptide neurotoxins resembling the activity profile of Bacq's "la nemertine," as well as cytolytic peptides.[16,17]

Many heteronemertines possess peptide neurotoxins, as assayed by their ability to rapidly paralyze shore crabs or freshwater crayfish.[16] However, the only heteronemertine toxins that have been purified and chemically characterized to date were obtained from the mucous secretions of two large (>1-m length) marine species. Although *Cerebratulus lacteus* belongs to a very large heteronemertine family (Lineidae) and is widely distributed in the colder latitudes of both the Atlantic and Pacific oceans, the largest species, *Parborlasia corrugatus*, is confined to Antarctic and nearby cold waters of the southern hemisphere.

Cerebratulus neurotoxins have molecular sizes of about 6000Da and are crosslinked by three disulfide bonds.[18] These were originally designated as "B" toxins because they eluted after a cytolytic peptide "A" fraction during gel chromatography. The very similar sequences of the two most abundant and active toxins, B-II and B-IV, are known.[5,8] Both are very basic peptides containing a single residue of 4-hydroxyproline near the N-terminus. Unlike the scorpion and sea anemone peptide sodium channel neurotoxins whose secondary structures mostly consist of antiparallel B-strands, the B toxins are devoid of B-sheet structure but rich in alpha-helix. The secondary structure of B-IV calculated from circular dichroism measurements was similar to that predicted from the sequence.[24] The solution structure of B-IV was eventually determined by NMR methods.[13] Two long stretches of α-helix occurring at positions 11–23 and 34–49 are connected by a loop consisting of two inverse gamma-turns and a beta-turn. The region encompassing residues 11–49 constitutes a rather unique helical hairpin structure.[2]

Considerable results are available implicating some amino acid side chains in the toxic action of toxin B-IV. The initial studies used a chemical modification approach and focused on the few aromatic residues (2 tyrosyls, 2 tryptophanyls). By manipulation of the conditions of the reactions, it was possible to differentially label these residues, the former by nitration[6] and the latter by alkylation.[4] By bioassay of the toxin samples at different degrees of modification, it was deduced that Tyr 9 and Trp 30 are probably involved in receptor binding, because toxicity was significantly reduced without changes in the secondary structure. Blumenthal's laboratory subsequently used molecular biological methods to express B-IV in *Escherichia coli* and to obtain mutants for structure–activity studies.[14,15] Initial experiments showed that replacement of the hydroxyproline at position 10 with Pro did not affect crayfish paralytic activity, nor did replacement of Ala residues at either position 3 or 8 with serine. In fact, the toxicity of B-IV was enhanced by the simultaneous substitution of serine at positions 3 and 8. Arg17 was implicated in receptor binding as toxicity was undetectable, although the toxin CD spectrum was unchanged when Glutamine, Ala or Lys was substituted at this position. Replacement of Arg25 with Lys reduced crayfish toxicity 400-fold.[35] Some of the side chains implicated in the toxicity of B-IV include the guanidinyl side chains of Args 17, 25, and 34 and the aromatic side chains of Tyr 9 and Trp 30. It was rather surprising that these residues are found along the entire length of one surface of the toxin.

Cerebratulus B-IV is not toxic when injected intravenously into mice, insects, and snails. However, it is extremely toxic to crustaceans, especially freshwater crayfish.[18] Initially, a crustacean displays tremors and flipping of the tail but then convulses with a massive contracture of the limbs and tail. Within a few minutes, the contractural paralysis is followed by flaccid paralysis and eventually leads to death. Toxicity of the *Cerebratulus* B toxins seems to be mediated through its action on crustacean nerves as tetrodotoxin effectively blocks the action of B-IV on isolated crayfish nerve-muscle preparations. At relatively high (micromolar) concentrations, toxin B-IV also causes some repetitive spiking in isolated crab nerves. It is probable that this toxin activates a small population of sodium channels sufficient to generate spontaneous nerve action potentials that cause a massive release of excitatory neurotransmitter at the neuromuscular synapse.

Lieberman and Blumenthal[29] measured the binding of iodinated toxin B-IV to membranes prepared from lobster (*Homarus vulgaris*) nerves. The specific binding could not be displaced by a scorpion alpha-toxin. SDS gel electrophoresis of radioactively labeled toxin crosslinked to solubilized lobster nerve membrane proteins revealed a 40,000-Da band, of a smaller molecular size than would be predicted for the interaction with the sodium channel alpha-subunit. This suggests that the toxin may bind to a smaller (β?) subunit of the sodium channel or that it interacts with some other membrane protein.

Assays of extracts from other heteronemertines belonging to the genus *Lineus* indicate that they are actually more toxic than the *Cerebratulus* extracts.[16] The molecular sizes of these toxic peptides are 3000–6000Da.[17] Although they paralyze crustaceans in a manner that is superficially indistinguishable from the *Cerebratulus* toxins, the *Lineus* toxins primarily prolong action potential duration in crustacean neurons, whereas *Cerebratulus* toxin B-IV causes repetitive spiking without significantly delaying repolarization of each action potential (Kem, unpublished results).

NEMERTINE PEPTIDE CYTOLYSINS

Lytic toxins are practically ubiquitous among all living organisms, including bacteria, plants, and animals. Almost all animal venoms include lytic substances that enhance the penetration of toxins into the circulation of the affected organism and possibly potentiate the actions of certain toxins. So far, cytolytic proteins have only been found in the anoplan class of nemertines, which includes both heternomertines (to be described below) and paleonemertines (Kem, unpublished results).

Cerebratulus contains at least four homologous integumentary protein lysins (MW ~10,000Da) called A toxins that contain many basic amino acids.[23,20] The most abundant isotoxin, A-III, was sequenced and shown to contain three disulfide bonds.[7] CD and Raman spectroscopic analyses of this toxin reveal the presence of approximately 60% alpha-helix and 10% B-sheet (Kem et al., unpublished results). The C-terminal portion, which is not crosslinked by a disulfide bond, is thought to exist as a helical hairpin structure. Because of its amphipathic nature, this part of the toxin sequence may interact with membrane lipids and contribute to membrane insertion.

Similar cytolysins have been isolated from the gigantic Antarctic heteronemertine *Parbolasia corrugatus* (Fig. 1). This species feeds on dead organic materials and live animals, and the only known predator is a jellyfish. Despite many attempts with a variety of chromatography supports, it was not possible to resolve the very similar isotoxins from each other. Nevertheless, Edman sequencing revealed an N-terminal sequence similar to that of the *Cerebratulus* A toxins and circular dichroism spectral analysis revealed a very similar secondary structure.[3]

The *Cerebratulus* A toxins are relatively potent cytolysins for a variety of cells. Although hemolysis assays are technically straightforward for identifying this type of toxin, hemolytic toxins presumably attack other sites under natural conditions, such as respiratory (gill) and digestive systems of potential predators. *Cerebratulus* toxin A-III blocks squid axon sodium channels and also affects the kinetics of opening and closing of voltage-gated potassium channels. It also permeabilizes membranes, causing loss of cellular potassium and depolarization of the membrane potential.[20] It is currently thought that the A toxins primarily act as natural detergents, disrupting lipid organization of cell membranes; this does not preclude channel forming or modifying mechanisms on certain cells at low concentrations. A-III inhibits brain phospholipid sensitive Ca^{2+}-dependent protein kinase *in vitro*, as do other peptide toxins that possess a detergent-like action.[27]

FIGURE 1 The gigantic Antarctic heteronemertine *Parbolasia corrugatus* and several adult starfish with diameters of approximately 30cm. See color plate 18.

In maritime Canada, *Cerebratulus lacteus* is a nuisance in aquaculture beds of bivalve mollusks where it is a dominant predator.[10] It inserts its proboscis between the two shells and may secrete the peptidic A and B toxins into this enclosed space of its prey.

ANNELID (*GLYCERA*) NEUROTOXIN

Bloodworms belonging to the genus *Glycera* are active intertidal predators that attack and paralyze their prey by means of a muscular pharynx that possesses four venom-injecting fangs, each attached to its own venom gland. Only very minute amounts of the venom peptide toxins have been partially purified.[9,30] The major neurotoxin possesses a molecular size of approximately 320,000Da by SDS-PAGE. This toxin causes a massive release of neurotransmitter at certain synapses. This action has been primarily studied electrophysiologically at amphibian neuromuscular synapses, as the toxin is not active at most or all mammalian neuromuscular synapses. The reason for this selectivity is that glycerotoxin targets a particular voltage-gated calcium channel, the so-called N-type, which is expressed to a greater degree at amphibian neuromuscular synapses.[30] Although its action is superficially similar to that of α-latrotoxin from the black widow spider, besides stimulating exocytotic release of neurotransmitter it also enhances the recycling of these vesicles so that nerve terminals do not become depleted of vesicles for neurotransmitter release.[31]

ANNELID ANTIBACTERIAL PEPTIDE TOXINS

The lugworm (genus *Arenicola*) was found to contain two potent antibacterial peptides that have been aptly named arenicins.[32,33] These amphipathic basic peptides contain 21 amino acid residues and a single disulfide bond that connects Cys3 to Cys20. A β-sheet secondary structure occurs between the first and second halves of each monomer sequence. In solution, two molecules form a twisted dimer that contains 9 hydrogen bonds between the two monomers.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Solid-state NMR and other spectroscopic studies show that this dimeric structure becomes less twisted, exposing a highly cationic surface that can readily interact with negatively charged phospholipid headgroups of acidic lipids present in bacterial membranes. Although relatively small conductance pores develop on artificial bilayers formed with lipids from Gram-negative bacteria, membranes formed with the more acidic lipids of Gram-positive bacteria develop much larger conductance pores indicative of the formation of a "torus" containing many arenicin dimers oriented perpendicular to the plane of the membrane, that are essentially arranged like the staves of a barrel.[34] Such pores cause the destruction of bacteria and fungi.

NEMATODE AND PLATYHELMINTH PEPTIDE CYTOLYSINS

Cytolytic peptides occur in parasitic helminth (liver fluke, phylum Platyhelminthes) and hookworms (phylum Nematoda). These pore-forming peptides are thought to be important for the initial breakdown of the host cells on which the parasite feeds. The helminth (schistosome) peptide clonorin (9000Da molecular size) possesses a sequence with six half cystines located at essentially the same positions as in amoebapore. Although the overall sequence similarity with amoebapore is quite low,[28] these peptides may be homologous. A hookworm hemolytic peptide has a molecular size of 60,000–65,000Da.[11]

CONCLUDING COMMENTS

More systematic screening of these organisms will probably reveal a plethora of peptide toxins used in either controlling other metazoans (predator–prey interactions) or defense against infectious organisms such as bacteria, fungi and viruses. Certain substances such as the arenicins may serve as useful lead compounds for the design of new antibiotics.

Chapter 66

Adrenomedullin

Frank Cuttitta and Alfredo Martínez

ABSTRACT

Adrenomedullin (AM), initially discovered almost two decades ago, is highly conserved in nonvertebrate and vertebrate evolution, essential for species survival, regulates diverse physiology, and underpins a variety of human diseases.[5] In this chapter, we review the role of AM in carcinogenesis, encompassing its regulatory effects on proliferation, migration, invasion, angiogenesis, and lymphangiogenesis. We also describe the complex cell/cell interactions occurring in the tumor microenvironment regarding anatomical sources of AM, modulation of component partner cells function in the stroma and their effects on augmenting the neoplastic process. Finally, we identify several therapeutic approaches to target AM for the potential clinical management of malignant disorders.

INTRODUCTION

Adrenomedullin (AM) was first isolated from a human pheochromocytoma and demonstrated to function as a hypotensive peptide.[20] Cumulative research findings over the past 18 years have revealed AM to play a critical role in diverse physiology and modulate cell growth associated with embryogenesis, and wound repair.[5] In addition, AM has been associated with a multitude of human diseases including: diabetes, asthma, cardiovascular disorders, renal anomalies, Alzheimer's, and cancer.[8,13,16,21,29] A variety of epithelial and neural tumors overexpress AM; these encompass neoplasms of the liver, kidney, lung, breast, pancreas, ovary, prostate, brain, and skin.[5] Elevated AM tumor mRNA or plasma levels correlate with a worsened prognosis for patients with ovarian, prostate, renal, and neuroendocrine cancers.[5,7,27] The process of epithelial to mesenchymal transition (EMT) can result in establishing a cancer stem cell niche, which in turn is known to be responsible for the initiation of malignant cell conversion and maintenance of a neoplastic phenotype.[2] Hypoxia and inflammation are critical pathways that drive EMT and also augment AM expression in normal and cancer cells.[2,5,31] Interestingly, AM, Wnt, hypoxia, and inflammation all seem to track with tumor cell EMT and survival.[4,5,10,17,22]

In the remaining text of this chapter, we outline the major anatomical sources of AM, the peptide's role in tumor progression and metastasis, potential therapeutic approaches for targeting AM and its receptor as modulators of malignant disease, and finally end with a discussion on using an established drug for type 2 diabetes as a therapy for cancer with an underlying focus on AM.

ANATOMICAL SOURCES OF AM

AM is produced in every major organ of the body including brain, heart, lung, intestine, liver, kidney, spleen, pancreas, skin, testes, and ovary and is present in specialized cells such as smooth muscle, macrophage, mast cells, adipocyte, fibroblast, and trophoblast, as well as epithelial and neural tumor cells.[3,5,13] Hence, there are multiple anatomical sources of AM expression that could serve to augment the carcinogenesis process under the right circumstances. In the next section, we discuss the possible biological events that could lead to AM overexpression.

REGULATORY PATHWAY THAT STIMULATE AM EXPRESSION

Hypoxia and chronic inflammation are major contributory pathways that enhance AM expression in normal cells and in cancer.[5,31] Hypoxia-inducible factor-1 (HIF-1) is a strong inducer of AM mRNA transduction via its interaction with several hypoxia response elements (HRE) on the AM gene.[5] Proinflammatory factors such as interleukin-1 (IL-1), tumor necrosis factor-alpha (TNF-α), and lipopolysaccharide (LPS) enhance AM expression.[5] Inflammatory infiltrate cells (macrophages and mast cells) of human tumors can produce AM which in turn can amplify multiple aggressive aspects of the neoplastic lesion as will be described in detail later on in this book chapter. Other alternative regulatory mechanisms of AM expression also exist. Exposure to environmental toxins augments AM levels in airway epithelium.[4] Given this observation, one obvious question is

Copyright Elsevier 2024

what would be the effect of tobacco smoke on pulmonary expression of AM and does this have any possible link to the know correlation between heavy cigarette smoking and lung cancer?[15] Finally, there is a single obscure 2008 report showing that the saliva of the soft tick contains AM which suppresses the host immune response and ameliorates the feeding process.[9] Although not a true pathway of AM induction, the soft tick infection sequence does represent an external source of AM which may parallel the known role of *Schistosoma* biological products in the development of human squamous cell bladder cancer.[1]

AM INDUCED CELL GROWTH

AM has been previously reported as a critical growth factor involved in cell proliferation during embryogenesis, wound repair and carcinogenesis.[5] We reported that AM is responsible for the autocrine/paracrine growth of multiple human tumor cell lines that include cancers of the lung, colon, breast, ovary and prostate.[5] More recently, human glioblastoma, pancreatic and endometrial cancer cells were also shown to be dependent on AM for proliferation.[5] Finally, Park et al. have reported that AM drives hepatocellular carcinoma growth, enhances tumor vascular density, and tracks with worsen prognosis.[26]

AM-MEDIATED ANTIAPOPTOSIS

In vitro serum starvation of both normal and cancer cells induces programmed cell death, which is circumvented by the exogenous addition of AM.[5] This peptide induced antiapoptotic protection event involves Max bHLH and Stat3 driven mechanisms and the downregulation of Bax, Bid, caspase 6–8, MEKK3, and TRADD.[5] AM suppressed apoptosis can be specifically blocked by either antiligand or antireceptor neutralizing antibodies validating the importance of this peptide in augmenting cell growth under stringent environmental conditions.[5,18]

AM-REGULATED CELL MIGRATION/ INVASION

We were one of the earliest laboratories to report that AM could induce human cancer cells migration after a rise/fall dose-dependent response curve.[5] We have also shown that tumor cell derived AM could enhance mast cell chemotaxis toward the neoplastic lesion, mediate a localized proinflammatory response, and in turn augment the malignant phenotype of the tumor.[5] Interestingly, AM induces the *in vitro* migration and invasion of clear-cell renal cancer cells.[7] An article by Chen et al. shows that AM stimulates the migration of human microvascular endothelial cells, and this peptide source could be generated from the macrophage infiltrates associated with human melanomas which track with increased tumor vascular density and worsened disease outcome.[3] Finally, AM enhances matrix metalloproteinase-2 (MMP-2) expression in fibroblast and induces stromal matrix degradation, a prerequisite event that leads to metastatic spread of cancer cells.[5]

AM EFFECTS ON THE IMMUNE RESPONSE

AM is both a positive and negative regulator of the immune response.[30] We have previously discussed the autocrine effects AM has on macrophages and mast cells, which include the stimulation of pro-angiogenesis factor release (AM, IL-1B, IL-6, MIF, histamine, VEGF-A, bFGF, and MCP-1), chemotaxis, and suppression of TNF-α release.[5] The abundance of macrophages or mast cells in tumor infiltrates are known to track with enhanced neoplastic vessel density, increased metastatic involvement, and worsened clinical outcome.[32] AM has now been implicated as a major macrophage factor released by tumor infiltrate cells that enhances neoplastic growth, local angiogenesis and metastasis.[3]

AM STIMULATES ANGIOGENESIS AND LYMPHANGIOGENESIS

Angiogenesis and lymphangiogenesis are known vascular pathways that increase tumor growth and the dissemination of primary cancer cells to distal anatomical sites.[35] AM is a critical regulator of embryonic angiogenesis and lymphangiogenesis.[11,34] In addition, AM has been linked to increased tumor growth attributed to its role in enhancing vessel density for cancers of the breast, brain, pancreas, endometrium and liver.[5,26] Given the current tread in using antiangiogenic drugs for the treatment of cancer, developing reagents that block AM ligand/receptor interaction would be a plausible approach to suppress tumor induced angiogenesis/lymphangiogenesis, thus potentially inhibiting cancer cell growth and metastasis.

AM-TARGETED THERAPIES FOR CANCER

Given that AM is known to drive the carcinogenesis process by enhancing tumor cell proliferation, migration, invasion, EMT, angiogenesis, and lymphangiogenesis as previously discussed in this book chapter, it becomes intuitively logical that drugs which disrupt AM bioactivity would in turn be candidate compounds for use in anticancer therapy. There are actually several approaches that have been applied or could be applied to cancer management by disrupting AM biology which include the use of peptide antagonists, anti-peptide antibodies, and anti-AM receptor antibodies.[5,18] In

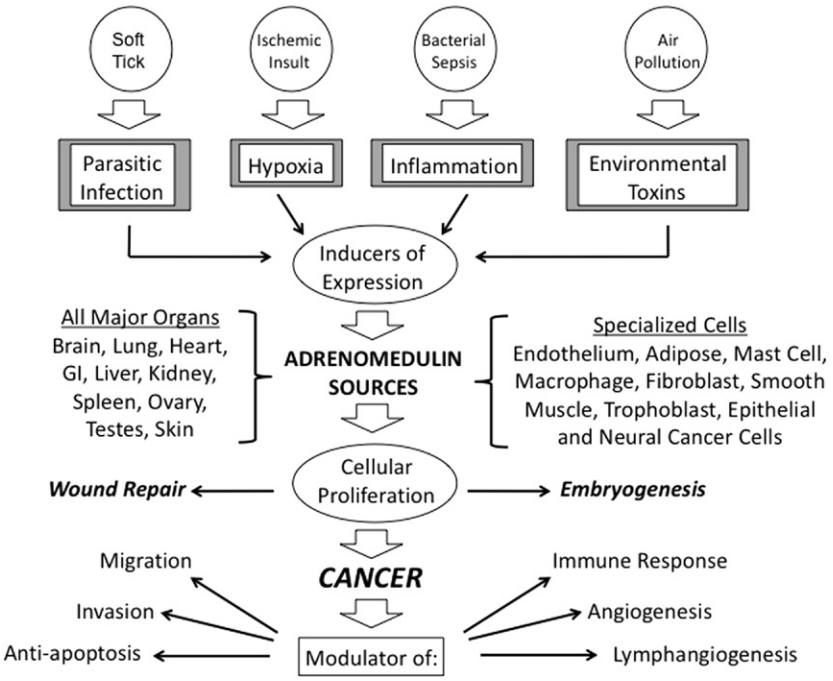

FIGURE 1 The adrenomedullin/cancer axial link.

addition, matrix metalloproteinase-2 (MMP2 or gelatinase A) selectively degrades intact $AM_{1–52}$, destroying its vasodilatory ability and generating the vasoconstrictor peptide $AM_{11–22}$ via enzymatic processing.[5] It would be extremely interesting to see what effect $AM_{11–22}$ has on the involvement of $AM_{1–52}$ in the carcinogenesis process.

Another promising line of research pursues the identification and iterative design of small molecules targeting the AM system. The first set of such molecules was identified with the help of a neutralizing antibody-based screening strategy.[5] The description of the three-dimensional structure of AM[28] and the resolution of the extracellular portion of the CGRP receptor complex[33] open the possibility of a rational design of novel small molecules based on their interaction with either the ligand or the receptor.

AM, OBESITY, DIABETES, AND CANCER—AXIAL LINK

As an extension of AM drug development, we would like to discuss a possible AM/obesity/diabetes/cancer axis and the potential use of an established type 2 diabetic therapy for cancer treatment.

Obesity increases the risk for at least twenty different anatomically distinct human cancers.[12] AM is produced by adipocytes and AM plasma levels are elevated in obese patients compared with that of normal volunteers.[23,25] Obesity and type 2 diabetes have a strong clinical correlative relationship underscored by low-grade chronic inflammation of adipose tissue.[14,19] Inflammation is a key modulator of AM expression.[5,31] Interestingly, AM is known to suppress insulin secretion increasing blood sugar and is elevated in the plasma of type 2 diabetic, whose peptide concentration parallels disease severity.[24] Finally, elevated plasma glucose levels preferentially augment hypoxia-inducible factor-1alpha (HIF-1α) expression in cancer cells while selectively suppressing production of this pro-AM transcription factor in normal cells.[6] Given the evidence presented above, it can be hypothesized that the cancer risk associated with obesity might potentially be related with enhanced AM expression generated in the inflamed adipose tissue or produced by HIF-1α stimulated transformed cells, thus augmenting the entire carcinogenesis pathway. Supporting this type of "connecting-the-dots" logic is the fact that metformin, a preferred drug for the treatment of type 2 diabetes, which lowers blood glucose and suppresses adipose function, is now being used in phase III clinical trials as an anticancer compound and has been shown to suppress angiogenesis.[12] What effect metformin has on AM and its role in diabetes and cancer may be a worthwhile research avenue to pursue to unravel the yet-to-be answered questions in the adrenomedullinergic field.

CONCLUSIONS

We have reviewed our current knowledge on the role of AM in the carcinogenesis pathway and have defined several areas of interest that are summarized in Fig. 1. Multiple environmental mechanisms can lead to the induction of AM expression in a given target cell, which primarily

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

involve hypoxia and inflammation but also include exposure to air pollutants and parasitic infections. Every major organ of the body can produce AM with alternative sources coming from specialized cells that include: endothelia, adipocytes, mast cells, macrophages, fibroblasts, smooth muscle, trophoblasts, and cancers of epithelial and neural origin. AM underpins a variety of fundamental characteristics of transformed cells that encompass growth, migration, invasion, circumventing immune surveillance, resistance to apoptosis, EMT conversion, angiogenesis, and lymphangiogenesis. We have identified several possible therapeutic approaches that negate AM biology and have potential anticancer application in the clinical management of malignant disease. Finally, we have introduced anecdotal evidence that implicates a new neoplastic axis based on the existence of an AM/obesity/diabetes/cancer relationship and have revealed that metformin is an interesting antidiabetic drug now being used in cancer therapy as a plausible candidate compound to be evaluated for negative modulatory effects on AM biology.

Chapter 67

Angiotensin II/ Angiotensin-(1–7)

Patricia E. Gallagher, Alison L. Arter, Bhavani Krishnan, Maria A. Garcia-Espinosa and E. Ann Tallant

ABSTRACT

The renin–angiotensin system (RAS) has classically been studied based on its role in the regulation of blood pressure and homeostasis. However, increasing evidence suggests that the angiotensin peptides have pleiotrophic cellular actions, such that the RAS may be involved in diverse pathologies. Two biological molecules of the RAS—the octapeptide angiotensin II (Ang II) and the heptapeptide angiotensin-(1–7) [Ang (1–7)]—have opposing actions, to either stimulate (Ang II) or inhibit [Ang-(1–7)] cell proliferation, angiogenesis, fibrosis, and inflammation. This chapter explores the more recent relevant information directly assessing the two angiotensin peptides and their role in the regulation of malignant cell growth. An increase in Ang II or a reduction in Ang-(1–7) may be involved in the initiation and progression of cancer, suggesting that therapeutics that regulate the circulating and tissue levels of the peptide hormones, their selective receptors, or synthesizing enzymes may serve as targets for intervention.

INTRODUCTION

Decades of research established the renin–angiotensin system (RAS) as a primary, physiological regulator of blood pressure, sodium balance, and fluid volume. However, it is the effects of the RAS on angiogenesis, fibrosis, inflammation, cell migration, and proliferation that play a role in diverse pathologies such as diabetes, pancreatitis, Alzheimer's disease, and cancer. The biological actions of the RAS are mediated by peptide hormones, and this chapter will focus on the octapeptide angiotensin II (Ang II) and the heptapeptide angiotensin-(1–7) [Ang-(1–7)]. In the RAS cascade (Fig. 1), angiotensinogen, predominately produced by the liver and secreted into the circulation, is cleaved by the enzyme renin, producing the decapeptide angiotensin I (Ang I). Proteolytic processing of Ang I by angiotensin-converting enzyme (ACE) yields Ang II; attenuation of ACE actions by selective inhibitors is commonly used to treat patients with high blood pressure. Ang-(1–7) is normally present in the circulation at concentrations similar to Ang II and is derived from Ang I by tissue peptidases, including neprilysin, thimet oligopeptidase, and prolyl endopeptidase (Fig. 1). The octapeptide hormone can be further metabolized by angiotensin-converting enzyme 2 (ACE2) to Ang-(1–7), whereas the heptapeptide hormone is degraded to the inactive metabolite Ang-(1–5) by ACE. Treatment of animals or patients with ACE inhibitors results in an increase in both circulating and urinary Ang-(1–7), by preventing the conversion of Ang I to Ang II and the degradation of the heptapeptide hormone.

Although differing by only a single amino acid, Ang II and Ang-(1–7) often have opposing biological actions. Ang II is a potent vasoconstrictor that also promotes fibrosis, oxidative stress, angiogenesis, cellular proliferation and migration, inflammation, hypertrophy, and atherogenesis. Conversely, Ang-(1–7) is a modest vasodilator with antiproliferative, antifibrotic, anti-inflammatory, antiangiogenic, antihypertrophic, and antithrombotic properties. These two peptide hormones mediate contrasting physiological responses through the activation of distinct, high-affinity cellular receptors. Ang II is an endogenous ligand for two pharmacological classes of seven transmembrane, G protein-coupled receptors—the angiotensin type 1 (AT_1) and angiotensin type II (AT_2) receptors. The majority of physiological effects associated with Ang II, including vasoconstriction, natriuresis, diuresis, and mitogenesis, are mediated by the AT_1 receptor and antagonists selective for blockade of AT_1 receptor function (angiotensin receptor blockers or ARBs) are commonly used to treat hypertension. The AT_2 receptor has a more limited tissue distribution but is present in increased amounts in prenatal tissues and after tissue injury. Ang-(1–7) binds and activates the seven transmembrane G protein-coupled receptor *mas* and counterregulates cellular signaling stimulated by a variety of mitogens, including Ang II.

Although the RAS was initially characterized as an endocrine system, ample evidence shows the presence of tissue RAS that are involved in local synthesis, release, and action

of angiotensin peptides. A functional tissue RAS was identified in every organ and tissue investigated, although some components of the pathway, particularly renin, are acquired from the endocrine RAS. In addition to normal tissues, RAS components are expressed in a variety of tumor cells, including carcinomas of the bladder, brain, cervix, colon, kidney, liver, lung, pancreas, prostate, skin, and stomach. Excellent reviews highlight the major studies on the role of the RAS in specific cancer types, the molecular mechanisms of RAS regulation of cancer growth, polymorphisms of RAS components, as well as the use of ACE inhibitors and ARBs as potential cancer therapeutics.[9,30] This chapter summarizes the major findings since 2005, specifically focusing on studies directly examining the effects of the angiotensin peptide hormones Ang II and Ang-(1–7) on cancer.

DETECTION OF ANG II IN TUMOR TISSUE AND CANCER CELL LINES

Positive immunostaining of Ang II and the AT_1 receptor occurs in both estrogen receptor positive and negative breast tumors as well as in human MDA-MB-468 and MCF-7 breast cancer cells.[10] Further, mRNA for angiotensinogen, renin, ACE, AT_1 receptor, and AT_2 receptor have been detected in the two breast cancer cell lines, suggesting the presence of a tissue RAS. Rhodes et al.[23] found that the AT_1 receptor is overexpressed in a subset of estrogen receptor positive tumors with a >20-fold increase in 7 of 45 tumors (15.5%) and >100-fold increase in 2 primary tumors and 1 metastatic tumor. Elevated numbers of AT_1 receptors are present in tumor cells with a gain in copy number and in tumor cells with the normal gene complement, indicating that multiple mechanisms are involved in the receptor overexpression. Zhou et al.[35] showed that the concentration of Ang II is greater in tissue homogenates of pancreatic ductal adenocarcinoma as compared with the surrounding normal tissue. Similarly, the Ang II levels in the tissue homogenates of twelve non-small-cell lung cancers are elevated significantly as compared with homogenates from matching nonmalignant lung tissue.[6] Taken together, these studies establish the presence of Ang II in premalignant and malignant cancer cells and suggest that the octapeptide hormone may be involved in tumorigenesis.

Ang II and AT_1 receptor immunostaining also was detected in 81.9% and 59.6% (94 cases), respectively, of primary endometrial carcinoma and correlates with reduced prognosis, suggesting that the assessment of RAS components may be a viable determinate of clinicopathological status.[26] Although there was no positive correlation between Ang II concentration and histopathological grades of gastric tumors, the octapeptide hormone is increased in the cancer tissue as compared with normal regions.[13] AT_1 receptor protein was also detected in 16 of 20 gastric tumors and >50% of gastric cancer cell lines examined. AT_1 receptor immunostaining is more robust in gastric tumors as compared with normal gastric mucosa. The basal epithelial cell layer of benign prostatic hyperplasias and all 28 human prostate cancers examined also showed positive immunoreactive Ang II with no significant difference in staining between cancer grades.[16] In 15 high-grade prostatic intraepithelial neoplasias, more intense Ang II staining occurred in the basal cells as compared with prostate cancer cells. Additionally, the androgen-dependent LNCaP as well as the androgen-independent DU145 and PC3 cell lines stained positive for immunoreactive Ang II. The observed increase in the AT_1 receptor probably results from Ang II-mediated upregulation in the cancer tissues. The elevated levels of the receptor coupled with increased Ang II may play a prominent role in

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

promoting cancer cell proliferation and tumor angiogenesis. If so, it would be expected that Ang II and/or AT_1 receptor concentrations would correlate with histological grade, prognosis or survival. Although this positive correlation was observed in patients with primary endometrial carcinoma,[26] no association was found for gastric or prostate cancer.[13,16] Obviously, these three studies are not sufficient to allow any conclusions. Further analyses are certainly warranted as this is an important question not only for the potential use of the RAS as a diagnostic predictor but also for an understanding of the role of the RAS in the carcinogenesis process.

Ang II is increased and ACE2 decreased in pancreatic ductal adenocarcinoma as compared with normal pancreatic tissue.[35] Further, Ang II treatment of human BxPC3 and SW1990 ductal carcinoma cells causes a significant downregulation of ACE2, and reduction of ACE2 by RNA interference enhances the proliferation of cultured pancreatic cancer cells. ACE2 is also decreased significantly in 11 of 15 non-small-cell lung cancers as compared with adjacent lung tissue, and this variation correlates with reduced Ang II in homogenates from the tumors.[6] These findings suggest that Ang II downregulates ACE2 in tumor tissue to promote Ang II-mediated mitogenic effects. As a corollary, it would be of interest to quantify the concentration of Ang-(1–7), the product of the Ang II catalysis by ACE2, to determine whether this antiproliferative hormone is reduced in tumor tissue. A reduction in Ang-(1–7) would implicate this peptide hormone in the progression of carcinogenesis. In addition, it would be valuable to know whether ACE is elevated in tumor cells and tissue, as this enzyme converts Ang I to Ang II and therefore would further increase the concentration of the mitogenic octapeptide hormone and reduce the antiproliferative Ang-(1–7), since ACE catalyzes the conversion of the heptapeptide hormone to Ang-(1–5).

ANG II STIMULATES CANCER CELL PROLIFERATION

Ang II induces cancer cell growth by activating the AT_1 receptor. The increased proliferation of OCUM2MD3 gastric cancer cells by the octapeptide hormone is effectively inhibited by a specific AT_1 receptor antagonist, candesartan.[13] Candesartan also significantly prolongs survival time in a mouse model of peritoneal carcinomatosis compared with the control group. Ang II activates ERK1/2, nuclear transcript factor-κB (NF-kB) and survivin, showing that cellular proliferation and survival pathways are involved in the response. The transcription factor PAX2 is also increased significantly in prostate epithelial cells and DU145 prostate cancer cells after incubation with Ang II.[3] The ARB losartan but not the AT_2 receptor antagonist attenuates the Ang II-mediated elevation in PAX2. In addition, Ang II stimulates the phosphorylation of PAX2 through activation of ERK1/2, JAK II, and STAT3 growth-promoting pathways, suggesting that regulation of PAX2 may be a potential chemotherapeutic target for prostate cancer. Ang II also induces DNA synthesis in human LNCaP prostate cancer cells; the ARB losartan inhibits the Ang II-stimulated incorporation of [^{3}H]-thymidine into DNA, whereas the AT_2 receptor agonist, CGP42112A or antagonist PD123,319 has no effect, indicating an AT_1 receptor-mediated process.[4] In human PC3 prostate cancer cells, Ang II does not stimulate DNA synthesis, and the authors suggest that PC3 cells do not have a functional AT_1 receptor, as previously reported by Uemura et al.[33] Ang II increases the proliferation of prostate cancer cells with an associated upregulation of prostate-specific antigen, NF-kB, c-myc, and the androgen receptor;[11] the effect is blocked by an siRNA to the AT_1 receptor. Further, AT_1 receptor KO mice have reduced androgen receptor expression in the prostate, suggesting a role for Ang II in the regulation of the androgen receptor in prostate cancer. Finally, Feng et al.[6] showed that overexpression of ACE2 reduces the proliferation of human A549 lung cancer cells and Ang II-induced VEGF production, suggesting that either reduction of Ang II, an increase in Ang-(1–7) or dysregulation of both peptide hormones effectively attenuates lung tumor growth and angiogenesis. These studies show that the Ang II axis of the RAS may promote tumorigenesis through enhanced proliferation of cancer cells by multiple molecular mechanisms, providing further support for therapies that target the AT_1 receptor signaling pathways.

ANG II PROMOTES TUMOR ANGIOGENESIS

Ang II regulates the production of angiogenic factors to stimulate blood vessel formation and tumor growth. The octapeptide hormone causes a significant increase in VEGF production by pancreatic ductal adenocarcinoma cells that involves tyrosine phosphorylation.[2] Preincubation of the cells with the MEK1/2 selective inhibitor PD098059 or U0126 prevents the elevation of VEGF by the octapeptide hormone, suggesting that MAP kinase activation is required. Incubation of human SKOV-3 ovarian cancer cells with Ang II causes a significant increase in VEGF mRNA and VEGF secretion.[28] Candesartan blocks the enhanced production of VEGF in SKOV-3 cells treated with Ang II and in SKOV-3 tumor xenografts in mice. In addition, AT_1 receptor expression, detected in 85% of the ovarian tumors examined, is positively correlated with VEGF and tumoral vessel density but not with histological subtype.[26] Ang II also significantly increases gene expression of HIF-2alpha, TIMP-1, and VEGF in human MDA-MB-468 cells. This effect is attenuated by the ARB candesartan,[10] suggesting that the octapeptide hormone may activate the AT_1 receptor to elevate VEGF concentrations through a HIF/TIMP-1 cascade to

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

enhance tumor angiogenesis. By contrast, no alteration in the expression of these target genes is observed after Ang II incubation with MCF-7 cells, even though these cells show positive immunostaining for the AT_1 receptor. The molecular mechanism for the lack of response by these breast cancer cells is not known. Candesartan blocks the increased secretion of IL-8 and VEGF secretion after incubation of human KU-19-19 bladder cancer cells with Ang II as well as attenuates microvessel density in KU-19-19 bladder tumor xenografts with an associated reduction in VEGF.[15] Ang II also induces VEGF production in *cis*-dichlorodiammineplatinum (CDDP)-treated human T24, KU-1, and KU-19-19 bladder cancer cells,[29] and the effect is blocked by an AT_1 receptor antagonist. More importantly, tumors from patients who underwent cystectomy after neoadjuvant CDDP-based chemotherapy have markedly increased concentrations of the AT_1 receptor and VEGF as compared with control transurethral resection specimens. Feng et al.[6] also showed that overexpression of ACE2 reduces the proliferation of human A549 lung cancer cells and Ang II-induced VEGF production, suggesting that either reduction of Ang II, an increase in Ang-(1–7) or dysregulation of both peptide hormones effectively attenuates lung tumor growth and angiogenesis. The current cardiovascular pathologies associated with antiangiogenic drugs and the short time to onset of resistance suggest a need for new therapeutic regimens with effective antiangiogenic activity and enhanced safety profiles. The blockade of the proangiogenic effects of Ang II with ACE inhibitors or angiotensin receptor blockers suggests that these drugs may serve as novel therapeutics to reduce angiogenesis and decrease tumor size.

EFFECTS OF ANG II ON THE TUMOR MICROENVIRONMENT

Ang II has a robust effect on cells of the tumor microenvironment. Tumor angiogenesis with an associated reduction in VEGF production is markedly inhibited in AT_{1a} receptor knockout mice harboring S-180 sarcoma xenografts.[7] This reduction in VEGF is not inhibited by an ARB, suggesting that Ang II regulates VEGF production in stromal cells to inhibit blood vessel formation and tumor growth. Similarly, a dose-dependent increase in COX-2 and prostaglandin E2 occurs in normal lung fibroblasts after incubation with Ang II; conversely no change occurs in human A549 lung adenocarcinoma cells.[17] Further, Ang II enhances the upregulation of COX-2 by the proinflammatory cytokines IL-1beta or TNF-alpha in normal lung fibroblasts, suggesting that the octapeptide hormone may promote lung tumorigenesis by activating inflammatory pathways in cells of the tumor microenvironment. Incubation of prostate stromal cells with Ang II results in a significant increase in cell proliferation with an associated activation of MAPK and secretion of IL-6.[32] Treatment of PC3 prostate cancer cells with the conditioned media from the prostate stromal cells incubated with Ang II enhances phosphorylation of MAPK. More importantly, the tumor volume of xenografts produced from PC3 prostate cancer cells and prostate stromal cells is markedly reduced after administration of an AT_1 receptor blocker, whereas PC3 xenografts are not affected. Because PC3 cells have reduced AT_1 receptors and do not respond to Ang II,[33] these studies suggest that Ang II indirectly promotes tumor growth by stimulating the production of secreted mitogenic factors from prostate stromal cells. The octapeptide hormone similarly increases the proliferation of hepatic stellate cells,[20] and the effect is blocked by an AT_1 receptor antagonist. Activation of pancreatic stellate cells by Ang II results in an upregulation of the AT_1 receptor as well as the fibrotic proteins, alpha-smooth muscle actin, collagen, and TGF-β.[24] These studies suggest Ang II may play a role in the conversion of stromal cells to activated myofibroblasts, which promote tumorigenesis through the secretion of growth factors and cytokines and provide structural support for tumor growth. Crosstalk between cancer cells and surrounding tissue is essential for the development and progression of tumors. The interaction between cancer cells and the adjacent microenvironment transforms the stroma into an abnormal phenotype, altering tissue architecture, cell morphology, and extracellular matrix–cell interactions that directly contribute to tumor formation. The study of Ang II effects on the tumor microenvironment is in its infancy and should provide a fruitful area of research with years of new discoveries that advance our understanding of the RAS and mitogenesis.

ANG II STIMULATES CANCER CELL MIGRATION AND INVASION

Ang II increases migration of human SKOV-3 ovarian cancer cells in a modified Boyden's chamber and peritoneal dissemination from ovarian tumor xenografts in a mouse model.[28] Ang II also reduces adhesion as well as invasion of MCF-7 and T47D breast cancer cells to collagen-, fibronectin- and laminin-coated wells and membranes, respectively, with an associated reduction in integrin alpha3 and beta1 through protein kinase C signaling.[22] This action is inhibited by cotreatment with the ARB losartan, indicating a functional AT_1 receptor in MCF-7 cells. Ang II induces the activation of matrix metalloproteinase (MMP) 2 and MMP-9 protein and mRNA in a dose-dependent manner in MKN-28 gastric cancer cells.[12] The stimulatory effect of Ang II could be blocked by an AT_1 receptor antagonist. Incubation of the gastric cancer cells with AG490, a selective JAK inhibitor, markedly reduces the MMP-2 concentrations induced by the octapeptide hormone, suggesting that Stat3 signaling may be involved in Ang II regulation of tumor metastasis and

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

invasion. Overexpression of ACE2 also inhibits the migration of human pancreatic cells[35] and decreased MMP-2 and MMP-9 to attenuate migration of human A549 lung cancer cells, suggesting that reduction in Ang II and an increase in Ang-(1–7) by elevated ACE2 may inhibit cancer cell migration and invasion.[6] Finally, cell invasion using a reconstituted basement membrane chamber assay is significantly enhanced after Ang II incubation of human epithelial or breast cancer cell lines overexpressing the AT_1 receptor; the effect is blocked by the AT_1 receptor antagonist losartan.[23] Ang II stimulation of breast cancer cells with low levels of the AT_1 receptor does not exhibit increased invasive properties. The initial treatment for many different types of cancer consists of resection of the primary tumor followed by chemotherapy to reduce metastasis. Because two important steps in the metastatic process include the migration of the tumor cells from the primary tumor before intravasation into the circulation as well as migration of the tumor cells into distant organs after extravasation, drugs that block tumor cell migration may reduce metastatic growth. Since Ang II increases migration, ACE inhibitors, ARBs or drugs that prevent the Ang II-mediated stimulation of migration may serve as novel chemotherapeutics to block migration and tumor metastasis.

ANG II INDUCED CANCER CELL SIGNALING

Multiple signaling pathways are activated by the octapeptide hormone to mediate the regulation of cancer cell proliferation, angiogenesis, migration, and invasion. Ang II stimulates the phosphorylation of protein kinase B (Akt) in human LNCaP cells through the activation of the AT_1 receptor.[31] Incubation of C4-2AT6 androgen positive, castration-resistant prostate cancer cells with phosphoinositide 3-kinase (PI3K)/Akt inhibitor Ly294002 causes a marked decrease in the AT_1 receptor, whereas the elevation of phosphorylated Akt by serum starvation enhances AT_1 receptor expression in C4-2 prostate cancer cells, suggesting that the activation of Akt is involved in the regulation of the AT_1 receptor.[14] AT_1 receptor activation by Ang II in MCF-7 breast cancer cells also induces the phosphorylation of Akt at threonine 308 and serine 473 as well as attenuates cleavage of the Akt-downstream effector caspase 9 to inhibit apoptosis.[34] In addition, the octapeptide hormone stimulates MCF-7 breast cancer cell proliferation with an associated activation of Akt, an increase in cyclin D1, an upregulation of GSK3beta serine/threonine kinase, and a reduction in the cyclin-dependent kinase inhibitor p27. Taken together, these studies indicate that Ang II may play a critical role in cancer cell growth, adhesion, invasion, and inhibition of apoptosis in part through activation of the Akt signaling pathway.

Ang II also upregulates p47phox, superoxide dismutase, and glutathione peroxidase in human LNCaP prostate cancer cells; the increase in these oxidative stress proteins is attenuated by the ARB candesartan or catalase.[31] In addition, incubation of human LNCaP prostate cancer cells with Ang II causes a significant increase in superoxide, which is prevented by candesartan or catalase treatment as well as LY294002, an inhibitor of PI3K. The octapeptide hormone also induces the phosphorylation of p53 at serine 15, lipid peroxidation, 8-hydroxyguanine, and inducible nitric oxide synthase, an effect blocked by candesartan or catalase. These studies show that Ang II induces oxidative stress in human prostate cancer cells and that an ARB, an antioxidant enzyme or an inhibitor of PI3K can attenuate the effect. Ang II treatment of human promyeloctic HL-60 cells also causes a significant increase in DNA damage production by reactive oxygen species.[25] The effect is prevented by the ARB candesartan or the antioxidants *N*-acetylcysteine and α-tocopheral but not by the AT_2-receptor antagonist PD123319. Taken together, these studies suggest that Ang II activation of the AT_1 receptor promotes oxidative stress in human cancer cells.

Studies have only begun to explore cell signaling pathways activated by Ang II in malignant cells or the supporting stroma that contribute to tumor growth and metastasis. With increased understanding of the molecular mechanisms by which Ang II stimulates cell growth, drugs that target Ang II synthesis, the Ang II receptor, or the signaling pathways that are activated by Ang II in either the tumor cells or the stromal cells that support tumor growth (tissue fibroblasts, vascular smooth muscle cells, or endothelial cells) may provide novel treatments for cancer, either alone or in combination with drugs that target other growth stimulatory pathways.

ANG-(1–7) ATTENUATES TUMOR GROWTH

The number of studies on the effect of the heptapeptide hormone Ang-(1–7) on cancer is limited. There are no publications that identify the presence of Ang-(1–7) in tumor cells, assess the concentration of the Ang-(1–7) receptor *mas* in cancer cells and tumors, or determine whether the heptapeptide hormone regulates tumor cell migration and invasion. However, there are several publications that describe the inhibition of tumor growth by Ang-(1–7).

We observed that the tumor volume of human A549 lung cancer xenografts is significantly reduced after infusion with Ang-(1–7) as compared with tumors from control animals.[18] The tumor size in the saline-treated animals increases 2.5-fold, whereas tumor volume is reduced by 30% after Ang-(1–7) administration as compared with the size before treatment. Similar results are obtained if the heptapeptide hormone is injected daily into tumor-bearing

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

mice.[27] Ang-(1–7) does not cause any observable adverse side effects, including changes in heart and body weight, heart rate, or blood pressure. The tumor inhibition correlates with a reduction in the proliferation marker Ki67 and cyclooxygenase-2 (COX-2) mRNA and protein in tumors from the Ang-(1–7)-treated animals as compared with the saline control tumor tissue. By contrast, no change in COX-1 mRNA is observed in xenograft tumors from animals infused with Ang-(1–7). Similar results for COX regulation are observed with the parent A549 human lung cancer cells in tissue culture. These results suggest that Ang-(1–7) may decrease COX-2 activity and proinflammatory prostaglandins to inhibit lung tumor growth.

We also found that Ang-(1–7) markedly decreases tumor volume and wet weight of orthotopic human breast tumors positive for the estrogen receptor (BT-474 or ZR-75-1) and overexpressed HER2 (BT-474).[5] Both types of breast tumors increase significantly over time after subcutaneous infusion with saline, while Ang-(1–7) significantly inhibits tumor growth. In addition, tumor burden of colorectal cancer cell metastases was markedly reduced in the liver after infusion of Ang-(1–7) as compared with untreated controls.[1] The ARB irbesartan alone or in combination with the heptapeptide hormone does not decrease liver metastasis. The mechanism for the lack of effect is not known. In a previous study, irbesartan alone did significantly reduce liver metastasis in the same mouse model.[19] Taken together, these studies suggest that Ang-(1–7) may serve as a first-in-class, targeted therapy for cancer.

ANG-(1–7) INHIBITS TUMOR ANGIOGENESIS

Infusion or subcutaneous injection of Ang-(1–7) not only causes a significant reduction in human A549 lung tumor xenograft growth in mice but it also markedly decreases vessel density.[27] Similarly, the heptapeptide hormone attenuates angiogenesis in orthotopic BT-474 and ZR-75-1 breast tumor xenograft,[5] suggesting that Ang-(1–7) inhibits angiogenesis to reduce tumor size. VEGF-A protein and mRNA are reduced in lung tumor xenografts from mice infused or injected with Ang-(1–7) as compared with tumors from saline-treated animals.[8,27] A similar decrease in VEGF-A is observed in parent A549 human lung cancer cells after incubation with Ang-(1–7). D-alanine-(7)-Ang-(1–7) [D-Ala^7-Ang-(1–7)], a specific antagonist for the Ang-(1–7) receptor, completely blocks the reduction in VEGF-A by the heptapeptide hormone. These results suggest that Ang-(1–7) attenuates tumor angiogenesis by reducing VEGF-A. In support, the heptapeptide hormone causes a significant decrease in human endothelial cell tubule formation in Matrigel.[8,27] The Ang-(1–7)-mediated effects are blocked by the specific Ang-(1–7) receptor antagonist [D-proline(7)]-Ang-(1–7). The chorioallantoic membrane (CAM) assay also was used to assess the effect of Ang-(1–7) on vascularization *in vivo*.[8,27] A 2-day incubation with Ang-(1–7) significantly inhibits blood vessel formation and vessel branching as compared with saline-treated control, effects that are blocked by an Ang-(1–7) receptor antagonist. These studies suggest that Ang-(1–7) activates the $AT_{(1–7)}$ receptor to attenuate blood vessel formation to reduce tumor growth.

EFFECTS OF ANG-(1–7) ON THE TUMOR MICROENVIRONMENT

We showed that Ang-(1–7) reduces interstitial fibrosis in human BT-474 and ZR-75-1 orthotopic breast tumors in association with a significant decrease in collagen I deposition, a similar reduction in perivascular fibrosis is observed in the ZR-75-1 tumors.[5] The heptapeptide hormone markedly attenuates *in vitro* growth of cancer associated fibroblasts (CAFs) isolated from orthotopic ZR-75-1 breast tumors, as well as reduces fibronectin, TGF-β, and ERK1/2 kinase activity. An associated increase in the MAPK phosphatase DUSP1 (dual-specificity phosphatase 1) after treatment with Ang-(1–7) suggests that the heptapeptide hormone reduces MAPK phosphorylation and activation by upregulating a MAP kinase phosphastase. Consistent with these *in vitro* observations, immunohistochemical analysis of Ang-(1–7)-treated orthotopic breast tumors reveals reduced TGF-β and increased DUSP1. Together, our findings indicate that Ang-(1–7) not only inhibits the proliferation of breast tumor cells and reduces tumor angiogenesis but also targets the tumor microenvironment to inhibit CAF growth and tumor fibrosis. Thus, Ang-(1–7) may serve as a first-in-class, antifibrotic agent that targets the tumor microenvironment to reduce breast cancer tumor growth and fibrosis.

ANG-(1–7) CLINICAL TRIALS

We conducted a Phase I Clinical Trial to determine the toxicity of Ang-(1–7) in patients with solid tumors.[21] Of 15 evaluable patients, 4 showed clinical benefit; three patients were treated for >3 months without tumor progression and one patient was treated for >10 months, with a 19% reduction in overall tumor measures. Clinical benefit was associated with a reduction in the proangiogenic factor placental growth factor (PlGF), in agreement with preclinical studies showing that Ang-(1–7) inhibits angiogenesis.[5,27] The drug was well tolerated with no hypertension, bleeding disorders, or drug-related deaths. A Phase II Clinical Trial, for the treatment of sarcoma patients with Ang-(1–7), is currently recruiting.

Ang-(1–7) is distinctive as a targeted therapy for cancer. The inhibition of cell growth by Ang-(1–7) is mediated by a novel, G protein-coupled receptor, *mas*, indicating

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

that the heptapeptide hormone targets a unique receptor. Ang-(1–7) does not affect a single molecule or pathway; the heptapeptide hormone has pleiotropic effects, including inhibition of proliferation, fibrosis, and angiogenesis. Our results suggest that Ang-(1–7) inhibits both tumor and fibroblast cell growth. Many targeted therapies in clinical use or being tested in clinical trials inhibit the activity of protein kinases to reduce cell growth. Because many of these kinases are critically involved in normal homeostasis, their inhibition causes the adverse quality-of-life side effects associated with their clinical use. By contrast, Ang-(1–7) reduces MAPK activity to control levels, such that the activated enzyme is available for normal cellular functions. Further, we showed that Ang-(1–7) decreases fibrosis in human orthotopic breast tumors.[5] Because increasing evidence suggests that interaction between tumor cells and stromal cells is essential to promote tumor growth, a drug such as Ang-(1–7) that targets both the primary tumor cells as well as the tumor microenvironment will have additive effects on tumor growth. Finally, Ang-(1–7) reduces tumor angiogenesis with a reduction in the proangiogenic factors.[5,21,27] Other antiangiogenic drugs target the growth factor receptor(s) or the signaling pathways that are stimulated by receptor activation. Thus, the molecular mechanisms for the antiangiogenic effects of the heptapeptide hormone are unique, suggesting that Ang-(1–7) may be used in combination with other antiangiogenic drugs to target multiple mechanisms and inhibit angiogenesis.

CONCLUSIONS

Although the RAS is a classic peptide hormone system and its role in the regulation of blood pressure, heart rate, and renal function is established, studies indicate that the angiotensin peptides may be involved in carcinogenesis. The study of the RAS and cancer is in its infancy, and there are many remaining questions about the role of the RAS in cancer. For example, is the RAS involved in the initiation or progression of carcinogenesis or is activation of the RAS in tumor tissue a consequence of tumorigenesis? Can components of the RAS—angiotensin peptides, angiotensin receptors, or processing enzymes—be used as effective diagnostic predictors of cancer? Does Ang II have true oncogenic properties and is Ang-(1–7) a tumor suppressor? Do alterations in the ratio of the angiotensin peptides play a role in cancer initiation? What are the molecular signaling pathways that are activated by Ang II to induce tumor cell proliferation and angiogenesis and by Ang-(1–7) to inhibit these processes? Is the RAS a viable target for drug intervention? These are but a few of the questions that need to be answered.

Drugs that regulate either the production of Ang II—ACE inhibitors—or the interaction of Ang II with its receptors—ARBs—are efficacious treatments for high blood pressure and heart disease with strong safety profiles. Unfortunately, the use of ACE inhibitors and ARBs as cancer therapeutics has had mixed success. The variability in success may be because of the tumor type assessed, tumor stage at treatment, or the particular ACE inhibitor or ARB used for treatment. The development of drugs that increase ACE2 activity or the use of recombinant human ACE2 may provide an additional avenue for the treatment of malignancies by regulating circulating or tissue Ang II and Ang-(1–7). Recent studies—both preclinical and our Phase I clinical trial—suggest that Ang-(1–7) may be useful as a novel, cancer therapeutic by inhibiting tumor cell growth and angiogenesis. Because Ang-(1–7) also inhibits fibrosis, the heptapeptide hormone may reduce tumor fibrosis and the growth of stromal cells that provide support and stimulate cytokines for tumor growth. In addition, many of the classical chemotherapeutic drugs that are effective at reducing tumor size are limited in their usefulness based on their cardiotoxicity. Because Ang-(1–7) reduces not only tumor fibrosis but also interstitial fibrosis in the heart and perivascular fibrosis surrounding coronary vessels, the use of the heptapeptide hormone as an adjuvant therapy to reduce cardiac toxicity should also be explored.

Chapter 68

Apelin

Frank Cuttitta and David S. Salomon

ABSTRACT

Apelin, a 13-amino-acid peptide (APL-13), was initially identified as a bovine GI hormone that regulates acid production and represented the cognate ligand for the orphan G-protein-coupled receptor, APJ. It is highly conserved in vertebrates, regulates diverse physiological activities, and underpins multiple disease states in humans. Recent advancements in the field have shown APL-13 to function as a major growth factor in tumor progression via its proliferative role in angiogenesis and lymphangiogenesis pathways. In the following text, we review the current literature on APL-13 in cancer and discuss its potential value as a prognostic tool or targeted therapy in the clinical management of malignant disorders.

INTRODUCTION

Apelin (APL) was initially isolated from cow's stomach and shown to modulate acid production and interact with the APJ receptor; its corresponding bovine/*Homo sapiens* cDNAs were determined.[37] In mammals, the APL gene codes for a 77-amino-acid prepro precursor molecule that is processed into apelin-36 (APL-36), apelin-31 (APL-31), apelin-28 (APL-28), and apelin-13 (APL-13) through a cascade of proteolytic cleavage events.[17] APL-13 is highly conserved in vertebrate evolution with a single amino acid substitution existing between the human derivative and that of bony fish, representing 500,000 years of genetic adaptation.[30] Given this fact, APL-13 is believed to play a critical role in species survival and was shown to be required for normal vascular development in the frog embryo.[5] Interestingly, APL gene knockout mice are not embryonic lethal but are phenotypically linked to aging-associated reduced cardiac contractility and increased susceptibility to pressure overload-induced heart failure.[21] Over the past decade, APL has been proven to be a pluripotent regulatory peptide involved in normal physiology and pathological conditions that include neurotransmission, water uptake, food consumption, gut motility, hormone release, glucose use, diuresis, immune response, embryogenesis, diabetes, liver cirrhosis, HIV susceptibility, cardiovascular disorders, angiogenesis, lymphangiogenesis, and carcinogenesis.[2,10,23]

The process of carcinogenesis (initiation, progression, and metastasis) involves complex pathways encompassing an accumulation of mutational insults that transforms normal cells to a neoplastic phenotype. This is followed by spatial/temporal influences of component cells of the surrounding tumor microenvironment, development of angiogenic/lymphangiogenic vascular networks in and around the tumor body, culminating in secondary site involvement that leads to organ failure and patient death via malignant expansion of cancer cells.[14] For cancer cells to advance through the carcinogenesis pathway completely, they must acquire the following characteristics: (1) replicative immortality, (2) sustained proliferative state, (3) resistance to cell death (apoptosis), (4) circumvent immune surveillance, (5) induce angiogenesis/lymphangiogensis, and (6) migrate to distal anatomic sites (invasion/metastasis).[14] For the remainder of this chapter, we will discuss the role of APL in the majority of these tumor cell characteristics, reveal cellular mechanisms that regulate APL expression and propose possible drug developmental avenues that target APL for anticancer therapies.

ROLE OF APELIN IN CANCER

APL induces growth and protection against apoptosis in a variety of anatomically distinct cell types.[33,35] Given this capability, APL was proven to be a positive influence in normal embryogenesis or wound repair.[20,32] Unfortunately, similar positive repercussions have been assigned to APL in carcinogenesis by selectively allowing the tumor cell to survive harsh microenvironmental conditions such as hypoxia and inflammation.[1,13] Epithelial to mesenchymal transition (EMT) plays a critical role in tumor formation/invasion process that is modulated by hypoxia/inflammatory insults and initiated through the Wnt/β-catenin, cripto-1/nodal, notch, and APL/APJ signaling pathways.[6,12,19,25] Hence, the APL/APJ system seems to be involved (directly or indirectly) in several complex mechanisms that influence tumor progress and metastasis, thereby mimicking a similar role it plays during normal embryo development and in stem cell function.[6,20]

Angiogenesis and lymphangiogenesis are important support infrastructures for cancer cell growth and metastasis.[16] As tumors exceed a 2-mm diameter, size they no longer can maintain proliferative self-sufficiency and undergo growth reduction that ultimately leads to a dormant state.[11] If however these tumor colonies begin to produce angiogenic or lymphangiogenic factors that induce endothelial cell chemotaxis and vessel sprouting, then newly formed vascular networks will supply the neoplastic lesion with additional nutrients from an enriched blood supply leading to expanded growth and establishing alternative routes for distal cancer cell dissemination.[11,16] Tumor metastasis is a multipronged process that involves the migration of the cancer cell through surrounding stromal tissue. These tumor cells then enter vascular networks (blood vessel or lymphatics) or traverse vascular/neural highways externally via angio-, lymphangio-, or neruotrophic mechanisms and eventually establishing foothold colonies at distal anatomical sites.[9,16,26,31] APL is a potent angiogenic/lymphangiogenic factor produced by human cancers and is thus considered a rational target for the development of anticancer therapies.[23] Interestingly, endothelial cells and neurons are an endogenous source of APL production that in turn can mediate tumor cell chemotaxis and stimulate the expression of MMP-3/MMP-9, which fosters cell migration through the extracellular matrix and increases the metastatic potential of cancer cells.[7,18,34] Berta et al. have shown that in nonsmall cell lung cancer patients, elevated APL tumor expression tracks with increased vascular density in the neoplastic lesion and worsens clinical outcome.[2]

Cancer patient fatalities stem from multiple organ failures caused by the displacement of normal cells with invading cancer cells.[26] Therefore, drugs that prevent the spread of cancer cells to distal tissue sites should have a major influence on the resulting mortality rates for a given neoplasm. Neutralizing antibody to APL decreases the peptide's ability to induced angiogenesis/lymphangiogenesis.[23] In addition, the peptide antagonist APL-13(P13A) suppresses APL regulated hypotension and neovascularization.[22,28] Finally, the carboxypeptidase, angiotensin-converting enzyme (AEC2), rapidly degrades APL by removing the peptide's carboxy-terminal phenylalanine making it biologically inert.[29] By applying these findings collectively, there seem to be a variety of compounds that could be evaluated in preclinical/clinical trails to inhibit APL bioactivity and potentially prove to be effective therapeutics in cancer management.

We have previously discussed the role of hypoxia and inflammation as direct mediators of APL expression and the influence of this peptide can have on cancer progression and invasion. There are several other physiological conditions that can lead to APL overexpression and indirectly contribute to the carcinogenesis pathway. Obesity, for example, is known to increase the risk of cancer development and has been associated with 20 different anatomical tumors.[15] APL is a product of adipocytes (a member of the adipokine family), blocks glucose-stimulated insulin secretion, and its plasma concentrations are increased in obese/type 2 diabetic patients.[10] Given these findings, APL may prove to be a regulatory link between obesity and cancer that propagates normal to malignant cell conversion. There exists another alternative possibility involving APL expression that might indirectly effect cancer cell progression as reflected in neural biology. APL was recently identified in proopiomelanocortin (POMC) neurons and functions to regulate the release of alpha-melanocyte-stimulating hormone (α-MSH) in an autocrine fashion.[24] Interestingly, Wnt/β-catenin signaling is activated by α-MSH in melanoma cells which in turn could lead to the initiation of a Cripto-1/Nodal, Notch, and APL/APJ cascade inducing EMT shifts and stem cell conversion that ultimately would stimulate cancer progression/invasion.[3,4,6,8,12,19,25] We have therefore defined multiple regulatory mechanisms whereby the apelinergic system may influence human carcinogenesis and serve as potential therapeutic targets for anticancer drug development.

CONCLUSIONS

In this chapter, we have presented an overview of the APL/APJ system's involvement in human carcinogenesis, stressing its role in cancer growth, angiogenesis, lymphangiogenesis, and dissemination to distal secondary sites. We have also discussed potential anticancer drug development that targets APL or the APJ receptor and prevents its promalignant bioactivities that encompass a neutralizing antibody, a peptide antagonist (APL-13[P13A]) and the catabolic enzyme ACE2 that selectively degrades the peptide. Finally, we have implicated APL as a regulator

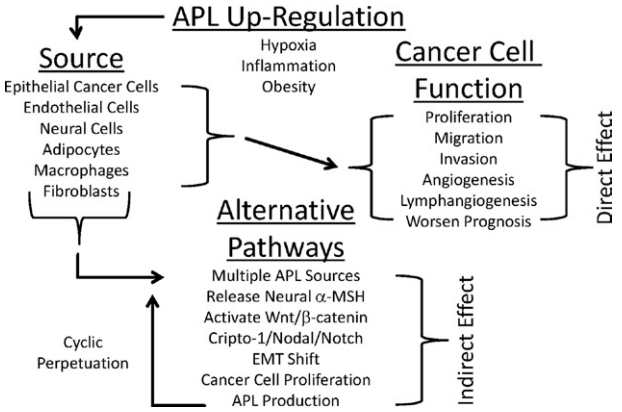

FIGURE 1 The role of apelin in cancer.

of complex interconnecting pathways involving Wnt/β-catenin, Cripto-1/Nodal, Notch, EMT pathways, and stem cell conversion that underlie cancer progression and invasion, thus making it a good candidate for targeted therapy in the clinical management of human cancer. As summarized in Fig. 1, there are multiple sources of APL production capable of driving tumor cells through the carcinogenesis pathway and both direct and indirect mechanisms on how APL can influence cancers. Future research along these lines will help confirm the critical role APL plays in tumor development and hopefully identify intervention strategies that will effectively prevent or suppress human cancers. As a closing note, we propose the following question: Are APL-36, APL-31, APL-28, APL-17, and APL-13 the only bioactive peptide products of the apelinegic family or are there potentially other gene-related factors that may prove to be even more important in human carcinogenesis.

Chapter 69

Bombesin Peptides

Robert T. Jensen and Terry W. Moody

ABSTRACT

Mammalian bombesin-related peptides and their receptors are frequently expressed by human cancers and have important effects on tumoral growth, in some cases in an autocrine fashion. Their receptors are one of the groups most frequently ectopically/overexpressed by human cancers, and this is increasingly being investigated for possible tumor localization and for receptor-mediated cytotoxicity in which ligands for these receptors are used to target cytotoxic agents to the tumors. In this chapter, their effects/role in human cancer are briefly updated from the previous addition of this book with particular attention to advances in their cellular signaling cascades in cancer, roles in imaging and possible cytotoxicity, and their potential roles in cancer treatment.

INTRODUCTION

Bombesin (Bn)-related peptides [Gastrin-releasing peptide (GRP) and neuromedin B (NMB)] are regulatory peptides that are widely distributed in the central nervous system and gastrointestinal (GI) tract, where they primarily function as neurotransmitters/neuromodulators.[6] In the previous edition of this book[7] their role in cancer current to 2006 was reviewed including their expression and their receptor's frequent ectopic/overexpression by human cancers, their proliferative effects on tumors, their signaling cascades, and their roles in treatment. A few important points from this previous 2006 chapter will briefly be summarized below and the rest of this chapter will review the important advances of their role in cancer, especially their signaling cascades and use in tumor localization and targeted tumoral therapies.

Bn-RELATED PEPTIDES (GRP, NMB)

General

The 27-amino acid peptide, GRP is derived from a 148-amino acid precursor, whereas NMB is a 10-amino acid peptide derived from a 32-amino acid precursor originating from a larger 76-amino acid precursor.[6] Their cellular actions are mediated by two G protein-coupled receptors (GPCR): a GRP-R (384 amino acids) and NMB-R (390 amino acids).[6] A third orphan GPCR, bombesin receptor subtype-3 (BRS-3)(399 amino acids)[6] has 46–49% amino acid identities with GRP-R/NMB-R, but the endogenous ligand for it is unknown; however it is included in the Bn-related receptor class because of its high homology to GRP-R/NMB-R. Each mammalian Bn receptor is coupled to phospholipase C (PLC) as well as tyrosine phosphorylation and MAP kinase cascades.[6]

Expression of Bn-Peptides and Their Receptors in Cancer

As summarized in the 2006 chapter,[7] a wide range of cancers synthesize Bn-related peptides and many ectopically and/or overexpress GRP-R, NMB-R, and/or BRS-3.[7] Either Bn receptors or receptor mRNA was detected frequently in 70–100% of small-cell lung cancer (SCLC), non-small-cell lung cancer (NSCLC), pancreatic cancer cell lines, prostate cancer, head/neck squamous cell cancer, glioblastomas, intestinal carcinoids, and neuroblastomas.[7] A study[19] examining 32 different types of human cancers (bladder, colon, renal, ovarian, uterus, sarcoma) shows that GRP-Rs are expressed in vessels in all the tumors and that they are localized with particularly high expression in a subgroup of vessels, which also have high VEGF expression. This study suggested this localization might be used to deliver targeted antiangiogenic therapy or angiodestructive targeted radiotherapy with radioactively labeled Bn analogs.[19]

Effect of Bn-Receptor Activation on Cancer Growth/Proliferation

Bn-like peptides alter growth and/or differentiation of a wide range of cancers frequently in an autocrine fashion.[5,7] They stimulate growth of cancers of the pancreas, lung, head/neck, glioblastomas, neuroblastomas, kidney, prostate, breast, colon, ovary, and intestine.[5,7,14,35] Bn-R receptor agonists directly stimulate the growth both *in vitro* and *in vivo* for many of these different tumors and/or Bn-R antagonists

or silencing of the GRP-R by receptor knockdown studies suppress tumorigenesis, metastatic potential or growth in various studies.[5,7,11,18,35] Furthermore, in some tumors such as head/neck squamous cell tumors, the addition of a GRP-R antagonist to an EGFR tyrosine kinase inhibitor (erlotinib) results in synergistic inhibition of growth and tumor invasion, increased apoptosis, cell cycle arrest of the tumor cells, and increased survival.[35] Furthermore, a similar result occurs in lung cancer cells where stimulation of the GRP-R results in increased resistance to the cytotoxic effects of the EGFR tyrosine kinase inhibitor, gefitinib, coupled with other findings to lead to the conclusion that GRP release can rescue the lung cancer cells exposed to gefitinib, leading the authors to propose that GRP-R blockade should be combined with EGFR inhibition to better modulate therapeutic effects in lung cancer.[11] Similarly, NMB-R can show similar growth synergistic effects with EGFR activation as shown in a study in lung cancer cells where the addition of an NMB-R antagonist results in an increased sensitivity to the cytotoxic effects of the EGFR tyrosine kinase inhibitor, gefitinib.[13] In colonic cancer cells, Bn-related peptides are weak mitogens, and extensive clinical and laboratory studies support the conclusion that the ectopic overexpression of GRP-R is functioning as a morphogen and is of benefit to the patient.[20,28,30] The clinical evidence includes the observation that the mean survival of patients with colon cancers expressing GRP-R is significantly longer than those without GRP-R expression; that only the better differentiated tumor cells express GRP/GRP-R, that expression of GRP or GRP/GRP-R by the tumor is associated with a delayed recurrence of the tumor and increased survival ($p=0.0124$) as well as fewer lymph node metastases.[20] These studies suggest that ectopic/overexpression of Bn-Rs by different tumors may have differing effects on growth/differentiation. Bn-related peptides also function as proangiogenic factors in various tumors.[7] In one study[17] NMB-R inhibition by PD168368, a specific NMB-R peptoid antagonist,[4] inhibits *in vivo* and *in vitro* angiogenesis; it inhibits MDA-MB-231 breast cancer cell growth by inducing cell cycle arrest and apoptosis and suppresses tumor growth in a xenograft model of breast cancer. This leads to the conclusion that NMB-R blockade has significant antitumor effects in breast cancer cells by simultaneously inhibiting neovascularization and cancer growth.[17]

Mechanism of Bn-Related Peptide Induced Growth Effects on Cancer Cells

Activation of all mammalian Bn-Rs stimulates phospholipase C (PLC) activity and causes activation of tyrosine and MAP kinase cascades.[5–7,31] In some tumors the growth stimulatory effects are mediated directly by the Bn-R activated cascades, whereas in other cases, transactivation of the EGF receptor (EGF-R) is required, and in still other cases by stimulation of the release of growth factors.[5–7,31] The growth stimulatory signaling cascades of the GRP-R have been investigated in the most detail.[7] GRP-R stimulates EGFR-independent growth of the hepatocellular carcinoma HepC2 cells, which is mediated by activation of ERK1/2.[9] In lung cancer cells GRP-R activation of PLC causing increased cytosolic calcium, but not the activation of PKC, is critical to mediating anchorage-independent growth and decreased survival. This requires the activation of Src family kinases, coupled with activation of the focal adhesion kinase, proline-rich tyrosine kinases (Pyk2), which result in GTP-loading of Ras and increased ERK1/2 activation.[21] Protein kinase D (PKD)[26] plays an important role in mediating GRP-R stimulated growth in Swiss 3T3 cells, with the early phase of PKD activation (<15min) resulting from PKC activation; however the later phase of PKD activation (>60 mins) is PKC-independent, but requires activation of EGFR. The ability of PKD activation to stimulate growth and DNA synthesis is partially mediated by its ability to increase the duration of ERK1/2 signaling. Prostate cancer cells very frequently overexpress the GRP-R and GRP-R activation can stimulate their growth.[7] In the androgen-insensitive cells line, PC-3, the activation of GRP-R results in increases in COX-2 mRNA and protein expression and the release of PGE2, which is mediated by the activation of the MAP kinase, p38 as well as requiring the activation of the PI3K/AKT pathway.[32] In the aggressive neuroblastoma cell line, BE (2)-C, the knockdown of GRP-R results in decreased proliferation, DNA synthesis and a cell cycle arrest at G2/M, which is associated with upregulation of PTEN, an inhibitor of the PI3K/AKT pathway, and a marked decrease in activated AKT, as well as phosph-p70S6K and its downstream target molecule S6, which are key regulators of protein synthesis and cell metabolism. Similarly, in various neuroblastoma cells (LAN-1, SK-N-SH, BE (2-C) in which GRP acts in an autocrine growth fashion, activation of the GRP-R stimulates AKT activity as well as pGSK-3B and an inhibitor of AKT, LY294002, abrogates GRP stimulated increases in phospho-AKT, and reverses GRP's effect on the cell cycle targets as well as inhibits GRP stimulated growth. The increase in p38 results in an increase in COX-2 mRNA by retarding its degradation.[32] The activation of the androgen receptor (AR) may play an important role in the growth of castration-resistant prostate cancer.[12] Activation of GRP-R can stimulate prostate cancer cells growth in an androgen-free environment, and this is partially mediated by the ability of GRP-R to stimulate androgen receptor phosphorylation at Tyr-534, which is dependent on Src activation.[12] Androgen receptor phosphorylation at Tyr-534 is linked to enhanced AR recruitment and expression of AR target genes at sub-optimal androgen concentrations.[12] GRP-R mediated transactivation of EGFR in head/neck squamous cell cancer cells (HNSCC cells) is mediated by Src-dependent cleavage of EGFR proligands, which result in MAPK activation.[35] The

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

combination of a GRP-R antagonist and an EGFR inhibitor (erlotinib) has synergistic effects on growth inhibition of HNSCC cells[35] and it was associated with decreased phospho-EGFR, phospho-MAPK, phospho-c-Jun, phospho-p70S6K, and phospho-p38 kinase.[35] Similarly, in lung cancer cells[11] GRP-R stimulates growth by transactivating EGFR, which is associated with AKT activation.[11] The AKT activation is mediated by c-Src-mediated transactivation of the EGFR resulting in the activation of matrix metalloproteinases, release of amphiregulin, and then through a PI3K mediated mechanism.[11] The cytotoxic effect of the EGFR inhibitor, gefitinib on lung cancer cells, is inhibited by GRP administration and this protective effect of GRP is mimicked by the pretreatment of lung cancer cells with amphiregulin and activation of the AKT pathway, suggesting that GRP-R and/or EGFR autocrine pathways in lung cancer cells may modulate therapeutic responses to EGFR inhibitors, by rescuing the cancer cells from its cytotoxic effects.[11]

In colonic cancer cells, where activation of ectopic, overexpressed GRP-R has a weak growth effect and it is proposed that GRP-R is functioning as a morphogen and is of benefit to the patient, a number of studies into the possible mechanisms involved are reported.[20,22,28,30] In a study to identify targets activated in response to GRP-R signaling a proteomic approach was used to analyze two colonic cell lines, Caco-2 and HT-29, which express GRP-R as a function of confluence.[22] With GRP-R expression/activation five proteins were specifically downregulated (Bach2, creatine kinase B, p47, 2-not identified) and six were upregulated (gephrin, heat shock protein 70(HSP70), HP1, ICAM-1, ACAT, 1-not identified).[22] In colon cancer cells.[28] GRP-R activation causes heat shock protein 72(Hsp72) to be expressed via activation of $p125^{FAK}$, which promotes the binding of CD16+ and CD94+ natural killer cell lymphocytes resulting in tumor cell cytolysis and thus providing a novel mechanism for tumor cell destruction. An additional study[30] attempted to provide an insight into the possible effects of overexpression of Hetochromatin protein 1 by the ectopic activation of GRP-R in colon cancer cells.[22] The Heterochromatin 1 family (HP1) are epigenetic modifiers of gene transcription consisting of three members ($HP1^{Hs}\alpha$, $HP1^{Hs}\beta$, $HP1^{Hs}\gamma$), which protect against tumor cell aggressiveness and metastases in other cancers.[30] In this study,[30] inhibiting GRP-R signaling decreases $HP1^{Hs}\beta$ expression and increases colon cancer cell invasiveness, providing a possible mechanism whereby GRP-R overexpression is improving the outcome of patients with colon cancer, a result which is seen in clinical studies.[20,22,28,30]

Two other studies provide evidence that activation of ectopically expressed/overexpressed NMB-R's or BRS-3 by tumors may have similar mechanisms causing tumor growth in some cases, like that reported above with the GRP-R.[13,14] In two studies of lung cancer cells, which frequently overexpress NMB-R's or BRS-3,[6,7] activation of either NMB-R or BRS-3 stimulates growth by transactivating EGFR. For both NMB-R and BRS-3 the transactivation of EGFR is inhibited by a matrix metalloproteinase inhibitor (GM6001), by a universal SFK inhibitor (PP2), and by agents that inhibited the generation of reactive oxygen species, N-acetylcysteine (antioxidant), Tiron (superoxide scavenger), DPI (NADPH oxidase inhibitor).[13] For the NMB-R, EGFR transactivation is mediated by the generation of transforming growth factor alpha.[13]

Role of Bn-Related Peptides in Treatment of Human Tumors

The presence of Bn-related peptides/receptors on human tumors and their effects on growth are not at present specifically used in the treatment/management of any tumors. However, there is much interest and many recent studies on their ability to play potentially important roles as prognostic factors; as molecular targets to inhibit tumor growth by inhibition of their growth promoting activities; as molecular targets to image tumor extent/location, and as molecular targets to deliver Bn-R mediated cytotoxicity through radioactively labeled compounds and/or cytotoxic agents coupled to Bn-R ligands.[5–7,15,23] Each of these areas will be briefly dealt with.

Bn Peptides as Prognostic Agents

In several studies, plasma levels of GRP precursors (i.e. such as proGRP) in patients with non-small-cell lung cancer or small-cell lung cancer gives important prognostic information and is useful in some studies to assess response to therapy.[3,16,29,34]

Bn Peptides as Molecular Targets to Inhibit Tumor Growth by Inhibition of Their Growth Promoting Activities

Studies continue to support the proposal the inhibition of the autocrine growth effect of Bn-like peptides on tumor growth using Bn-receptor antagonists, antisense constructs, or other inhibitors, may be a novel approach for antitumor treatment.[7,18] Potentially particularly important is the observation in both lung tumors and head/neck squamous cell tumors that the blockade of Bn-R receptor activation (GRP-R, NMB-R, BRS-3) potentiates the ability of various EGFR antagonists such as gefitinib to inhibit tumor growth.[11,13,14,35] With non-small-cell lung cancer, one of the main treatments is the use of EGFR tyrosine kinase inhibitors such as gefitinib, however many patients do no respond or develop resistance to these with continued treatment, therefore the finding that Bn-R blockade potentiates

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

EGFR inhibitors action may be of particular importance in the treatment of this tumor.[13,14]

Bn-Rs as Molecular Targets to Image Tumor Extent/Location

The potential usefulness of using the ectopic expression/ overexpression G protein-coupled receptors for tumor localization/imaging such as with Bn-Rs is best seen with the use of this approach with somatostatin receptor overexpression by neuroendocrine tumors.[23] With neuroendocrine tumors, which >80% overexpress somatostatin receptors, the use of various radioactively labeled somatostatin analogs is now one of the most clinically widely used and sensitive methods to both localize the primary tumor as well as to stage the disease.[23] However, many of the common malignancies, such as breast, pancreatic, colon, gastric, head/neck squamous tumors, and prostate cancers do not overexpress somatostatin receptors; however >70% overexpress Bn-Rs, and therefore there is a increasing interest in trying to apply this approach with radioactively labeled Bn analogs to these tumors.[7,23] The results from >200 studies have been summarized in one review[23] and other reviews cover various aspects of this approach.[1] Many synthetic analogs of Bn-related peptides are used in these studies including primarily COOH terminal analogs of GRP, Bn, or litorin and particularly analogs of Bn (2–14), Bn (6–14), and Bn (7–14).[23] These analogs are labeled with different isotopes depending on whether they are primarily going to be used for imaging, the type of imaging, or for Bn receptor-mediated cytotoxicity (next section), with the isotopes used including ^{99m}Technetium, ^{111}Indium, ^{64}Copper, ^{125}Iodine, $^{185/187}$Rhenium, ^{18}Fluorine, ^{68}Gallium, ^{90}Yttrium or ^{177}Lutetium.[23] Both *in vitro* studies and *in vivo* studies using conventional gamma radiation detection or PET imaging (positron emission tomography), most of the various Bn-R analogs examined were able to specifically identify tumors containing Bn-R-bearing cells.[23] In all of the original studies radioactively labeled Bn-receptor agonists were used, based on analogies to results with somatostatin analogs and numerous studies that showed only agonists are internalized and thus thought likely to give better imaging.[2,6,23] However, radioactively labeled Bn-receptor antagonists may be superior targeting agents to agonists.[2] One study compared the agonist, desmobesin 4 [Tetramine^0, Pro^1, Tyr^4, NLeu^{14}] Bn and the GRP-R antagonist, desmobesin 1 [Tetramine^0, D-Phe^6-Leu-NHEt^{13}, desMet^{14}] Bn (6–14)], which had similar affinities for the GRP-R, and found almost a 8-fold greater tumor to kidney ratio with the antagonist, ^{99m}Tc-Desmobesin 1, four hours after injection in prostate cancer (PC-3) bearing mice.[2] At present the difference in the molecular basis of the greater binding and superior imaging properties of Bn-R antagonists over agonists is unknown. There is particular interest in imaging prostate cancers which frequently (>70%) overexpress/ ectopically express GRP-R.[6,7,25] In *in vitro* studies of various prostate cancer cells and *in vivo* studies both in humans and in prostate cancer-bearing animal, imaging results with various GRP-R agonists and antagonists, are promising.[1,23,25] One important finding that will be particularly important for imaging with GRP-R analogs in patients with prostate cancer is that the expression of human GRP-R in human androgen-dependent prostate cancer xenografts is markedly reduced by androgen ablation. Some studies[4,24,31] for the first time report systematic evaluations of the absolute and relative affinities/potencies for various human Bn-R subtypes (GRP-R, NMB-R, BRS-3) for a large number of Bn-related peptides that are reported to function as agonists or antagonists, primarily in nonhuman cells. These studies show a number of important differences in the pharmacophore of human Bn-Rs compared with that of rat Bn-Rs that are commonly used in experimental studies, and besides providing possible templates for further studies, they also make the point that the pharmacology of any proposed ligands for human studies should be performed in human Bn-R containing cells.

Bn-Rs as Molecular Targets to Deliver Bn-R-Mediated Cytotoxicity Through Radiolabeled Compounds and/or Cytotoxic Agents Coupled to Bn-R Ligands

Because many common tumors frequently (>70%) overexpress Bn-Rs,[7] not only can labeled analogs of various Bn-related peptides possibly be used to image the tumors, as discussed in the preceding paragraph, but there is also increased interest in using them to target cytotoxic agents (radioactively labeled other cytotoxic agents) to the tumor.[23] Results from >100 studies have been summarized and reviewed.[23] This approach is given support by the very promising results with radioactively labeled analogs of somatostatin [^{111}In-, ^{90}Y-, ^{177}Lu-labeled somatostatin analogs], which are being widely used to treat advanced malignant neuroendocrine tumors.[8,23] Similar to the imaging studies discussed above, numerous synthetic agonist analogs of Bn-related peptides [i.e. especially analogs of GRP, Bn, litorin equivalent to Bn (2–14), Bn (6–14), and Bn (7–14)[23]] were used in these cytotoxic studies.[23] For Bn receptor-mediated radio-cytotoxicity, the isotopes primarily used including ^{68}Gallium, ^{90}Yttrium, or ^{177}Lutetium,[23] which were coupled to various Bn analogs using various linkers and chemical groups that would avidly bind the isotopes (DOTA, DOTA analogs, DO3A, NOTA, or NOTA-Aca).[23] A number of these describe radioactively labeled Bn analogs that retain high affinity for the Bn-R bearing tumors *in vivo* have reduced renal toxicity and tumoricidal effects *in vivo*.[23] In human prostate cancer cells, Bn analogs coupled

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

to alpha particle emitters (such as ^{213}Bismuth) have greater cytotoxicity than do the β-emitter ^{177}Lu–Bn analog,[33] suggesting that this approach should be consider in the future.

In addition to coupling Bn analogs to radioactively labeled Bn-related analogs that have cytotoxic effects, there is increasing interest in targeting other cytotoxic agents to tumors overexpressing/ectopically expressing Bn receptors.[23] Cytotoxic Bn analogs formed by coupling Bn-related peptides to chemotherapeutic agents (doxorubicin) (AN-215) inhibit the growth of pancreatic, lung, prostate, and gastric cancers[7,23] and GRP analogs coupled to camptothecin inhibit lung cancer growth.[10,15,23] The camptothecin-coupled Bn analogs mediate their cytotoxic effects by interacting with tumoral Bn-Rs.[15] Bn analogs have also been coupled to the marine toxins, hemisasterlin and dolastin, and the conjugates have cytotoxic effects on the lung cancer cell line, NCI-H1299, which contains Bn-Rs.[27] Similarly, conjugation of Bn agonist analogs to magainin, an antimicrobial peptide, markedly enhances (10-fold) its cytotoxicity for tumor cells.[10]

At present, the usefulness of using Bn-like peptides or the presence of Bn-R overexpression/ectopic expression by tumors in any of the areas of investigation reviewed above for tumor treatment/diagnosis is not established.

Chapter 70

Endothelin-1

Samer-ul Haque, Hazel Welch and Marilena Loizidou

ABSTRACT

Endothelin-1 (ET-1) is a small vasoactive peptide that was first identified in 1988. It is one of a family of three endothelins that exert their action through two G-protein coupled receptors, ET_A and ET_B. This chapter reviews the evidence implicating ET-1 in tumorigenesis. In particular, we concentrate on the role of ET-1 in mitogenesis, apoptosis, angiogenesis, tumor invasion, and metastasis. Evidence relating to downstream effectors is discussed, and trials relating to the potential for endothelin-system modulation as an adjuvant therapeutic strategy are reviewed.

ENDOTHELIN-1

The potent vasoconstrictor peptide endothelin-1 (ET-1) is one of a family of three multifunctional peptides (ET-1, 2, and 3). They comprise a 21-amino acid structure characterized by a single α-helix and 2 disulfide bridges, encoded on chromosomes 6, 1, and 20 respectively. Initially described in 1988 as a vasoconstrictive substance isolated from bovine aortic endothelial cells, ET-1 is the most extensively studied of the three peptides and the one most implicated in tumorigenesis.

The ET physiological effect is exerted via ET_A and ET_B receptors, which are G-protein coupled transmembrane receptors (GPCR) found in both vascular and non-vascular tissues. The ET_A receptor has varying affinities for each isoform (higher for ET-1 than for ET-2, with a two-fold lower affinity for ET-3), whereas the ET_B receptor shows no selective affinity for any of the ET subtypes.[29]

The endothelins have been implicated in numerous pathological conditions including hypertension and cardiac failure. Interest in the role of ET-1 in cancer has grown over the last decades, and currently there is evidence that ET-1 can modulate mitogenesis, apoptosis, angiogenesis, tumor invasion, and development of metastases.

ET-1 ASSOCIATED SIGNAL TRANSDUCTION PATHWAYS

Translation of the ET-1 gene produces a number of precursors that eventually result in the production of Big-ET-1. This has negligible biological activity and is converted by the metalloproteinase endothelin-converting enzyme 1 (ECE-1) into the active ET-1 peptide. Production of ET-1 is stimulated by Interleukin (IL-1ß), tumor necrosis factor (TNFα), transforming growth factor (TGFß), platelet derived growth factor (PDGF), vasopressin, hypoxia, and shear stress. ET-1 inhibitory factors include nitric oxide, prostacyclins, and atrial natriuretic peptide (ANP).[24]

The consequences of ET-1-induced receptor stimulation are complex with many intracellular pathways being activated (Fig. 1). ET-1 binding to its receptor results in dissociation of the α and βγ subunits of one of several possible associated G-proteins. The activated G-protein then phosphorylates one of several upstream pathway initiators, which include phospholipase C and D, phospholipase A_2, adenylate cyclase, and guanylate cyclase.[31] The former two initiators activate PI3K and Protein Kinase C (PKC) which ultimately result in mitogen activating protein kinase (MAPK) pathway activation. This is achieved either directly by Ras activation through PI3K or indirectly via increased intracellular Ca2+ through PKC. Raf-1 (downstream in the MAPK pathway) is activated directly via PKC.[6] Ultimately, MAPK results in early response gene transcription of fos and jun. Resultant cellular effects include mitogenesis and motility.

More recently, transactivation of other cell surface receptors as a result of ET receptor stimulation has been shown in Rat-1 fibroblasts,[9] ovarian cancer and colorectal cancer (CRC) cells, the Tyrosine Kinase Epidermal Growth Factor Receptor (EGFR) is transactivated and induces MAPK activity.[12] ET-1 has also been shown to potentiate the effects of PDGF on human smooth muscle cells, suggesting interactions with other tyrosine kinase receptors.[35]

As ET_B receptor-binding affinity is equal for all isoforms, this suggests a role in the clearance pathway via lysosomal degradation after receptor uptake.[7] A second clearance pathway has been suggested involving catabolism by the extracellular neutral peptidase nepilysin (NEP).

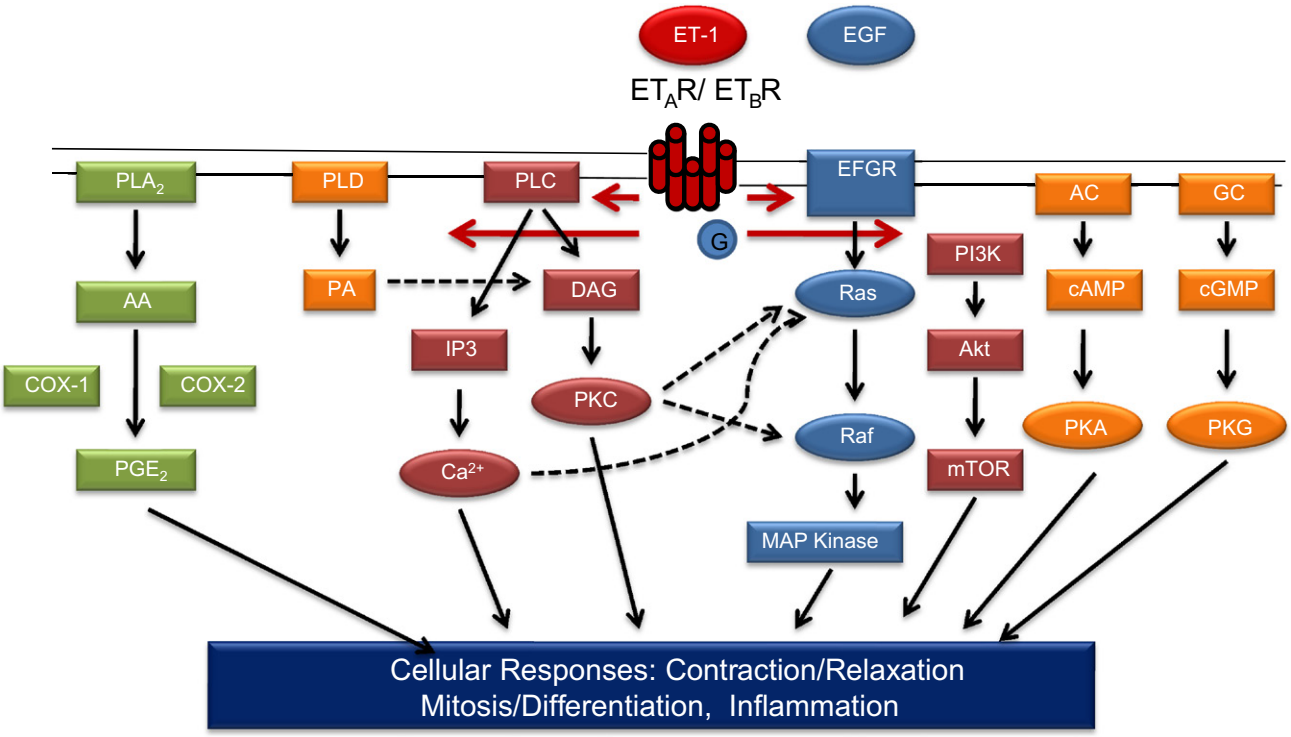

FIGURE 1 Schematic representation of the signal transduction pathways associated with stimulation of the Endothelin receptors. Upstream transduction molecules activated (phosphorylated) by the G-protein are shown at the top of each pathway and include the Epidermal Growth Factor Receptor (EGFR), Phospholipase A_2, C, D (PLA_2, PLC, PLD), Adenylate Cyclase (AC), Guanylate Cyclase (GC), and Phosphoinositide 3-Kinase (PI3K). Downstream effectors include phosphatidyl inositol 3 kinase (IP_3), diacylglycerol (DAG), phospholipase A (PA), cyclic GMP (cGMP), protein kinase A, C, G (PKA, PKC, PKG), Akt, mTOR, cyclooxygenase 1, 2 (COX-1, COX-2), and prostaglandin E_2 (PGE_2). See color plate 19.

ET-1 EXPRESSION IN CANCER

Many human cancer cell lines have been shown to synthesize ET-1, including colonic, breast, stomach, prostate, and glioblastoma cells.[2,20] Similarly, *in vivo*, increased tissue immunoreactivity for ET-1 has been seen in several cancer types, including ovarian, breast, and colorectal tumors.[5]

In normal colorectal tissue, low expression of ET-1 and ECE-1 was reported. However, these molecules are significantly upregulated in 80% of primary CRCs and in the majority of metastatic disease. Furthermore, ET-1 expression levels within tumor-adjacent stromal and endothelial cells are raised, in keeping with its known paracrine function.[4,30] Our group showed that plasma levels of ET-1 are increased in patients with both primary colorectal cancers with or without liver metastasis.[4,20] Other studies have found that both preoperative and intraoperative portal plasma levels are significantly higher in metastatic disease. Elevated plasma concentrations of ET-1 have also been detected in patients with other various solid tumors, including gastric and prostate cancer, where levels are greatest in patients with metastastic, hormone refractory disease.[22]

ET-1 dysregulation as an early event in colorectal tumorigenesis was suggested by the observation that premalignant colorectal adenomas show increased expression of Big-ET-1 and ECE-1 mRNA when compared with normal colon. ET-1 immunoreactivity in breast ductal carcinoma *in situ* (DCIS) specimens is also significantly higher ($P<0.005$) than that of normal breast tissue, suggesting that the modulation of the endothelin system may be an early phenomenon in tumorigenesis.

ENDOTHELIN RECEPTOR EXPRESSION IN CANCER

Varied expression levels of ET receptor subtypes in different cancers have been investigated by use of immunohistochemistry, autoradiography, and mRNA studies. Expression of the ET_A receptor is upregulated predominately in colorectal, ovarian, renal, and prostate cancers,[1,5,22] whereas ET_B receptors are downregulated. On the other hand, not only are ET_A receptors upregulated, but ET_B receptors are also upregulated or have varied expression levels in lung and breast carcinomas. The question remains whether the variety of techniques used to examine levels may give conflicting or false results for ET_B expression.

Specifically within CRCs, we showed that pharmacologically functional ET_A receptors are over-expressed in

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

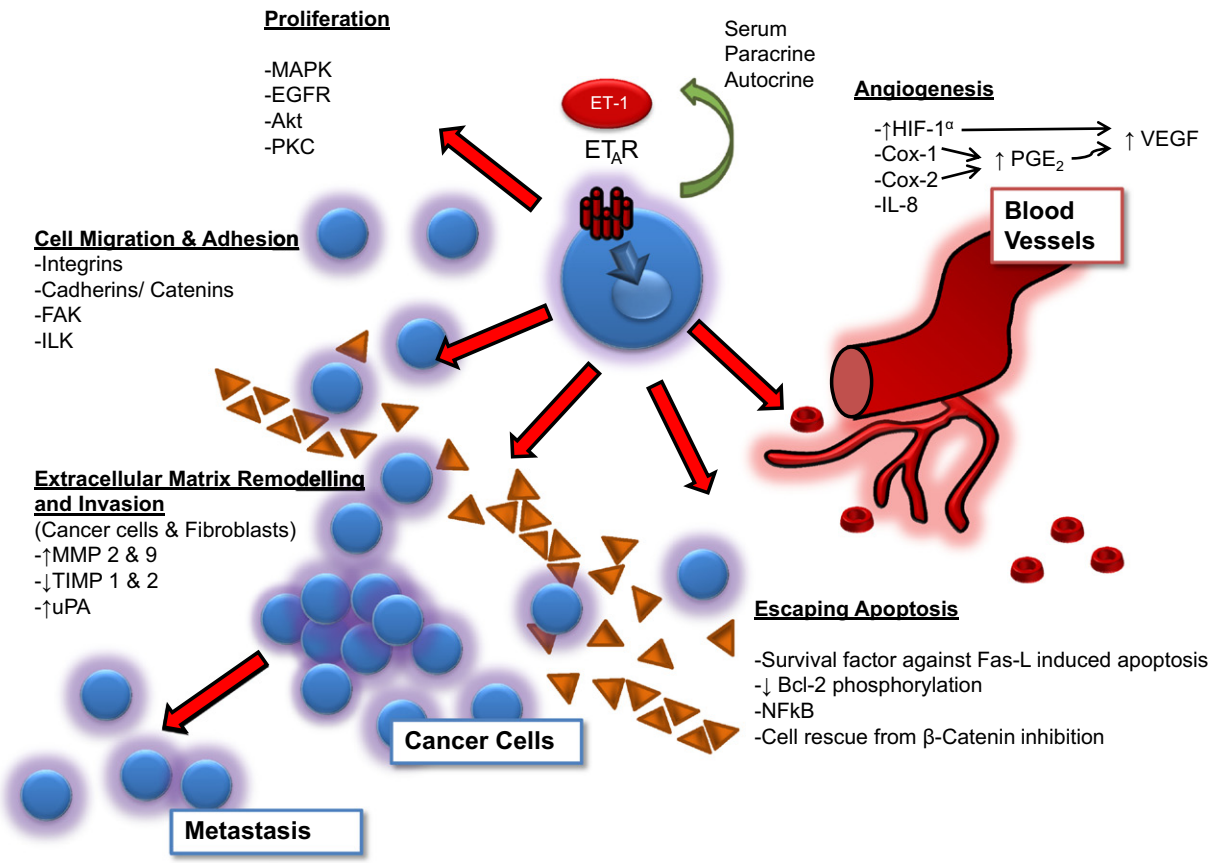

FIGURE 2 Summary of the role of ET-1 in the spread of cancer. See color plate 20.

all colorectal cancer tissues, compared with normal. Most of this localization is around blood vessels and fibroblasts, with less localization to epithelial cancer cells. By contrast, ET_B receptors are prominent in normal tissue with a marked down-regulation in cancer associated blood vessels, fibroblasts, and cancer epithelial cells.[15] In prostate tumors, levels of receptor expression have been found to correlate with the presence of metastases, similar to the findings in CRCs.

Interestingly, relative hypermethylation of the ET_B gene has been reported in prostate, bladder, and colon cancer cell lines. Furthermore, this correlates with transcriptional down-regulation, providing a plausible mechanism for reduced ET_B receptor expression in malignant tissue.

ET-1 AS A MITOGEN

Effects on mitogenesis are the most intensely studied among all the different tumorigenic actions of ET-1 (Fig. 2); they are driven through a complex network of multiple pathways, presented earlier, and involve the MAPK cascade. For example, in ovarian cancer cell lines, ET_A receptor antagonism reduces EGFR transactivation, implicating this receptor in mitogenesis. ET-1 stimulates the growth of several human cancer cell lines. In CRC experimental models, ET_A receptor antagonism significantly reduces proliferation not only in cancer cell lines but also in colonic fibroblasts.[2,19] In ovarian cancers, the use of ET_A receptor antagonists ABT-627 and ZD4054 inhibits cell proliferation and protects against paclitaxel induced apoptosis.[27] The same receptor is associated with prostate and cervical cancer proliferation.[24,25] In the latter atrasentan, an ET_A receptor antagonist, inhibits growth in xenografts. Other tumors with ET-1 mitogenic activity via the ET_A receptor include lung, bladder, and nasopharyngeal carcinomas. In breast and Kaposi's sarcomas, both ET_A and ET_B receptors are over-expressed. The use of dual receptor antagonists, bosentan in breast and A-182086 in Kaposi's sarcomas, significantly inhibits tumor growth and vascularity.[10] Studies on human melanoma cells show that the mitogenic effect of ET-1 is purely ET_B receptor dependent. This has also been confirmed *in vivo*, where the specific ET_B antagonist (BQ788) significantly slows melanoma tumor growth in nude mice.[21]

The role of ET-1 as an autocrine growth factor has been shown in human ovarian and colon cancer cell lines.[1] A paracrine role for ET-1 has also been elucidated in ovarian cancer, where ET-1 production by human ovarian cancer cells stimulates growth of carcinoma associated fibroblasts

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

in co-culture, an effect which is partially inhibited by both ET_A and ET_B antagonism.

ET-1 AND APOPTOSIS

ET-1 also modulates apoptosis. Within rat colon carcinomas, Peduto-Eberl et al. showed that ET-1 acts as a survival factor for rat colon carcinoma cells against FasL-induced apoptosis.[26] They also showed that dual endothelial receptor antagonism with bosentan results in human CRC sensitization to FasL-induced caspase mediated apoptosis. Protection from FasL-induced apoptosis, through suppressed Bcl-2 phosphorylation and PI3K mediated Akt activation, also occurs in ovarian cancers.[26] Furthermore in CRC, ET-1 (which is a direct target of β-Catenin) rescues cells from growth arrest and apoptosis, which were originally caused by β-Catenin inhibition.[18] This suggests that ET-1 has an oncogenic effect by interfering with the β-Catenin pathway.

In both melanocytes and melanoma cell lines, ET-1 decreases basic apoptotic rates. Like the proliferative action of ET-1 in these cells, the effect on apoptosis is ET_B dependent.

ET-1 AND ANGIOGENESIS

In addition to mitogenic actions on epithelial cancer cells, ET-1 stimulates growth of endothelial cells, vascular smooth muscle cells (VSMC), fibroblasts, and pericytes. Furthermore, ET-1 potentiates the effect of several pro-angiogenic factors *in vitro*, including PDGF and VEGF. ET-1 promotes cancer neovascularization via ET_A receptor stimulation on vascular smooth muscle cells and ET_B receptor stimulation on endothelial cells. ET-1 also stimulates various stages of neovascularisation, including protease production, tubular formation, endothelial cell proliferation, migration, and invasion.

There is a significant correlation between microvascular density, ET-1 and VEGF expression in ovarian cancer specimens. From *in vitro* studies, in both an ovarian cancer cell line and vascular smooth muscle cells, ET-1 promotes transcription and protein expression of VEGF to a level similar to that stimulated after hypoxia. This effect is mediated through ET-1 binding to ET_A receptors, stimulation of hypoxia inducible factor (HIF-1) production (or its stabilization in normoxic conditions), which then binds to hypoxia responsive elements and in turn increases VEGF production.[32] A reciprocal relationship exists where HIF-1 itself also stimulates ET-1 production. Furthermore, ET-1 acting via the ET_A receptor increases the expression of COX-1 and COX-2 in ovarian cancer cells. This results in increased prostaglandin signaling, particularly PGE_2, and stimulation of several MAPK dependent signaling pathways, including p38 MAPK and p42/22 MAPK. This results in the production of VEGF, MMP activation and angiogenic cellular invasion.[33]

Invasive tumor cells, including melanomas, prostate, breast, and ovarian carcinomas form *de novo* extracellular matrix rich vascular channels expressing vascular associated molecules. Both MMP2 and MT1-MMP, which are expressed by invasive ovarian cancer cells, play a key role in developing vasculogenic-like networks and matrix remodeling. Interestingly, ET_A receptor antagonism of these cells inhibits the formation of tumor-like vascular channels.

In vivo studies using subcutaneous implants of matrigel impregnated with either ET-1 or VEGF confirm increased vascular effects and vascularity above that of other angiogenic factors, for example, bFGF.

In addition to an effect on tumor cells, ET-1 protects human endothelial cells and VSMCs from serum deprivation induced apoptosis *in vitro*. This suggests that ET-1 could have a pro-angiogenic effect by acting as a survival factor for newly formed blood vessels.

ET-1 AND TUMOR PROGRESSION/ METASTASES

Further to its pro-angiogenic role, ET-1 may also influence tumor invasion and metastases by stimulating secretion of matrix remodeling proteins. In colonic fibroblasts, we reported that ET-1 increases TIMP-1 and MMP-2 protein expression, which are known to be involved in key tumorigenic processes: matrix degradation, activation of growth factors and degrading enzymes, and modulation of angiogenesis.[19] Expression of both these molecules is inhibited by predominantly ET_A and also ET_B receptor antagonism. Furthermore, we showed that ET-1 stimulates expression of CTGF and Collagen Type XI mainly via the ET_A receptor. CTGF activates intracellular pathways resulting in increased migration, proliferation, and MMP production, whereas Collagen Type XI is associated with colonic diseases. We also conducted proliferation and desmoplastic activation studies in colonic fibroblast strains using the specific ET_A receptor antagonist zibotentan: ET_A receptor blockade inhibits growth, contraction, migration, and MMP production by these cells.[13,14]

In ovarian cancer, ET-1 stimulates the expression of several MMPs, particularly MMP-2 and MMP-9, and down-regulates tissue inhibitors of matrix metalloproteinases, TIMP1 and 2. Similar up-regulation of MMPs has also been shown in Kaposi's sarcoma cells. Furthermore, ET-1 can contribute to the creation of a "reactive" tumor stroma, by stimulating myofibroblast induction (via ET_A), and the expression of matrix remodeling genes by these cells.[34] Interestingly, tumor adherence to collagen is enhanced by integrin-linked kinase (ILK), a multidomain focal adhesion protein. Blockade of ET-1/ET_A receptor induced ILK results in the inhibition of MMP activation, as well as cell motility

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

and invasiveness, indicating that the ET-1 axis is involved in aggressive cellular behavior.

In prostate cancer, ET-1 may contribute to the growth of bony metastases. *In vitro*, ET-1 production by prostate cancer cells is enhanced by bone contact, which in turn blocks osteoclastic bone reabsorption. Similarly, in an *in vivo* osteoblastic tumor model, tumors transfected to overexpress ET-1 produced significantly more bone growth in nude mice compared with vector only controls.[23]

Furthermore, we have shown increased ET-1 immunoreactivity in endothelial cells within colorectal liver metastases compared with surrounding vessels,[13] suggesting that ET-1 may be involved in modulation of tumor blood flow.

ENDOTHELIN ANTAGONISM *IN VIVO*

Several *in vivo* models have been used to assess the role of endothelin antagonism in tumorigenesis. Work originating from our department using intra-portally injected syngeneic MC28 cells in rats showed that ET_A antagonism with BQ123 significantly reduces hepatic tumor load compared with controls[4]

The effect of bosentan, a dual receptor antagonist, on growth of peritoneal tumors derived from a syngeneic rat colonic adenocarcinoma cell line has been investigated. Although bosentan was not able to control tumor progression, tumors are generally of lower grade, and there are fewer spontaneous deaths in the treated versus the untreated groups. Egidy et al. used the same tumor model to assess histological differences between tumors of bosentan treated animals and controls.[11] They showed that tumor cells are less densely packed, and there is less collagen matrix around tumor nodules in the treated compared with the untreated group.

Using an osteoblastic tumor model in nude mice Nelson et al. have shown that ET_A antagonism with A127722 significantly reduces the growth of new bone compared with vehicle treated controls.[23]

Finally, Rosano et al. have combined targeting of the ET_A and EGF receptors with promising results. They showed that co-administration of ZD4054 and gefitinib led to a partial (82%) or complete tumor regression on HEY ovarian carcinoma xenografts. This also results in decreased vascularization, MMP2, VEGF, MAPK and EGFR, and enhances E-Cadherin expression.[28]

To date, results from *in vivo* models are encouraging and warrant further investigation.

CLINICAL TRIALS

The availability of orally active bioavailable endothelin receptor antagonists offers potential opportunities in adjuvant cancer treatment. One example is the drug atrasentan, which has a 1000-fold greater affinity for the ET_A receptor than the ET_B receptor. A phase II randomized, placebo-controlled trial in 288 patients with asymptomatic hormone-resistant metastatic prostate cancer evaluated three groups; placebo, 2.5mg, or 10mg atrasentan. Delayed time to progression (TTP) was observed in the 10-mg group, and stabilization of biochemical markers, including prostate specific antigen and lactate dehydrogenase compared with controls. In phase III clinical trials involving 809 prostate cancer patients, 10mg of atrasentan daily was shown to delay time to disease progression when compared with placebo, albeit statistically non-significant, in men with metastatic hormone-resistant prostate cancer.[8] However, secondary end-point analysis showed significantly delayed progression of bone acid phosphatase levels, and preserved prostate cancer-specific quality of life, particularly in terms of pain-related symptoms. Another phase III trial in non-metastatic prostate cancer once again showed statistically non-significant delay in disease progression (93 days) when compared with placebo with the same dosing of this drug.[25] It has been suggested that the future use of atrasentan may lie in combining it with other drugs. This was shown by a phase I–II trial in patients with resistant prostate cancer, where results from this drug combined with docetaxel were comparable to results produced by docetaxel and prednisolone.[3]

Another orally active ET receptor antagonist, currently used in pulmonary hypertension, is Bosentan. This is a non-selective, dual ET_A and ET_B receptor antagonist. Promising preclinical results showing inhibition of tumor progression occurred in *in vitro* and *in vivo* models of melanoma.[21] However, a phase II clinical trial reported that patients with stage 4 metastatic melanoma developed progressive disease despite receiving 500mg BD of Bosentan.[17]

The novel specific ET_A receptor antagonist Zibotentan (trans,trans-2(4-methoxydhenyl)-4-(1-3-benzodiazol-5-yl)-1-(dibutylaminocarbonylmethyl)-pyrrolidine-3-carboxylic acid (ZD4054)), has been investigated in a number of clinical trials. In the clinical arena, the original focus was within the field of prostate cancer. A phase II double blinded clinical trial allocated a total of 312 patients with pain free or mildly symptomatic hormone-resistant prostate cancer patients with bony metastases to either receive daily doses of ZD4054 (10–15mg) or placebo. There was no significant difference seen for progression-free survival although there was a difference in the overall survival of these patients compared with the placebo group. Importantly this drug has an acceptable safety and tolerability profile.[16] A Phase III clinical trial looked at ZD4054 in non-metastatic hormone-resistant prostate cancer. This was terminated early in 2011 as it was unlikely that the trial would meet its primary efficacy end-point of progression-free survival and overall survival benefits. Because of the disappointment of monotherapy, interest has grown in its use as adjuvant

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

therapy, for example the latest ongoing phase II clinical trial (FOLFERA), which combines ZD4054 with chemotherapy agents irinotecan, fluorouracil, and folinic acid (FOLFIRI) in patients with advanced colorectal cancer.

The endothelin axis is altered in cancer, aiding tumor growth and progression. It seems that selective ET_A antagonism provides the most effective method of endothelin-system inhibition in cancer. With generally acceptable side effects, and suggested anti-tumor activity, further clinical evaluation of these agents is warranted to determine possible therapeutic potential as an adjuvant anti-cancer strategy.

Chapter 71

Gastrin

Jens F. Rehfeld and Jens P. Goetze

ABSTRACT

The gastrin and gastrin receptor genes are frequently expressed in common carcinomas in the esophagus, stomach, pancreas, colorectal mucosa, bronchial mucosa, ovary, and thyroid gland. In addition, rare neuroendocrine tumors also express gastrin and its receptor. The expression is often modified at the posttranscriptional and posttranslational levels. As a result of less complete processing, progastrin and processing intermediates are therefore often released from cancer cells in increased fractions. Moreover, the receptor gene may be expressed as splice variants and in larger or truncated forms due to abnormal posttranslational modifications. The growth-promoting effect of gastrin peptides suggests that the gastrin system (ligands and receptor) has broad carcinogenic significance. Consequently, attempts to target different components of the gastrin system in cancer therapy by receptor antagonists or vaccination are under way.

INTRODUCTION

Gastrin was discovered in extracts of the gastric antrum in 1905 and identified as a pair of heptadecapeptides in 1964.[10] Until the 1970s, gastrin was believed to be produced only in antroduodenal cells and its function only to be the regulation of gastric acid secretion.

Now, the structure of gastrin and gastrin receptor genes as well as their widespread expression also outside the stomach are well known (for a review, see Ref. 23). Moreover, gastrin is also a growth factor. Thus, gastrin controls the growth of the fundic mucosa cells and seems to influence also the growth of epithelial mucosal cells elsewhere (for a review, see Ref. 29).

Growth factors are often involved in cancer. But the oncogenic role of gastrin is still not well defined. A large number of studies, however, implicate gastrin peptides and their receptors in cancer development.[5-7,28] This chapter discusses the carcinogenetic role of gastrin critically.

EXPRESSION OF GASTRINS IN NORMAL TISSUE

By far the most gastrin in the normal organism is produced in antroduodenal G-cells (for a review, see Ref. 23). Consequently, gastrin biosynthesis studies have focused on antral tissue[4,12,16] and shown that the cellular gastrin synthesis is quite complex.

As a result of the elaborate biosynthetic pathway, antral G-cells release a mixture of progastrin products from the secretory granules. A small percentage are nonamidated processing intermediates, of which glycine-extended gastrins have attracted some interest.[12,30] But in man, >98% are α-amidated bioactive gastrins, of which nearly 85% are gastrin-17, 5–10% are gastrin-34, and the rest is a mixture of gastrin-71, -52, -14, and -6.[16,23,24]

Because of major differences of metabolic clearance rates, the larger gastrins with long half lives predominate over gastrin-17 and shorter gastrins in plasma.[16] In achlorhydria and gastrinomas, the translational activity in the gastrin-producing cells increases considerably, and apparently the processing enzymes cannot keep up with such rate of synthesis. Consequently, the fraction of immature precursors and processing intermediates increases markedly in tissue and plasma.[2,16]

The gastrin gene[35] is expressed also in extraantral cells that normally, however, contribute only little to the gastrin measured in the blood. So far, we have encountered extraantral gastrin expression in the small intestinal and in the colorectal mucosa,[19] in pancreatic islet cells,[3,18] in pituitary corticotrophs and melanotrophs, hypothalamic–pituitary, cerebellar, and vagal neurons, in bronchial mucosa,[26] and in spermatogenic cells (for a review, see Ref. 25 and Table 1).

The significance of extraantral gastrin synthesis is largely unknown, but it may have carcinogenetic relevance. Thus, gastrin-producing cancers seem to originate from cells that normally express the gastrin gene at low levels at some stage of the development (for a review, see Ref. 25).

THE GASTRIN RECEPTOR(S)

The gastrin receptor was cloned and identified as a protein of 453-amino acid residues. It belongs to the superfamily of G protein–coupled receptors with seven transmembrane α-helical domains. The gastrin receptor binds acid-stimulatory peptides containing the C-terminal sequence -Gly-Trp-Met-Asp-PhNH_2.

TABLE 1 Gastrin Expression at the Peptide Level in Normal Mammalian Tissue*

Tissue	Total translation product (pmol per gram tissue)	Precursor percentage
Gastrointestinal tract		
Antral mucosa	10,000	5
Duodenal musoca	400	20
Jejunal mucosa	40	30
Ileal mucosa	20	85
Colonic mucosa	0.2	100
Neuroendocrine tissue		
Cerebellum	5	20
Vagal nerve	8	10
Adenohypophysis	200	98
Neurohypophysis	30	5
Adrenal medulla	2	100
Pancreas	2	95
Genital tract		
Ovaries	0.5	100
Testicles	6	100
Spermatozoa	2	55
Respiratory tract		
Bronchial mucosa	0.3	100

**Orders of magnitude based on examination of different mammalian species.*

Hence, the receptor binds all carboxyamidated gastrins and the homologous cholecystokinins (CCK). The gastrin and CCK peptides are bound with similar affinity regardless of length and degree of tyrosyl sulfation. But in terms of hormonal regulation, the CCK peptides are of marginal significance as gastrin receptor ligands because they circulate in 10- to 20-fold lower concentrations than the gastrins in plasma. The gastrin receptor is structurally closely related to the CCK receptor. The amino acid sequences of the two receptors display nearly 50% homology. But the CCK receptor is more selective as it binds only tyrosyl sulfated CCK peptides with high affinity (for a review, see Ref. 34).

The naming of the gastrin and CCK receptors has been confusing because the gastrin receptor also binds CCK peptides. It has therefore been proposed[22] that the CCK receptor should be named the "CCK-A or CCK_1" receptor and the gastrin receptor the "CCK-B or CCK_2" receptor. In this review, however, the original names, gastrin and CCK receptors, will be used.

The gastrin receptor in normal mammals is expressed primarily on ECL and parietal cells in the stomach and on neurons in most regions of the brain. In the central nervous system, CCK-8 seems to be the principal ligand, whereas gastrin-17 and -34 are major ligands in the periphery. The gastrin receptor is promiscuous in the sense that it is expressed — although with some species differences — at a lower level on other cells and in other tissues during ontogenetic development and during malignant transformation (for a review, see Ref. 25).

A number of gastrin receptor variants have been discovered. One isoform is the result of a splicing variation of the fourth exon, and it encodes a receptor with five additional amino acid residues near the third intracellular loop.[14,32] Another form is truncated without the N-terminal extracellular domain.[21] Moreover, both high (74kDa) and low (40kDa) molecular weight forms have been described. The differences are assumed to reflect different degrees of glycosylation and other posttranslational modifications. Finally, a gastrin receptor variant of particular oncogenetic relevance has been found in pancreatic[31] and colorectal carcinomas.[11] This variant has retained the fourth intron of the receptor gene and encodes accordingly an extra sequence of 69 amino acid residues in the third intracellular loop.[11,31] The prolongation changes the function of G-proteins associated with calcium signaling. The splicing variation is caused by reduced activity of the U2AF35 ribonudeoprotein particle splicing factor.[8] The intron-4 containing splice variant is of major interest for pancreatic and colorectal carcinogenesis and has led to the suggestion that it deserves the name of a "CCK-C" receptor.[31] At our present state of knowledge, and considering that other variants exist, such a name may, however, be premature.

EXPRESSION OF GASTRIN IN TUMORS

In 1955, Zollinger and Ellison described a syndrome consisting of severe duodenal ulcer disease, gastric acid hypersecretion, and neuroendocrine tumors in the pancreas. The syndrome was subsequently shown to result from hypersecretion of gastrin from pancreatic G-cell tumors, gastrinomas. Although many gastrinomas originate in the pancreas, small gastrinomas have also been found with increasing frequency in the duodenum, ovaries, and a few other locations. Some pancreatic gastrinomas also contain cells that produce other pancreatic hormones. The gastrinoma syndrome occurs with a frequency of one new case per million inhabitants per year.[15] It is important to diagnose and localize gastrinomas at an early stage because, in spite of slow growth, gastrinomas are malignant adenocaracinomas.[2,27]

The gastrin gene, however, is more frequently expressed at the peptide level in some brain tumors, pituitary adenomas,

TABLE 2 Gastrin Expression at the Peptide Level in Tumors (Range)

Tumor*	Total translation product (pmol per gram tissue)	Precursor percentage
Neuroendocrine tumors		
Acustic neuromas† (14/19)	0.2–10	10–10
Pituitary adenomas (12/87)	0.5–200	20–90
Pancreatico-duodenal gastrinomas (27/27)	400–2,500,000	15–19
Pheochromocytomas† (13/13)	0.2–400	90–100
Common carcinomas		
Bronchogenic carcinomas† (17/17)	0.2–20	25–100
Colorectal carcinomas (12/12)	0.5–2.0	85–100
Gastric carcinomas (19/20)	0.1–400	10–100
Ovarian carcinomas† (16/16)	0.8–25	10–50

**Numbers in parentheses indicate the number of tumors with detectable gastrin expression in relation to total number of tumors examined.*
†Tumor type in which carboxyamidated, bioactive gastrin occurs only as gastrin-17.

pheochromocytomas, and bronchogenic,[26] pancreatic,[9,31] and colorectal[11,13,33] carcinomas. The level of expression is often so low that gastrins from these tumors do not contribute significantly to the concentration of bioactive gastrin in plasma (Table 2). Consequently, these neoplasias do not elicit symptoms associated with the gastrinoma syndrome. Often, only a minor fraction of the progastrin is processed to bioactive gastrins although the processing varies considerably in each individual tumor. However, even though the secretion of gastrin from brain, lung, pancreatic, and colonic tumors is too small to increase the concentration in plasma, the expression of gastrin may have carcinogenic significance. Local secretion may stimulate growth of tumor cells equipped with receptors for gastrin, variants or not.[13] Moreover, it is possible that the release of progastrin and processing intermediates may contribute to the precursor concentrations in plasma and make progastrin a tumor marker.[2,26,33] Progastrin in plasma may even be an indicator of the degree of malignancy.[2]

GASTRIN AS A TUMOR GROWTH FACTOR

Gastrin has growth-promoting effects on the normal gastric and colorectal mucosa,[17] and several normal gastric, pancreatic, and colorectal epithelial cells are equipped with gastrin receptors (for a review, see Ref. 25). Moreover, in countless studies of cancer cell lines, gastrin peptides stimulate growth. Consequently, it is probable that *in vivo* growth of human bronchial, gastric, colorectal ovarian, esophageal, and pancreatic carcinomas is stimulated by autocrine, endocrine, neurocrine, or paracrine release of gastrin.

There is, however, confusion about the molecular nature of the growth-promoting gastrins. It is generally agreed that carboxyamidated and acid-stimulatory gastrins (mainly gastrin-17 and gastrin-34) can stimulate growth of normal and transformed epithelial cells that express the gastrin receptor. But the observation that the progastrin products in colorectal carcinomas are incompletely processed and not carboxyamidated has led to the suggestion that also processing intermediates such as glycine-extended gastrins via specific receptors stimulate the growth of carcinoma cells.[30] The suggestion is interesting, but two essential pieces of evidence are missing. First, 18 years after the initial suggestion and in spite of subsequent intensive search in many laboratories, the proposed receptor or receptor mechanism has still not materialized. Second, half of all known bioactive peptide systems in vertebrates are carboxyamidated and often affect, as does gastrin, growth of their target cells. Because the glycine residue is the obligatory amide donor for carboxyamidated peptides, glycine-extended precursors for all amidated bioactive peptides are necessarily produced during hormone and neuropeptide biosynthesis. Nevertheless, it is striking that independent activity via specific receptors of glycine-extended intermediates has been proposed only for the gastrin system. Taken together, the idea about a growth-promoting carcinogenetic role of glycine-extended gastrins is therefore still short of decisive support.

Another confusing issue is the progastrin molecule as such. Several authors have suggested that the progastrin molecule in itself stimulates growth (for a review, see Ref. 1). Because the concentration of progastrin in normal, adult tissue, and plasma is negligible,[2,24] progastrin as such is not available for promotion of growth of normal cells. But in bronchogenic, colorectal, and pancreatic cancer cells is an accumulation of progastrin.[9,26,33] Hence, the cellular concentration of progastrin and cellular growth may correlate in certain carcinomas. Such correlation, however, constitutes no proof. Moreover, in most reports on this issue, progastrin is rarely or poorly defined.[1] The expression often refers to immunoreactivity without precise epitope or sequence definition. Consequently, the studies may have dealt with undefined progastrin products and not with the progastrin molecule itself. Again, as for glycine-extended gastrins, progastrin as such is not a ligand for the gastrin receptor, and therefore, a separate progastrin receptor mechanism remains to be found. Finally, specific bioactivity of the primary precursor (i.e. the proper prohormone) has so far not been observed for other prohormones.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

In view of the pronounced molecular heterogeneity of carboxyamidated gastrins and the many processing intermediates produced along the biosynthetic pathway in cells that express the gastrin gene, there is a need for precise definition and naming of the progastrin products. Hopefully, systematic definitions will reduce the confusion about gastrins as tumor growth factors, especially because of the many variants of the gastrin receptor.

CONCLUSIONS

The evidence for a role of gastrin in the carcinogenesis of common cancers within and outside the gastrointestinal tract has grown markedly in the last decades. The poor prognosis and limited success in treatment of, for instance, ovarian, pancreatic, colorectal, and lung carcinomas have so far brought gastrin peptides and their receptors (in their multiple molecular variants) into focus as possible targets for new therapeutic approaches. These include specific receptor antagonists and programs for vaccination against gastrin peptides (for a review, see Ref. 20). Rational and effective therapy, however, requires precise molecular understanding and definition of the system and an unequivocal naming of the targets. The literature published so far abounds with inconsistencies in these respects. When the necessary ambiguity has been resolved, the gastrin system may open new avenues for rational attacks on widespread cancers.

Chapter 72

Leptin/Adiponectin

Hong Tu

ABSTRACT

Obesity is associated with an increased risk of many types of cancers. Leptin and adiponectin, both mainly produced by adipose tissue, were originally described as circulating hormones involved in food intake and energy homeostasis. Growing evidence has shown that leptin and adiponectin not only have a relevance in obesity and insulin resistance, but they may be also involved in tumorigenesis, especially in the development of obesity-associated cancers such as breast, colorectal, and prostate cancers. *In vitro* studies have shown that leptin promotes human cancer cell proliferation, whereas adiponectin exhibits antiproliferative effects. This chapter summarizes our recent understanding of leptin and adiponectin as two potential molecular targets for cancer prediction, prevention, and therapy.

INTRODUCTION

Recently, adipose tissue has been considered as a major endocrine organ that secretes a wide range of biologically active molecules including leptin, adiponectin, vascular endothelial growth factor (VEGF), tumor necrosis factor-alpha (TNF-α), and interleukin-6 (IL-6). These factors are collectively termed 'adipocytokines,' and are thought to be key mediators in the obesity-related disorders.

Epidemiological results have shown that obesity is closely associated with increased risk of some types of cancers.[23] Moreover, an excess of adipose tissue favors metastasis and recurrence of cancer and is associated with a higher mortality. Adipokines, particularly leptin and adiponectin, have been postulated to be a potential link between obesity and cancer. Recent studies have revealed that the functions of leptin and adiponectin extend far beyond metabolism. Most of the *in vitro* studies indicate that leptin promotes cell proliferation, whereas adiponectin exhibits antiproliferative actions. Levels of leptin and adiponectin in the circulation and in tumor microenvironments are frequently altered in cancer patients. In addition, animal studies also suggest a possible role of leptin and adiponectin in cancer progression.

LEPTIN AND CANCER

Leptin, a 16-kDa protein encoded by the ob gene, is predominantly produced by adipocytes. Leptin was originally described as a circulating hormone involved in feeding behavior and energy homeostasis through its actions on the hypothalamus where leptin receptor (ObR) is highly expressed. Later, ObRs were found to have a wide distribution in different tissues, suggesting that leptin may have numerous peripheral effects. Indeed, leptin has since been found to act as a mitogen, survival factor, metabolic regulator, or angiogenic factor depending on the target tissue.

CLINICAL EVIDENCE OF LEPTIN RELATED TO CANCER[10]

In humans, obesity is not related to leptin deficiency but to the development of leptin resistance. Thus, leptin concentrations are usually elevated in obese individuals. Leptin is generally present in human serum in the range of 5–50 ng/ml. However, in obese individuals, concentrations >100 ng/ml are common. Whether elevated concentrations of leptin are associated with an increased risk of cancer is not conclusive. The inconsistent data obtained on circulating leptin in cancer patients might result from the different analytic method used, or different sample preparation where some influencing factors, such as food intake and circadian rhythm, were not properly controlled. It is also possible that the carcinogenic effect of leptin is induced by an overabundance of local rather than systemic leptin.

Leptin and Breast Cancer

Expression of leptin and its receptors in breast cancer cells has been addressed by the use of immunohistochemistry or RT-PCR. Studies have documented the overexpression of leptin and ObR in breast cancer tissues versus noncancer breast epithelium. In addition, there is an increased incidence of hematogenous metastasis or cancer recurrence in

distant organs in patients with increased ObRb expression in primary breast tumors.[12]

The association between circulating leptin levels and breast cancer or breast cancer risk has not been clarified.[28] Some authors have observed that serum leptin is associated with breast cancer regardless of the menopausal status, whereas others describe a negative correlation between leptin and breast cancer in the premenopausal but not in the postmenopausal group. Other reports claim that circulating leptin is not associated with breast cancer risk in premenopausal or postmenopausal women. Clearly, better controlled studies are needed to unequivocally establish whether serum leptin is associated with breast cancer etiology.

Leptin and Colorectal Cancer

Increased plasma leptin concentrations are associated with a 2- to 3-fold increased risk of colorectal cancer or adenoma in men, but not in women, in northern Europe and America.[5] These associations did not result from differences in body mass index (BMI) because adjustment for BMI only caused a modest attenuation in risk. More recently, high circulating levels of soluble leptin receptor were detected in patients with advanced stage of colon cancer, further suggesting a role for leptin in cancer progression and aggressiveness.[29] On the other hand, other authors note that leptin levels are lower in colon cancer patients.

Leptin and Prostate Cancer

Among four prospective and three case-control published studies, two report a significant positive association of leptin with prostate cancer. Interestingly, those two studies report higher leptin concentrations associated with more advanced tumors, characterized by larger size and higher grade. However, more studies, including a 25-year prospective cohort study,[16] conclude that circulating leptin is unrelated to either prostate cancer risk or mortality.

Leptin and Hepatocellular Carcinoma (HCC)

Several studies have attempted to elucidate the possible effects of leptin in HCC development.[32] In a report that evaluated the expression of leptin and its receptor in HCC and adjacent nontumor tissues, leptin was involved in the carcinogenesis of HCC. High leptin expression was also found to be associated with an increased intratumor microvessel density. However, several studies have reported contradictory effects of leptin in HCC growth. One report showed the expression of ObR in HCC specimens inversely correlates with vascular invasion of HCC. Furthermore, high leptin expression was associated with better survival of HCC patients who treated postoperatively with medroxyprogesterone acetate.[31]

IN VITRO RESULTS OF LEPTIN AS A MITOGENIC FACTOR

In vitro, leptin can stimulate the proliferation and counteract apoptosis in many types of cancer cell lines. It can also promote the invasiveness of human cancer cells in collagen gel. The proliferative activity of leptin is mediated through different signaling pathways;[13] (1) Leptin induces the phosphoinositide 3-kinase (PI3 K)/Akt survival pathway by activating the phosphorylation of Akt Thr308 or Akt Ser473 and by stimulating the protein expression of protein kinase C-alpha (PKCα), which is controlled by PI3 K. (2) Leptin activates the mitogen-activated protein kinase (MAPK) pathway by inducing extracellular signal-regulated kinase 1/2 (ERK1/2) phosphorylation. (3) Leptin directly stimulates the signal transducer and activator of transcription 3 (STAT3) pathway through the crossphosphorylation and activation of Janus-family tyrosine kinase (JAK). STAT3 protein is an important mediator for leptin to upregulate the expression of the c-myc gene. (4) Leptin accelerates cell cycle progression by upregulating the expression of cdk2 and cyclin D1 genes.

The procarcinogenic effect of leptin results not only from an enhanced activity of proliferation process but also from a downregulation of apoptosis.[13] Leptin can upregulate the expression of antiapoptotic genes Bcl2 and survivin and downregulate the expression of apoptosis inducer genes p53 and BAX. Leptin has been shown to suppress docetaxel-induced apoptosis by inhibiting caspase-9 activity.[14] Interestingly, although leptin alone shows proliferative effects on the breast cancer cell line MDA-MB-231, leptin cotreatment with cAMP elevating agents shows a strong apoptotic action. Thus, at least in some cases, leptin can potentiate the action of antiproliferative compounds and may exert opposite actions related to the apoptosis process.

Leptin can promote tumor angiogenesis by itself or with vascular endothelial growth factor (VEGF) and fibroblast growth factor (FGF).[6,26] Leptin enhances vascular endothelial cell proliferation *in vitro* with a potency similar to that of VEGF. In addition, leptin increases the expression of VEGF and its receptor VEGFR-2 in mouse mammary cancer cells. Blockade of leptin receptor signaling slows down breast cancer growth and results in reduced expression of VEGF, VEGFR-2, and cyclin D1 *in vivo*. Inhibition of JAK, PI3 K, and MEK-1/MAPK signaling prevents the leptin-induced VEGF secretion and VEGFR-2 expression. The role of leptin in neovascularization is supported additionally by the observation that it can increase the levels and activity of enzymes involved in angiogenesis, for example, matrix metalloproteinases (MMPs) 2 and 9.

SYSTEMIC REGULATION OF LEPTIN ON CANCER

Several reports indicate that ObR are highly abundant in many tumor tissues compared with nontumor tissues. ObR-overexpressed tumors include breast cancer, pancreatic cancer, gastrointestinal tumors (such as esophageal, gastric, and colon cancer).[22] Meanwhile, leptin has also been detected in many types of cancer tissues. In breast cancer, the expression level of leptin is be positively correlated with ObR, and both molecules are most abundant in less differentiated G3 tumors. Importantly, distant metastases are more frequently seen in ObR positive cancers with strong immunoreactivity for leptin.[12] These results suggest the regulation of leptin on cancer may act in three ways:[13] in an endocrine manner (via external adipose depots), in a paracrine pathway (via local adipose tissue and non adipose sources including stromal cells and inflammatory cells) and in an autocrine action (via tumor cell itself). Leptin produced by adipose tissue or local sources binds to ObRb expressing cells within the tumor microenvironment and activates the downstream kinases, such as PI3 K, ERK1/2, and Jak2/STAT3. These pathways contribute to various steps of tumor progression, from cancer stem cell survival and proliferation to metastatic tumor growth.[22]

IN VIVO RESULTS OF LEPTIN AND CANCER

Obese mice with congenital leptin deficiency resulting from a mutation in leptin gene ob (ob/ob mice) and obese mice with leptin resistance resulting from a spontaneous mutation on the leptin receptor gene db (db/db mice) are useful models to assess the potential of leptin on cancer development and metastasis. Most of the existing reports support the positive association between leptin and cancer *in vivo*. Obese mice have both an increase incidence of spontaneous tumors and burden of transplanted tumors. MMTV-Wnt-1 mammary tumors transplanted into db/db mice grow to eight times the volume of tumors transplanted into lean wild-type mice. However, such tumors are reduced in leptin-deficient ob/ob mice.[35] Along the same line of evidence, genetically obese MMTV-TGF-alpha/Lep −/− female mice fail to develop oncogene-induced breast tumor, whereas mice Lep +/+ and Lep +/− developed tumors in 50% and 67% of cases, respectively.[7] In addition, homozygous db/db mice promote the cell growth of gastric and colon carcinomas and enhance the metastasis of B16-BL6 melanoma and Lewis lung carcinoma with elevated serum concentrations of leptin.

On the other hand, there are also several lines of evidence suggesting that leptin deficiency is unlikely to have contributed significantly to the enhancement of carcinogenesis. In carcinogen-induced skin papilloma and p53 deficiency animal models, ob/ob mice developed malignancies similarly to their lean littermates. The volume of transplanted murine prostate cancer in ob/ob mice are significantly larger, whereas in db/db mice, they are significantly smaller compared with controls. In the same study, an inverse correlation is observed between leptin plasma concentrations and tumor weight and tumor proliferative markers.[24] The inverse relationship between leptin and cancer is also supported by the observation that experimental pulmonary metastasis of melanoma B16-BL6 is markedly promoted in leptin-deficient ob/ob mice.[18]

Results from mice with normal weight concerning the action of leptin on cell growth are contradictory. Leptin injection stimulates,[17] or has no effect,[2] or even inhibits the growth of cancer xenografts.[1] In rats, the promoting effect of leptin on cell proliferation was shown on the right, but not the left, colonic mucosa.

Taken together, leptin exerts a more complex action on the tumor cells than first suspected. It has not been conclusive *in vivo* whether leptin is a hazard or protective factor for cancer. The controversial results could be related to the different tumor models. Meanwhile, it is worth noting that ob/ob or db/db mice diverge not only in leptin levels but also in other circulating factors, such as glucose, insulin, and other hormones or cytokines. All these factors collectively decide the fate of cancer cells *in vivo*. It will be important in future experiments to adjust all the confounders that are also altered in obesity and evaluate the independent role of leptin in cancer.

ADIPONECTIN AND CANCER

Adiponectin is a 244-amino acid hormone expressed mainly in adipoctyes. Adiponectin contains four differentiable domains: an amino-terminal signal sequence, a variable region, a collagenous domain, and a carboxy-terminal globular domain. The monomeric (30 kDa) form of adiponectin is thought to appear only in the adipocyte, because it has not yet been detected in the circulation. The most abundant configuration of adiponectin is the trimer, formed by a strong association between three monomers at their globular domains.

To date, three putative adiponectin receptors have been identified: adiponectin receptor R1 (AdipoR1), adiponectin receptor R2 (AdipoR2), and more recently, T-cadherin. AdipoR1 and AdipoR2 are ubiquitously expressed. The wide distribution of adiponectin in peripheral organs suggests that adiponectin exerts pleiotropic effects in the human other than regulating the energy metabolism. Indeed, *in vitro* assays show that a number of different cancer cell lines express one or both of the adiponectin receptors and undergo reduced growth and/or increased apoptosis in response to the treatment of adiponectin.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

CLINICAL EVIDENCE OF ADIPONECTIN RELATED TO CANCER

Adiponectin is abundant in human plasma, with the concentration ranging from 2 to 10 μg/ml and accounting for up to 0.05% of total plasma protein. In contrast to the other adipokines, plasma adiponectin concentrations are lower in obese than in lean subjects. A negative correlation between circulating adiponectin and obesity, insulin resistance, and type 2 diabetes has been well established. Accordingly, adiponectin levels are inversely associated with the risk of malignancies associated with obesity and insulin resistance in most cases. Low plasma adiponectin concentrations may be a novel risk factor for cancer.

It has been postulated that the different adiponectin conformations exert diverse effects. Thus, it is important to characterize the forms of adiponectin, that is, trimers, hexamers, or high-molecular-weight oligomers, when detecting the concentration of adiponectin in the circulation. However, the conventional analytic techniques such as ELISA or radioimmunoassay are not able to characterize the forms of adiponectin. These technical handicaps may partially explain the contradictory results concerning the relationship between adiponectin and cancer.

Adiponectin and Breast Cancer[4]

Since the female sex and hormone levels are well-recognized risk factors for breast cancer, the relationship between adiponectin levels and breast cancer risk has been investigated extensively. Although some studies found a robust inverse association between adiponectin and breast cancer risk among both premenopausal and postmenopausal women, other studies, including one prospective case-control study involving 1477 breast cancer cases and 2196 controls,[30] reported that low adiponectin levels are associated with breast cancer only in postmenopausal women. The effect of female hormones on adiponectin might help resolve this divergence because serum adiponectin concentration has a significant negative correlation with serum estradiol concentration in postmenopausal but not in premenopausal and perimenopausal women.

The relationships of adiponectin levels with breast cancer stage and prognosis have also been explored. Low serum adiponectin concentrations usually associate with larger tumor size, higher histological grade, and higher frequency of lymph node metastasis. However, some studies disproved the negative correlation of circulation and tissue adiponectin levels with tumor stage, size, and lymph node metastasis. The association between low levels of adiponectin and increased breast cancer survivor was evaluated in a multiethnic, prospective cohort study containing 527 women diagnosed with stage I–IIIA breast cancer.[9] After adjustment for possible confounders, the hazard risk of higher levels of adiponectin to longer breast cancer survival was 0.39.

Adiponectin and Colorectal Cancer

A meta-analysis has been performed to evaluate the associations between circulating adiponectin levels and colorectal cancer or adenoma.[34] After gathering data from 13 case-control studies including 3015 cases of colorectal cancer and adenoma, the authors conclude that patients with colorectal cancer and adenoma have markedly lower adiponectin values than controls, although there is obvious heterogeneity across the studies. In men, there is a 2% decreased risk of colorectal neoplasm for a 1-mg/mL increment in adiponectin levels, whereas among women, there is no evidence of such a trend.

Adiponectin and Prostate Cancer

Based on a 25-year prospective cohort, adiponectin concentrations are reversely associated with the risk of developing high grade or lethal cancer. In addition, higher adiponectin concentrations predict lower mortality independent of BMI, leptin, clinical stage, and tumor grade.[16] These observations are in line with previous clinical results showing prostate cancer patients with a Gleason score ≥8 or extraprostatic cancer had lower adiponectin concentrations.

Adiponectin and Pancreatic Cancer

In a prospective cohort study with 452 pancreatic cancer cases and 452 matched controls, higher circulating concentrations of adiponectin are associated with a reduction in pancreatic cancer risk among never smokers (OR = 0.44).[11] Adiponectin is also more specific than standard tumor markers in differentiating pancreatic cancer from chronic pancreatitis.

POTENTIAL MECHANISMS OF ADIPONECTIN AS A PROTECTIVE FACTOR OF CANCER

The role of adiponectin in cancer might include several mechanisms, including antiproliferation, apoptosis, antiangiogenesis and vascularization, regulation of inflammatory cytokines, and improvement in insulin resistance.

Adiponectin is a potent regulator of cell proliferation and apoptosis. Adiponectin significantly suppresses the proliferation of many types of cancer cell lines. The antiproliferative effect is mediated partly via AdipoRs. The binding of adiponectin to its receptor triggers various signaling pathways by which adiponectin accomplishes its antiproliferative and apoptotic activities.[13] Treatment of the cancer cells with adiponectin can cause: (1) downregulation of MAPK 1

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

and 3 expression; (2) stimulation of AMPK activity by phosphorylation at Thr172; (3) a decrease in Akt phosphorylation at Thr308 leading to a reduction of mTOR activity; (4) suppression of the intracellular accumulation of β-catenin and its nuclear activities, which consequently reduces cyclin D1 and c-myc expression. Activation of AMPK has been considered as one of the critical signaling molecules in adiponectin-mediated metabolic signaling. The downstream events include the enhanced expression of Bax and p53, reduced expression of cyclin D1, blockage of c-Jun N-terminal kinase (JNK) signaling, and increased poly(ADP-ribose) polymerase (PARP) cleavage.

Some studies indicate that adiponectin is a negative regulator of angiogenesis.[4] Adiponectin potently inhibits endothelial cell proliferation and migration and remarkably prevents new blood vessel growth in chick chorioallantoic membrane and mouse corneal angiogenesis models. In a hypervascularized murine T241 fibrosarcoma mouse tumor model, adiponectin significantly inhibits primary tumor growth, which is associated with decreased neovascularization. Intraperitoneal and intravitreal injection of recombinant adiponectin dramatically inhibits the size of choroidal neovascularization in a laser-induced neovascularization model. By contrast, in some studies, adiponectin has shown pro-angiogenic effects. Adiponectin-null transgenic mice have reduced vascularization, decreased rate of tumor growth, and increased frequency of pulmonary metastases.[8]

IN VIVO RESULTS OF ADIPONECTIN AND CANCER

Adiponectin deficiency enhances colorectal carcinogenesis and liver tumor formation *in vivo*. Adiponectin knockout (KO) mice develop larger and histologically more progressive colorectal tumors with greater frequency after azoxymethane-induced treatment. In addition, KO mice show a higher incidence and frequency of liver tumors.[19] In B16F10 melanoma and Lewis Lung Carcinoma mice model, adiponectin deficiency markedly promotes the growth of both tumors. Interestingly, the anticancer effect is not related to cell mitosis, apoptosis, or tumor-associated angiogenesis but results from the reduction of macrophage recruitment to the tumor. The restoration of macrophage infiltration at an early stage of tumorigenesis reverses the increased tumor growth in adiponectin KO mice.[27] In MDA-MB-231 breast cancer xenograft nude female mice, both supplementation of recombinant adiponectin and adenovirus-mediated overexpression of adiponectin substantially reduce tumor growth and tumor weight gain. These treatments substantially decrease metastasis of tumor cells into lung tissue and decrease the development of secondary tumors in the mammary fat pads.[33] These *in vivo* results suggest adiponectin as a promising molecular target for cancer therapy.

CANCER-RELATED POLYMORPHISMS OF ADIPONECTIN AND ADIPOR1 GENES

Polymorphisms of adiponectin (ADIPOQ) and AdipoR1(ADIPOR1) genes might be related to the risk of cancer. This association has been reported in colorectal, breast, lung and prostate cancers. In a case-control study with a total of 1497 individuals, the SNP rs266729 (GG/CG genotype), which tags the 5′ flanking region of ADIPOQ, is associated with decreased colorectal cancer risk.[15] Later, this correlation was confirmed in prostate cancer. Another important SNP involved in the cancer risk is rs1501299 located in intron 2 of ADIPOQ. The low expressing rs1501299 G allele (G/G or G/T) is associated with increased risk for breast, prostate, and non-small-cell lung cancers. Interestingly, rs1501299 GG also correlates with decreased levels of serum adiponectin. To date, a total of eight SNPs, namely, rs266729, rs822395, rs822396, rs1501299, and rs2241766 of the ADIPOQ gene and rs12733285, rs1342387, and rs7539542 of the ADIPOR1 gene, have been suggested as cancer-related SNPs. In contrast to the above findings, one large case-control study from the UK failed to replicate the association between variants of ADIPOQ/ADIPOR1 and colorectal cancer.[3] After screening 82 tagging SNPs spanning 250kb around the ADIPOQ locus in 921 familial cases of colorectal tumor and 929 cancer-free controls, Cazier's group failed to find any SNP associated with colorectal tumor risk. The inconsistent results could be because of the different ethnic subjects involved in the study. More epidemiological studies are needed to elucidate the link between genetics of ADIPOQ/ADIPOR1 and cancer, and to address the potential mechanisms of genetic variations in the prognosis of cancer.

INTERPLAY BETWEEN LEPTIN AND ADIPONECTIN

Leptin and adiponectin may downregulate each other's pathway. *In vivo* treatment of adiponectin decreases leptin and Ob-R mRNA expression, and leptin inhibits the mRNA level of AdipoR1. This suggests that obesity-associated hypoadiponectinemia should increase the leptin sensitivity of cancer cells. In the HCC cell lines HepG2 and Huh7, adiponectin treatment effectively blocks leptin-induced cell proliferation and invasion and reverses the inhibitory effect of leptin on apoptosis. More importantly, adiponectin reduces leptin-induced tumor burden in nude mice.[25] The effect of the adiponectin and leptin cotreatment on breast cancer cells is however more complex. Incubation of both adiponectin and leptin increases the number of apoptotic MCF-7 cells but decreases the number of apoptotic T47D cells.[20] These results suggest a very subtle regulation in the molecular mechanisms by which the different adipokines regulate tumor cell proliferation and apoptosis.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

SUMMARY

As two major factors secreted by adipose tissue, leptin and adiponectin play important roles not only in metabolism but also in the development and progression of various types of cancers. Circulating levels of leptin and adiponectin may be novel tumor markers that can serve as useful screening tools for predicting risk for obesity-related cancers. Moreover, the leptin and adiponectin signaling pathways emerge as attractive therapeutic targets for cancer patients. A peptide-based leptin receptor antagonist has been developed to treat human breast cancer.[21] Regulating the ratio of leptin to adiponectin in circulation might be another effective approach toward cancer prevention and therapy.

Chapter 73

LHRH Analogs

Andrew V. Schally, Jorg B. Engel, Jacek Pinski and Norman L. Block

ABSTRACT

This chapter reviews the hypothalamic neuropeptide luteinizing hormore–releasing hormone (LHRH) including its discovery, elucidation of structure, and synthesis. Many analogs, both agonistic and antagonistic, have been synthesized. LHRH receptors from man through the animal kingdom are discussed, and their role is detailed. The presence of LHRH receptors on numerous human cell lines and cells of surgically explanted tumors is reviewed. These are detected by immunohistochemistry, Western blots, radioligand binding assays, and RT-PCR for mRNA of the LHRH receptor. The therapeutic implications and applications thereof are discussed. The synthesis, mechanisms, and use of targeted cytotoxic LHRH compounds are described. Phase II clinical trials of cytotoxic LHRH analogs for ovarian and endometrial cancers have been completed and Phase III trials are being formulated. Phase I/II clinical trials for castration-resistant prostate cancer and urothelial cancer are underway with promising early results. Multiple other clinical applications of LHRH analogs are briefly listed and discussed.

INTRODUCTION

Forty years have passed since the isolation, structural elucidation, and synthesis of porcine hypothalamic luteinizing hormone-releasing hormone-I (LHRH-I) was first accomplished in the laboratory of one of us (AVS).[21,22,28,29] Figure 1 shows the molecular structure of LHRH-1. The structure of hypothalamic LHRH-I in all mammalian species, including human, is identical. LHRH-I subsequently was also identified in primitive bony fish, lungfish, and amphibians.[23,28] At least 23 molecular isoforms of LHRH, each differing structurally, have been identified in birds, reptiles, amphibians, fishes, and other vertebrates, protochordata, mollusks, and cnidaria, such as coral.[23,28] Besides the hypothalamic site, LHRH-I is also found in extrahypothalamic regions of the central nervous system, and in nonneuronal tissues, such as placenta, ovary, mammary gland, and lymphoid cells, and in many cancers.

Another isoform of LHRH decapeptide, LHRH-II, differing by three amino acid residues (His^5, Trp^6, Tyr^8), called chicken LHRH, as it was first isolated from chicken, has also been reported in various animals, mammalian brain, peripheral organs, and some tumors such as breast carcinomas. LHRH-II seems to influence reproductive behavior and may have other functions.[10,23,28]

Most vertebrate species possess genes for both LHRH-I and LHRH-II. In humans, the gene for LHRH-I is located on chromosome 8p11.2-p21. LHRH-I is a central regulator in the hypothalamic–pituitary–gonadal axis and plays a vital role in vertebrate reproduction.[10,28] LHRH is also known as gonadotropin-releasing hormone (GnRH), because it controls, by pulsatile secretion, the release of luteinizing hormone (LH) and of follicle-stimulating hormone (FSH) from the anterior pituitary gland. In turn, FSH and LH are responsible for gonadal steroidogenesis and gametogenesis.[10,28] The abbreviation GnRH is too similar to GH-RH (growth hormone-releasing hormone) for which many agonistic and antagonistic analogs already exist and the use of the abbreviation LHRH is therefore recommended by us.[10,28] LHRH-I may also act as a chemokine, a growth factor, and differentiation-inducing factor, influencing cancer cells in reproductive tissues.[35]

RECEPTORS FOR LHRH-I AND LHRH-II

The actions of LHRH are mediated by high-affinity receptors for LHRH found on the plasma membrane of pituitary gonadotrophs.[10,23,28,35] The LHRH-I receptor is a member of the G protein-coupled receptor (GPCR) superfamily. The receptor consists of seven α-helical transmembrane domains and an extracellular amino-terminal domain.[23,35] The intracellular carboxy terminal domain typical of the GPCR family is absent. The LHRH type I receptor is predominantly coupled to the $G\alpha_{q/11}$-protein, through which it regulates the secretion of FSH and LH. In humans the LHRH-I receptor has 328 amino acids and its gene is located on the chromosome 4q21.2.[23,35] In rats and mice, LHRH-I receptors have 327 amino acids, and their genes are located on chromosomes 14p21 and 5e1, respectively.

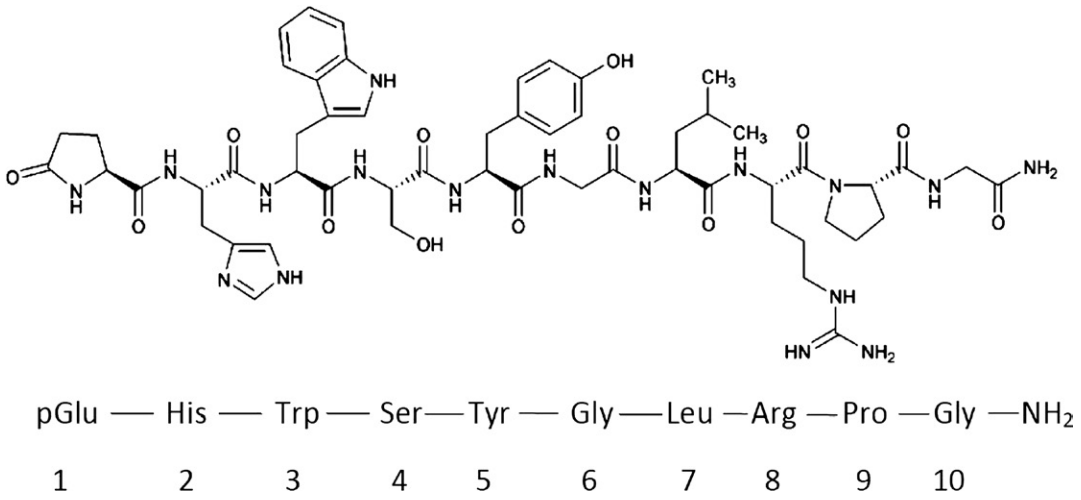

FIGURE 1 The molecular structure of LHRH (GnRH).

Specific LHRH-I receptors are also found on breast, prostatic, ovarian, and endometrial cancers as well as in malignant tumors of urogenital origin such as bladder cancer and tumors of nonreproductive tissues such as colon, pancreas, and brain. These LHRH-I receptors on tumor cells can mediate direct effects of LHRH agonists and antagonists.[10,28]

In man and other mammals, the receptor for LHRH-II (the type II LHRH receptor) is nonfunctional because it is disrupted by frame-shift mutations or premature stop codons and the signaling of LHRH-II thus occurs through type 1 receptor. Thus, in man, there is one functional receptor.[23,35]

SIGNALING MECHANISMS FROM LHRH RECEPTORS

The binding of LHRH-I to its pituitary receptors causes a microaggregation of receptors and complex formation. The complex formed is then internalized and degraded. The LHRH receptors are coupled to guanosine triphosphate GTP-binding proteins ("G proteins"). In the pituitary, these $G\alpha_{q/11}$ proteins activate phospholipase C, which leads to the production of inositol phosphates and diacylglycerol. This process induces Ca^{++} mobilization and activation of protein kinase C, resulting in the release of LH and FSH.[3,14,20,23,35]

With respect to tumoral LHRH receptors, different pathways of signal transduction have been described. In some tumors, after binding to its ligand, the LHRH receptor couples to G protein αi and activates a phosphotyrosine phosphatase, which then dephosphorylates epidermal growth factor (EGF) receptors. As a result, mitogenic signaling induced by binding of EGF to its receptor is abolished.[3,23,25,35]

Recent experimental evidence, however, suggests that LHRH-receptor levels and cell context affect tumor cell responses to LHRH agonists.[20,23,25,35] Thus, after transfection of various human tumor cell lines with LHRH receptors, marked differences in receptor levels, magnitude of inositol phosphate generation, dynamics of inositol phosphate turnover, and activation of ERK1/2 is evident in the different cells. Activation of receptors by LHRH agonists induces apoptosis only if receptor expression is high or moderate. Thus, differences in levels of LHRH receptor and signaling may differentially affect the apoptotic machinery within cell lines and contribute to the cell type-specific effects of LHRH on growth.[23,35]

Furthermore, in HEK 293 cells stably transfected with the LHRH-I-receptor, modification of the LHRH ligand peptide by amino acid substitution modulated its growth inhibiting effect.[20] Thus, different ligands on the LHRH receptor stabilize different receptor conformations mediating differential intracellular signaling and effects on cell growth; this could be the basis for the design of LHRH analogs specifically targeting tumoral LHRH receptors.

DEVELOPMENT OF ANALOGS OF LHRH

During the past 40 years, >3000 analogs of LHRH-I have been synthesized with a view to their potential medical applications.[10,28–31] The substitution of one or more amino acids in the sequence of LHRH-I can result in analogs with increased LH-releasing activity or with antagonistic action. The studies on the relationship between the structure and biologic activity show that histidine in position 2 and tryptophan in position 3 play a functional role in the biologic activity of LHRH. Positions 2 and 3 are also the preferred ones for substitutions generating inhibitory activity.[28] Amino acids in positions 1 and 4–10 exert conformational effects and are essential for binding to the receptors. Substitution of a D-amino acid for Gly[6] enhances the β-II′ type turn conformation by which the peptide is bound to the LHRH-I receptor and increases the activity. We have

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

produced three categories of LHRH analogs: 1. agonistic analogs, 2. antagonistic analogs, 3. cytotoxic analogs.[28–31]

AGONISTIC ANALOGS OF LHRH-I

D-Amino acid substitution in positions 6 can lead to superactive peptides. Several LHRH analogs substituted in positions 6, 10, or both, are 50–100 times more active than LHRH and also possess prolonged activity. Of these, the most important analogs are [D-Leu^6,Pro^9-NHET]LHRH (Leuprolide, Lupron) (Takeda-Abbot, TAP), [D-Trp^6] LHRH (Decapeptyl, Triptorelin) (Ipsen, Ferring, Aventis), [D-Ser(Bu^t)^6,Pro^9-NHET]LHRH SUPREFACT (Buserelin) (formerly Hoechst Marion-Roussel, now Sanofi-Aventis), [D-Ser(Bu^t)^6,Aza-Gly^{10}]LHRH (Zoladex, goserelin) (formerly ICI, now Astra-Zeneca).[10,28,29]

The greater biologic activity of these analogs is due to both increased resistance to enzymatic degradation and an enhancement in receptor affinity. The substitution of Gly^6 by D-amino acids renders the analog more resistant to degradation by endopeptidases, which cleave LHRH at this position, and which are widely distributed in mammalian tissues.[28]

For tumor therapy, long-acting depot formulations of LHRH analogs dispersed in microcapsules of biodegradable polymers or in implants are used. Leuprolide depot and Decapeptyl LP are available in the form of slow-release formulations containing the analogs in microcapsules of poly(D,L-lactide-co-glycolide) and are administered intramuscularly at monthly intervals. Depot formulations of Leuprolide acetate and Triptorelin (Trelstar LA) are also available in forms that release the drugs over several months. Implants containing goserelin are designed for subcutaneous injection and produce continuous release over a 4- to 12-week period.[28,29]

MECHANISM OF BIOLOGICAL ACTION OF LHRH AND ITS AGONISTS

An acute injection of LHRH or a superactive agonist induces a marked and sustained release of LH and FSH, whereas a chronic administration produces inhibitory effects. Thus, continuous stimulation of the pituitary by repeated injections of superactive agonists of LHRH or monthly administration of depot preparations induces an inhibition of the hypophyseal–gonadal axis through the process of "downregulation" of pituitary receptors for LHRH, desensitization of the pituitary gonadotrophs, and creation of a state of reversible medical castration with suppression of circulating levels of LH, FSH, and the sex steroids. For the therapy of sex hormone-dependent malignant neoplasms, such as prostate and breast cancer, the inhibitory process produced by depot preparations of LHRH agonists depends on the creation of a state of sex steroid deprivation. LHRH agonists and antagonists also exert direct inhibitory effects on breast, prostate, ovarian, and endometrial cancers mediated through LHRH receptors on the tumor cells.[10,28,29]

APPLICATIONS OF AGONISTS OF LHRH-I

Downregulation of LHRH receptors, produced by repeated administration or by depot preparations of LHRH agonists, provides the basis for clinical applications in gynecology, urology, and oncology of this class of compounds. Management of central precocious puberty, polycystic ovarian syndrome, and *in vitro* fertilization and embryo transfer (IVF-ET) programs (controlled ovarian stimulation-assisted reproductive technology) (COS-ART) are based on the suppression of gonadotropin secretion (selective medical hypophysectomy). Treatment of sex hormone-dependent malignant neoplasms, represented by prostate, breast and endometrial carcinoma, and other diseases or conditions, such as benign prostatic hyperplasia, uterine leiomyomata, and endometriosis, is based on the reversible medical castration created by sex steroid deprivation.[10,28,29]

ANTAGONISTS OF LHRH

Hundreds of LHRH antagonists have been synthesized since 1971. To eliminate the undesirable anaphylactic effects caused by insertion of D-arginine in position 6, analogs with neutral D-uridoalkyl amino acids, such as D-Cit at position 6, have been synthesized in our laboratory. Among these antagonists [Ac-D-Nal(2)^1, D-Phe(4Cl)^2,D-Pal(3)^3,D-Cit^6,D-Ala^{10}]LHRH (Cetrorelix, Aeterna-Zentaris) had the highest inhibitory activity and receptor binding affinity.[10,28,29] Other groups have also synthesized LHRH antagonists with diminished anaphylactoid activity. Among antagonists that were developed are antide [N-Ac-D-Nal(2)^1, D-Phe(4Cl)^2,D-Pal(3)^3,Lys(Nic)^5,D-Lys(Nic)6,Lys(iPr)^8,D-Ala^{10}]LHRH (Ares-Serono) and Nal-Glu antagonist [Ac-D-Nal(2)^1,D-Phe(4Cl)^2,D-Pal(3)^3,Arg^5,D-Glu^6(AA),D-Ala^{10}] LHRH (NIH), Azaline-B [Ac-D-Na]^1,D-Phe(4cl)^2,D-Pal^3,Aph^5(Atz),Aph^5(Atz),Ilys^8,D-Ala^{10}0]LHRH, Ganirelix [N-Ac-D-Nal(2)^1, D-*p*-Cl-Phe^2,D-Pal(3)^3, D-hArg (Et2)^6,L-hArg(Et2)^8,D-Ala^{10}]LHRH (Organon), Abarelix (PPI-149) [N-Ac-D-Nal (^{2})-D-(p-Cl)-Phe-D-Pal(3)-Ser-Nm-Tyr-Asn-Leu-ILys-Pro-Gly-NH2] (Precis),[10,28,29] and Degarelix [N-acetyl-3-(naphtalen-2-yl)-D-alanyl-4-chloro-D-phenylalanyl-3-(pyridin-3-yl)-D-alanyl-L-seryl-4-((((4S)-2,6-dioxohexahydropyrimidin-4-yl)carbonyl) amino)-L-phenylalanyl-4-(carbamoylamino)-D-phenylalanyl-L-leucyl-N6-(1-methylethyl)-L-lysyl-L-prolyl-D-alaninamide], (Ferring Pharmaceuticals).[34]

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Antagonists of LHRH exhibit no intrinsic biologic stimulatory activity but compete with LHRH for the same receptor sites. LHRH antagonists thus produce a competitive blockade of LHRH receptors, preventing stimulation by endogenous LHRH, and causing an immediate inhibition of the release of gonadotropins and sex steroids. LHRH antagonists can greatly reduce the onset time of therapeutic effects as compared with agonists. LHRH antagonists such as Cetrorelix already have major uses in gynecology, especially in COS-ART and seem to have various advantages over the agonists.[10,28,29] The use of antagonists can prevent the undesirable clinical "flare" of disease caused by transient initial LH and sex steroid release that can occur during agonist administration in cancer patients. Degarelix is being developed by Ferring Pharmaceuticals for prostate cancer therapy.[34] Although the principal mechanism of action of LHRH antagonists is based on a competitive occupancy of LHRH receptors, administration of LHRH antagonist Cetrorelix to rats can also produce downregulation of pituitary LHRH receptors and a decrease in the levels of mRNA for LHRH receptors. An orally active nonpeptide antagonist of LHRH receptor, Elagolix, has been reported.

TARGETED CYTOTOXIC ANALOGS OF LHRH

An additional new class of antitumor compounds consisting of LHRH agonists conjugated to chemotherapeutic agents has been recently developed for targeted chemotherapy.[28–31] The hypothesis of "magic bullet"-like compounds, which could specifically eradicate cancers, was conceived by Paul Ehrlich, but remained unexplored for nearly a century. Based on the presence of LHRH receptors in breast, endometrial, ovarian, and prostatic cancers, our laboratory, >20 years ago, started the synthesis and evaluation of targeted antitumor compounds made by linking LHRH analogs to cytotoxic compounds.[30,31]

After 15 years of exploring various antineoplastic radicals and chemical linkages, we decided to conjugate the agonist [D-Lys^6]LHRH to doxorubicin (DOX), one of the most widely used anticancer agent. The conjugation was made through the ε-amino group of the D-Lys moiety and a glutaric acid spacer to the 14-OH group of doxorubicin, to form the cytotoxic LHRH analog, AN-152 (AEZS-108). Subsequently, we synthesized another cytotoxic analog (AN-207) by linking 2-pyrrolino-DOX (AN-201), a daunosamine-modified derivative of DOX, to the same [D-Lys^6] LHRH carrier. We have demonstrated that these cytotoxic LHRH analogs, AN-152 (AEZS-108) and AN-207, powerfully inhibit the growth of multiple experimental tumors. The same cytotoxic radicals were then also conjugated to analogs of somatostatin and bombesin/gastrin-releasing peptide (GRP) to form cytotoxic peptides that could be targeted to their corresponding receptors on tumors.[7,30,31]

MECHANISM OF ACTION OF CYTOTOXIC LHRH ANALOGS

After binding to receptors for LHRH, cytotoxic LHRH analogs are internalized by rat pituitary cells and by human ovarian, endometrial, or breast cancer cells. The entry of AN-152 (AEZS-108) into the cells is followed by its appearance in the cytoplasm. The labeled carrier peptide is localized mainly in the cytosols of tumor cells and not in the nucleus. However, the fluorescent label linked to AN-152 (AEZS-108) and coupled to the daunosamine nitrogen of DOX was found only in the nuclei.[30,31] The presence of LHRH receptors on cells is essential for this internalization process, because no binding and internalization of AN-152 (AEZS-108) occurs in cells, such as UCI-107 ovarian cancer, which do not express LHRH receptors.

RECEPTORS FOR LHRH ON HUMAN TUMORS

Receptors for LHRH are expressed on the cells of many human cancer specimens as well as human cancer cell lines.[3,5,28,31] One method of their detection is immunohistochemistry (IHC), which has been used mainly for the demonstration of LHRH receptors in specimens of lymphoma, renal cell carcinoma, melanoma, bladder cancer, prostate cancer, breast and ovarian and endometrial cancers. Other methods of detection include western blots, radioligand binding assays, and RT-PCR for mRNA of LHRH receptor. Inhibition *in vivo* of the growth of human cancers xenografted into nude mice in response to targeted cytotoxic LHRH analogs AN-152 (AEZS-108) and AN-207 may also be considered proof of receptor presence and suggested therapeutic applications. The blockage of the LHRH receptors with agonist D-Trp^6-LHRH abolishes these inhibitory responses. LHRH receptors are not expressed in UCI-107 and SKOV-3 ovarian cancer cell lines or in MFE 296 endometrial cancer cell line, and so these are not affected by cytotoxic or other analogs of LHRH.

The following human tumor specimens and human cancer lines are positive for LHRH receptors by IHC:

1. Non-Hodgkin's Lymphomas (NHL)—Human specimens and NHL cell lines HT and RL;[16]
2. Renal Cell Carcinoma (RCC)—Human specimens and RCC cell lines A-498, ACHN, 7860;[17]
3. Malignant Cutaneous Melanomas (MM)—Human specimens and MM cell lines MRI-H255, MRI-H187;[18]
4. Pancreatic Cancers—Human specimens and PANC-1 cell line;[28–31]
5. Urinary Bladder Cancer—Human specimens and HT-1376 cell line [Ref. 1, Keller & Schally unpublished];

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

6. Prostate Cancer—Human specimens and cell lines: LNCaP, MDA-PCa-2b, C4-2, PC-82, DU-145, and LUCaP-35;[15,29,31]
7. Breast Cancer—Human specimens and cell lines: HCC-1806, HCC-1937, MDA-MB-231, MX-1, MDA-MB-435, MCF-7, and T47D;[11,15,31]
8. Ovarian Cancer—Human specimens and cell lines: OV-1063, ES-2, EFO-21, EFO-27, OVCAR-3, and HTOA;[5,14,31]
9. Endometrial Cancer—Human specimens and cell lines: HEC-1A, HEC-1B, RL-95-2, and Ishikawa line;[9,14]
10. Colorectal Cancer—Human specimens and cell lines: HT29, HCT116, HCT-15, LoVo, and COLO-320DM;[32]
11. Benign Prostatic Hyperplasia (BPH)—Human BPH Specimens and Cell line BPH-1.[27]

ANTITUMOR EFFECTS OF AGONISTS AND ANTAGONISTS OF LHRH—EXPERIMENTAL AND CLINICAL FINDINGS

Prostate Cancer

The greatest therapeutic impact of LHRH analogs came about in the field of prostate cancer.[28,29] Carcinoma of the prostate is the most common noncutaneous malignancy in men. About 70% of human prostate cancers are testosterone dependent, and the endocrine therapy of advanced prostate cancer with agonists of LHRH is based on the resultant desired androgen deprivation.[28,29]

The finding that prolonged treatment with agonistic analogs of LHRH causes testicular inhibition and chemical castration prompted us to try this method to induce the regression of prostate tumors in rat models.[26] Treatment of male rats bearing the Dunning R3327H prostate adenocarcinoma with D-Trp^6-LHRH reduces tumor volume and decreases actual tumor weight as compared with untreated controls.[26] Serum LH, FSH, and testosterone levels are significantly reduced. This demonstration led to clinical applications. The first successful palliative treatment of advanced prostatic carcinoma by agonistic analogs of LHRH was shown in a collaborative trial performed with G. Tolis in the late 1970s at the Royal Victoria Hospital in Montreal.[33] This trial showed for the first time that superactive agonistic LHRH analogs are effective therapeutic agents in patients with androgen-sensitive prostatic adenocarcinoma.[33] These findings were confirmed and extended by other clinical trials of LHRH agonists in patients with prostate cancer in Europe and North America. In addition to Decapeptyl, the agonists buserelin, leuprolide, and goserelin were tested.[2]

At present, the use of sustained-release formulations of agonists, which can be administered at intervals of 1–6 months, makes the treatment of prostate cancer even more convenient, practical and effective.[10,28,29] These regimens also ensure better patient compliance. Medical castration produced by chronic administration of LHRH analogs accounts for most of the clinical benefits of this treatment, but LHRH agonists and antagonists can also exert direct effects on prostate tumor cells. Occasional "flare" in the disease with an increase in bone pain during the first weeks of administration of LHRH agonists was reported in approximately 10% of patients, but such "flares" can be prevented by administration of an antiandrogen before and for 2–4 weeks after the first injection with the agonist.[10,28,29] The clinical acceptance of LHRH analogs is excellent. Therapy with agonists of LHRH is presently the preferred method of primary treatment for men with advanced prostate cancer, and recent surveys indicate that LHRH agonists are selected for primary treatment in approximately 70% of cases.[10,28,29] More recently, LHRH agonists with or without antiandrogens have been used before, during, or after various local treatments in patients with localized prostate cancer. Treatment with LHRH agonists is now recommended in patients who have a rising prostate specific antigen (PSA) levels after surgery and/or radiotherapy. Androgen deprivation produced by LHRH agonists however leads to a decrease in libido, impotence, hot flashes, weight gain, muscle loss, osteopenia, and other side effects concomitant with decreased sex steroids.

The use of LHRH antagonists would avoid the temporary "flare" of the disease that can occur when LHRH agonists are given as single agents. We first showed inhibitory effects of the LHRH antagonist Cetrorelix on experimental androgen-dependent Dunning R-3327-H in rats and human PC-82 prostate cancers in nude mice.[28] Subsequent clinical trials showed that a decrease in testosterone, PSA levels, and prostate size, measured by ultrasonography, can be achieved in patients with advanced prostate cancer treated with Cetrorelix. Patients who were paraplegic due to metastatic invasion of the spine show neurologic improvement during therapy with Cetrorelix. Cetrorelix or other antagonists could be indicated for patients with prostate cancer having metastases to the spine, bone marrow, bladder base and other sites in which the LHRH agonists cannot be used as single drugs because of the possibility of "flare".[10,28] Studies performed with a depot formulation of the LHRH antagonist Abarelix show that its administration leads to a faster decline of the testosterone levels than that of leuprolide with or without antiandrogens. A new LHRH antagonist, Degarelix, is presently in clinical trials for prostate cancer.

Cetrorelix may be also useful for the therapy of BPH. Cetrorelix can produce long-term improvement in patients with BPH.[10,28]

All hormonal therapies, including orchidectomy and LHRH agonists or antagonists, however, provide a cancer remission with a limited duration, and most patients relapse

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

within two to three years. The relapse may be manifested clinically, radiolographically, and/or biochemically by an increase in serum PSA levels. These patients eventually die of androgen-independent prostatic cancer (CRPC) which is apparently stimulated by various growth factors. The prognosis for patients with hormone-refractory prostate cancer is very poor, and no effective treatment exists at present. Chemotherapy produces poor response rates, although Docetaxel-based therapy confers some improvement in survival.[10,28]

APPLICATIONS OF CYTOTOXIC LHRH ANALOGS

Cytotoxic analogs of LHRH could be useful in the management of relapsed prostate cancer. First, we showed inhibitory effects of the cytotoxic LHRH analog AN-207 in rats with Dunning prostate cancers and in nude mice with human PC-82 tumors.[30,31] We then showed that AN-207 inhibits growth of MDA-PCa-2B prostate cancers xenografted into nude mice and lowers PSA levels. AN-207 also inhibits growth of DU-145 and LuCaP-25 human prostate cancers and is less toxic than its cytotoxic radical used independently.[30,31] Although AN-207 could not be easily synthesized on a large scale, this work supports the concept that targeted chemotherapy based on cytotoxic LHRH analogs should be more efficacious and less toxic than the current systemic chemotherapy. We then started tests with AN-152 (AEZS-108) containing doxorubicin (DOX). In castrated nude mice bearing LNCaP androgen-sensitive prostate cancers treatment with AN-152 (AEZS-108) produces a nearly 70% reduction of tumor volume.[30,31] The cytotoxic analog, AN-152 (AEZS-108), also strongly suppresses growth of androgen-sensitive MDA-PCa-2b prostate cancers and is more effective than equimolar doses of DOX. In nude mice bearing androgen-independent intraosseous C4-2 prostate cancers, treatment with AN-152 (AEZS-108) decreases serum PSA levels, whereas DOX has no effect. These three lines are LHRH receptor positive. AN-152 (AEZS-108) also inhibits the growth of human androgen-independent DU-145 prostate cancers.[30,31] The results suggest that the cytotoxic analog, AN-152 (AEZS-108), should be effective in those patients with prostate cancer who relapse after androgen deprivation therapy. Thus, targeted cytotoxic analogs of LHRH may be useful for the treatment of advanced prostate cancer after it relapses.

CLINICAL TRIALS WITH AN-152 (AEZS-108) IN MEN WITH PROSTATE CANCER

AN-152 (AEZS-108) is the only cytotoxic hybrid that has entered early clinical study. A Phase I and two Phase II studies in women with endometrial and ovarian cancers have been completed.[4,6–8] In prostate cancer, accrual recently began in an accelerated Phase I lead-in to a Phase II trial of AN-152 (AEZS-108) [Pinski et al., unpublished]. This NIH funded trial is enrolling men with CRPC previously treated with a taxane but with no other limit on previous therapy. Eligibility criteria include adequate hematologic and organ function and an Eastern Cooperative Oncology Group performance status of 0 or 1. As LHRH agonists will compete for binding sites with AN-152 (AEZS-108), a previous washout period from LHRH agonists is required. The primary endpoint of this trial is clinical benefit rate and the trial features several unique correlative studies. Tissue from previous biopsies will be assessed for strength of LHRH receptor expression, which will then be correlated to response. Circulating tumor cells (CTCs) will be captured at several prespecified time points by a novel microfiltration assay and the FDA approved CellSearch assay for comparison. In addition to quantification of CTC number, this novel microfiltration assay will permit direct evaluation of LHRH receptor expression on the captured cells. This also will be correlated with response and changes in expression over time will be monitored during therapy. Furthermore, the unique autofluorescence properties of the doxorubicin moiety will be exploited to directly visualize internalization of AN-152 (AEZS-108) in captured CTCs for a unique pharmacokinetic study. Preliminary results from the phase I portion of this clinical trial indicate that AN-152 (AEZS-108) is well tolerated by most of the patients and has shown activity in the form of diminished PSA, other objective responses, or stabilization of the disease [Pinski et al., unpublished].

BREAST CANCER

Breast cancer is the most common malignancy in women and a leading cause of cancer related deaths among women in the Western world.[10,29] Various groups, including ours, showed an inhibition of rat and mouse mammary tumors after administration of agonists or antagonists of LHRH.[10,28] Later we showed that LHRH antagonists such as Cetrorelix can also inhibit growth of human breast cancer lines *in vitro* by direct action, mediated by LHRH receptors, on tumor cells. Thus, considerable evidence supports the view that the proliferation of human breast cancer cells *in vitro* and *in vivo* can be suppressed by LHRH agonists and antagonists.[28] In early studies *in vivo*, targeted cytotoxic LHRH analogs, AN-152 (AEZS-108) and AN-207, both inhibit growth of estrogen-independent MXT mouse mammary cancers.[31] In another investigation, AN-207 causes a regression of MX-1 hormone-independent doxorubicin-resistant human breast cancers that express significant levels of LHRH receptors in nude mice. Similar inhibition of tumor growth with AN-207 is obtained in MDA-MB-435 human estrogen-independent mammary carcinomas implanted s.c. or orthotopically in the mammary fat pad of nude mice. This effect of AN-207

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

could be blocked by pretreatment of nude mice with the agonist [D-Trp^6]LHRH, which competes for LHRH receptors before the administration of AN-207.[30,31]

Because it was decided to choose AN-152 (AEZS-108) (*vide supra*) for clinical trials, we evaluated its effects on MX-1 human mammary carcinoma line xenografted into nude mice. Treatment with AN-152 (AEZS-108) significantly decreases the tumor volume and extends tumor doubling time. The levels of HER-2 and HER-3 proteins are also significantly reduced by AN-152 (AEZS-108).[30,31] AN-152 (AEZS-108) also can suppress growth of other triple-negative human breast cancer lines including MDA-MB-231 and HCC-1806.[12]

Cytotoxic LHRH analogs such as AN-152 (AEZS-108) have a selective transient inhibitory effect on pituitary LH cells. However, the dose-limiting toxicity of AN-152 (AEZS-108) will probably be myelotoxicity caused by doxorubicin. Our results show that targeted cytotoxic LHRH analogs such as AN-152 (AEZS-108) could be considered for treatment of LHRH receptor-positive advanced or metastatic breast cancers.[30,31]

Clinical Effects of Analogs of LHRH in Women with Breast Cancer

Klijn and De Jong[19] were the first to report that two of four premenopausal women with metastatic breast cancer improve after seven weeks of treatment with the LHRH agonist, buserelin (Suprafact). Clinical trials with microcapsules of triptorelin or implants of goserelin (Zoladex) in patients with advanced breast carcinoma show that the responses occurred primarily in women with ER-positive tumors.[10,28,29] Kaufman et al. used depot implants of goserelin (Zoladex) in 134 premenopausal women with breast cancer and found a 54% objective tumor response (reviewed in Refs 10, 28, 29). These studies indicated that LHRH agonists are efficacious for the treatment of premenopausal women with estrogen-dependent, ER-positive breast cancer. Subsequent trials showed beneficial effects of LHRH analogs in combination with tamoxifen in early breast cancer. Combined therapy with an LHRH agonist and tamoxifen is superior to either treatment modality alone.[10] Results from a large clinical trial indicate that goserelin alone or in combination with tamoxifen is at least as effective as chemotherapy with cytoxan, methotrexate, 5-FU (CMF) in patients with estrogen-dependent early disease.[10] In postmenopausal patients with metastatic breast cancer, the overall response rate of only about 8% can be explained by direct inhibitory effects of LHRH agonists on tumors.[10,28,29]

Epithelial Ovarian Cancer

The treatment of epithelial ovarian cancer, based on surgery and/or chemotherapy, is not very effective, and new approaches are needed.[28,29] Specific receptors for LHRH have been found in 78% of surgically removed human ovarian carcinomas as well as in EFO-21, EFO-27, and OV-1063 and ES-2 human ovarian cancer cell lines.[5,14,30,31] These receptors mediate direct inhibitory effects of LHRH analogs on the growth of ovarian cell lines *in vitro*.[5] The agonist, [D-Trp^6]LHRH, and antagonist, Cetrorelix, inhibit *in vivo* growth of human OV-1063 and ES-2 epithelial ovarian cancers xenografted into nude mice. However, in patients with advanced ovarian carcinoma, no beneficial effects of therapy with [D-Trp^6]LHRH were found in a multicenter trial.[30,31]

Targeted cytotoxic LHRH analogs, AN-152 (AEZS-108) and AN-207, in nude mice, inhibit the growth of LHRH receptor-positive OV-1063 ovarian tumors, but not of LHRH receptor-negative UCI-107 human ovarian carcinomas, showing that the presence of LHRH receptors is essential.[30,31] For clinical trials, see the next section on endometrial cancer.

Endometrial Cancer

New methods are needed for the treatment of advanced or relapsed endometrial cancer.[29] High-affinity receptors for LHRH are present on nearly 80% of human endometrial cancers and endometrial cancer cell lines.[9,14,28–30] The agonist [D-Trp^6]LHRH and the antagonist Cetrorelix inhibit the proliferation of endometrial cancer cell lines *in vitro*. Only limited clinical studies have been carried out so far, but administration of LHRH agonists produces a partial or complete remission in 35% of patients with recurrent endometrial cancer.[13]

Because LHRH receptors are found on 80% of endometrial cancers, the use of targeted cytotoxic analogs has been investigated. Thus, AN-152 (AEZS-108) inhibits the growth of HEC-1A and HEC-1B human endometrial cancers in nude mice. AN-207 also significantly suppresses the proliferation *in vivo* of HEC-1A and RL-95-2 endometrial cancers.[9]

Clinical Studies with AN-152 (AEZS-108) Women with Endometrial and Ovarian Cancers

There is one phase I[4,7] and two phase II studies on AN-152 (AEZS-108).[6,8] The phase I study includes 17 women with histologically confirmed epithelial cancer of the ovary, endometrium, or breast that is metastatic or unresectable and for which standard curative or palliative measures could not be used or are no longer effective or tolerated.[4,7] In each patient, immunohistochemistry of primary tumor or metastatic lesion confirmed that the tumors express LHRH receptors.[4,7] The study is designed as a dose-escalation trial to determine the maximum tolerated dose of AN-152 (AEZS-108). One patient each received intravenous doses of 10, 20, 40, or 80mg/m^2 of AN-152 (AEZS-108), six received

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

160mg/m^2 and seven 267mg/m^2 at 3 week intervals. Dose-limiting leukopenia and neutropenia were observed at the highest dose. Although efficacy was not a primary endpoint, tumor response was assessed whenever possible. In the low dose group, none of the patients showed a response; however, a total of 6 patients of 13 in both upper dose groups (3 patients at 160mg/m^2, 3 at 267mg/m^2) showed responses to AN-152 (AEZS-108) (2 complete remissions, 1 partial remission, 3 disease stabilization). The maximum tolerated dose of AN-152 (AEZS-108) in the absence of supportive medication was 267mg/m^2, and this dose was used as starting dose for therapeutic phase II studies.[4,7]

The first phase II study was performed on behalf of Arbeitsgemeinschaft Gynäkologische Onkologie (AGO) in 43 patients with platinum-resistant advanced ovarian cancer and was presented at the ASCO symposium in 2010.[8] Patients with histologically confirmed taxane-pretreated platinum-resistant/refractory, LHRH-receptor positive, advanced (FIGO III or IV) or recurrent ovarian cancer received up to 6 cycles of AN-152 (AEZS-108) at doses of 267mg/m^2. At least 1 measurable lesion or CA-125 ≥ 200% of the upper normal range limit was required at baseline. An independent radiologic review was performed. Response rate (RECIST and/or GCIG criteria) was defined as primary endpoint. Secondary endpoints were safety, time-to-progression (TTP) and overall survival (OS). Efficacy included partial remissions in 5 patients (11.6%) and disease stabilization for > 12 weeks in 14 patients (32.6%). AN-152 (AEZS-108) was active and well tolerated in patients with heavily pretreated platinum-/taxane-resistant ovarian cancer. The safety profile confirmed the dose of 267mg/m^2.

The second phase II study was a multicenter trial also performed by AGO and includes 43 patients with histologically confirmed, LHRH-R positive, advanced (FIGO III or IV) or recurrent endometrial cancer.[6] Patients receive AN-152 (AEZS-108) for a planned duration of 6 treatment courses at doses of 267mg/m^2. At least 1 measurable lesion is required at baseline with an independent radiologic review. The response rate per RECIST is defined as the primary endpoint. Secondary endpoints are safety, time-to-progression (TTP) and overall survival (OS). Tumors of all the patients were confirmed as LHRH-R positive; percentages of tumor cells staining for LHRH-R ranged 30%–90% (median 70%); 27 patients had a primary diagnosis of EC FIGO III/IV and 31 patients had tumors with endometrioid and 8 with serous histology. Previous treatment included surgery (42 patients), radiotherapy (29 patients), chemotherapy (9 patients) and hormonal therapy (11patients). Twenty-eight patients (62.8%) received AN-152 (AEZS-108) for 6 courses (2 patients with 8 courses), only one patient was retreated at a reduced dose. Independent review, which is currently ongoing, has confirmed the target minimum of 5 responses. Definite results for further reported responses (preliminary judgment) were 4 complete remissions, 10 partial remissions and—at end of course—6–15 disease stabilizations.[6]

Renal Cell Carcinoma

The prognosis of patients with metastatic renal cell carcinoma (RCC) is poor, and the present methods of treatment of RCC should be improved.[17,28,30] Therapy with the LHRH antagonist, Cetrorelix, inhibits the growth of the CAKI-I RCC line xenografted into nude mice. The expression of LHRH receptors is found by immunohistochemistry in 28 of 28 surgically removed specimens of human renal cell carcinoma and in three RCC cell lines, A-498, ACHN, and 786-0, by Western immunoblotting and RT-PCR.[17] The cytotoxic LHRH analog, AN-207, significantly inhibits the growth of these three human RCC lines xenografted into nude mice. Our findings indicate that LHRH receptors expressed in human RCC specimens can be used for targeted chemotherapy with cytotoxic LHRH analogs.[17,30]

Non-Hodgkin's Lymphoma

Non-Hodgkin's lymphoma (NHL) is the most frequently diagnosed hematological malignancy in the U.S.[16,30] Patients with advanced disease show a five-year survival rate of only 26%, emphasizing the need for new therapies. LHRH receptors were detected in 92% of surgically removed human NHL specimens and in RL and HT NHL cell lines. AN-207 significantly inhibits the growth of RL and HT tumors.[16,30] Thus, LHRH receptors found in human NHL could also be therapeutic targets for the cytotoxic LHRH analogs.

Melanoma

The prognosis for metastatic melanoma is very poor and new effective therapies must be developed.[18,30] The first demonstration of LHRH receptors on rat melanomas was made by Moretti et al.[24] We found LHRH receptor expression by immunohistochemistry in 19 of 19 human melanoma specimens. The mRNA for LHRH receptors and LHRH receptor protein were similarly detected in transplantable MRI-H255 and MRI-H187 human melanoma tumor lines.[18] We then showed that AN-207 significantly inhibits the growth of MRI-H255 and MRI-H187 tumors xenografted into nude mice.[18] Thus, LHRH receptors expressed in human malignant melanoma could be used for targeted chemotherapy with LHRH analogs.[30]

Colorectal Cancer

Colon cancer lines including HT-29, HCT-116, HCT-15, LoVo, and Colo-320DM, show high-affinity binding sites for LHRH.[30,32] Cytotoxic LHRH analogs AN-207 and AN-152 (AEZS-108) strongly inhibit growth of these colon

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

cancer cell lines.[32] Thus, targeted therapy with cytotoxic LHRH analogs could be considered for the treatment of metastatic colorectal cancer.

Pancreatic Cancers

The prognosis for patients with ductal pancreatic cancers is dismal, and it is essential to develop new therapeutic approaches.[29] Human and hamster pancreatic cancers express LHRH receptors that are localized mostly in the cell nuclei;[28,30] their function is not known. Various clinical trials with LHRH agonists in patients with pancreatic carcinoma were unsuccessful.[28–30] Treatment with cytotoxic LHRH analog, AN-152 (AEZS-108), inhibits growth of SW-1990, PANC-1 and CFPAC-1 human pancreatic cancer lines xenografted into nude mice [Szepeshazi and Schally, in press]. Phase I/II clinical trials with the cytotoxic LHRH analog, AN-152 (AEZS-108), in patients with advanced pancreatic cancers are pending.

Urinary Bladder Cancers

New therapeutic methods are needed for the treatment of metastatic bladder cancer.[30] Immunohistochemical studies indicate that human bladder cancers express receptors for LHRH [1, Keller and Schally, unpublished]. We (Szepeshazi and Schally) have shown that the growth of HT-1197, RT-4, and J-82 human bladder cancer lines xenografted into nude mice is strongly inhibited by the cytotoxic LHRH analog AN-152 (AEZS-108). A phase I/II clinical trial (Fernandez G. et al.) with AN-152 (AEZS-108) in patients with metastatic urothelial carcinoma, resistant to platinum chemotherapy, is in progress, and early patient responses have been encouraging.

SUMMARY

In the 40 years that have elapsed since the elucidation of the structure of LHRH-I, more than its 23 molecular isoforms have been identified in other species. Interest in the medical applications of LHRH derivatives led to the synthesis of >3000 analogs. Various uses in gynecology, reproductive medicine, and oncology have been established for LHRH-I agonists and antagonists. Clinical applications of LHRH agonists are based on gradual downregulation of pituitary receptors for LHRH and inhibition of the pituitary and gonads. LHRH antagonists produce an immediate suppression of the secretion of gonadotropins and sex steroids and thus achieve rapid therapeutic effects. LHRH agonists and antagonists can be also used for the treatment of endometriosis, uterine leiomyomas, and in assisted reproduction programs. The preferred primary treatment of advanced androgen-dependent prostate cancer is based on the periodic administration of depot preparations of LHRH agonists. LHRH agonists can likewise be applied for treatment of breast cancer. Besides their action on the pituitary, LHRH agonists and antagonists can also exert direct effects on tumor cells. The presence of specific receptors for LHRH on various cancers provided a rationale for the design and synthesis of cytotoxic hybrids, consisting of chemotherapeutic agents conjugated to the analogs of these peptides, which can be targeted to these tumoral receptors. Cytotoxic LHRH analogs, targeted to tumors, were tested on many human cancer lines xenografted into nude mice. Thus, cytotoxic analogs of LHRH, AN-152 (AEZS-108) and AN-207, containing DOX or 2-pyrrolino-DOX (AN-201), respectively, targeting LHRH receptors, inhibited growth of prostatic, bladder, breast, ovarian, endometrial, colorectal, and pancreatic cancers as well as lymphomas, melanomas, and RCCs. The clinical applications of the cytotoxic LHRH analog, AN-152 (AEZS-108), was successful in a phase I/II trial in women with gynecologic cancers, and this analog is now in phase III trials. Other clinical trials are pending. Continued development of targeted cytotoxic LHRH analogs should lead to a more efficacious therapy for many human cancers.

Chapter 74

Orexins (Hypocretins)

Marc Laburthe and Thierry Voisin

ABSTRACT

Orexin-A and orexin-B are closely related peptides expressed by hypothalamic neurons that regulate sleep, wakefulness, and other central functions. There is factual evidence for their role in the control of gastrointestinal motility, gastric acid secretion, duodenal bicarbonate secretion, jejunal glucose absorption, and pancreatic hormone (insulin, glucagon) secretion. The orexin receptor OX1R is aberrantly expressed at all steps of colorectal tumor progression and after metastasis. Treatment of colon cancer cells in culture with orexins promotes robust apoptosis even in cells that are resistant to classical chemotherapy. When human colon cancer cells are xenografted in nude mice, injections of orexins dramatically slow down tumor growth and even reverse the development of established tumors. In this respect, OX1R may be considered as an Achilles heel of colon cancer. OX1R drives mitochondrial apoptosis through a new paradigm of G protein-coupled signaling involving phosphorylation of the immunoreceptor tyrosine-based inhibitory motifs (ITIMs) and recruitment/activation of the tyrosine phosphatase SHP-2.

INTRODUCTION

Orexin-A and orexin-B, also named hypocretin-1 and hypocretin-2, are two neuropeptides encoded in a single gene and expressed in lateral hypothalamus neurons that project throughout the brain[8,28] and regulate sleep, wakefulness, feeding, energy homeostasis, breathing, reward system, or drug addiction.[20] Loss of orexin neurons or deficiency in orexin signaling results in the sleep disorder narcolepsy–cataplexy in humans, dogs, and rodents[20] and possibly other neurological disorders.[11] Functions and expression of orexins in peripheral tissues, including the digestive system, have been also documented.[4,13,35] This chapter presents and discusses the current understanding of orexin and orexin receptors with special attention on a new paradigm of G protein-coupled receptor signaling by orexin receptors through phosphorylation of the tyrosine-based motifs ITIMs. It also focuses on the possible physiological role of orexins in the digestive system, which is still under debate. Finally, it reviews recent findings showing that orexin receptors are aberrantly expressed in colon cancer in which they drive apoptosis and represent thereby a novel and promising target in colon cancer therapy.

DISCOVERY

Hypocretins[8]/orexins[28] were discovered at the same time by two independent groups using different strategies and technologies. Analysis of expression pattern of cDNA selectively expressed in the hypothalamus revealed an original 569 nucleotide clone encoding a 131-residue putative secretory protein (in humans), which can generate two homologous peptides sharing very weak sequence homology with secretin. They were named hypocretin-1 and hypocretin-2 thereby.[8] At the same time, rat brain extracts were screened for their ability to induce intracellular calcium transients in a battery of orphan G protein-coupled receptor-expressing cells.[28] Two peptides were purified and named orexin-A and orexin-B because of their orexigenic effects in rats.[28] This latter strategy allowed the description of two G protein-coupled receptors for orexins referred to as OX1R and OX2R.[28] The 28 amino acid orexin-B and 33 amino acid orexin-A were identical to hypocretin-2 and hypocretin-1, respectively. Both names are problematic because regulation of feeding and appetite is probably not the major action of the neuropeptides, and they have no clear sequence homology with secretin. In the absence of recommendations by the International Union of Pharmacology, and for the sake of clarity, we have used the names orexin and orexin receptor OXR in this chapter.

STRUCTURE OF THE mRNA/GENE

Orexin-A and orexin-B are derived from a single prepro-orexin precursor. The human mRNA was predicted to encode a 131-residue precursor peptide.[8,28] The human preproorexin gene is located at human chromosome 17q21 and consists of two exons and one intron distributed over 1432 bp.[28] The 143 bp first exon includes the 5′-untranslated region and a small part of the coding region that encodes the first seven residues of the

secretory signal sequence. The second 473 bp exon contains the remaining portion of the open reading frame and a 102 bp 3′-untranslated region. The two exons are separated by an 816 bp intron.

PROCESSING OF THE PRECURSOR

The first 33 amino acids of the human 131-residue preproorexin exhibits the characteristics of a secretory signal sequence with a putative cleavage site at Ala^{33}-Gln^{34}.[35] Orexin-A sequence starts with Gln^{34}. which is cyclized into an N-terminal pyroglutamyl residue presumably by enzymatic transamidation. The last Leu^{66} residue of mature orexin-A is followed by a Gly^{67} in the precursor allowing C-terminal amidation by peptidylglycine monooxygenase and peptidylaminoglycolase. Gly^{67} is followed by a pair of basic amino acids, Lys^{68}-Arg^{69}, which constitutes a recognition site for prohormone convertase. The next segment Arg^{70} to Met^{97} constitutes orexin-B. The Met^{97} residue is again followed by Gly and a pair of basic residues which constitute a C-terminal amidation/cleavage signal. The mature 33 amino acid peptide orexin-A contains two intrachain disulfide bonds, whereas the mature 28 amino acid peptide orexin-B is devoid of a Cys and thereby of any disulfide bonds. Nevertheless, the structures of orexin-A and orexin-B exhibit high similarity with two alpha helices connected by a short linker (Fig. 1).[35]

DISTRIBUTION OF THE mRNA/PEPTIDE

The main site of orexin synthesis in the body is the lateral hypothalamus, which contains orexin neuron cell bodies that project in many areas of the brain.[8,23,28] Several lines of evidence also support the expression of orexins in the periphery, including the digestive tract, though reported results are somewhat inconsistent.[4,13,35] Preproorexin mRNA was identified by RT-qPCR in the testis and at very low levels in the heart but not in other tissues of rats including stomach, duodenum, jejunum, pancreas, and liver.[15] Similarly,

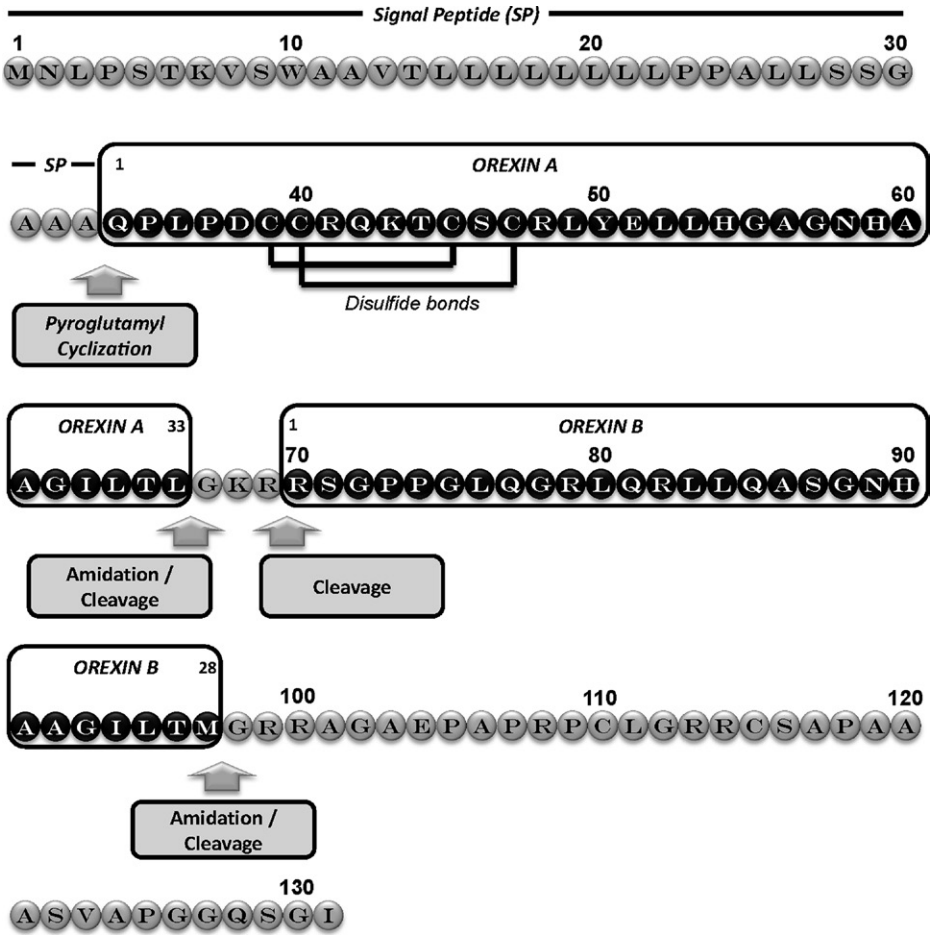

FIGURE 1 Human preproorexin processing. The 131-residue preproorexin precursor encompasses the signal peptide, orexin-A and orexin-B. Arrows indicate predictive enzymatic cleavage sites and chemical modifications. Note that orexin-A has two disulfide bonds.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

no preproorexin mRNA could be identified by RT-qPCR in the human colon and the liver.[33] These results contrast markedly with immunostaining of neurons or endocrine cells with anti-orexin antibodies in various parts of the gut mucosa and smooth muscles in several species.[16] Problems with the specificity of antibodies and/or species variations in the expression of peripheral orexins may be responsible for discrepancies in the results. Alternatively, the existence of neuronal populations that project from hypothalamus to the periphery[30] may explain the presence of orexins in the gut, at least in neurons, but the absence of preproorexin mRNA which would be present in orexin neuron cell bodies located outside the gut. Orexin-A was also identified in both β- and α-cells of the rat endocrine pancreas.[24] Orexin-B was identified in β-cells and nerves in the wall of blood vessels of rat pancreas.[2] Again, these observations contrast with the absence of detectable preproorexin mRNA in the pancreas of rats.[15] A few studies reported the radioimmunological detection of very low concentrations of orexin-A in human plasma but results probably need to be interpreted with caution.[13]

RECEPTORS AND SIGNALING CASCADES

Two orexin receptors, OX1R and OX2R, also named HCTR1 and HCTR2, have been characterized.[8,28] They have seven transmembrane domains and belong to the family A of G protein-coupled receptors.[35] In humans, the two OXRs show 64% identity in amino acid sequences. OXRs are highly selective for orexins with no significant binding of other natural peptide hormones or neuropeptides.[35] Contrary to other peptide receptors, only few reports described binding studies of orexins to OXRs.[35] In some studies, OX1R seems to have more affinity for orexin-A than for orexin-B, a selectivity that is also observed when measuring calcium transients.[29,35] However, in other studies orexin-A and orexin-B have identical potencies in promoting OX1R-mediated cell apoptosis or inhibition of cell growth with EC_{50} in the nanomolar range.[18] The OX2 receptor seems to have similar affinity for orexin-A and orexin-B in binding studies[35] and biological response such as stimulation of apoptosis.[18,34]

Although subtype-selective orexin receptor peptide agonists have been described,[3,19] the selectivity of some of them has been reported to be somewhat weak and variable[26] depending on the cellular context for native receptors or expression system for recombinant receptors. No orexin receptor small-molecule agonist has been described yet.[26] By contrast, numerous small-molecule orexin receptor antagonists have been described because of their potential interest as a novel therapy for the treatment of insomnia.[6,29] Both OX1R-selective and OX2R-selective antagonists have been synthesized and dual OX1R/OX2R antagonists are also described.[6,29]

Classically, the activation of both orexin receptors induces cellular calcium transients in receptor-transfected cells and native receptor-expressing cells.[35] This occurs through the increase of intracellular inositol triphosphate and subsequent release of calcium from intracellular stores.[32] OX1R connects to multiple phospholipase activities including phospholipases C and D.[14] OX1R has also been shown to be linked to calcium influx through the canonical transient receptor potential channel TRPC3.[25] A few reports also suggest that the activation of OXRs can result in stimulation of cAMP production.[35] These observations are consistent with the coupling of OXRs to Gq, Gi/Go and/or Gs proteins.

Although the classical calcium pathway is considered to play an important role in OXR signaling, a new paradigm of OX1R signaling has recently emerged.[10,17,32] Activation of OX1R drives apoptosis in colon cancer cells or OX1R-transfected cells through Gq protein but independently of classical Gαq activation of phospholipase C and calcium pathway. On OX1R activation, βγ dimers of Gq are freed resulting in the stimulation of Src-tyrosine kinase. Src then phosphorylates two immunoreceptor tyrosine-based inhibitory motifs (ITIMs) in OX1R allowing the recruitment of the phosphotyrosine phosphatase SHP-2, which is activated thereby.[10,32] Activated SHP-2 triggers a cascade of downstream events resulting in mitochondrial apoptosis.[17,27] The role of ITIMs in OX1R-driven apoptosis represents a new paradigm of G protein-coupled receptor signaling.[17] Figure 2 schematizes classical and ITIM-driven OX1R signaling.

BIOLOGICAL ACTIONS WITHIN THE GASTROINTESTINAL TRACT AND THE PANCREAS

Many reports indicate that orexins are able to affect motility and secretions in the digestive tract via both central and peripheral actions. They also show that peripheral actions can be neurally mediated and/or triggered by direct interaction of orexins with smooth muscle, exocrine or endocrine cells.[4,13,35] However, although OXRs have been detected by immunohistochemistry in the gut and pancreas in different species including rats,[35] RT-qPCR experiments performed on rat tissues failed to identify any significant amounts of OX1R and OX2R mRNA in the stomach, duodenum, and pancreas, while OX1R mRNA could be identified in jejunum.[15] Again, problems associated with the specificity of antibodies and/or species variations in the expression of peripheral OXRs may be responsible for the discrepancies in the results. In this context, the possibility of a direct control of digestive functions by orexins still remains to be firmly established in many cases. The actions of orexins

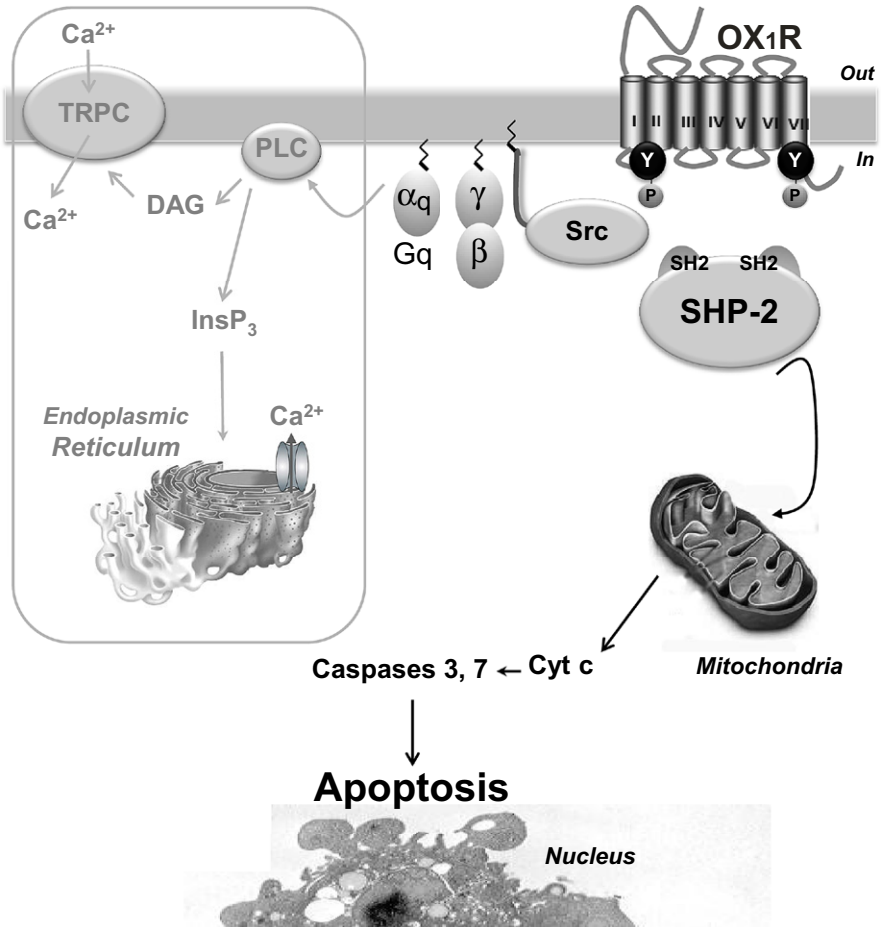

FIGURE 2 Mechanism of OX1R-driven apoptosis. Activation of the heptahelical orexin receptor OX1R by orexins promotes the dissociation of G_q protein into α_q and $\beta\gamma$ dimers. The classical pathway resulting in phospholipase C activation by αq is not involved in OX1R-mediated apoptosis and is shown in a box. Freed $\beta\gamma$ dimers stimulate the Src-tyrosine kinase resulting in the tyrosine phosphorylation of the two ITIMs of OX1R. The phosphotyrosine phosphatase SHP-2 is then recruited by OX1R and activated thereby. Activated SHP-2 is mandatory for subsequent cytochrome c-mediated mitochondrial apoptosis. Cyt c, cytochrome c; DAG, diacylglycerol; $InsP_3$, inositol triphosphate; SHP-2, SH2 domain-containing phosphotyrosine phosphate-2; TRPC, canonical transient receptor potential channel.

on gastric, intestinal, and pancreatic functions are briefly reviewed below:

- Gastrointestinal motility

Central and peripheral administrations of orexins have been shown to modify motility in stomach and small intestine and to lower gastric emptying rate.[4,13] However, because of the variability in the results and methodology used, the effects of orexins on gastrointestinal motility are still under debate.[13]

- Gastrointestinal secretion

Central, but not peripheral, administration of orexin-A causes an increase in gastric acid secretion in rats most probably by modulating the vagal system.[31] Peripheral administration of orexins stimulates duodenal bicarbonate secretion in fed but not in fasted rats and is independent of vagal control.[5]

- Small intestinal absorption

Orexin-A and orexin-B acting at OX1R or OX2R inhibit rat jejunal glucose absorption through a complex mechanism that involves distinct neuronal, endocrine, and direct epithelial pathways.[9] It is suggested that orexins are involved in a regulatory loop between enteric glucose entry and central evaluation of peripheral available energy levels[9] in agreement with results indicating that orexin neurons in the hypothalamus are specialized cells for sensing blood glucose.[7]

- Pancreatic secretions

Central administration of orexin-A stimulates pancreatic exocrine secretion of fluid and protein via the vagus.[21] Several reports also suggest that orexins can modulate the function of endocrine pancreas though, again, the variability in the results and methodology used makes it difficult to

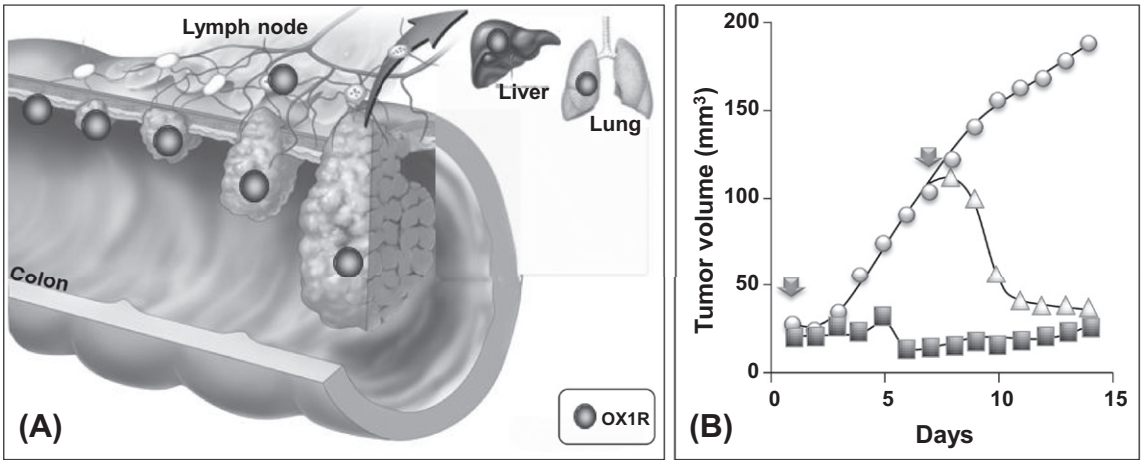

FIGURE 3 Expression of the orexin receptor OX1R during colon cancer progression and metastasis and treatment of colon tumors with orexins *in vivo*. Left, OX1R (circles) is aberrantly expressed in primary colon tumors and metastases but not in normal colon. It is expressed very early during carcinogenesis and whatever Dukes' stage of the primary tumors. After metastasis in the colon (lymph node) and in distant organs (liver, lung) OX1R is still expressed (see Ref. 33 for details). Right, effect of inoculation of orexin-A on the growth of tumors developed by xenografting human colon cancer cells LoVo in nude mice. Mice were daily injected intraperitoneally without (circles) or with 1.12 μmol of orexin-A/kg body weight starting on day 0 (squares) or day 7 (triangles). See Ref. 33 for details.

clearly understand their physiological role, if any. Subcutaneous injection of orexin-A in rats results in an increase in blood insulin and orexin-A stimulates insulin secretion in an *in vitro* perfusion system of rat pancreas.[22] Orexin-B evokes insulin and glucagon release from pancreatic tissue fragments.[2] This is in line with the ability of orexin-A to reduce glucagon secretion from perfused rat pancreas and isolated rat pancreatic islets.[12] However, all these results contrast markedly with a report suggesting that orexin-A increases glucagon secretion and decreases glucose-stimulated insulin release from isolated rat islets and that orexin-A infusion increases plasma glucagon and decreases plasma insulin in fasted rats.[24]

PATHOPHYSIOLOGICAL IMPLICATIONS

Considering that brain orexins can control gastrointestinal functions through the vagal system, the lack of orexin signaling in the brain observed in narcolepsy and perhaps other neurological diseases (see above) might trigger the development of functional gastrointestinal disorders. However, a direct relationship between orexin/orexin receptors and gastrointestinal diseases has only been firmly shown for colon cancer.[17,33]

After earlier work showing that orexins are able to promote apoptosis in human colon cancer cell lines in culture through interaction with the OX1R,[27] the role of OX1R in colorectal cancers has been clearly shown.[17,33] The OX1R is aberrantly expressed at all steps of primary colorectal tumor progression as shown in a large collection of resected tumors.[33] The same occurs after local (lymph node) and distant (liver, lung) metastasis (Fig. 3A). In sharp contrast, no OX1R is detected in normal human colonic epithelial cells from which cancer cells derive. Treatment of human colon cancer cells in culture with orexins promotes robust apoptosis and subsequent reduction of cell growth even in cells that are resistant to 5-fluorouracil, the most commonly used drug in chemotherapy.[33] When human colon cancer cells are xenografted in nude mice, daily ip injections of orexins dramatically slow down tumor growth and even reverse the development of established tumors by promoting a selective apoptosis in tumor cells (Fig. 3B).[33] Because neither colon tumors nor normal colon expresses preproorexin mRNA in humans,[33] the OX1R aberrantly expressed in colon tumors is most probably not activated by endogenous orexins in patients. In this context, it has been suggested that OX1R in colorectal cancers constitutes a gate to apoptosis that probably remains unopened *in vivo* but could be openable by therapeutic administration of exogenous orexins or OX1R agonists.[17] In this respect, OX1R may be considered as an Achilles heel of colon cancer, because targeting OX1R with agonists leads to cancer cell death by apoptosis. Therefore, forthcoming OX1R agonists might be novel candidates for colorectal cancer therapy, which could be used alone or in combination with classical chemotherapeutic drugs such as 5-fluorouracil.[33]

Ox1r in colon cancer might be considered as a new type of gene involved in cancer, because it is aberrantly expressed as a functional protein whose function, when activated by an agonist, is to promote apoptosis of the cancer cell. The colon cancer cells unexpectedly provide a new gate to promote their death, which was not present in the normal colonocyte from which they derive.[33] Whether or not orexins may be useful in the treatment of other

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

digestive cancers remains an open question, but preliminary data suggest that orexins can also promote apoptosis in pancreatic tumor cells through interaction with the OX2 receptor.[34]

After initial characterization of orexins as potent inducers of cell apoptosis,[18,27] it has been shown that streptozotocin-induced diabetes mellitus in rats, which constitutes a model of type 1 diabetes, requires the orexigenic system and OX1R to cause severe apoptosis in pancreatic islets.[1] Whether or not OX1R participates in the onset and/or outcome of type 1 diabetes in humans remains an open question.

CONCLUSIONS AND PERSPECTIVES

Orexins are certainly very important peptides in the central nervous system in health and diseases. Their role in the periphery remains much less understood in physiology. However, the discovery that orexin receptors OX1R are aberrantly expressed in human colorectal cancers opens a gate to the therapeutic induction of apoptosis in cancer cells and shows that orexins may have considerable interest for cancer research. The development of long-lived peptide agonists or nonpeptide agonists of orexin receptors will represent an important advance not only in neuroscience but also in cancer research. Moreover, the identification of th e role of ITIMs in OX1R-driven apoptosis paves the way to the development of a new paradigm of G protein-coupled receptor signaling. In this respect, the presence of ITIM canonical sequences in most GPCRs[17] should encourage studies to understand the role of ITIM-driven biological responses in all classes of GPCRs.

Chapter 75

Somatostatin/NPY

Meike Körner and Jean Claude Reubi

ABSTRACT

Somatostatin and NPY are two different peptide hormones with multiple functions in neoplasia. Somatostatin exerts inhibitory effects on tumor hormonal secretion, growth, and angiogenesis, which represent the basis for the clinical use of long-acting somatostatin analogs in tumor therapy. Conversely, emerging results show variable effects of NPY on tumor cell proliferation, migration, hormonal release, and angiogenesis of unknown significance *in vivo*. Moreover, many tumors overexpress enough somatostatin receptors to be targeted with radioactive and cytotoxic somatostatin analogs for diagnostic and therapeutic purposes. Similarly, an increasing number of tumors highly overexpress NPY receptors, which may also be targeted *in vivo* with adequate NPY analogs.

INTRODUCTION

The two peptides discussed in this chapter do not have much in common at first glance. Physiologically, they control and regulate different biological systems in the body. Historically, somatostatin was discovered in 1973,[2] whereas NPY was first reported in 1982.[33] This one decade implies that much more information is available on the somatostatin than on the NPY systems, not only in general biology but also regarding clinical applications. In particular, the relation between somatostatin and cancer has been known for a relatively long time, whereas NPY has only recently been linked to neoplasia. Nevertheless, there are numerous converging features appearing that suggest that the very young NPY cancer field may learn and strongly be influenced by the decades' experience of the somatostatin cancer field (Table 1).

SOMATOSTATIN

Somatostatin and Cancer

Somatostatin is a peptide hormone that is widely distributed in nervous, endocrine, gastrointestinal, and other systems of the human body where it has mainly inhibitory regulative functions (see the Somatostatin chapters in the Brain and Gastrointestinal Peptides sections of the book). These inhibitory actions of somatostatin are not only restricted to physiologic processes but they also play a role in neoplasia, for which mainly three mechanisms have to be considered: the inhibition of tumoral hormone secretion, the direct and indirect inhibition of tumor cell proliferation, and the inhibition of tumoral angiogenesis. These aspects are of current interest, as they represent one molecular basis for the clinical use of somatostatin in tumor therapy.

Inhibition of Hormone Release from Tumors by Somatostatin

Somatostatin strongly inhibits hormonal secretion from normal endocrine cells and their neoplastic counterparts. Thus, somatostatin and somatostatin analogs are highly effective in reducing hormonal symptoms caused by hypersecretory endocrine tumors. Therefore, they form an integral part of the routine therapy of several such tumors. For somatostatin therapy, metabolically stable and/or long-acting somatostatin analogs have been developed, such as octreotide acetate (Sandostatin®), lanreotide, and their respective long-lasting release (LAR) formulations, as native somatostatin has a very short half-life in the circulation. These somatostatin analogs are generally well tolerated and cause only mild side effects. They potently inhibit tumoral growth hormone (GH) secretion and reduce GH-related symptoms in patients suffering from GH-producing pituitary adenomas. They are also the drugs of first choice to control hormone-related symptoms in several functionally active gastroenteropancreatic neuroendocrine tumors. For instance, in patients with the carcinoid syndrome, somatostatin analogs achieve symptomatic control in 73% and a significant improvement of the quality of life.[9]

Direct and Indirect Antiproliferative Effects of Somatostatin in Tumors

More than 20 years ago, Schally et al. performed seminal studies in various animal tumor models showing that somatostatin and somatostatin analogs inhibit tumor cell proliferation.[29] This effect is probably achieved via

several independent mechanisms. Somatostatin may indirectly reduce tumor cell proliferation via the inhibition of various physiologically occurring growth stimulating pathways such as pituitary GH and prolactin release or the GH/insulin-like growth factor (IGF)-I axis. Moreover, somatostatin may directly act on tumor cells by binding to tumoral somatostatin receptors and interfering with intracellular signaling cascades of cell cycle and apoptosis.[20,29]

The tumor growth inhibitory effect of somatostatin has been documented in many experimental models. In animals bearing pancreatic, breast, or prostate carcinomas, or chondrosarcoma or osteosarcoma, somatostatin analogs reduce tumor size and prolong survival.[29] In human tumor cell lines, including pancreatic, breast, and small-cell lung cancer (SCLC) cell lines, the antiproliferative effect of somatostatin analogs could also be reproduced. Worth mentioning are the elegant studies by Susini and collaborators, showing that the introduction of the somatostatin receptor subtype 2 (sst2) in pancreatic tumor cell lines originally devoid of sst2 lead to a marked inhibition of tumor growth, indicating the pivotal role of sst2.[4] In patients, reproducible inhibitory effects of somatostatin analogs on tumor growth are observed primarily in GH-producing pituitary adenomas; overall, 42 % of patients have a mean tumor size reduction of 50%. Unfortunately, however, results of clinical trials on other tumors are disappointing. Although a reduction of tumor size under somatostatin therapy is only very rarely observed in a few patients with advanced gastroenteropancreatic neuroendocrine tumors,[9] the more recent ProMid study by Rinke et al.[28] reports that octreotide LAR can have a substantial antitumor effect, with a longer progression-free survival compared with placebo in patients with well-differentiated neuroendocrine tumors.

Antiangiogenic Effects of Somatostatin

Induction of new blood vessels is an important feature of malignant tumors necessary for growth and metastasis, and inhibition of tumoral angiogenesis is a promising therapeutic approach. Somatostatin acts antiangiogenically by inhibiting endothelial cell proliferation. It reduces the new formation of both normal and tumor-associated blood vessels in several experimental animal and human models. In particular, octreotide can reduce tumor vascularization *in vivo* in human breast cancer.[35]

Vascular somatostatin receptors are locally upregulated in the vicinity of tumors.[6] This is important for a somatostatin-based antiangiogenic tumor therapy, as it may allow specific targeting of tumor-associated vessels while sparing normal vessels. Although the present *in vitro* and animal tumor model results look promising, no clinical experience exists on an antiangiogenic effect of somatostatin analogs in tumor patients so far.

Molecular Signaling of Somatostatin Receptors

The multiple somatostatin effects are mediated by six different somatostatin receptor (sst) subtypes, named sst1, sst2A, sst2B, sst3, sst4, and sst5 (see the Somatostatin chapter in Brain Peptides section). The molecular signaling of sst is complex, as sst couple to various different pertussis-toxin-sensitive and pertussis-toxin-insensitive G proteins, which in turn modulate multiple interdependent intracellular signal transduction pathways.[20] Correspondingly, the effect of somatostatin on normal and tumor cell proliferation can be mediated by multiple mechanisms. Cell cycle arrest is mediated by various sst subtypes, leading for instance to activation of tyrosine phosphatases, interference with the MAP kinase ERK pathway, induction of cyclin-dependent kinase inhibitors, and accumulation of hypophosphorylated Rb protein. Moreover, the antiproliferative effect of somatostatin may also be mediated indirectly by the induction of apoptosis via several sst. Endothelial cell proliferation is regulated by sst3-mediated inhibition of endothelial nitric oxide synthase activity.[20]

Only more recently was it recognized that ssts are not only activated by somatostatin agonist binding to a single sst entity but they may also undergo complex and yet poorly understood regulating mechanisms of homooligomerization and heterooligomerization.[20] Sst oligomerization not only affects intracellular signal transduction but it also alters sst binding affinity and internalization. For instance, sst3 is completely inactivated by heterodimerization with sst2A, and sst1 internalization depends on heterodimerization with sst5. These effects have been observed only in transfected cells and have not been established in native tissues so far, in particular not in sst expressing tumors. However, as tumors often coexpress multiple sst subtypes,[23] sst heterodimerization may significantly affect binding and internalization properties of the various tumoral sst.

Somatostatin Receptors in Cancer

The discovery that sst are expressed in many malignant human tumors has led to further important clinical applications that are based on sst properties independent of the regulation of hormone release, proliferation, and angiogenesis.[23] Tumoral sst overexpression allows a highly effective *in vivo* tumor targeting for diagnostic and therapeutic purposes based on the binding and internalization of radiolabeled and cytotoxic somatostatin analogs to sst.[19,21,31]

Somatostatin Receptor Expression in Human Tumors

Sst are expressed on the tumor cell surface in a broad spectrum of human cancers. As expected from the sst distribution in nonneoplastic tissues, the sst expression is very high in (neuro-)endocrine and brain tumors, particularly in gastroenteropancreatic and bronchial neuroendocrine tumors, pheochromocytomas, paragangliomas, GH-producing pituitary adenomas, neuroblastomas, medulloblastomas, meningiomas, medullary thyroid carcinomas, and SCLC. By comparison, ssts are expressed in lower incidence and density in many common epithelial tumors (breast carcinomas, prostatic carcinomas, renal cell carcinomas, gastrointestinal adenocarcinomas, hepatocellular carcinomas, ovarian carcinomas), lymphomas, and mesenchymal tumors.[23]

Ssts are also overexpressed in tumor-associated blood vessels, in particular in peritumoral veins and, more rarely, in intratumoral blood vessels, as compared with normal blood vessels in corresponding nonneoplastic tissues.[6] The degree of vascular sst expression varies according to the tumor type. Tumor-associated vascular sst expression is important because it may also render tumors that do not express sst on tumor cells[35] responsive to *in vivo* sst targeting (see below).

The six sst subtypes are differentially and often concomitantly expressed in tumors. However, sst2A is by far the most common and most predominant subtype both on tumor cells and in tumor-associated blood vessels.[23,35] This is of great clinical advantage because sst2A, compared with other sst subtypes, has a high affinity for the commercially available somatostatin analogs.

Moreover, because sst2A is the most abundant somatostatin receptor subtype, specific antibodies against sst2A have been developed for immunohistochemical sst2A detection in tumors. Antibodies such as R2–88 or UMB-1 have been able to localize sst2A at the cell membrane of neuroendocrine tumor cells.[17,25] An example is shown in Figure 1. This histopathological measurement is of great importance

See color plate 21.

for the clinical management of the neuroendocrine tumor patients. Further, in patients under octreotide therapy, the sst2A receptors are trafficking from the membrane to the inside of the tumor cells, a mechanism that appears to be extremely potent and of great biological relevance.[27] Such an sst2 internalization is triggered by somatostatin agonists but not by antagonists. An example of internalized sst2 in a neuroendocrine tumor of an octreotide-treated patient is seen in Figure 1.

Somatostatin Receptor-Targeted Tumor Imaging

Sst overexpressing tumors can be specifically visualized with scintigraphy using radioactively labeled somatostatin analogs such as ^{111}In-DTPA-octreotide (OctreoScan®). This method is very effective in detecting tumors with high and homogeneous sst expression and therefore became the gold standard method for localizing and staging gastroenteropancreatic neuroendocrine tumors. Compared with computed tomography and ultrasound, OctreoScan® often shows more lesions and thus modifies tumor staging and changes surgical strategy in a substantial number of cases. For the detection of gastrinomas, OctreoScan® is superior to all other imaging techniques.

Although ^{111}In-DTPA-octreotide has been used for >15 years in the diagnosis and staging of sst-positive tumors, its performance has been compared with new SPECT and PET tracers based on ^{99m}Tc and ^{68}Ga. For instance, ^{68}Ga-based PET tracers are widely used in Europe, in particular ^{68}Ga-DOTA-TOC, ^{68}Ga-DOTA-TATE, and ^{68}Ga-DOTA-NOC; the latter has affinity for sst2, sst3, and sst5 resulting in a somewhat higher diagnostic sensitivity than ^{68}Ga-DOTA-TATE, which has the highest sst2 affinity of all these tracers.[26] Several studies comparing the ^{68}Ga-based peptides with ^{111}In-DTPA-octreotide show the distinctly higher sensitivity of the PET tracers.[7]

Although the past decade has led to the development of a large number of excellent somatostatin agonist radioligands, more recently, many observations have challenged this strategy. Potent somatostatin receptor antagonists, known to poorly internalize into tumor cells, can visualize tumors *in vivo* as well, or even better than agonists.[8] This unexpected phenomenon was found for sst2- and sst3-selective somatostatin analogs. It may result from the binding of the antagonist to a larger number of receptor sites and from its lower dissociation rate from the receptors. Figure 2 shows that the ^{177}Lu-DOTA-BASS antagonist binds to many more sst2 sites in a neuroendocrine tumor than the ^{177}Lu-DOTA-TATE agonist does. A pilot clinical trial with an ^{111}In-DOTA-linked sst2 antagonist confirms these results.[34] More potent sst2 antagonists aimed at that same purpose are in development.[3]

Somatostatin Receptor-Targeted Tumor Therapy

Somatostatin analogs labeled with cytotoxic radionuclides such as ^{111}In, ^{90}Y or ^{177}Lu, or alternatively with cytotoxic chemotherapeutic agents, may be used to specifically target tumoral sst for therapeutic purposes. They will be internalized into the cells and develop their radiotoxic and cytotoxic effects in tumor cells and tumor vessels. Such an sst targeting represents a very promising approach in cancer therapy, with the advantage of a more favorable benefit-toxicity profile compared with conventional radio- and cytotoxic therapy.[19,31] In Europe, numerous centers provide somatostatin targeted radionuclide therapy to patients suffering from metastasized or unresectable neuroendocrine tumors. The most frequently used radioactively labeled peptides are ^{90}Y-DOTA-TOC and ^{177}Lu-DOTA-TATE, and their combinations. Several Phase I and II clinical studies have been published.[19] Tumor shrinkage in almost 45%, clinical improvement in over half of the patients, as well as a median time to progression from 29 to 40 months and a median overall survival from 37 to 46 months have been reported for patients with gastroenteropancreatic neuroendocrine tumors. It is very probable that sst-targeted radiotherapy will be clinically effective also in other human tumors with high sst expression. A relative limitation of sst-targeted radiotherapy is the renal toxicity of the radionuclide compounds, a problem that has been

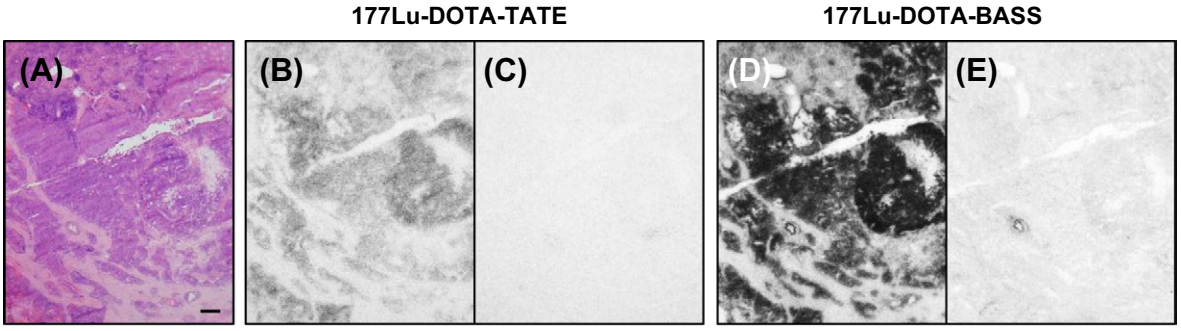

FIGURE 2 Receptor autoradiography of a somatostatin-receptor-expressing neuroendocrine tumor (A = Hematoxylin–eosin section. Bar = 1 mm.) The agonist ^{177}Lu-DOTA-TATE binds to less sst2A receptors (B) than the antagonist ^{177}Lu-DOTA-BASS (D). (C, E) Respective nonspecific binding.

given full consideration for renal protection by infusion of amino acid solutions together with the radioactively labeled tracer.

Sst-targeted cytotoxic therapy is an alternative approach unimpaired by this renal side effect. The most active compounds developed are doxorubicin derivatives coupled to somatostatin analog. They have been extensively tested in animal models, in particular in human cancer cell lines xenografted in nude mice,[30] where they achieve significant growth inhibition. More recently, first clinical trials with sst-targeted cytotoxic tumor therapy in humans with doxorubicin-coupled somatostatin analogs have been performed with encouraging results, and follow-up studies are foreseen in the near future.[30]

NPY

Neuropeptide Y (NPY) forms together with the structurally related peptide YY (PYY) and pancreatic polypeptide (PP) the NPY family of peptides (see the chapters on these peptides in the Brain, Ingestive, and Gastrointestinal Peptides sections of the book). NPY is primarily a neurotransmitter that is widely distributed in the central, peripheral, and vegetative nervous system where it regulates many diverse functions, such as feeding and anxiety behavior, reproduction, and blood pressure. Although these NPY effects have been extensively investigated and are discussed elsewhere in this book, evidence of a role of NPY in cancer has only recently been emerging.

NPY Receptors

The actions of NPY are mediated by at least five different NPY receptor subtypes that form the NPY receptor family.[22] In humans, the subtypes Y1, Y2, Y4, and Y5 are expressed, whereas a physiological correlate of y6 has not been described and the existence of the putative Y3 receptor has not been proven. All NPY receptor subtypes are members of the G-protein-coupled receptor superfamily. The NPY receptors almost universally act *via* pertussis-toxin-sensitive G_i- and G_o-proteins and inhibit adenylyl cyclase; in a restricted number of cell types they modulate calcium and potassium channels. The intracellular signaling pathways downstream to G-protein coupling are incompletely characterized and may vary depending on NPY receptor subtypes, cell lines, tissues, and species.

NPY Receptor Expression in Human Tumors

A decade ago, it was recognized for the first time that NPY receptors are expressed not only in normal tissues and in selected tumor cell lines but also at high levels in original human tumors.[24] This represents the molecular basis for potential clinical applications of NPY analogs in cancer, analogous to somatostatin receptor targeting of tumors.

NPY Receptor Expression in Tumor Cells

During the last 10 years, the NPY receptor expression has extensively been studied in a large spectrum of human tumors using *in vitro* NPY receptor autoradiography, a method that quantitatively assesses the binding site of the NPY receptor protein in tissues. NPY receptors were thus found to be variably expressed in the tumor cells of a large number of different cancer types, including epithelial, mesenchymal, brain, endocrine, and embryonal tumors (Table 1). Particularly noteworthy are breast adenocarcinomas, Ewing sarcomas, and glioblastomas because of their extremely high NPY receptor expression with respect to both incidence and density levels.[12,16,24] This is illustrated with typical examples in Figure 3. Also moderate to high NPY receptor levels are found in adrenal cortical tumors, pheochromocytomas, and paragangliomas,[13] ovarian sex cord-stromal tumors,[14] and renal cell carcinomas.[15] NPY receptors are also found in high incidence in embryonal tumors, including neuroblastomas, nephroblastomas, and medulloblastomas/CNS-PNET,[12,13,15] in accordance with NPY receptor expression during human fetal development. Conversely, in other common epithelial, endocrine, and

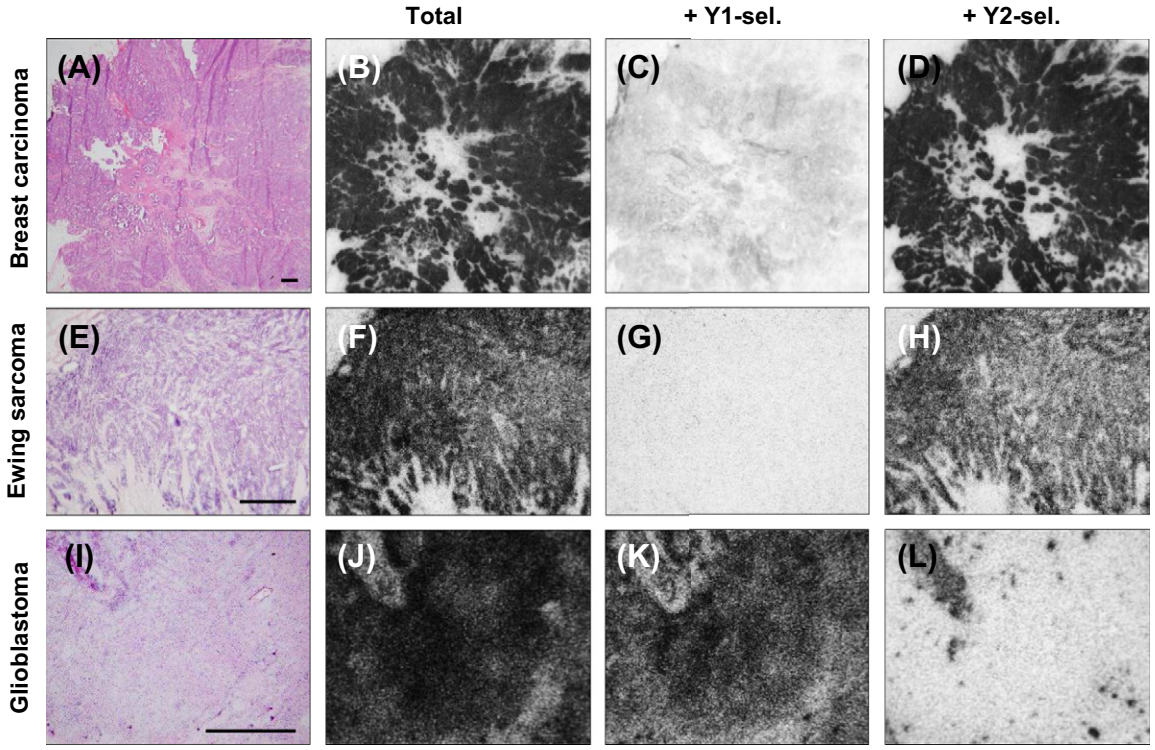

FIGURE 3 *In vitro* NPY receptor autoradiography on serial tissue sections of a breast carcinoma (A–D), an Ewing sarcoma (E–H), and a glioblastoma (I–L). A, E, I: H&E-stained tissue section showing the tumor tissues (bars = 1 mm). B, F, J: Autoradiograms showing strong total binding of ^{125}I-PYY to the tumors, corresponding to very high NPY receptor levels. C, G, K: Autoradiograms showing ^{125}I-PYY binding in the presence of 25 nM of the Y1-selective ligand [Leu^{31}, Pro^{34}]-PYY. Complete displacement of ^{125}I-PYY in the breast carcinoma (C) and the Ewing sarcoma (G) provides proof of predominant expression of the Y1 subtype. No displacement in the glioblastoma (K). D, H, L: Autoradiograms showing ^{125}I-PYY binding in the presence of 25 nM of the Y2-selective ligand PYY(3–36). No displacement in the Y1-expressing breast carcinoma (D) and Ewing sarcoma (H). Complete displacement in the glioblastoma is consistent with predominant Y2 expression (L).

mesenchymal tumors, NPY receptors have been identified in a relatively small number of cases and in low density[14,16] (Körner and Reubi, unpublished results).

NPY Receptor Expression in Intratumoral Blood Vessels

NPY receptors occur not only on tumor cells but also in intratumoral blood vessels. These vessels correspond to small arteries where the receptors are located in the muscle cells. This vascular NPY receptor expression seems to depend on the tumor type. It is particularly frequent in seminomas and liposarcomas, that is, tumors with low NPY receptor expression in tumor cells,[16,18] and also commonly observed in renal cell carcinomas and adrenal cortical adenomas, whereas it is rare or absent in breast cancers and glioblastomas.

NPY Receptor Subtypes in Tumors

Regarding NPY receptor subtypes, tumor cells express predominantly Y1 and/or Y2, and tumoral blood vessels express exclusively Y1. Although Y4 and Y5 have been detected with RT-PCR in selected tumor cell lines,[11] expression of significant amounts of these subtypes at the protein level in original tumors could be ruled out with pharmacological displacement experiments.[13,16,24] Some tumors express the same NPY receptor subtype as their nonneoplastic counterpart tissues, as is the case for adrenal cortical tumors and renal cell carcinomas. Conversely, other tumors express a different NPY receptor subtype. In particular, ductal and lobular breast carcinomas express predominantly Y1, whereas normal breast ducts and acini express Y2,[24] suggesting a switch in NPY receptor subtype expression during neoplastic transformation.

NPY Receptor Functions in Tumors

A functional role of tumoral NPY receptors is suggested by the presence of endogenous NPY in close proximity to tumoral NPY receptors in various tumor types. Indeed, NPY-containing nerve fibers are observed next to tumor cells and tumoral blood vessels particularly in renal cell carcinomas, adrenal cortical adenomas, and gliomas, suggestive of an interaction of the peripheral and central nervous system with these tumors via NPY.[12,13,15] Further,

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

concomitant NPY peptide production and NPY receptor expression in tumor cells are present in pheochromocytomas, paragangliomas, and neuroblastomas, indicative of an autocrine effect of NPY on tumor cells and a paracrine action on tumor blood vessels.

Moreover, the tumoral NPY receptors could be shown to be functional using agonist-stimulated [^{35}S]-GTPγS-binding autoradiography. This method is effective in original tumor tissues if agonist binding to a G-protein-coupled receptor induces GTP binding to the receptor–ligand complex, which represents the first step in the intracellular signal transduction cascade initiated by receptor binding. It could thus be visualized that the NPY receptors in glioblastomas, neuroblastomas, and breast cancers are indeed activated by agonist binding[12] (Cescato and Reubi, unpublished results).

The functional effects of NPY on tumors, particularly on growth, invasion, hormone release, and angiogenesis, have been investigated in different tumor types *in vitro* and *in vivo* in animal models. Regarding tumor cell proliferation, NPY may exert either stimulating or inhibitory effects, possibly depending on the tumor type, the NPY receptor subtype, or the NPY concentration. An antiproliferative effect of NPY is repeatedly observed in the Y1-expressing human Ewing sarcoma cell line SK-N-MC,[11,24] in Y1-expressing human breast cancer cell lines[1] as well as in human cholangiocarcinoma cell lines via Y2.[5] Tumor growth reduction was found to be related to Y1-mediated activation of proapoptotic caspases-3/7 in Ewing sarcoma cells.[11] Conversely, stimulation of tumor growth by NPY was reported in the Y2-expressing human neuroblastoma cell line SK-N-BE(2) *via* the MAP kinase pathway.[11] Moreover, opposite effects of NPY on tumor cell migration were described. NPY inhibited migration of a Y2-expressing cholangiocarcinoma cell line,[5] whereas it stimulated it in a Y5-expressing breast cancer cell line.[32] Further, NPY may possibly affect hormone production or release from tumor cells, based on the high NPY receptor expression in steroid hormone producing tissues.

NPY may modulate not only tumor cell functions but also tumoral blood supply via several pathways. First, NPY may stimulate angiogenesis. This has extensively been investigated in normal and ischemic nonneoplastic tissues, where it may require complex activation of several NPY receptors, including 1 and Y2. Similarly, it was repeatedly shown that NPY may also induce tumoral angiogenesis: Human Ewing sarcoma and neuroblastoma cell lines xenografted in mice show increased tumor vascularity after treatment with NPY.[11] Second, it may also be speculated that NPY may have a negative effect on tumoral blood perfusion. Indeed, NPY physiologically exerts potent vasoconstrictive actions on arterial blood vessels via Y1. Similar effects may occur in intratumoral small arteries that often exhibit a prominent Y1 expression and, moreover, are accompanied by NPY-containing nerve fibers.

Of importance, the data on possible NPY-receptor-mediated actions of NPY in tumors are derived from cell line models. The *in vivo* significance of tumoral NPY receptors in humans is presently unknown.

In vivo NPY-Receptor Targeting of Tumors

By analogy to somatostatin receptor targeting of tumors, the use of NPY analogs to target NPY receptors for tumor diagnostics and therapy has been proposed. As the effects of NPY itself on tumor biology such as growth or hormone release are not yet fully elucidated, a tumor targeting with NPY analogs coupled with a radioactively labeled nuclide or a chemotherapeutic agent is more timely and promising. First choice candidate tumors for such applications are breast carcinomas, glioblastomas, and Ewing sarcomas based on their very high NPY receptor levels in the tumor cells. These tumors seem to be suitable for an NPY-receptor-targeted imaging due to the favorable tumor-to-background ratio of NPY receptor levels at the sites of tumor origin and at common sites of metastasis such as lymph nodes, liver, and lung[12,24] (Körner and Reubi, unpublished results). NPY analogs suitable for this purpose are developed in increasing numbers. An NPY analog labeled with ^{99m}Tc has been tested in the first clinical pilot study of NPY receptor targeting in breast carcinoma patients.[10] The preliminary results are favorable: primary tumors and metastases could be visualized, and no side effects occurred. Thus, the proof of principle of NPY receptor targeting of tumors is provided. Moreover, this also represents the basis for an NPY receptor-targeted therapy using NPY analogs coupled with either a cytotoxic radionuclide or a chemotherapeutic agent. Another attractive strategy for therapy may represent the targeting of tumor blood vessels, alone or together with NPY-receptor-expressing tumor cells. Finally, as many of the NPY receptor-expressing tumors can express multiple peptide receptors concomitantly, NPY receptors may be suitable for a multireceptor targeting with a cocktail containing NPY and other therapeutic peptide analogs directed against various peptide hormone receptors. For such a multireceptor approach, good candidate tumors seem to be breast tumors targeted with NPY and bombesin analogs.

Chapter 76

VIP/PACAP Receptors

Terry W. Moody and Robert T. Jensen

ABSTRACT

VIP and PACAP function in a paracrine manner in the normal brain, pituitary, as well as the digestive, cardiovascular and respiratory systems. VIP and PACAP function in an autocrine manner, however, in cancer to stimulate cellular proliferation. VIP and PACAP bind with high affinity to human breast cancer and lung cancer cell lines. $VPAC_1$ and PAC_1 receptor (R) mRNA is present in lung and breast cancer cells. VIP and PACAP increase cAMP in breast and lung cancer cells, whereas PACAP causes phosphatidyl inositol (PI) turnover leading to elevated cytosolic Ca^{2+}. VIP and PACAP cause the tyrosine phosphorylation of numerous proteins, for example, the epidermal growth factor receptor, mitogen-activated protein kinases, and focal adhesion kinase. The growth of lung cancer cells is stimulated by VIP or PACAP addition, whereas $VPAC_1$-R antagonists such as VIPhybrid or PAC_1-R antagonists such as PACAP(6–38) inhibit proliferation. These results suggest that $VPAC_1$-R and/or PAC_1-R are molecular targets for breast and lung cancer.

INTRODUCTION

Pituitary adenylate cyclase–activating polypeptide (PACAP) and vasoactive intestinal peptide (VIP) are 28 and 27 amino acid peptides, respectively, which are biologically active in the normal brain, pituitary, digestive system, cardiovascular system, and respiratory system (see the chapters in these sections of the book). VIP and PACAP function as autocrine growth factors in cancer.[21] Breast cancer patients (40,000 women in the United States die annually) and lung cancer patients (160,000 patients die annually in the United States) are traditionally treated with chemotherapeutic agents and radiation therapy.[5] Because the 5-year survival rate for lung cancer patients is only 16%, new therapeutic approaches are needed. In preclinical studies, PACAP receptor antagonists such as PACAP(6–38) or VIP receptor antagonists such as VIPhybrid (VIPhyb) inhibit the growth of breast and lung cancer cells.[23,35] These results suggest that VIP/PACAP receptors may be used to impair breast and/or lung cancer progression.

The actions of VIP and PACAP are mediated by three G protein–coupled receptors (GPCR). The human $VPAC_1$ receptor (R), which binds PACAP and VIP with high affinity, is a 457-amino acid glycoprotein.[11] It has 49% homology with the human $VPAC_2$-R, which contains 438 amino acids and binds PACAP and VIP with high affinity.[9] The PAC1-R contains 467 amino acids and binds PACAP but not VIP with high affinity.[26,30] All breast cancer cells examined contain $VPAC_1$-R.[7,34] $VPAC_1$-R and PAC_1-R immunoreactivity is present in all breast tumors examined, whereas 50% of the tumors have $VPAC_2$-R immunoreactivity.[29] $VPAC_1$-R and PAC_1-R immunoreactivity are more abundant in lung cancer biopsy specimens than $VPAC_2$-R.[2] By *in vitro* autoradiographic techniques, the $VPAC_1$-R is abundant in bladder, breast, colon, liver, lung, prostate, stomach, thyroid, and uterine cancer tumors, whereas the $VPAC_2$-R is present in stomach leiomyomas.[28] PAC_1-R predominate in glioblastoma, neuroblastoma, adrenal, and pituitary cancer.[28] Seven of 8 lung cancer cell lines examined have $VPAC_1$-R and PAC_1-R mRNA including cell line NCI-H1299, whereas only 1 cell line (NCI-H345) has $VPAC_2$-R mRNA.[18] This review will focus on $VPAC_1$-R and PAC_1-R as molecular targets in breast and lung cancer.

$VPAC_1$-R

A large protein groove may be present in the $VPAC_1$-R whereby acidic amino acids (Glu^{36} and Asp^{68}) interact electrostatically with basic VIP amino acids (Arg^{14}, Lys^{15} and Lys^{21}).[24] Substitution of Ala for VIP amino acids at positions 1, 6, 12, 14, or 23 reduce binding affinity to $VPAC_1$-R by more than 2 orders of magnitude. Substitution of Ala for VIP amino acids at positions 3, 5, 7, 10, 15, 20, or 21 reduce binding affinity to $VPAC_1$-R by more than 1 order of magnitude. The analog ($Ala^{2,8,9,11,19,24,25,27,28}$) VIP is a potent $VPAC_1$-R agonist, which is resistant to degradation.[10] A VIP analog ($Ala^{2,8,9,11,19,24,25,27}$, Norleucine^{17}, Lysine^{28})VIP, (ANK) VIP,[17] inhibits specific ^{125}I-VIP binding to lung cancer cells with an IC_{50} value of 2nM (Table 1). The topoisomerase inhibitor camptothecin (CPT) coupled to the C-terminal of (ANK)VIP with a linker (L2) inhibits specific ^{125}I-VIP binding to lung cancer cells with an IC_{50} value of 150nM.[22] (ANK)VIP-L2-CPT functions as a $VPAC_1$-R agonist that is cytotoxic for lung cancer cells. The N-terminal nonapeptide of VIP and N-terminal pentapeptide of PACAP-38 can be

TABLE 1 Binding of VIP/PACAP-Like Peptides to Lung Cancer Cells

	IC_{50}, nM	
Addition	^{125}I-VIP binding	^{125}I-PACAP-27 binding
PACAP-27	5 ± 1	3 ± 0.4
PACAP(6–38)	>1000	30 ± 4
VIP	11 ± 2	>1000
VIPhyb	300 ± 40	700 ± 100
VIP-LALA-E	500 ± 50	>1000
(ANK)VIP	2 ± 0.2	>1000
(ANK)VIP-L2-CPT	150 ± 20	>1000

The IC_{50} (nM) to inhibit specific ^{125}I-VIP or ^{125}I-PACAP-27 binding to NCI-H1299 lung cancer cells is indicated. The mean value ± S.D. of 3 experiments each repeated in quadruplicate is indicated. Abbreviations: Leu, L; Ala, A; nor-Leu, N; Lys, K; ellipticine, E; camptothecin, CPT; linker 2; L2. The structures of VIP and PACAP are.
VIP: His-Ser-Asp-Ala-Val-Phe-Thr-Asp-Asn-Tyr-Thr-Arg-Leu-Arg-Lys-Gln-Met-Ala-Val-Lys-Lys-Tyr-Leu-Glu-Ser-Ile-Leu-Asn-NH2.
PACAP-27: His-Ser-Asp-Gly-Ile-Phe-Thr-Asp-Ser-Tyr-Ser-Arg-Tyr-Arg-Lys-Gln-Met-Ala-Val-Lys-Lys-Tyr-Ala-Ala-Val-Leu-NH2.
Sequence homologies relative to VIP are underlined.

deleted resulting in VIP(10–28) and PACAP(6–38), which function as antagonists for $VPAC_1$-R and PAC_1-R, respectively.[14] Chimeric peptides such as neurotensin$^{6–11}$ VIP$^{7–28}$ (VIPhyb) were developed.[23] Table 1 shows that VIPhyb is a broad spectrum antagonist that binds to $VPAC_1$-R and PAC_1-R. PG 97-269, a chimeric peptide of VIP and GHRH, has 300-fold selectivity for $VPAC_1$-R relative to $VPAC_2$-R.[25] PG 97-269 inhibits the proliferation of lung cancer cells and antagonizes the increase in cAMP caused by VIP. Subsequently, the C-terminal of the antagonist was PEGylated resulting in a long-lasting $VPAC_1$-R antagonist.[25]

When VIP agonists bind to lung cancer cells, they are rapidly internalized at 37°C. Previously, we found that the $VPAC_1$-R could deliver VIP-chemotherapeutic conjugates into breast and lung cancer cells.[17] The C-terminal of VIP was conjugated with a linker containing elipticine (VIP-LALA-E) and on addition to lung cancer cells VIP-LALA-E functions as an agonist in that it causes the elevation of cAMP and increased c-fos mRNA. VIP-LALA-E is metabolized by breast cancer enzymes with E resulting in the inhibition of topoisomerase, leading to cancer cell apoptosis. The $VPAC_1$-R is localized to the plasma membrane and nucleus of breast cancer cells.[32] Traditionally, topoisomerase inhibitors prevent unwinding of DNA in the nucleus before replication of DNA. Unfortunately, toxic side effects occur because the topoisomerase inhibitors kill both normal and cancer cells. Our strategy is to use VPAC1-R, which is enriched in cancer cells, to deliver E. Alternatively, VIP was conjugated to a linker containing camptothecin (CPT). The resulting VIP-L2-CPT binds with high affinity to lung cancer cells and functions as an agonist. VIP-L2-CPT is internalized by lung cancer cells, and the CPT is released into the cells after metabolism by lysozomes. Thus, $VPAC_1$-R can be used to deliver chemotherapeutic drugs into cancer cells. Another chapter in this section of the book by Schally's group indicates that the LHRH-R can be used to deliver doxorubicin to cancer cells.

PAC_1-R

The PAC1-R regular (Reg) form contains 467 amino acids; however, splice variants (SVs) occur in intracellular loop 3 (IC3).[30] SV-1 or the hip receptor has a 28 amino acid insert in IC3. SV-2 or the hop receptor (HOP1) has a different 28-amino acid insert in IC3. SV-3 or the hip-hop receptor has both 28 amino acid inserts in IC3. PACAP addition to cells transfected with PAC_1-R SV-2 strongly increases PI turnover, whereas cells transfected with Reg, SV-1 or SV-3 had a weaker Ca^{2+} response.[27] Also, extracellular loop 1 (EC1) deletions or SV insertions exist.[15] Ushiyama et al.[31] expressed variants of the EC1 domain (N or S form) and variants of IC3 (Reg or HOP1). The resulting 4 PAC_1-R isoforms (N/Reg, N/HOP1, S/Reg or S/HOP1) binds PACAP-27 with high affinity. N/Reg, S/Reg, or S/HOP1 but not N/HOP1 strongly increases cAMP. These results indicate that alterations in EC1 or IC3 do not affect PAC_1-R binding but do affect second messenger production. Table 1 shows that PACAP and PACAP(6–38), but not VIP, inhibit ^{125}I-PACAP-27 binding to NCI-H1299 cells with high affinity (IC_{50} = 3 and 30nM, respectively). The results indicate that biologically active $VPAC_1$-R and PAC_1-R are present on lung cancer cells.

SECOND MESSENGERS

Upon binding VIP, the $VPAC_1$ receptor interacts with a stimulatory guanine nucleotide binding protein (Gs), which activates adenylyl cyclase.[18] The addition of 10nM VIP increases the cAMP 10–30-fold within minutes after addition to human breast or lung cancer cells. The elevated cAMP activates protein kinase (PK) A, resulting in increased phosphorylation of protein substrates such as Creb.[8] Figure 1 shows that when Creb is phosphorylated, it alters gene expression. Nanomolar concentrations of VIP cause increased expression of c-fos, c-jun, and c-myc oncogenes 1h after the addition to lung or breast cancer cells.[35] After translation, the c-fos and c-jun proteins may form heterodimers and activate AP-1 sites on the 5′ regulatory region of growth factor genes such as VEGF. In this regard, 10nM VIP increased VEGF expression in lung cancer cells after 4h.[3] The VEGF may be secreted from cancer cells and bind to receptors on endothelial cells, facilitating tumor

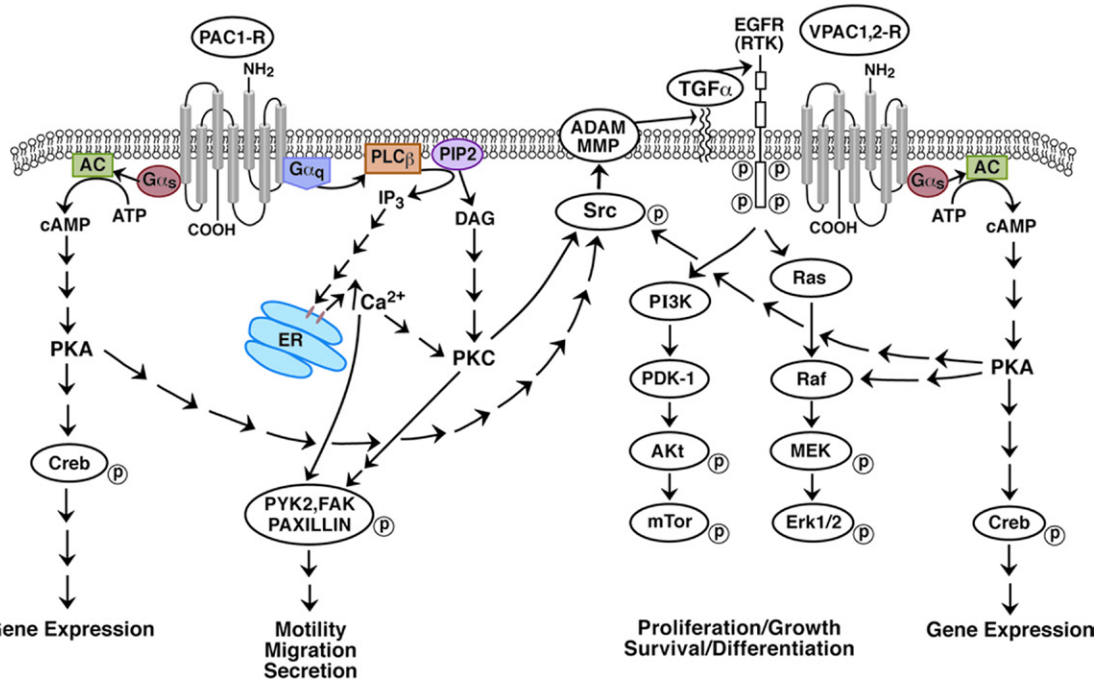

FIGURE 1 Signal transduction mechanisms for $VPAC_1$-R, $VPAC_2$-R and PAC_1-R. Activated $VPAC_1$-R and $VPAC_2$-R interacts with Gαs stimulating adenylyl cyclase (AC) leading to PKA activation, Creb phosphorylation and altered gene expression. PKA activates MMP and/or ADAM releasing TGFα from its precursor protein in the plasma membrane. VIP addition to lung or breast cancer cells causes EGFR and Her2/Neu phosphorylation. The phosphorylated EGFR causes Ras and Raf activation resulting in phosphorylation of MEK and Erk1/2 leading to proliferation. The phosphorylated EGFR causes tyrosine phosphorylation of PI3K resulting in activation of PDK-1, Akt and mTor phosphorylation leading to cancer cellular survival. Activated PAC_1-R interacts with Gαs and Gαq leading to phospholipase (PL) C stimulation and PI turnover. The IP_3 and DAG released cause the elevation of cytosolic Ca^{2+} and PKC activation, respectively. The PKC or Ca^{2+} increased tyrosine phosphorylation of FAK, PYK2, and paxillin leading to altered cellular secretion and migration.

angiogenesis. VIPhyb blocks the increase in cAMP and c-fos mRNA caused by VIP addition to lung cancer cells.[35]

When PACAP-27 binds to the PAC_1-R in NCI-H1299 cells, it causes an increase in the cAMP. Also, PACAP-27 addition to NCI-H1299 or H838 cells causes increased PI turnover (Fig. 1). The diacylglycerol (DAG) released activates PKC, whereas the inositol-1,4,5-trisphosphate (IP_3) released causes Ca^{2+} release from the endoplasmic reticulum (ER) resulting in a transient increase in cytosolic Ca^{2+}. Addition of PACAP-27 to NCI-H1299 cells increases cytosolic Ca^{2+} from 150 to 200nM within 15s.[18] The actions of PACAP-27 on cAMP and PI turnover are antagonized by addition PACAP(6–38) to lung or breast cancer cells.[14]

PROTEIN PHOSPHORYLATION

VIP and PACAP increase the tyrosine phosphorylation of a wide variety of proteins. In GH4C1 pituitary cells, VIP and PACAP increases extracellular signal-regulated kinase (Erk1/2) phosphorylation that is blocked by H89, a PKA inhibitor but not GF109203X, a PKC inhibitor.[13] Addition of PACAP-27 to NCI-H1299 lung cancer cells increases phosphorylation of Erk1/2 3-fold after 5min.[20] The increase in P-Erk1/2 caused by PACAP-27 addition to NCI-H1299 cells is inhibited by PACAP(6–38) or PD98059 (MEK inhibitor). VIP stimulates HT29 cell proliferation and induced Erk1/2 activation and activation of the small GTPase Rap1 and the 95kDa isoform of the serine/threonine kinase Raf.[1]

Figure 1 shows that VIP causes tyrosine phosphorylation of receptor tyrosine kinsases (RTK). These include the epidermal growth factor (EGF)R and HER2/Neu in MDA-MB-468 breast cancer cells.[33] The effects of VIP were reversed by JV-1-53, a nonselective antagonist of $VPAC_1$-R and $VPAC_2$-R. The transactivation of the EGFR caused by VIP is reversed by PKA inhibitors (H89) or disintegrin and metalloprotease (ADAM) inhibitor (TAPI-1).[33] Src inhibitors, e.g. PP2, prevent VIP from increasing tyrosine phosphorylation of the EGFR. Figure 1 shows that Src may be activated by PKA or PKC. The results suggest that VIP addition to breast cancer cells may cause release of an endogenous EGFR ligand, for example, transforming growth factor (TGF)α resulting in the tyrosine phosphorylation of the EGFR. When TGFα binds to the EGFR, PI 3K is phosphorylated leading to activation of PDK-1. Figure 1 shows that Akt and mTor are then phosphorylated increasing cancer cell survival.

The ability of PACAP to cause transactivation of the EGFR in lung cancer cells is reversed by gefitinib, an EGFR tyrosine kinase inhibitor (T. Moody, unpublished). Further,

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

the EGFR (gefitinib) or HER2/Neu (trastuzumab) tyrosine kinase inhibitors reduces the growth of SK-BR-3 and BT-474 breast cancer cells.[4] Because the EGFR and HER2/Neu can form heterodimers, VIP or PACAP can result in the tyrosine phosphorylation of the EGFR and HER2/Neu. These results suggest that some of the growth effects of VIP and PACAP may result from RTK transactivation.

VIP and PACAP may function as promoters of lung carcinogenesis. Subsequently, lung cancer cells undergo metastasis to other organs such as the liver, lymph nodes, bone, and/or brain. Metastasis is increased by activation of protein tyrosine kinase (PYK) 2B and focal adhesion kinase (FAK). PACAP-27 causes paxillin and PYK2 tyrosine phosphorylation in human monocytes.[6] PACAP addition to monocytes significantly increases hydrogen peroxide and superoxide production, which is reduced by the phospholipase C inhibitor U73122.[6] U73122 addition to monocytes blocks PI turnover, reducing the ability of PACAP to increase PYK2 or paxillin tyrosine phosphorylation [T. Moody, unpublished]. PYK2 is a cytosolic tyrosine kinase that interacts with the SH2 domain of Src, whereas paxillin coordinates Rho family GTPases, which regulate the actin skeleton (Fig. 1). PACAP modulates NMDA receptors in CA1 hippocampal neurons as a result of Src tyrosine phosphorylation.[16] The results suggest that PACAP causes PI turnover and that both PKC activation and Ca^{2+} can stimulate Src. Activation of Src results in phosphorylation of FAK on multiple residues, causing an increase in FAK activity and its recruitment to the actin cytoskeleton. G-proteins can also activate the GTPase, Rho, which participates in cytoskeletal reorganization and tyrosine phosphorylation of FAK. When these cascades are activated, actin stress fiber formation occurs and resulting in phosphorylation of cytoskeletal proteins paxillin, p130Cas and Crk. Proteins recruited to the multimolecular signaling complex include GSK, SRK, paxillin, Grb2/Sos, p130Cas/Crk, and PI 3K. PACAP addition to PC12 pheochromocytoma cells causes phosphorylation of the tyrosine kinase TrkA, which was reversed by K252a, a tyrosine kinase inhibitor, and PP1, an inhibitor of Src.[12] The results indicate that VIP and PACAP cause the tyrosine phosphorylation of a wide variety of proteins.

PROLIFERATION

VIP or PACAP stimulate the clonal growth of breast or lung cancer cells.[18] The increase in growth is reversed by VIPhyb.[19] VIPhyb, however, inhibits the basal growth of breast or lung cancer cells. These results suggest that VIP and/or PACAP are autocrine growth factors for breast and lung cancer cells. Taxol, which interacts with microtubules, inhibited the proliferation of MDA-MB-231 breast cancer cells and was synergistic with VIPhyb at inhibiting breast cancer cellular proliferation. Table 2 shows that 1μM VIPhyb reduced the clonal growth of MCF7 cells to 74%, whereas 3ng/ml taxol reduced the clonal growth to 34%. The combination of VIPhyb and taxol reduced MCF7 growth to 27%. In nude mice bearing MDA-MB-231 xenografts *in vivo*, 0.4mg/kg of VIPhyb injected daily reduces tumor volume by 25% and 6mg/kg taxol reduces tumor volume by 30%. The combination of VIPhyb + taxol reduces tumor volume by 65%. These results indicate that VIPhyb increased the potency of taxol to cause apoptosis of breast cancer cells *in vitro* and *in vivo*.

TABLE 2 Effects of VIPhyb and Taxol on Breast Cancer Proliferation

Addition	% Proliferation	
None	100 ± 9	100 ± 12
VIPhyb	74 ± 6	75 ± 9
Taxol	34 ± 4	70 ± 8
VIPhyb + Taxol	27 ± 3	35 ± 5

The % proliferation of MDA-MB-231 was determined *in vitro* using the clonogenic assay and 0.1μM VIPhyb and/or 3ng/ml taxol. The mean value ± S.D. of 4 determinations each repeated in triplicate is indicated. The % proliferation was calculated based on *in vivo* data using nude mice with MDA-MB-231 tumors. VIPhyb (0.4mg/kg) was injected daily s.c, whereas taxol (6mg/kg) was injected daily i.p. The mean value ± S.D. of 6 determinations is indicated 5 weeks after drug treatment.

SUMMARY

VIP and PACAP are peptide growth factors synthesized in breast and lung cancer cells. After secretion, they bind to cell surface $VPAC_1$-R and/or PAC_1-R leading to second messenger production. The $VPAC_1$-R interacts with Gs leading to increased cAMP, which activates PKA. The PKA may activate Src and/or ADAM leading to EGFR and HER2/Neu tyrosine phosphorylation. Thus, GPCR can transactivate RTK leading to increased breast cancer and lung cancer proliferation. These results suggest that some of the effects of VIP on proliferation are mediated by RTK. It remains to be determined if $VPAC_1$-R antagonists and RTK inhibitors are synergistic at inhibiting breast cancer proliferation.

The PAC_1-R signaling pathway involves PI turnover in addition to adenylyl cyclase stimulation. After metabolism by PLC, IP_3 plus DAG result leading to increased lung cancer cytosolic Ca^{2+} and PKC activity, respectively. Src is activated resulting in tyrosine phosphorylation of numerous proteins such as FAK and paxillin, which play a role in the formation of focal adhesions. Also, SFK activation results in Raf, MEK, and Erk1/2 phosphorylation leading to lung cancer proliferation. It remains to be determined if PAC_1-R antagonists and Src inhibitors are synergistic at inhibiting tumor growth.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

$VPAC_1$-R antagonists are synergistic with chemotherapeutic agents at inhibiting breast and lung cancer proliferation. Alternatively, VIP-chemotherapeutic conjugates were synthesized, which were internalized into breast and lung cancer cells containing $VPAC_1$-R by receptor-mediated endocytosis. New VIP-chemotherapeutic conjugates need to be developed, which bind with high affinity to VPAC1-R and are resistant to degradation by blood proteases.

The $VPAC_1$-R is present in high densities (100,000 per cell) in almost all breast and lung cancer cell lines examined. ^{123}I and ^{99m}Tc-labeled VIP analogs have been used for imaging tumors in colon and breast cancer patients. It remains to be determined whether a radioactively labeled VIP analog can be used for early detection of breast and/or lung cancer. Alternatively, the $VPAC_1$-R can be used to deliver VIP-chemotherapeutic conjugates into breast and lung cancer cells. In preclinical studies, VIP-L2-CPT inhibited the growth of lung cancer tumors, and it remains to be determined whether VIP-L2-CPT inhibits tumor growth in clinical studies.

Chapter 77

Antiadhesin Peptide-Based Vaccines for *Pseudomonas aeruginosa*

Wendy J. Hartsock, Clifton Hackbarth and Robert S. Hodges

ABSTRACT

Pseudomonas aeruginosa (*Pa*), a ubiquitous Gram-negative bacterial pathogen, is responsible for a growing number of hospital-acquired infections and is highly resistant to current antibiotics. Synthetic peptide-based vaccines that target functionally relevant motifs such as the receptor binding domain (RBD) of the pilin protein of *Pa*, which is responsible for bacterial adhesion to host receptors, are a novel alternative to traditional vaccines and antibiotics to combat *Pa* infection. Structural features in the RBD are conserved across multiple strains of *Pa* making the pilin RBD an excellent candidate to design a consensus sequence immunogen. Direct comparison of a synthetic RBD peptide and its parent pilin protein shows that the peptide is able to elicit higher titer antisera against the native RBD. The consensus sequence vaccine generates highly protective antibodies in active immunization studies using a mouse model of *Pa* infection. The results show that synthetic peptides have clear advantages over traditional subunit, whole-killed, or live attenuated vaccines against *Pa*.

SIGNIFICANCE AND BACKGROUND

Pseudomonas aeruginosa (*Pa*) is an opportunistic Gram-negative pathogen that has achieved superbug status and is a member of the so-called 'ESKAPE' (*Enterococcus faecium*, *Staphylococcus aureus*, *Klebsiella pneumoniae*, *Acinetobacter baumannii*, *Pseudomonas aeruginosa*, and *Enterobacter* species) pathogens[2] that pose an increasing threat to human health as multidrug resistant microorganisms.

Pa is a ubiquitous organism that is isolated from terrestrial and aquatic environments as well as plants and animals; it can colonize medical equipment, including ventilators, endoscopes, and implants; it can bind to and grow on stainless steel and plastics and can even grow in distilled water. *Pa* expresses multiple virulence factors that are classified as exoproducts or constitutive factors. Exoproducts, which are involved in bacterial invasion, immune suppression, and antibiotic degradation, consist of proteases, exotoxins, β-lactamases, and several other extracellular products. Constitutive factors are involved in adhesion, molecular transport, and metabolism and include the type-IV pili, flagellum, outer membrane proteins, and lipopolysaccharide. The first step in *Pa* infection is the adhesion of the bacterium to target cells by the type-IV pili. The receptor-binding domain (RBD) located in the tip of the pilus of *Pa* specifically interacts with the receptors on tracheal, buccal, and corneal epithelial cells and epidermal cells.[33] Infections are common in the respiratory tract, urinary tract, eye, and extremities of immunocompromised patients but do not occur in healthy individuals.[30] *Pa* is a major agent of nosocomial infections in the United States and is of particular burden to cystic fibrosis (CF) patients, burn victims, and soldiers injured in combat.

Common antipseudomonals include β-lactams, aminoglycosides, and fluoroquinolones; *Pa* has mechanisms to render each of these drug classes ineffective.[3,34] *Pa* possesses inherently low susceptibility to many antibiotics as a result of the low permeability of its outer membrane. It is highly adaptable and readily develops resistance to antibiotics by nearly all known mechanisms of bacterial resistance including expression of antibiotic destroying enzymes, mutation of drug targets, modification of outer membrane proteins, changes to membrane composition, and overexpression of efflux pumps. *Pa* has several intrinsic mechanisms of resistance and is also capable of acquiring resistance through transfer of genetic information.

New regimens consisting of various combinations of "old" drugs are currently used to treat multidrug resistant (MDR) strains, but the inevitable failure of our current arsenal of antibiotics to treat MDR *Pa* necessitates the discovery of new therapeutic options.[21,30] Vaccination may be the more appropriate choice to diminish *Pa* infections given the ability of *Pa* to readily develop resistance to multiple antibiotics.

PSEUDOMONAS AERUGINOSA PILI AS A VACCINE TARGET

The *Pa* pilus is a key virulence factor[12] as binding to the oligosaccharide (GalNAcβ(1-4) Gal) of the target receptors (asialo-GM1 and asialo-GM2) is the first step in establishing infection. Therefore, a vaccine that elicits antibodies that target the RBD of the type-IV pili of *Pa* would prevent bacterial colonization and effectively prevent infection.

Traditional vaccines that comprise whole-killed *Pa*, live attenuated *Pa*, or whole pilin protein have shown efficacy in clinical trials.[11,31,32] However, each suffers complications arising from safety concerns and complications of production as well as the likelihood of antigenic competition and low crossreactivity. Antigenic competition results from the inhibition of the desired immune response against certain antigens or determinants when multivalent vaccines or peptide cocktails are used to immunize an individual.[5] An example of such antigenic competition was shown when multivalent vaccines targeting the type-IV pilus of *Dichelobacter nodosus* were administered to sheep to combat footrot.[16–18] Of the nine serogroups targeted by a multivalent vaccine comprised of recombinant pili, only a limited number actually elicit a robust immune response. Monovalent vaccines show superior protection against certain *D. nodosus* serogroups compared with the multivalent vaccine; the levels of antibody elicited against specific serogroups by multivalent vaccines consisting of six or more *D. nodosus* pili are reduced compared with antibody levels generated by their monovalent counterparts. Because the pili of *D. nodosus* (type-IV) are structurally similar to those of *Pa* (also type-IV), it is reasonable to assume that vaccines that target the type-IV pili of *Pa* probably also suffer from antigenic competition. This would probably occur for both traditional multivalent vaccines and synthetic peptide-based cocktail vaccines.

Thus, although synthetic peptide-based vaccines have several inherent advantages over traditional vaccines,[28] it is still necessary to design an appropriate peptide immunogen that elicits crossreactive antibodies but avoids antigenic competition. One of the main advantages of peptide vaccines is the ability to target regions of proteins that have evolved to maintain a critical function. The immunogenicities of such regions are often masked in native structures either as a result of antigenic domination by other more immunogenic regions or more accessible regions. The functional importance of these regions dramatically reduces the organism's ability to create mutations to evade antipeptide antibodies, and such mutations most probably produce dysfunctional proteins with the complete loss of function and virulence. One concern regarding peptide vaccines is that to elicit antibodies that react with the native epitope, the peptides should structurally mimic the native proteins from which they are derived and therefore may require conformational constraints to maintain the structure in the peptide immunogen. A second issue that can be potentially detrimental to the efficacy of peptide-based vaccines is the inherently low immunogenicty of small peptides. To circumvent poor immunogenicity, peptides are commonly conjugated to highly immunogenic carrier proteins such as tetanus toxiod (TT) or keyhole limpet hemocyanin (KLH).[29] The disulfide-bridged loop of the *Pa* pilin protein RBD is an intrinsically optimized epitope for the design of a synthetic peptide-based vaccine because it consists of a continuous peptide that has secondary structural elements incorporated into the sequence in the form of β-turns and a β-strand (Fig. 1). Still, an effective synthetic peptide-based vaccine

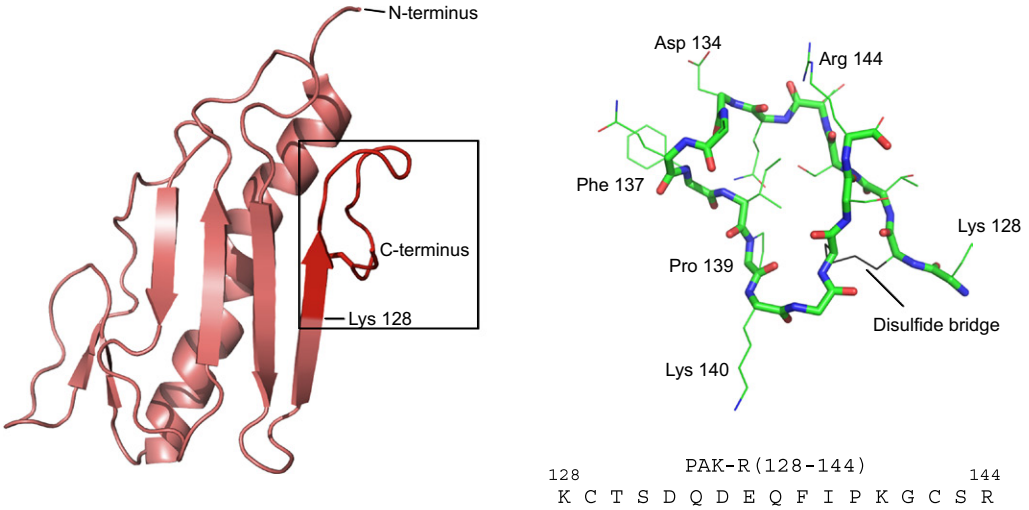

FIGURE 1 Ribbon diagram of the truncated PAK pilin protein monomer (PAK-R, residues 29–144) and the RBD is boxed (left), stick diagram of the PAK pilin RBD (PAK-R, residues 128–144) (top right) and sequence (bottom right). Residues Asp134 and Phe137 that form the type-I β-turn as well as residues Pro139, Lys140, and Cys142, which comprise the type-II β-turn and residues Lys128 and Asp132 of the β-strand are indicated along the loop (top right).

based on the RBD must elicit antibodies that crossreact with pilin from different strains of *Pa*. Because multivalent vaccines composed of synthetic peptides targeting the pili of various *Pa* strains have the potential for antigenic competition,[5] we have focused much of our research efforts on the consensus sequence approach, which avoids antigenic competition.

The type-IV pili are filamentous structures that comprise thousands of monomeric pilin proteins arranged in a helical array whereby one turn comprises 5 protein monomers (Fig. 2).[10] Pili are polar tubes that are typically 5.2nm in outer diameter with a 1.2nm central channel and an average length of 2.5μm.[9,26] Structural elements of the type-IV pilin proteins include an N-terminal extended α-helix, a globular head region, a major β-sheet, a minor β-sheet, and a C-terminal disulfide-bridged loop (Fig. 1). The loop structure is either 14 residues or 19 residues long (including the Cys residues) depending on the *Pa* strain. The 14-residue loops, which comprise residues 129–142, consist of two Cys residues at positions 129 and 142, conserved or semiconserved residues at positions 131, 134, 137, and 139–141 and variable residues at positions 130, 132, 133, 135, 136, and 138 (Fig. 3). The N-terminus of the pilin protein monomer (residues 1–28) is responsible for oligomerization. Truncation of the pilin protein at the N-terminus allows for an X-ray structure of the *Pa* strain K (PAK) pilin (29–144),[15] which shows prominent secondary structures in the RBD loop region including a type-I β-turn that comprises residues Asp134 through Phe137, a type-II β-turn that comprises residues Pro139-Cys142 and a β-strand that comprises residues 128–132. The loop, which is exposed only at the tip of the pilus, is involved in pilus assembly and importantly in receptor recognition and surface binding.[13,22,24,33] The structural elements in the RBD are conserved in pilin proteins of various strains, specifically, the β-turns of the C-terminal disulfide loop.[1] NMR solution structures of 17 residue peptides of PAK,[25] PAO and KB7[7] pilin (128–144) and a 23-residue peptide from P1 pilin (126–148)[8] showed that all these peptides possessed consecutive type-I and type-II β-turns. The diversity of sequence of the RBDs was addressed by obtaining sequence information from 100 clinical *Pa* isolates with 14-residue disulfide loop regions. The sequence of the five native strains shown in Fig. 3, represents essentially 100% of the residues found in the RBDs at each position from 128 to 144. There is limited diversity in the six variable positions shown in Fig. 3 (positions 130, 132, 133, 135, 136, and 138). Only 3 different residues are observed at positions 130, 132, 133, and 136 and only 4 different residues at positions 135 and 138. These results further support the idea that the development of a consensus sequence vaccine is feasible.

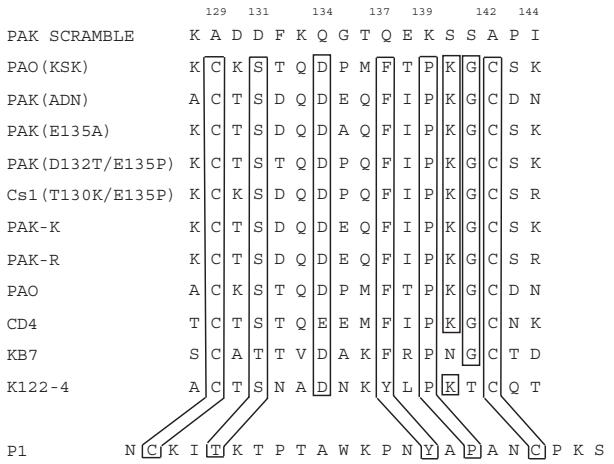

FIGURE 3 Amino acid sequences of the PAK scramble peptide, PAO(KSK) and PAK(ADN) mutants, Ala substituted PAK analog (E135A) and disubstituted PAK analog (D132T/E135P), the consensus peptide (Cs1: T130K/E135P) and seven *Pa* strains (PAK-K, PAK-R, PAO, CD4, KB7, K122-4, and P1). The sequences of PAK-K and PAK-R are identical to the exception of residue 144, which is Lys in PAK-K and Arg in PAK-R. The scramble peptide, Ala substituted analog and PAO(KSK) mutant were designed based on the PAK-K sequence, whereas the Cs1 peptide was designed from the PAK-R sequence. The boxed residues correspond to identical positions in the sequences and conservative amino acid substitutions.

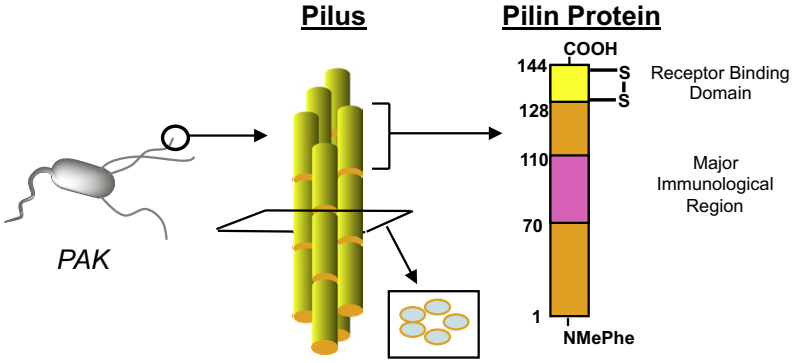

FIGURE 2 Cartoon diagram of PAK showing pili, which are located on the surface of the bacterium (left) and a magnified view of the pilus (middle), which consists of pilin protein monomers arranged in a helical array with five-fold-symmetry (cross section). The C-terminus of the pilin protein monomer (right) houses the RBD between residues 128 and 144. The major immunological region is located between the residues 70 and 110.

SYNTHETIC CONSENSUS SEQUENCE PEPTIDE-BASED *PSEUDOMONAS AERUGINOSA* VACCINES

The antibodies to the RBD of the pilin protein are able to block and prevent the infection process.[23] Alanine substitution of the peptides representing the RBD of *Pa* strains PAK and KB7 were used to map the residues responsible for adhesion to the target receptor (known as adhesintopes).[35] NMR solution structures of these regions show that although there was sequence variation between the two strains, the structural elements are similar, probably as a result of compensatory mutations that allow changes to the RBD sequence without hindering interactions between the pilus and its target. As there is sequence and structural homology in the RBD and all *Pa* strains examined bind to the same cell surface receptor, we reasoned out that it should be possible to produce a synthetic peptide consensus sequence vaccine that would provide crossreactive antibodies from a single peptide immunogen. These antibodies would inhibit the adherence of all known strains of *Pa* and prevent *Pa* infection. Early work on *Pa* in the Hodges laboratory showed that antisera raised against a native PAK C-terminal pilin peptide (residues 128–144) also bound a PAO peptide (residues 128–144) and the PAO pilin. It was possible to enhance antibody crossreactivity to various strains of *Pa* by manipulating the amino acid sequence of the peptide immunogen.[4–6] We have developed novel technology to measure antibody affinity by surface plasmon resonance.[6] A single substitution analog of PAK peptide RBD (E135A) and a double substitution analog where two PAO residues were inserted into the PAK sequence (T130K/E135P) generated antibodies in rabbits with enhanced crossreactivity to the PAK, PAO, KB7, and P1 RBD peptides.[4–6] Active immunization in mice with RBD peptides conjugated to TT (PAK, PAO, and PAK (D132T/E135P)) showed that the PAK (D132T/E135P) peptide gives 100% protection against active challenge with PAOwt (wild-type) bacteria and that this protection is enhanced more than that from active immunization with native PAK and PAO peptide conjugates.

Kao and Hodges[20] directly compared the immunogenicity of the truncated PAK pilin protein (29–144) with a synthetic 17-residue disulfide-bridged PAK RBD peptide (Fig. 3) comprising residues 128–144 conjugated to KLH. This peptide conjugate was then used to immunize mice along with the truncated PAK pilin protein monomer. Antisera collected from mice that were immunized with the peptide immunogen show higher titers compared with the antisera from mice immunized with the pilin protein monomer. In addition, although the pilin protein generates an IgG response, a large portion of the antibodies is directed against regions other than the desired region (i.e. the RBD, residues 128–144). This was also documented by using a pilin protein construct with a scrambled RBD sequence (Fig. 3) that is not recognized by RBD specific antibodies. Furthermore, the antibodies raised against the peptide immunogen bound with greater affinity to native PAK pilin compared with antibodies raised against the pilin protein monomer. Because animals immunized with peptide conjugate only generate antibodies against the RBD and these antibodies are able to recognize the RBD on the native pilin protein, there is a clear advantage in using the synthetic peptide conjugate over the monomeric pilin protein as an immunogen.[20] This result also emphasizes the advantages of synthetic peptide vaccines not only over subunit vaccines but also over killed vaccines or attenuated vaccines all of which may not generate the desired antibodies in terms of titer and affinity to the desired target.

One of the main obstacles in the development of a vaccine against *Pa* is the requirement that it is protective against a wide range of virulent strains. Thus, we investigated our synthetic RBD peptide immunogen PAK T130K/E135P (Cs1) conjugated to TT in active vaccination of mice for protection against lethal challenge with 4 different strains of *Pa* (PAK, PAO, KB7, and P1). Mice were also immunized with a scrambled PAK sequence, native PAK and native PAO peptide conjugates.[19] The A.BY/Sn J mouse strain has a competent humoral immune response, but genetic defects make it naturally susceptible to infection by *Pa*. Thus, it is a convenient mouse model that does not require additional immunosuppressive procedures.[27] Mice immunized with PAO peptide TT-conjugate, then challenged with PAK strain bacteria or immunized with PAK peptide TT-conjugate, and then challenged with PAO strain bacteria are not as well protected as mice immunized with Cs1 peptide conjugate. The Cs1 peptide TT-conjugate provides increased protection against challenge by KB7 and P1 bacterial strains compared with immunization with adjuvant alone.[19] The amino acid sequences of KB7 and P1 RBD regions are quite different from the Cs1 sequence, which is based only on the PAK and PAO sequences (Fig. 3). The scrambled RBD sequence allows for a rigorous examination of the efficacy of the Cs1 peptide sequence in protecting mice from *Pa* challenge. As seen in Fig. 4, the PAK-scrambled RBD provides no protection from PAO or PAK challenge. However, immunization with Cs1 peptide TT-conjugate provides excellent protection from challenge with PAO or PAK bacteria (Fig. 4).

The Cs1 peptide was also engineered into the PAK pilin monomer to examine the RBD by X-ray analysis in the structural context of the monomeric pilin protein. Each of the secondary structural elements of the RBD loop, the type- I β-turn, type-II β-turn, and β-strand, when individually assessed, is similar in the PAK and Cs1 pilin structures. However, a notable difference is observed when the RDB of PAK and Cs1 are compared with K122-4. The differences exist as a result of changes in the hydrogen bond network that anchor the RBD to the pilin in Cs1 and PAK that is replaced by hydrophobic clustering in K122-4 and possibly due to the

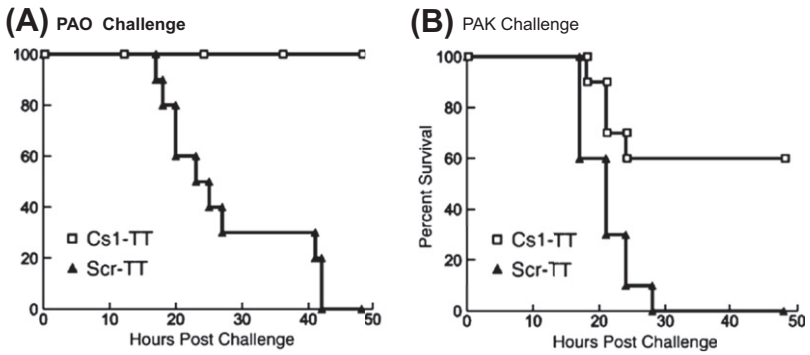

FIGURE 4 Active immunization of A.BY/SnJ mice. Protection of mice from challenge with (A) wild-type PAO and (B) wild-type PAK by the consensus peptide (Cs1)-TT-conjugate and the PAK scramble peptide TT-conjugate. Cs1 peptide affords 100% protection from PAO challenge compared with no protection from the PAK-scrambled peptide. Cs1 peptide also shows protection in mice challenged with PAKwt (60% survival), whereas the PAK scramble provides no protection from PAKwt challenge. Taken from Ref. 19.

presence of Ile, a β-branched amino acid at position 133 in K122-4 versus Leu in PAK and Cs1 (Fig. 3). These differences manifest as changes to the orientation of the RBD and of the individual β-turns in K122-4 relative to those in the PAK and Cs1 pilin proteins.[19] It is possible and even probable that the Cs1 peptide is flexible enough to adopt various conformations mimicking different pilin proteins.

To further examine the ability to produce crossreactive immunogens, a series of 17-residue peptides were made by substitution of two to five amino acid residues from the PAK sequence into the native PAO sequence as shown in Fig. 5.[14] The objective of this project was to generate a synthetic peptide immunogen that displays two distinct epitopes such that one epitope would generate antibodies that were PAO specific and the other epitope would generate antibodies that were PAK specific. Immunogen A is the native PAO (128–144) sequence, whereas immunogens B–E systematically increase the number of PAK residues substituted into the PAO template from 2 to 5 residues within the disulfide loop region. These five synthetic peptides were conjugated to KLH and used to immunize rabbits. IgG was purified from the sera and antibody crossreactivity determined using competitive enzyme-linked immunosorbent assays (ELISA) (Fig. 6). As expected, immunogen A (native PAO sequence) generates strain-specific antibodies that bind only native PAO pilin but not PAK pilin. All other immunogens B, C, D, and E generate crossreactive antibodies that bind both PAK and PAO pilins. Immunogen B has only two PAK amino acid residues E135 and Q136 transplanted into the PAO sequence (Fig. 5). Competitive ELISA clearly shows that polyclonal antibodies raised against peptide immunogen B bind to both PAO and PAK pilins (Fig. 6). Furthermore, the antibodies that bind PAO pilin are competed off with PAO pilin and not PAK pilin; antibodies that bind PAK pilin are competed off with PAK pilin and not PAO pilin. Thus, there are at least two different antibodies contained in the polyclonal sera raised against a single peptide immunogen containing two distinct epitopes, one that is specific for PAK pilin and one that is specific for PAO pilin. The affinity of the antibodies elicited by different peptide immunogens for both PAO and PAK pilins are similar, and antibodies obtained from different rabbits immunized with the same peptide immunogens bind with similar affinity to the *Pa* pilin antigens. To delineate the epitope sequence responsible for PAO and PAK pilin antibody interactions, a PAO mutant was engineered with three PAK residues, namely, K128, S143, and K144, PAO(KSK), which are located outside the disulfide loop (Fig. 3). Similarly, a PAK mutant was engineered with three PAO residues A128, D143, and N144, PAK(ADN).

PAO-specific antibodies were then analyzed for reactivity to the two mutants. PAO-specific antibodies (Immunogen A)

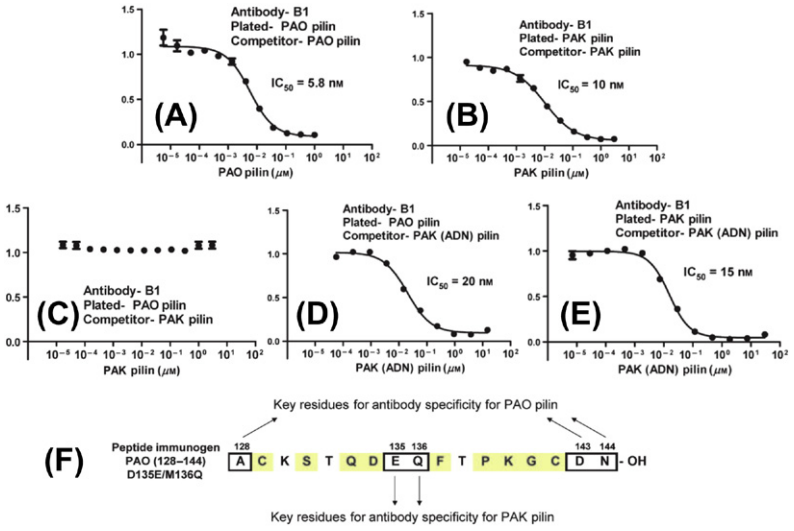

FIGURE 6 Competitive ELISA results for antibody B1 binding to PAK and PAO pilin proteins (panels A–E) and the substituted PAO peptide sequence that corresponds to peptide B (PAO 128-144 D135E/M136Q, panel F). The B1 antibody crossreacts with PAO (panel A) and PAK (panel B) pilins. The PAK pilin cannot compete for B1 antibody binding to PAO (panel C). However, the PAK(ADN) mutant is able to inhibit B1 binding to either PAO pilin (panel D) or PAK pilin (panel E). The concentration of pilin protein required for 50% inhibition of antibody binding (IC_{50}) is reported in each panel. The key residues to elicit PAK-specific antibodies (E135 and Q136) and PAO-specific antibodies (A128, D143 and N144) are boxed in the amino acid sequence of peptide B (panel F). Taken from Ref. 14.

are capable of interacting with both the PAO(KSK) mutant and the PAK(ADN) mutant with IC_{50} values in the low nanomolar range. These results show that PAO-specific antibodies recognize epitopes displayed inside the disulfide loop and also interact with an epitope located outside the disulfide-bridged loop. Antibody B1 was generated by immunizing rabbits with peptide B-KLH conjugate, a peptide that contains only 2 PAK residue substitutions into the PAO peptide and produces crossreactive antibodies to both PAK and PAO. The binding of this antibody to PAO could be competed off by native PAO but not native PAK. However, the PAK(ADN) mutant is able to inhibit B1 antibody binding to PAO pilin with an IC_{50} value of 20nM (Fig. 6D). The B1 antibodies could not bind to the PAO(KSK) mutant pilin. These results clearly indicate that residues A128, D143, and N144, which are located outside the disulfide-bridged loop, comprise part of the epitope responsible for generating PAO-specific antibodies to the peptide immunogen B1. On the other hand, the epitope responsible for generating PAK-specific antibodies is located within the disulfide loop and includes residues E135 and Q136. Therefore, this peptide generates crossreactive polyclonal sera with two specificities (Fig. 6).

The ability to rationally design effective peptide vaccines relies partly on our ability to analyze structural elements of the native protein immunogens from which they are derived. The filamentous nature of *Pa* pili make the pilin protein notably difficult to crystallize. Therefore, we used the native strain PAK, which was previously crystallized[15] as a template to insert the RBD of the PAO pilin protein using site-directed mutagenesis. The three-dimensional structures of the PAK PAO RBD chimera and native PAK are similar (Hackbarth and Hodges, unpublished results). The β-turns located in the RBD of the PAK PAO RBD chimera are nearly identical to the PAK RBD with an r.m.s.d. of 0.368Å. This result strongly suggests that the use of PAK pilin protein to incorporate RBDs from other strains is an excellent approach to generate X-ray structures. The surface-exposed residues of the PAK and PAO PAK chimera RBD are shown in Fig. 7. As expected, residues at positions 128, 143, and 144, which were deemed critical for epitope recognition by PAO-specific antibodies generated against the peptide immunogens and pilin mutants form a cluster and residues at positions 135 and 136, which make up at least part of the PAK epitope, are also clustered into a particular region on the surface of the pilin protein.

CONCLUSIONS

The RBD of the *Pa* pilin protein is an intrinsically optimized epitope for the design of a synthetic peptide-based vaccine because it consists of a continuous peptide that has secondary structural elements inherent to the sequence and is integral to *Pa* virulence. Because peptides have the potential to mimic functionally relevant domains of different pilin proteins, peptide-based vaccines may show more favorable characteristics such as enhanced crossreactivity compared with subunit, whole-killed, or live attenuated vaccines. The consensus sequence approach avoids antigenic competition by presenting a single immunogen to the immune system.

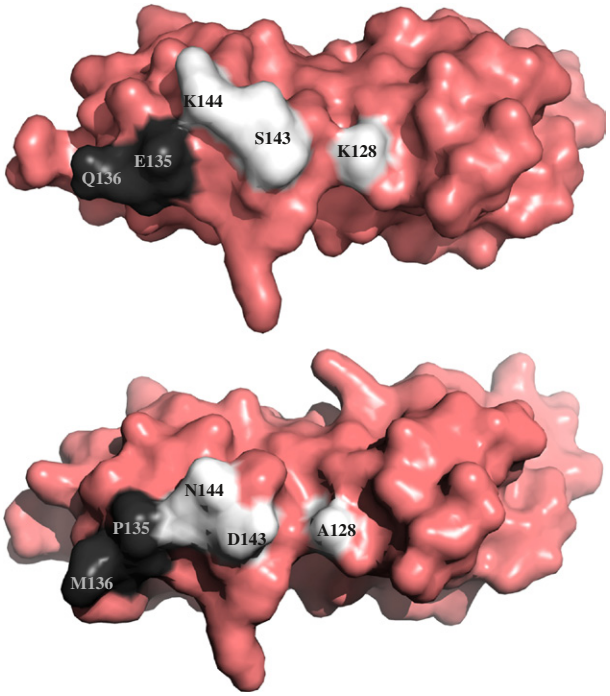

FIGURE 7 Molecular surface diagrams of PAK (top) and PAK PAO chimera (bottom) RBDs. The key residues responsible for PAK-specific antibodies (positions 135 and 136) and those responsible for PAO-specific antibodies (positions 128, 143, and 144), form separate clusters on the surface of the RBD (Hackbarth and Hodges, unpublished results).

We have clearly shown that to design a consensus sequence vaccine we can manipulate the sequence within and outside the disulfide loop region of the RBD. It is interesting that only three residues outside the disulfide loop can create high-affinity antibodies to a specific pilin strain. This suggests that we can use the epitope outside the loop (residues 128, 143, and 144) to enhance antibody crossreactivity to immunogens that lack crossreactivity to a particular strain.

To date, four X-ray crystallographic structures have been obtained for monomeric pilin proteins (29–144), native PAK[15] and K122-4[1] pilins, and two chimeric pilin proteins, PAK with a PAO RBD 128–144 and Cs1 pilin, which is PAK with two substitutions, T130K and E135P, in the RBD.[19] Based on the X-ray structures of these pilin proteins and NMR structures of the RBDs 128–144, it is clear that synthetic peptide vaccines must maintain the conserved conformation of the RBD consisting of two β-turns, one β-strand, and the disulfide bond to constrain the structure. Thus, our current hypothesis is that a consensus sequence immunogen must maintain this conserved conformation of the RBD while displaying a particular combination of variable residues on its surface that will induce antibodies that are crossreactive. Of the 6 variable positions in the RBD loop, only four are prominent on the exposed surface of the RBD (Lys130, Asp132, Pro135, and Gln136). We have shown that Pro135 in Cs1 may bolster the β-turn propensity of the RBD.[19] Thus, we propose to maintain Pro in this position in further design of a structure-based consensus sequence immunogen. Because the three variable residues Lys 130, Asp132, and Gln136 do not seem to play other structural roles in the RBD, we will focus our attention on these positions. The limited diversity at variable positions in native strains of *Pa* has led us to hypothesize that non-native substitutions will perturb the conformation of the RBD. On the other hand, substitutions derived from native strains at variable positions will maintain the conformation. Therefore, future consensus sequence RBD peptides should be derived from the residues that occur in native strains at each position.

Chapter 78

Lipo-Peptides/Saccharides for Peptide Vaccine Delivery

Mariusz Skwarczynski, Mehfuz Zaman and IstvanToth

ABSTRACT

A subunit vaccine is a vaccine that contains only the minimal microbial elements. Despite the fact that elimination of redundant components brings several advantages, it also removes the "danger signal" necessary to trigger the desired immune response. To overcome this problem, adjuvants (immunostimulants) have been widely used in vaccine formulations. Many currently available adjuvants suffer from side toxicity or poor efficacy; therefore, numerous vaccine delivery systems have been developed to improve the immunogenicity of peptide subunit vaccines. Among them, self-adjuvanting lipopeptides/saccharides-based delivery systems have shown high efficiency in inducing strong immune responses to incorporated peptide-based immunogens and are considered a promising platform for development of human vaccines.

INTRODUCTION

Vaccination is considered to be one of the most effective public health interventions since the eradication of smallpox through a worldwide vaccination campaign during the last century. Considering that until the 18th century smallpox caused about 10% of global mortalities in Europe, the success of this vaccine can be only compared with the introduction of penicillin. The first "controlled" infections were made in India, China, and North America hundreds of years ago, but the beginning of vaccination has been attributed to the time Jenner's cow-derived smallpox vaccine (the word vaccination is derived from the Latin word for cow = *vacca*) was introduced to the public. Vaccinology has changed greatly since that time, but the classical vaccine strategy based on attenuated or inactivated pathogens is still used. Problems associated with conventional vaccines include risks of infection especially in the case of immune compromised humans, difficulties with the production of pathogens *in vitro*, and instability of the biological material. The use of whole microorganisms is associated with the exposure of the patient to unnecessary and possibly harmful oncogenic microbial components, and the possible elicitation of autoimmunity or strong allergic responses. Concerns about vaccine safety are especially high because vaccines are usually administered to healthy humans, including children, for prophylaxis. Therefore, more recently, the use of whole pathogens has fallen out of favor, and most of the newly licensed vaccines are recombinant products.

SUBUNIT VACCINES

A subunit vaccine is a vaccine that contains only the minimal microbial elements necessary to stimulate long-lasting protective/therapeutic immune responses. In such vaccines, the disadvantages of classical vaccines are diminished. The absence of whole microorganisms eliminates the risk of its reversion to a virulent state while improving storage stability. Potentially oncogenic, allergenic, or toxic materials are removed. In addition, some pathogens are problematic to culture (e.g. sporozoites for malaria vaccines), and a subunit-based vaccine might be the only solution in such cases. However, such vaccines usually need several injections (primary and boosts) for long-lasting protection. Moreover, subunit-based vaccines generally require the use of an immunostimulant (adjuvant) as elimination of redundant components often removes the "danger signal" necessary to trigger the desired immune response. Currently available experimental adjuvants suffer from side toxicity, while commercially available (safe for human) adjuvants are mostly limited to aluminum derivatives that have limited potency. Aluminum-type adjuvants are also not suitable for eliciting cell-mediated immunity, and therefore cannot be used in therapeutic vaccines. Only recently, Cervarix®, a vaccine containing a new adjuvant, aluminum hydroxide and 3-*O*-desacyl-4′-monophosphoryl lipid A, was approved in the USA. This event did not change global demand for new and safe adjuvants, which are able to improve not only vaccine humoral responses but also cell-mediated immune responses. Despite the fact that modern vaccines consist mainly of proteins, such vaccines have major weaknesses such as cost of production, purity, and stability problems and in some cases the use of whole protein is prohibited because of the risk of triggering of autoimmune responses. For example, development of a vaccine against Group A

Streptococcus (*Streptococcus pyogenes*; GAS) bacteria, based on the GAS virulence factor, M Protein, was suppressed because of the production of antibodies that cross-reacted with human heart muscle.[3] Considering that the minimal microbial elements necessary to stimulate the required immune response can be as small as a short synthetic peptide, peptide subunit-based vaccines have seemed to be ideal candidates to solve all of the above-mentioned problems.[22,30] Peptide-based vaccines can be accurately designed to induce only the desired immune responses, as the sequences possessing similarity with human proteins can be easily excluded, eliminating the risk of autoimmunity. Such vaccines can be more precisely designed to recognize cancer specific targets. Nowadays, peptides can be easily and relatively inexpensively synthesized using solid phase peptide synthesis (SPPS) in a highly reproducible manner and pure state, in linear or dendritic form, incorporating only natural amino acids or synthetic analogs. Such compounds are usually exceptionally well defined and characterized and more stable during postproduction (including freeze drying), and under storage and transportation conditions than whole proteins. Peptide vaccines can include several different epitopes to target diverse subtypes of a pathogen during any stage of its life cycle. Peptide-based vaccines can incorporate B-cell epitopes to induce humoral response (antibody-mediated immunity), and/or T-cell epitopes for cellular adaptive immune response (cytotoxic T-lymphocytes/CTL, CD8+ T-cells/ mediated immunity), as well as helper T-lympocytes (TH cells, CD4+ cells) for eliciting long-lasting immune responses in outbred populations. Functional dissection and proteomic analysis of the peptide epitopes from pathogens have broadened the choice of peptide epitopes. Genomic information has allowed identification of proteins and antigens from pathogens, enabling the prediction of CD4+ T-cell and CD8+ T-cell epitopes using bioinformatic methods. These epitopes have been analyzed for the relevance of their immunogenicity via synthesis of overlapping peptide sequences. While the prediction of B-cell epitopes is a more challenging task, major progress has been made in this field. Despite many of well-defined peptide antigens being available for vaccine applications, those antigens are not immunogenic themselves and require appropriate delivery systems and even stronger adjuvants than those required to stimulate immune responses against recombinant vaccines. Indeed, the development of potent but safe adjuvants has become the holy grail of modern vaccinology. Lipoproteins and bacterial lipids such as lipopolysaccharide (LPS, a cell-wall component of Gram-negative bacteria), predominantly lipid A, have been identified as natural adjuvants.[8] However, because of the significant toxicity associated with natural bacterial lipids, synthetic analogs have been investigated for some time. This had resulted in the lipidation of peptides emerging as a promising strategy for delivery of peptide subunit vaccines.[16,30]

Dendritic Cell Toll-Like Receptor – The Keyhole for Lipopeptide Vaccines

Dendritic cells (DCs) are bone marrow-derived leukocytes that can be found throughout lymphoid and nonlymphoid tissues, afferent lymph vessels, and in peripheral blood. DCs are a group of heterogeneous multifunctional antigen presenting cells (APCs). Functionally, DCs are potent stimulators of B- and T-lymphocytes, the key mediators of immunity. T-lymphocytes require the antigen to be processed and presented to them by an APC such as a DC. After recognition of pathogen associated molecular patterns, DCs undergo a process called maturation, where they express high levels of several cell surface molecules including major histocompatibility complex (MHC) I and II, CD40, CD80, etc. The T-cell antigen receptors (TCRs) recognize antigen-specific peptide fragments bound to MHC molecules on the surface of DCs. MHC class I and MHC class II molecules stimulate cytotoxic T-cells (CTLs) and helper T-cells, respectively. Thus, intracellular antigens (such as tumor specific protein), when processed and bound to MHC class I molecules and recognized by CTLs, directly kill a target cell after activation. Extracellular antigens (e.g. from bacteria) are presented by the MHC class II molecules on DCs to T-helper cells. Activated T-helper cells then interact with antigen-specific B-cells causing the B-cells to proliferate and to differentiate into antibody-secreting plasma cells. Activated T-helper cells also play various roles in the quality of immunity including switching to certain immunoglobulin isotypes. Given the important role of DCs in mediating immunity, significant scientific focus has been on targeting DCs in vaccine development. Several lipid-based vaccine candidates have been examined and their efficacy in different systems was initially attributed to the ability of the lipid tail to enhance intracellular epitope delivery into APCs. A more recent understanding of how the lipid component enables the potent adjuvanting properties by targeting DCs has provided a rational basis for lipid-based vaccine development.

The endocytic route of entry is usually triggered by receptor-mediated events and lipid moiety mediated endocytosis of antigens toward Toll-like receptors (TLRs) as an obvious candidate for the mechanism of action.[4] There are 10 TLRs in humans that recognize different microbial molecular patterns during infection and trigger signaling pathways that lead to activation of transcription factors such as nuclear factor-κB (NF-κB). This consequently leads to the induction of immune and inflammatory genes. TLR2 is responsible for the recognition of bacterial lipoprotein and lipopeptides. The interaction between TLR2 present on DCs and its ligand initiates a signaling cascade that results in the translocation of NF-κB to the nucleus and activation of NF-κB-dependent genes responsible for the phenotypic and functional changes associated with DC maturation. Lipopeptide/saccharide vaccine candidates mimic bacterial

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

lipoproteins, which results in their self-adjuvanting activity.[32] The discovery of TLRs and their significance in the recognition of pathogens and the consequent immune response has expanded the spectrum of vaccine adjuvants. This is exemplified by current investigations incorporating a range of lipid moieties to form lipopeptide/saccharide-based vaccine candidates.

LIPIDATION

Lipidation has been extensively used for peptide delivery. Lipidation involves increasing peptide hydrophobicity, which improves their permeation of biological membranes and therefore increases their bioavailability. Modification with lipids often increases the chemical stability of peptides and protects them against enzymatic degradation.[24] Importantly, lipidic moieties can target peptides to particular cells, such as dentritic[8] or cancer cells,[26] thus increasing peptide immunogenicity or antitumor efficacy, respectively. There are several different strategies to incorporate lipid moieties into peptide epitopes, such as introduction of lipid via an *S*-glyceryl cysteine moiety, and use of a carbohydrate scaffold, or lipopeptide units.[16,34]

Lipid Core Peptide

The lipid core peptide (LCP) system for drug and vaccine delivery was first reported in the early 1990s. Since then, many modifications and improvements have been implemented but the LCP vaccine delivery system still consists of three major persistent components: (a) a nonmicrobial lipopeptide moiety (composed of synthetic lipidic amino acids (LAAs)), which might be arranged into the peptide sequence with a glycine spacer; (b) a branching moiety (usually based on polylysine); and (c) appropriate peptide epitopes.[28] The typical LCP system is presented in Fig. 1. The lipidic self-adjuvanting moiety can be easily modified in terms of the presence of a spacer, the number of LAAs and the length of their alkyne chains.[6] The lysine branching, allows the advantageous use of a multiple antigenic peptide (MAP) system. The level of the branching can be adjusted to suit the requirements. The lysine carrier permits the conjugation of multiple copies of the same peptide epitope and conjugation of many different peptide antigens.[34] LCP vaccine candidates can be freeze dried, are generally stable against peptidase degradation, and can be stored at room temperature.[16]

The first LCP system was tested *in vivo*[35] and was designed by Toth et al. as a vaccine against *Chlamydia trachomatis*, bacteria associated with infectious eye disease and the commonest infectious cause of blindness. The LCP system is composed of three C16-LAAs (2-amino-*R*,*S*-hexadecanoic acid), no glycine spacers, and branched lysines to which 8 copies of peptide epitope (A ETIFD VTTLN PTIAG or SAETI FDVTT LNPTI AGSDV AGLQN DPTTN), derived from the variable domains of *Chlamydia trachomatis* outer membrane protein, are attached. Compounds with a single epitope attached to two lipoamino acids were also synthesized. All antigens were administered with external adjuvant. The multiepitopic LCP constructs show significantly enhanced immunogenicity compared with monomeric counterparts or peptides alone.[35] Despite high antibody titers elicited by LCP constructs, these antibodies have only limited neutralizing ability, most probably because of conformational differences between the synthetic peptides and the corresponding native antigens.

Most research involving LCP delivery systems has been focused on development of a vaccine against GAS. This Gram-positive bacterial pathogen causes a variety of diseases that range from common bacterial pharyngitis to life-threatening streptococcal toxic shock syndrome and autoimmune postinfectious diseases such as rheumatic fever (RF) and rheumatic heart disease (RHD). In 2010, it was estimated that around 70 million individuals worldwide currently had RHD, which would result in 1.4 million deaths per year from RHD and its complications. Classical intervention with antibiotics is not very effective, especially in developing countries; therefore, there is high interest in the development of a vaccine to prevent streptococcal infections. As protection against GAS infection was correlated with opsonic antibody against the GAS major virulence factor, M protein, most designs of the vaccine candidates worldwide are based on M protein or its fragments. The use of whole protein in vaccine development was abandoned because of the high risk of autoimmune side reactions caused by antibodies and T-cells against whole protein because of the molecular mimicry between cardiac myosin and streptococcal M protein.

M protein, a coiled-coil protein consists of three major domains: an N-terminal domain, which is highly variable and able to induce production of protective antibodies; a B-repeat domain, which induces production of nonopsonic antibodies; and a highly conserved C-repeat domain. In 2002, Hyman et al. reported LCP constructs incorporating a p145 epitope (LRRDL DASRE AKKQV EKALE) from the C-terminal region of M protein.[7] Using a different number of LAAs and LAAs with different lengths of side chains, more lipophilic compounds induce stronger immune responses against p145. The level of antibody titers after subcutaneous immunization with LCP constructs, without use of any adjuvant, is similar to that when p145 was administered with toxic Complete Freund's Adjuvant (CFA). Increasing, the number of antigen copies from 4 to 8 does not improve humoral immune response. After further structure–activity relationship (SAR) study, the LCP core with C12-LAAs (Fig. 1, $n=8$), and glycine spacer was suggested as the most promising construct for vaccine delivery.[12] More hydrophobic structures ($n>8$) were difficult to synthesize and purify

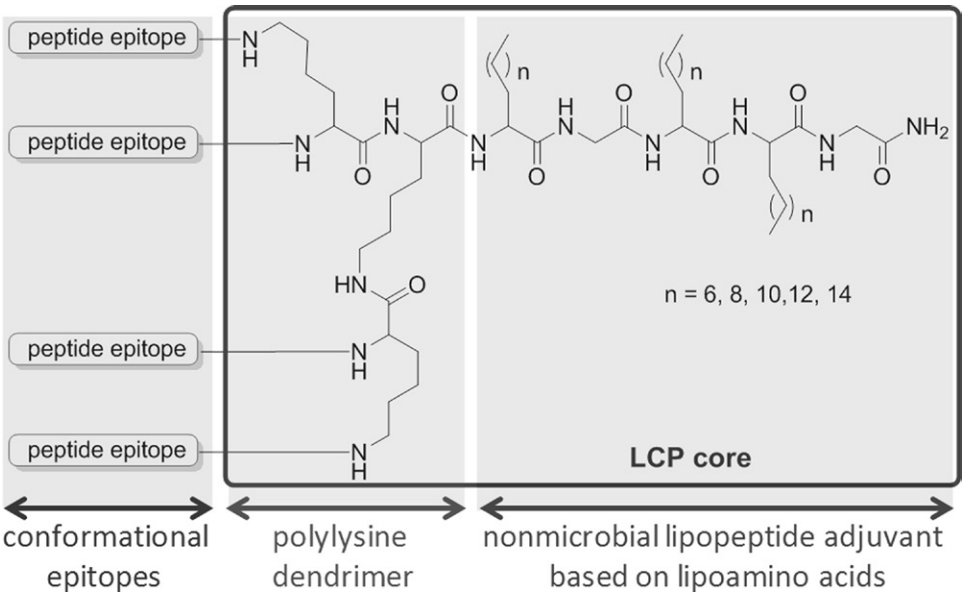

FIGURE 1 The typical structure of peptide subunit vaccine based on a lipid core peptide (LCP) system.

and were poorly water soluble making them less practical as components of vaccine candidates. Further studies were discontinued as T-cells specific to the p145 epitope were able to crossreact with human heart. To overcome problems associated with potential autoimmune responses to the p145 peptide epitope, the minimal B-cell epitopes have been identified in the p145 peptide. Because M protein has an α-helical coiled-coil structure and minimal epitopes, in contrast to p145, and does not demonstrate helical potential, the coil-promoting sequences from the yeast GCN4 protein were attached to the N- and C-termini of the minimal epitopes. Two of them were chosen as the most promising/immunogenic and non-crossreactive with human heart epitopes for vaccine design: J8 (QAE DKVKQ *SREAK KQVEK AL*KQL EDKVQ, minimal epitope is in italics) and J14 with a similar sequence (KQAE DKVK*A SREAK KQVEK ALE*QL EDKVK). However, like other short peptides, these epitopes do not stimulate an immune response without the help of adjuvant. With the incorporation of multiple copies of J8 epitope into LCP system,[28] the conjugates induce strong immune responses in mice without the need for coadministration with additional adjuvant.[10,12,17] Similar diepitopic constructs possessing both J8, and 8830 (DNGKA IYERA RERAL QELGP), epitope from the N-terminal domain elicit high antibody titers against both epitopes.[10] The system possessing these two epitopes protect, to almost 100%, mice that were challenged intraperitoneally with the 8830 GAS strain after intranasal immunization.[20] The additional epitope (in this case 8830) was incorporated to further increase the strain coverage of these vaccine candidates, as the conserved-region determinant (J8) is identical in at least 70% of GAS isolates but not all of them.

To examine the potential of the LCP system to incorporate more than two peptide epitopes and to analyze when each component (epitope) induced specific and strong immune responses, three and four epitopic constructs (**1**, **2**) were designed and synthesized (Fig. 2). These conjugates incorporate the conserved J8 epitope, and two or three epitopes from the variable N-terminal region of M protein, namely, 8830, NS1 (RVTTR SQAQD AAGLK EKAD), and PL1 (EVLTR RQSQD PKYVT QRIS) serotype-specific peptide epitopes.[18] All compounds were synthesized using a simple branching procedure during SPPS. After coupling of Boc-Lys(Boc)-OH to the lipopeptide, both Boc protective groups were removed. The LCP constructs were branched using α-Fmoc-Lys(ε-Boc)-OH which was at first coupled to the Lys-lipopeptide. After selective deprotection of the ε-amine group of α-Fmoc-Lys(ε-Boc)-Lys-lipopetide, two copies of the first peptide epitope (J8) were coupled using standard SPPS and protected at the N-termini by an acetyl group. After Fmoc deprotection, α-Fmoc-Lys(ε-Boc)-OH was coupled to the construct on the resin, and the whole process was repeated until the desired number of epitopes was attached to the LCP core. All compounds induce significant immune responses. After administration of the compounds (presented in Fig. 2), mice are protected against the challenge of GAS strain 8830 but the level of protection is not significantly different when four epitopic compounds are compared with a mixture of two diepitopic compounds. These results suggest that antibody response levels are not unfavorably affected by mixing different LCP constructs. The physical mixture of simpler LCP compounds might be advantageous in terms of simplicity of synthesis and purification when compared with sophisticated tetravalent

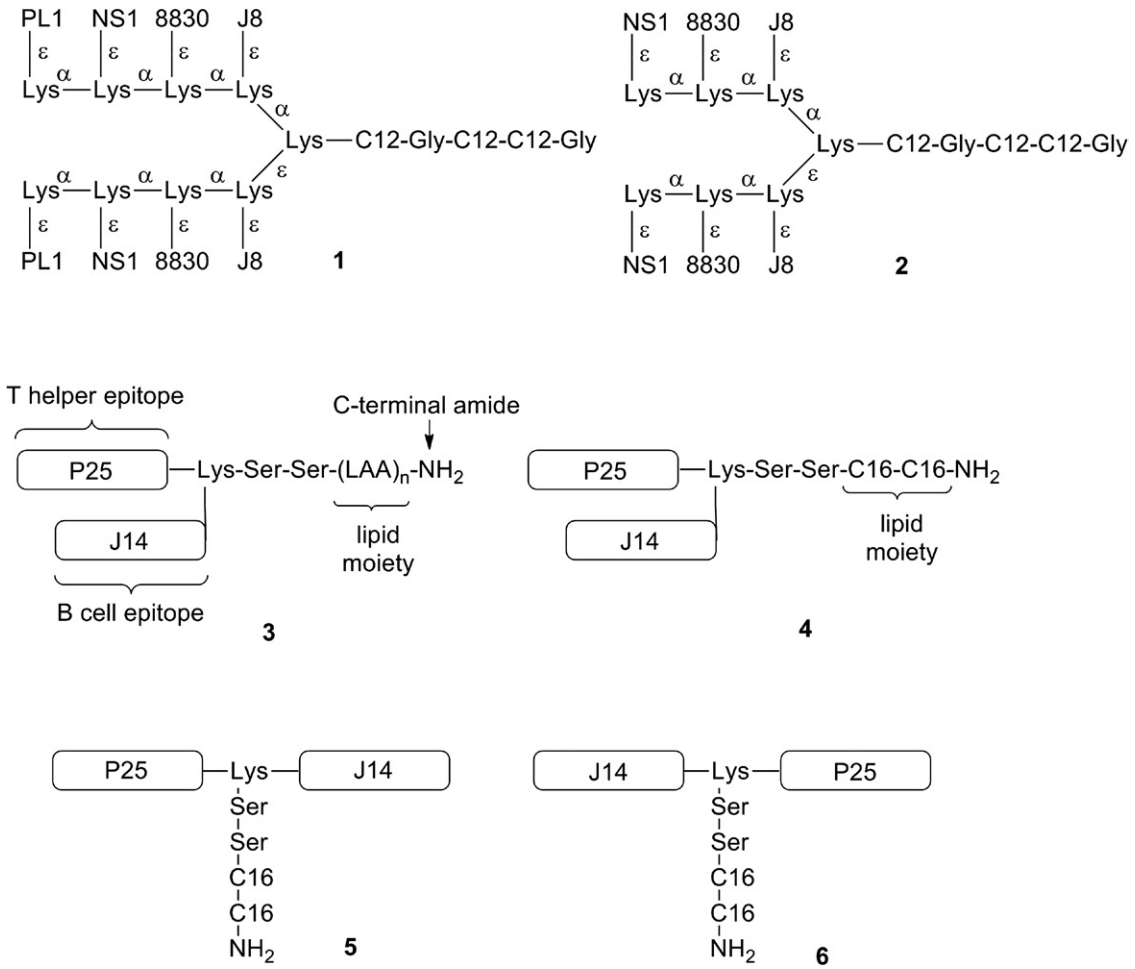

FIGURE 2 Examples of multiepitopic LCP vaccine candidates against GAS infection (1, 2) and the lipopeptide GAS vaccine candidates 3-6 from a "one lysine branching" series (where C12, C16 = LAAs possessing 12 and 16 carbon atoms, respectively).

or even more branched constructs. A tetraepitopic vaccine candidate was also examined for its ability to induce long-lasting immune responses (290 days) and showed high antibody titers, especially when administered with CFA.[18]

Another GAS virulent factor SfbI, a fibronectin-binding protein, plays a key role in bacterial attachment to host cells and colonization of pharyngeal mucosa, as well as in cellular invasion. The highly conserved fibronectin-binding repeats region (FNBR) is the minimal protein domain required to elicit protective immunity. The constructs possessing, J8 or FNBR epitopes (positions 373–402 and 393–422), from M protein and SfbI, respectively, were synthesized.[19] Mice were immunized intranasally with a physical mixture of monoepitopic J8-LCP and FNBR-LCP or with each construct alone. In all cases, LCPs were coadministered with the TLR2/6 agonist MALP-2 as the mucosal adjuvant. Immune responses stimulated at systemic and mucosal levels are strongest when mice are immunized with the mixture of both antigens. In the challenge experiment, the mice are fully protected against *S. pyogenes* only when the mixture of both LCPs is used for immunization. The mixture without external mucosal adjuvant (MALP-2) is not able to protect mice, even partially, against the bacteria.

The Toth group synthesized and examined a library of lipopeptide vaccine candidates consisting of B-cell epitope J14, a CD4+ T-helper epitope P25 (to improve immune responses in outbred populations), and a lipid (LAAs) variously attached to a central lysine core via its carboxylic acid or alpha- or episilon-amino groups to create different molecular geometries (see compounds **3**–**6**, Fig. 2). The position of epitopes was optimized to elicit a higher immune response. At the same time, the influence of the length of the alkyl chain on the immune response was investigated. Molecular geometry has a significant effect on the immune response after subcutaneous immunization.[1] Vaccine candidates featuring C-terminus lipid moiety (**3**) are optimal for systemic antibody production. The length of the alkyl chain and number of lipoamino acids in the sequence have more variable influence on the level of IgG elicited.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

After intranasal administration of the same library of lipopeptides, the best systemic antibody response is seen with a lipopeptide featuring a lipid moiety consisting of two 16 carbon chains incorporated at the *C*-terminus of the lipopeptide and the J14 epitope attached to the epsilon group of lysine (see **4**, Fig. 2).[2] However, this candidate does not protect mice against bacterial challenge. The best protection is by a lipopeptide featuring a *C*-terminal J14, conjugated through a lysine residue to P25 at the *N*-terminus, and the C16 lipoamino acids attached on the lysine side chain (see **4**, Fig. 2). Lipopeptide **5**, unlike **4**, maintains the native conformation of the J14 epitope required to produce protective J14-specific antibodies. These studies provide important information for the design of effective lipopeptide-based vaccines and highlight the influence of molecular geometry on induction of a protective immune response.

To overcome the problems related to synthesis and purification of LCP vaccine candidates using stepwise SPPS, especially in the case of the systems possessing various epitopes, conjugation techniques were applied. These methods involve synthesis of individual unprotected peptide blocks that are then purified before conjugation. At first, native chemical ligation for the selective conjugation of epitopes and LCP core was employed. Aniko Horvath et al. synthesized three epitope constructs (J8+PL1+8830) without lipid moiety. As expected, upon immunization of mice, this polypeptide elicited immune responses only with the help of an external adjuvant.[9] Incorporation of the LCP core into the constructs via ligation was difficult because of the highly lipophilic nature of LCP. Poor water solubility of the lipid fragment in the aqueous reaction environment blocked the conjugation. To overcome this obstacle, sodium dodecyl sulfate (SDS) as a solubilizing agent was used during the conjugation of the LCP core with peptide epitopes.[13] This technique was applied successfully to the ligation of multiple single epitopes to the lipidic core and to polyvalent epitopes[13,14] as shown in Scheme 1. Subcutaneous immunization of mice with compound **7** without the addition of adjuvant elicited high antibody titers against the incorporated epitopes (J8+PL1+8830). A compound that possesses four copies of 8830 epitopes attached to classical LCP (Fig. 1) was easily synthesized using SDS-assisted ligation, but the incorporation of two copies of two different epitopes was more challenging because of steric hindrance arising during conjugation of the first two peptide epitopes. The difficulties were mostly overcome by using alternative protective groups for the cysteine moieties.

The use of a copper-catalyzed alkyne–azide 1,3-dipolar cycloaddition "click" reaction was successfully exploited to obtain a polymer-based delivery system binding J14 GAS epitope to the hydrophobic core.[29] The use of copper wires, instead of the typically employed copper/ligand catalyst system, allowed reduction of copper and ligand impurities, and therefore simplified the purification of final products. The problem with components' solubility reported in the case of native chemical ligation was eliminated by the use of organic solvent (*N*,*N*,-dimethylformamide), which was able to readily solubilize polar and hydrophobic starting

materials. When this technique was used for the synthesis of LCP constructs almost quantitative conjugation was observed. [25,33] Upon conjugation with LCP core (Scheme 1), the J14 epitope adopts the desired (native) α-helical conformation and compounds are able to self-assemble into large nanoparticles (>100nm) under aqueous conditions. In contrast to the compounds from the series shown in Fig. 2, molecular geometry does not play a significant role in compounds **8** and **9**, and both constructs elicit similar titers of systemic IgG antibodies against the J14 epitope without the need of adjuvant. The Particle size of the peptide-based subunit vaccines usually plays a role in immunogenicity, and in most cases, 20- to 40-nm nanoparticles are favorable for the induction of strong immune responses.[22,30] The LCP constructs were examined for their ability to form small nanoparticles.[27] With the help of the click reaction, five LCP conjugates were prepared possessing J14, FNBR-B (VETED TKEPG VLMGG QSESV EFTKD TQTGM), FNBR-BT (EFTKD TQTGM SGQTT PQVET EDTKE PGVLM), J14+FNBR-B, and J14+FNBR-BT epitopes. Only diepitopic compounds formed small nanoparticles (5–15nm). Both FNBR compounds formed large particles, and the J14 construct did not aggregate. The ability to form small nanoparticles for diepitopic compounds is related to the balance between hydrophilic and hydrophobic properties of individual segments of the constructs. The immunological evaluation of these compounds has not been reported yet.

The mode of action of LCP-based vaccine candidates has been analyzed.[21,31] MHC II levels increase in splenic DCs after administration of LCP in mice. Furthermore, LCP enhanced DC-mediated proliferation of T-cells and cytokine production by DCs. Using cells expressing TLR2 and a luciferase reporter gene under the transcriptional control of NF-κB, the LCP system triggers activation of NF-κB in a TLR2-specific manner.[31] As such LAA-based lipid moieties exert their self-adjuvanting activity similarly in part to other lipopeptides via TLR2 mediated DC activation.[32]

GLYCOLIPOPEPTIDES

Carbohydrates have been used as building blocks in lipopeptide delivery systems to: serve as scaffold/branching moieties for epitopes display, or in the form of liposaccharides as self-adjuvanting moiety, to possibly protect peptides against enzymatic degradation, and as targeting moieties to specific carbohydrate-recognizing receptors.[24,34] They have been used as branching moieties because multiple copies of the peptide antigen can be easily attached to their hydroxy groups, the antigen can be attached in different spatial orientations depending on carbohydrate configuration, and the use of suitable protective groups allows attachment of different antigens to a single carbohydrate moiety. Several linkers have been designed to conjugate peptide to carbohydrate hydroxyls.[34] The rigid three-dimensional geometry of carbohydrates has been used to predetermine the conformation of attached peptides. Glucose, mannose, and galactose-based LCP vaccine candidates incorporating 8830 or J14i (ASRE AKKQV EKALE) GAS epitopes adopt an α-helical conformation[34] Such constructs (**10**, Fig. 3) are able to elicit high titers of systemic antibody after immunization in mice. The immune responses against those glycolipopeptides are similar to those against constructs based on lysine branching moiety showing that the carbohydrate scaffold is an interesting alternative to polylysine dendrimers.[23]

Glycosylated proteins and their interaction with carbohydrate-binding proteins (lectins) play a major role in the cellular recognition processes. Mannose receptors are highly expressed in cells responsible for immune responses such as macrophages and dendritic cells.[11] Mannosylation of an antigen to target receptors on the surface of dendritic cells improves vaccine efficacy.[28] A mannose receptor-targeting strategy was used for the development of a vaccine against human papillomavirus (HPV) infection, which is one of the leading causes of cancer deaths in women. The mannosylated antigen (8Q: QAEP DRAHY NIVTF CCKCD possessing CTL, Th-cell, and B-cell epitopes from the HPV-16 E7 protein) was incorporated by stepwise SPPS into a classical LCP structure (Fig. 1, where $n=8$).[15] Constructs without the help of additional adjuvant were evaluated for their capacity to reduce the size of HPV-16 associated tumors in mice. The mannosylated LCP vaccine candidates are more effective in reducing tumor sizes when compared with the nonmannosylated analog. In contrast to glycolipopeptides, the nonmannosylated compound is poorly water soluble. Thus, the improved protection of mice under tumor challenge might result from improvement in water solubility of the construct and not from the targeting properties of mannose. To examine this possibility, mannosylated, mannosylated (with acetylated mannose), nonmannosylated, and glucosylated constructs were examined in an additional experiment, but no significant difference was observed in the efficacy of the compounds.[15] Noticeably, the LCP-based constructs are able to offer superior anticancer activity and usually complete prevention of the formation of detectable tumors but improve vaccine efficacy because of the ability of mannosylated compounds to target dendritic cells yet to be clearly confirmed.

Monophosphoryl lipid A (MPL), a less toxic version of a major cell-wall component of Gram-negative bacteria lipid A, is an adjuvant which stimulates TLR4 mediated DC activation. MPL has been approved for use in vaccines for human use relatively recently (Fig. 3). Synthetic analogs of lipid A and MPL have been studied with the goal to maintain high adjuvant activity of these glycolipids but to produce fully defined, highly pure compounds and to

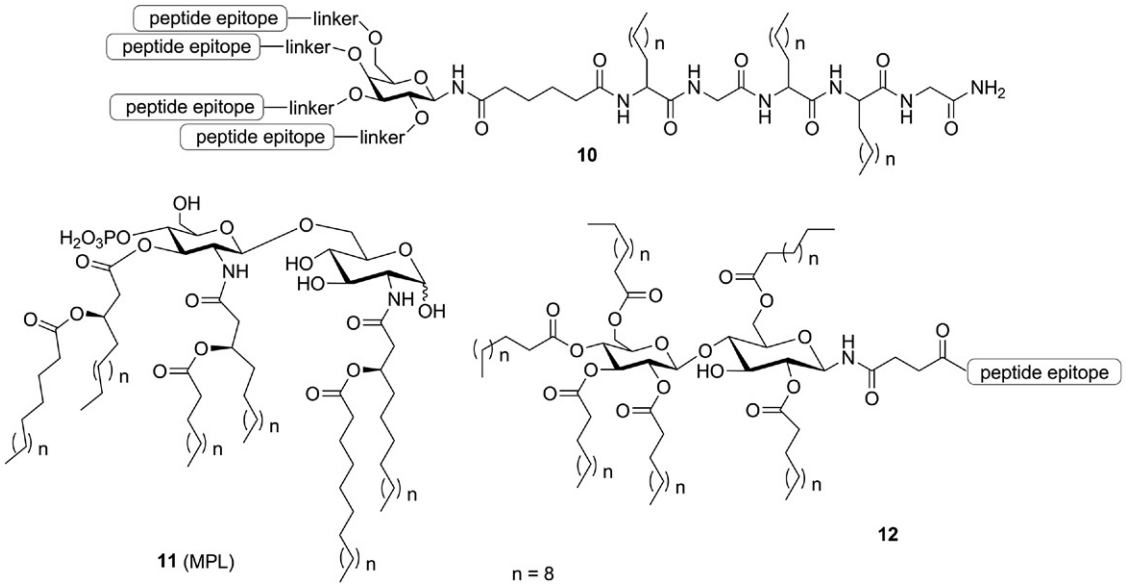

FIGURE 3 Vaccine candidates with carbohydrate as a branching scaffold for epitope display (10) and glycolipid adjuvants (11: monophosphoryl lipid A derived from cell wall lipopolysaccharide of Gram-negative *Salmonella minnesota;* 12: the most immunogenic liposaccharide from the series reported by Fujita et al.).

avoid any toxic bacterial traces. Thus, carbohydrates are not only attractive scaffolds for peptide antigens, but they can also be used to display lipid moieties in an organized fashion and with potential adjuvant activity. A synthetic simplified mimic of MPL was introduced to the LCP-like construct **12** (Fig. 3) and its efficacy to induce immune responses was compared with a physical mixture of glycolipid and peptide (J8).[5] Interestingly, although the new glycolipid does not show any adjuvant activity in the mixture, but when conjugated to the one and only peptide epitope is equally efficient as classical LCP-J8 with four copies of the peptide epitope. Disaccharide derivative **12** elicits a high level of J8-specific antibody after subcutaneous immunization of mice, similar to that elicited by LCP-J8 or J8 mixed with CFA while monosaccharide replacements are less immunogenic.

CONCLUSIONS

Numerous vaccine delivery systems have been developed to improve immunogenicity of peptide-based vaccines. Among them self-adjuvanting lipid- and glycolipid-based delivery systems have shown high efficiency in inducing strong immune responses to incorporated peptide-based immunogens. In most cases, the chemical conjugation between lipid moiety and peptide epitopes is necessary to induce these strong immune responses after the administration of subunit vaccines. Thus, LCP units serve usually as self-adjuvanting moieties but not as adjuvants in the physical mixtures. Many of these experimental vaccines have been analyzed in the context of their size, lipophilicity, spatial arrangement, and morphological properties, showing that physicochemical properties of the delivery system can have an important influence on vaccine efficacy. These ongoing studies expect to provide vaccinologists with more alternatives to develop new vaccines against a wide range of diseases. The use of lipopeptides/saccharides in peptide vaccine delivery should allow production of highly customized multicomponent, while still caged in a single chemical molecule, human vaccines with the ability to induce immune responses in an acceptably controllable fashion.

Chapter 79

Novel Tumor Derived Peptides in Vaccines

Anthony W. Purcell, Nathan P. Croft and Nadine L. Dudek

ABSTRACT

Traditionally, cancer vaccines have consisted of recombinant antigens or tumor cell lysates. Whole tumor-derived preparations contain predominantly normal self-proteins of no therapeutic benefit or material with the potential to induce further malignancy. Thus, the identification and administration of tumor-specific antigens rather than crude tumor preparations are desirable. The most precise selection of vaccine components exists in epitope-based peptide vaccines, which represent the minimal immunogenic region of an antigen and allow exquisite control of immune responses. The difficulties associated with peptide-based vaccines; including stability, delivery, and the diversity of human immunogenetics have now mostly been overcome by high throughput sequencing of haplotype-specific peptide ligands and the ability to modify peptides to enhance both their immunogenicity and stability. Such recent progress makes it very probable that peptide-based cancer vaccines will enter the human therapeutics marketplace in the near future.

INTRODUCTION

The cellular immune response depends on recognition of small protein fragments presented on the cell surface by Major Histocompatibility Complex (MHC) molecules. These peptides are derived from the degradation of proteins from either intracellular or extracellular sources with tens to hundreds of thousands of different MHC-bound peptides (the immunopeptidome) simultaneously displayed for scrutiny by T-cells. Traditionally, T-cell epitopes have been defined using peptide libraries that span a given antigen and less frequently by biochemical definition using Edman sequencing or tandem mass spectrometry (MS/MS).[6] However, for many human diseases, including most cancers, the vast majority of peptide epitopes remain poorly defined.[23] One reason for this is the great complexity of the immunopeptidome and the relatively small proportion of tumor-specific peptides presented on the surface of cancer cells. The complexity of the immunopeptidome arises from both the large number of endogenous and exogenous peptides sampled by antigen presentation and the chemical diversity of these peptides. In particular, the immunopeptidome contains a significant proportion of peptides of atypical or heterogeneous length and peptides bearing a multitude of posttranslational modifications (PTMs). The factors that predispose to heterogeneous peptide length and the impact of PTMs on antigen processing are poorly understood. Mass spectrometry offers a powerful approach to dissect this complexity, not only to identify new targets of immunity but to also provide accurate quantitative measurement of antigen presentation. We discuss how mass spectrometry can be used to identify novel tumor-specific peptide antigens and how such information can be harnessed in vaccine design.

ANTIGEN PROCESSING AND ITS ROLE IN PEPTIDE-BASED VACCINOLOGY

The adaptive immune system is regulated by the recognition of antigenic peptides complexed to MHC molecules by clonally distributed T-cell receptors (TcRs). This interaction occurs at the immune synapse, where intimate membrane contacts are made between the T-cell and the antigen-presenting cell (APC). The outcome of this interaction may lead to the eradication of infected or malignant cells, the secretion of cytokines that recruit, and activate additional immune effector cells, or lead to the generation of antibodies. Immune surveillance relies upon accurate reporting of molecular events occurring within the cell via antigen presentation. As such, viral infection or malignant transformation alters the array of peptides presented on the cell surface bound to MHC molecules. There are two classes of MHC molecules that sample distinct peptides and present them to T-cells, namely, MHC class I molecules (MHC I) and class II molecules (MHC II).

Intracellular Immunosurveillance and the MHC Class 1 Pathway

Cytotoxic T-lymphocytes are generally activated by antigens derived from intracellular proteins, presented on the surface

of cells complexed with MHC I molecules. Intracellular proteins (including, e.g. nuclear or cytoplasmic tumor antigens) are degraded to oligopeptides in the cytoplasm through the action of a multicatalytic protease structure known as the proteasome. These peptides are transported into the lumen of the endoplasmic reticulum (ER) where they assemble with MHC I and transit through the Golgi bodies to the cell surface (Fig. 1). The MHC I molecules themselves consist of a complex of a polymorphic heavy chain, a monomorphic light chain (β-2 microglobulin) and an antigenic peptide. The heavy chain forms an antigen-binding groove that accommodates peptides most commonly 8–10 amino acid residues long. The amino acid residues that line the binding groove are the focus for the majority of MHC polymorphism and determine allelic differences in peptide binding. Structural and biochemical studies of MHC-bound peptides have underpinned our knowledge of the binding characteristics of different MHC I-alleles (Table 1). In particular, these studies have highlighted the role of conserved amino acids at different positions of all allele-specific peptide ligands that are involved in binding to the cleft of MHC I molecules (anchor residues). Other more variable amino acids at different positions within the peptide project out of the antigen-binding cleft and make critical contacts with TcRs. The identification of specific MHC I binding motifs has been used to successfully predict T-cell epitopes with listings and search tools conveniently web based (e.g. http://www.immuneepitope.org/).[10] However, the success rate for de novo prediction of T-cell epitopes, even for well-studied MHC allotypes, is only about 60%, whereas for newly

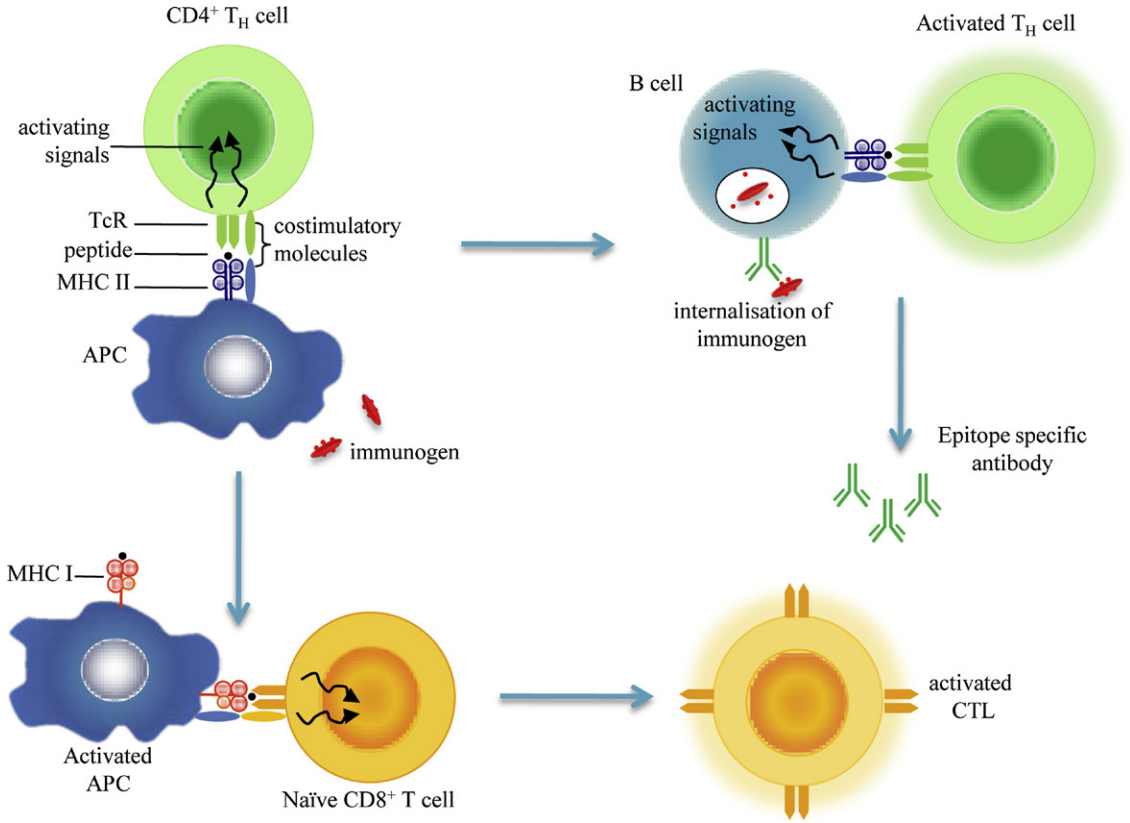

FIGURE 1 Key concepts of peptide vaccine immunology The adaptive immune system comprises two arms, responsible for the cytotoxic and the humoral immune response, respectively. Cytotoxic T-lymphocytes (CTLs, also referred to as CD8+ T-cells) eradicate tumor cells via direct cytotoxic action, and B-cells are the main players of the humoral immune response by generating antibodies toward tumor-specific molecules. Both processes are further dependent on T helper cells (T_H cells, also referred to as CD4+ T-cells). CTLs detect malignant cells by recognition of MHC class I molecules in complex with peptides derived from proteins expressed within the cell, whereas T_H cells recognize MHC class II molecules complexed to peptides derived from predominantly exogenous proteins. All nucleated cells present peptides derived from intracellular proteins on their surface bound to MHC I, whereas peptides derived from extracellular proteins are mainly presented by MHC II on specialized antigen-presenting cells (APC) such dendritic cells and macrophages. In both cases, the T-cell receptor (TcR) on the surface of the CTL or T_H cell ligates an MHC I/peptide complex or MHC II/peptide complex, respectively, aided by the CD8/CD4 coreceptors, respectively. The complex interplay of these peptide dependent recognition events results in the propagation of immune responses that ideally control cancer. The goal of vaccination is to induce immunity toward these states by selectively stimulating antigen-specific CTL or B-cells and T_H cells. A vaccine must therefore contain two antigenic epitopes—a T_H-epitope and an epitope that will either induce specific B-cell- or CTL responses. In some cases, these can overlap substantially within the sequence of an antigen and in others they may be present in discrete regions of the antigen or present in different antigens from the tumor cell.

described, rare or poorly studied MHC I molecules no binding motifs are available. More advanced approaches have yielded higher success rates for some alleles.[10–12] One reason for the poor predictability resides in the occurrence of non-motif-based ligands, peptides of unusual length, PTM ligands, or of the failure of antigen processing to liberate all predicted peptides. Furthermore, many T-cell responses focus on a handful of immunodominant peptides despite numerous potential MHC ligands derived from a given antigen.[3] Such immunodominance limits the number of distinct epitopes required in a peptide-based vaccine to elicit protective immunity and also provides a challenge in the correct selection of candidate epitopes. Despite this, epitope prediction remains a popular first screening method to identify candidate epitopes for subsequent biological validation. Thus, in silico design of peptide-based vaccines must consider MHC-peptide binding, the abundance of specific MHC-peptide complexes on the surface of both APC and target tumor cells, the time of expression of the antigen during pathogenesis, correct processing and luminal transport of the epitope as well as the available T-cell repertoire in the host organism.

Extracellular Immunosurveillance and the MHC Class II Antigen Presentation Pathway

Unlike the more ubiquitous distribution of MHC I, class II molecules are only expressed on the surface of professional APC (e.g. dendritic cells, macrophages, B-cells). Extracellular antigen endocytosed via receptor-mediated processes is taken up less selectively by highly phagocytic APC like dendritic cells, and macrophages are degraded in the early and late endosomes. These compartments provide a rich source of antigenic peptides that are transported to the cell surface bound to MHC II for display and scrutiny by T helper (T_H) cells. This process is mechanistically and physically distinct to the MHC class I processing pathway.[6] Likewise, MHC II are physically distinct to MHC I molecules and are composed of two polymorphic polypeptide chains forming an αβ heterodimer, which combine to form a binding cleft that accommodates peptide antigens. B-cells that bind to a given antigen via their clonally distributed surface immunoglobulin receptor, and display a specific MHC II/peptide complex by virtue of the capture of antigen, can be triggered to differentiate into antibody producing plasma cells with the help of T_H cells (Fig. 1).

The mode of peptide binding and ligand repertoire of MHC II differs from that of MHC I molecules. The peptide-binding cleft of MHC II is not closed like that observed in MHC I molecules, which allows the termini of the bound peptides to hang out of the ends of the cleft. As a result, MHC II peptides are typically longer than class I ligands, averaging around 13–30 amino acids in length. Like MHC I, polymorphic amino acid residues line the pockets of the binding cleft, with amino acid side chains at residues 1, 4, 6, and 9 of the class II–bound peptide typically interacting with these pockets conferring allelic specificity and 'anchoring' the peptide into the cleft. It has also been suggested that the binding of ligands to MHC II is more promiscuous than the binding of peptides to MHC I, because of their free termini and ability to use alternate anchor residues or shift binding register.[18] This observation makes it more difficult to define anchor residues and to predict which peptides will be able to bind particular MHC II molecules. Amino- and C-terminal exopeptidase activities can trim the peptides bound to class II molecules during their transit to the cell surface further hampering the efforts to define MHC II binding motifs and reliably predict MHC II ligands.

New Insights into the Immunopeptidome

Although the mechanisms of peptide liberation and binding to MHC have been elucidated,[22] the relationship between the composition of the immunopeptidome and the cellular proteome remains controversial. The establishment of nanoscale preparative techniques and cutting edge mass spectrometry to study the immunopeptidome has provided critical insights into this complexity. We have focussed on naturally processed and presented MHC-bound peptides that contain PTMs. Our initial results indicate that up to 10% of MHC class I–bound peptides are greater than the expected length (Fig. 2), the majority of MHC class II–bound peptides show N- or C-terminal heterogeneity, and 5–10% (and in extreme cases up to 30%) of the immunopeptidome contains PTM peptides. These modifications are commonplace and play a crucial role in regulating cellular processes. PTMs can influence protein structure, protein–protein interactions, protein location, half life, and enzymatic function.[20] Their representation in the immunopeptidome has significant implications for traditional methods of epitope discovery, which do not normally take such peptides into account, as it implies that on an average 5–10% of immunogenic epitopes could be missed.

CTL Epitopes of Unusual Length

Despite antigen processing in the class I compartment predisposing toward peptides of 8–10 amino acids in length, peptides considerably longer than this bind to and are naturally presented by MHC I. These include naturally presented self-peptides of which at least 5% are over ten amino acids in length. The structures of several peptides considerably longer than ten residues in complex with MHC I molecules have been studied and, in each case, the peptide adopts a bulging conformation while maintaining a conserved hydrogen bonding network at the peptide amino and carboxy termini.[27] These bulged epitopes can be rigid and display a defined conformation or exhibit a considerable degree of flexibility

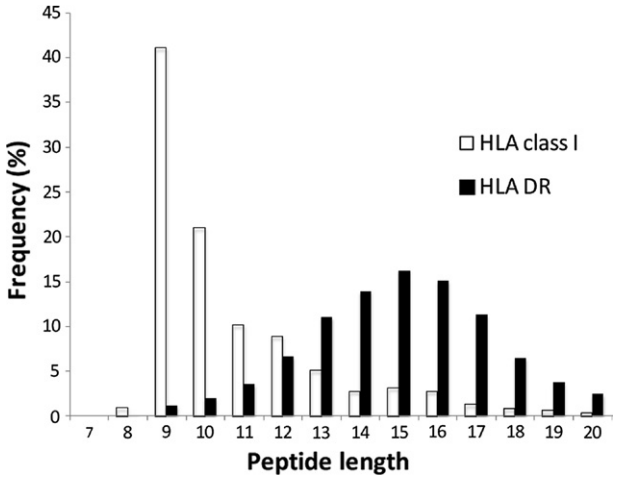

FIGURE 2 Length heterogeneity in MHC class I and class II peptides. The length of MHC-bound peptides was analyzed from approximately 5000 nonredundant peptide sequences isolated from HLA class I and HLA DR molecules. MHC–peptide complexes were purified from 5×10^8 9022 B-lymphoblastoid cells using solid phase bound monoclonal antibodies specific for HLA-DR and HLA-class I and the bound complexes eluted with 10% acetic acid. The eluted material was fractionated by reversed-phase HPLC and peptide-containing fractions analyzed by LC–MS/MS (Eksigent NanoUltra cHiPLC and an AB SCIEX 5600 TripleTOF mass spectrometer). Data were analyzed with ProteinPilot™ (AB SCIEX) software and peptide identities determined subject to strict bioinformatic criteria that included the use of a decoy database to calculate the false discovery rate (FDR). An FDR cut-off of 5% was applied, and the dataset was further filtered to exclude redundant peptides and known contaminants.

when bound to the antigen-binding cleft. For example, we have studied a highly immunogenic region from the BZLF1 antigen of Epstein–Barr Virus (EBV) that is presented by HLA-B35 family members in a length and conformation-specific manner.[29] Some of these longer epitopes contain within their sequences shorter core peptides of more conventional length that can bind to MHC I and are frequently naturally presented yet fail to induce a CTL response.[27,28] Why these longer peptides are preferentially selected as targets of CTL is most probably the result of biases in antigen processing and T cell repertoire toward the longer peptide.[29,30] The existence of such epitopes presents new challenges to vaccine design, both in terms of controlling the processing of these long peptides and ensuring the correct conformation is assumed by the epitope bound to MHC I. There are already several examples of unusually long CTL epitopes from tumor antigens including NY-ESO, M-CSF, tyrosinase, MART-2, CAMEL, and p53.[7] Thus, inclusion of such epitopes may be essential for optimal peptide-based cancer vaccines

T-cell Recognition of Posttranslationally Modified Peptides

The recognition of modified antigens by antibodies and T-cells can have important implications in disease.[20] Several studies have linked immune recognition of PTM peptides to disease states,[14,15,21] and the biology surrounding the formation and accumulation of PTM proteins and the peptides liberated from them has emerged as a new paradigm in autoimmunity. A role for immune recognition of PTMs has also been established in tumor immunology.[17,21,35] For example, HLA A2-bound peptides resulting from the differential phosphorylation of β-catenin, associated with nuclear accumulation of this molecule and the malignant phenotype, have been isolated from several tumor cell lines.[35] This highlights the link between deregulated signaling and the ability of antigen processing to alert T-cells to such molecular events. Moreover, T-cell epitopes have been characterized that include other PTMs including glycopeptides, deamidated peptides (both through the action of N-glycanases and enzymes such as transglutaminase), peptides exhibiting asparagine bond isomerism, acetylation, methylation, cysteinylation, nitration, and peptides containing disulphide bonds.[20] Such PTMs can be reliably and accurately incorporated into peptides at the time of their synthesis, allowing the end product of complex antigen presentation to be mimicked by a simple compound and the desired immune response to be elicited. Perhaps the most extreme form of PTM can be evidenced from recent reports of epitopes generated from discontinuous peptide sequences via a protein splicing mechanism.[5] Such processing may occur in a tissue-specific manner, and therefore, such epitopes are not only impossible to predict but also peptide-based vaccines may be the only reliable way of delivering such epitopes to the immune system.

T-cell Recognition of Tumor-Associated Peptides

There are at least five classes of tumor-associated antigens of relevance to peptide-based immunotherapy that include differentiation antigens, reactivated embryonic antigens, oncogene or suppressor gene products, mutated proteins, and some cancer-associated viral proteins. For instance, mutated tumor suppressor gene products may not only play a key role in tumorigenesis but may also create new T-cell epitopes. A prime example of such a protein is the p53 oncoprotein. Mutated p53 is found in >50% of all human cancers and a number of T-cell epitopes have been reported representing such mutated peptides.[9,19] Likewise, there has been much interest in defining epitopes derived from differentiation antigens such as the NY-ESO[16,24] and from cancer-associated viruses such as EBV found in lymphomas.[31] The identification of such peptides using peptide libraries or mass spectrometry is only complicated by the necessity to use both human and viral protein databases in library design or data search workflows and by the sometimes relatively low levels of presentation of

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

such species. Once identified, such peptides are frequently engineered to produce more potent immunogens through the enhancement of MHC binding. As discussed later, the generation of these peptides often substituted at their anchor residue positions induce heteroclitic immunity often breaking tolerance to the often poorly immunogenic native tumor peptides.

MASS SPECTROMETRY AND THE IDENTIFICATION OF T-CELL EPITOPES

There are a number of methods that have been used for epitope identification, and recent advances in tandem mass spectrometry (MS/MS) have allowed cell-free methods to study the antigen processing and presentation. These approaches typically involve the purification of cell-surface MHC/peptide complexes using immunoaffinity chromatography followed by the extraction of the peptides and their analysis by MS/MS.[6] Recent improvements in this approach allow up to ten thousand peptides to be identified from a single MHC-peptide isolation experiment. These new methods incorporate several key changes including (i) serial purification of MHC allotypes using specific monoclonal antibodies to delineate allele-specific peptidomes; (ii) multiple dimensions of liquid chromatography (LC) of the peptides extracted from the individually purified MHC allotype-peptide complexes to enhance peptide separation and aid in MS/MS analysis; and (iii) fast, high resolution mass spectrometers to deal with the sample complexity (Scull et al. *Mol. Immunol*., in press; Dudek et al., in preparation). This depth of coverage of the immunopeptidome not only allows a significant proportion of the constitutive peptide repertoire to be identified, but this analysis also allows changes in the immunopeptidome to be examined during infection, drug treatment, tumorigenesis and metastasis. Such studies will open up personalized medicine and allow specific treatment of cancer and prevention of metastatic disease.

Despite considerable improvements in the number of peptides that can be confidently identified in the global LC–MS/MS analysis of MHC-bound peptides, the analysis of antigen- or disease-specific peptides can often still be challenging. This results from the relatively low abundance of many disease-specific epitopes compared with constitutively presented self-peptides. For the same reasons, modified peptides are also difficult to detect, and the interpretation of their spectra is complicated by the computational penalties associated with searching raw data while considering multiple potential PTMs. One way to circumvent this problem is to use affinity techniques to enrich for subpopulations of peptides. For example, Zarling et al. have used immobilized metal affinity chromatography to selectively capture phosphopeptides from HLA A2-peptide complexes isolated from the surface of tumor cell lines.[35] This study identified 36 HLA A2-bound phosphopeptides, including 5 that were common to several different cancers. Importantly, some of these phosphopeptides could be recognized by antitumor CTL.[35] Although affinity capture is a powerful method, only one modification can be targeted at a time, and a specific affinity technique is required for each modification. Alternatively, the mass spectrometer can be used to selectively screen for modified peptides using experiments such as neutral loss or precursor ion scanning.[34] For example, monitoring for the presence of phosphopeptides can be accomplished by detecting the m/z -79 ion derived from phosphate. Likewise, monitoring at m/z 216 can selectively identify phosphotyrosine-containing peptides in a complex mixture. Thus, by the use of appropriate diagnostic fragment ions, peptides with different PTMs can be detected. We have recently extended this approach to enable antigen-specific peptides to be identified using characteristic low mass reporter ions for precursor scanning experiments. This approach coined NIIPe (^{15}N immonium ion precursor scanning) takes advantage of unique MS/MS signatures of isotopically labeled antigen to effectively fish out antigen-specific peptides from cells pulsed with full length ^{15}N- labeled antigen by targeting heavy immonium ions for precursor scanning experiment. This approach has recently been used to successfully identify MHC-bound antigen-specific peptides (Reilly et al., submitted).

In addition to discovery-based workflows, we have used multiple reaction monitoring (MRM) to detect and quantitate peptide epitopes. The incorporation of MRM into LC–MS analyses provides the benchmark in sensitivity of detection of peptides isolated from biological samples. It combines a knowledge of the mass of the targeted peptide with fragmentation information to provide highly sensitive and specific peptide detection – in essence, it searches for the mass spectral fingerprint of peptide(s) being monitored and when combined with an isotopically labeled peptide standard allows absolute quantitation in the same experiment (Fig. 3). Thus, MRM can be used in experiments in which the presence of a particular peptide epitope needs to be confirmed or where the abundance of a peptide epitope is under consideration.[26] Moreover, MRMs may be designed in silico to probe antigen presentation by combining epitope prediction with experimental analysis of the resultant immunopeptidome postinfection or on introduction of a tumor-specific antigen. Finally, the sensitivity of this technique promises to allow rapid translation from *in vitro* studies using cultured cells to directly examine antigen presentation in biopsies or from tissues. Such information will provide a critical link between laboratory-based epitope discovery and clinical validation and will guide the composition of personalized peptide-based vaccines in the future.

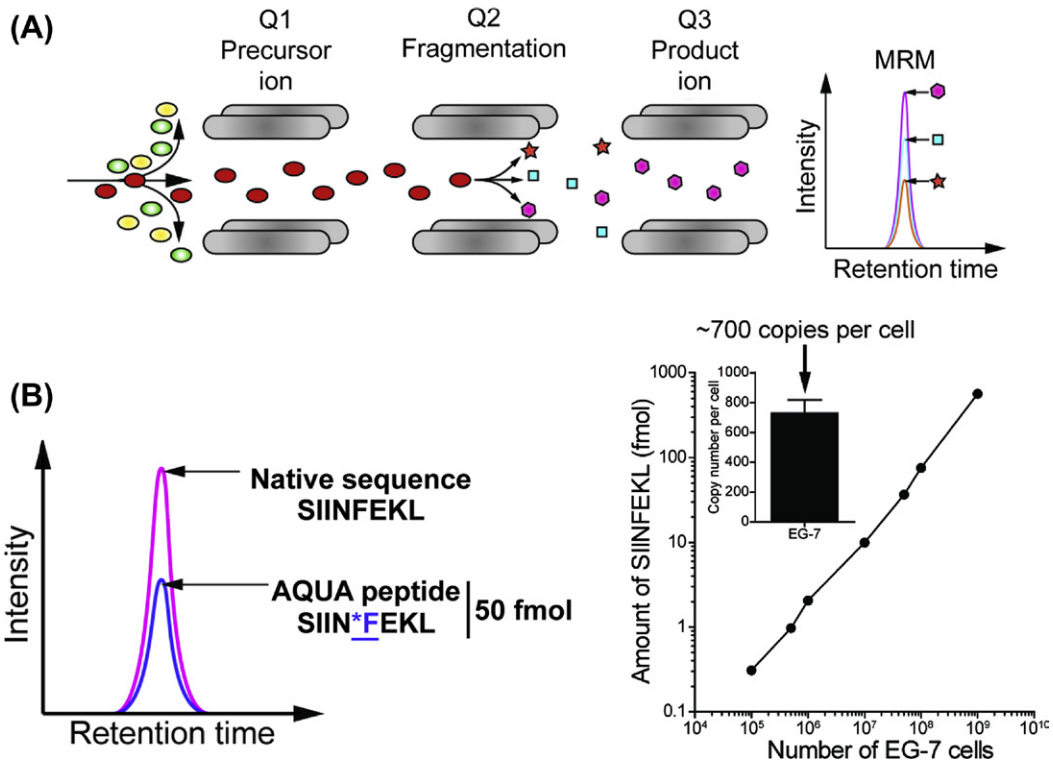

FIGURE 3 Multiple reaction monitoring and epitope quantitation (A). The concept of multiple reaction monitoring (MRM) Using a triple quadrupole mass spectrometer each mass analyzer can be used to spatially manipulate ions for the specific detection of a given analyte. The first quadrupole (Q1) is used to isolate a precursor ion of known m/z, in Q2 these ions are fragmented and in Q3 only fragment ions characteristic of the desired target analyte are detected. In a typical experiment, 3–4 fragment ions characteristic of the target peptide are monitored. The intensity of each Q1/Q3 mass pair (transition) is then plotted against retention time, and the area under each curve provides quantitative information. When used in combination with a heavy isotope labeled–peptide standard, the absolute quantity of the peptide can be determined (B). Shown in panel (b) is the estimation of the concentration of the SIINFEKL epitope derived from the surrogate tumor antigen chicken ovalbumin expressed by EG/7 thymoma cells.[1] For MRM analysis, peptide fractions were analyzed using a Eksigent TempoNanoLC cHiPLC coupled to a 5500 QTRAP mass spectrometer (AB SCIEX). The acquisition method was set to perform an MRM scanning experiment and to trigger a full mass MS/MS experiment for transitions that exceeded 500 counts. To quantify the amount of peptide present in each HPLC fraction, the area under each MRM transition peak was compared with an internal standard AQUA peptide. The copy number of SIINFEKL epitope per cell was calculated using Multiquant software by taking the molar quantity of peptides, multiplying by Avogadro's number and dividing by the cell number.

SYNTHETIC PEPTIDES AS VACCINES

Synthetic peptides offer several advantages over other forms of vaccines, particularly concerning safety and ease of production.[23] However, there are several disadvantages, the main issue being the poor immunogenicity of simple peptides and the need to more potently stimulate T-cells and elicit immunological memory. Adjuvant science, lipopeptide conjugation, and direct delivery to dendritic cells are some of the approaches currently being used to overcome this problem. Epitope-based vaccines are also restricted to use in patients of a given tissue type (HLA haplotype) and as such need to be personalized to accommodate natural variation in HLA genes. Although initially thought to be a major impediment, new technologies have made this personalized medicine approach quite feasible.[23] Moreover, the existence of HLA supertypes can simplify the use of epitope-based vaccines that target MHC I–restricted cytotoxic T-cells to essentially 9 super families, with shared peptide-binding specificity and shared epitope presentation (Table 1). Supertype motifs generally allow a significant reduction in the number of epitopes required to give good population coverage. However, supertypes are not always predictive of stable peptide binding, and significant variation even between closely related alleles can occur.[13] The binding of class II MHC ligands is much more promiscuous and as such motifs have been difficult to delineate with any great reliability. An alternative approach to the delivery of peptides with broad relevance to many different HLA allotypes is to use longer peptides and rely on their accurate processing to shorter allele-specific peptides. However, the use of longer peptide precursors is not always desirable

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

because tissue-specific processing and the frequent non-concordance of processing of longer exogenous peptides compared with endogenous antigens can result in unwanted immune responses.

Finally, the path that peptide vaccines follow is less well understood than that for endogenous peptides liberated from intact antigens either within the cell or captured from the extracellular environment. On vaccination, peptides are immediately exposed to relatively harsh conditions rich in proteases and peptides are thus rapidly degraded and cleared from the body. Peptide-based vaccination strategies therefore must take into account the poor stability of native peptides and their requirements for incorporation into their relevant MHC/peptide complex.

Incorporation of Tumor-Derived Peptides into Vaccines

Because most known tumor-specific antigens recognized by T-cells represent overexpressed or aberrantly expressed proteins, which are not mutated and to which immunological tolerance has been developed, many vaccine efforts have focussed on substitution of specific amino acid residues to produce more immunogenic analogs. Typically, this has been done using the 19 remaining naturally occurring amino acids (for a review of this area see Ref. 25) with the goal being to improve MHC-binding affinity. The rationale here is that the majority of immunogenic tumor epitopes fail to elicit full immunological tolerance. This may result from either weak MHC binding or that the available T-cell repertoire comprises low-affinity TcRs after thymic selection. Although such substituted peptides can readily elicit T-cells, they do not in themselves possess improved bioavailability. The authors and others have chosen additional chemical augmentation of peptides to not only enhance MHC binding but to also improve their bioavailability. Such modification of tumor epitope sequences can include the incorporation of nonnatural amino acids and peptide bond modifications. The synthesis of these peptidomimetic vaccines still has all the advantages of synthetic peptide vaccines but with the added benefit of improved bioavailability predominantly through protease resistance.[4] Peptidomimetic vaccine research began in earnest in the early 1990s through the analysis of the effect of introducing stereoisomers of amino acids into peptide sequences, that is, replacing L-amino acids with their D-enantiomers. This represented an empirical strategy to increase peptide bioavailability based on the observation that cellular proteases are unable to cleave peptide bonds incorporating D-amino acids. More rational approaches then undertook the analysis of retroinversion of a peptide whereby all amino acids are substituted with their D-enantiomer but in reverse sequence. This inverts the side-chain topochemistry into a conformation that closely resembles that of the L-amino acid side chains. It should be noted that for studies utilizing retroinverso peptides, N- and C-terminal modifications are required particularly for CTL epitopes. In addition to retroinversion, other forms of peptide bond alteration are also possible. These so-called pseudopeptides often have reduced peptide bonds whereby the carbonyl moiety in the natural peptide bond is replaced by a methylene group. A separate class of peptide mimetics that undergo backbone modification are *N*-hydroxylated peptides—modification of the amide nitrogen to contain a hydroxyl group, a process that renders the resultant peptide resistant to proteolytic degradation.

In addition to direct alteration of the peptide backbone, there is considerable interest within the peptide vaccine design in the replacement of individual or multiple amino acids with nonnatural amino acids. These may be functional homologs of natural amino acids or entirely novel chemical entities. For example, we have used a steroisomer of cysteine, L-amino butyric acid (Abu), as a functional homolog in several epitopes[2,32] resulting from the natural amino acids propensity to oxidize and mask immunogenicity. For example, the C-terminal cysteine residue in the HLA A2 tumor epitope NY-ESO$_{157\text{-}165}$[32] was replaced using this substitution. The Abu modification enabled the mimetic to maintain HLA-A2 binding and up to 1000-fold improvements in T-cell recognition by wild-type epitope-specific CD8$^+$ T-cells. This primarily results from a small increase in binding affinity and the prevention of undesirable consequences associated with synthetic cysteine-containing peptides; namely epitope-dimerization, oxidative damage and cysteinylation.[32]

Ideally, for agonistic peptides, the closer a peptidomimetic is to the native unaltered epitope, the more likely it is to remain immunogenic. We have explored the use of homologous β-amino acid substitution as a generic platform for generating peptidomimetic based vaccines. A β-amino acid contains an extra methyl group within the amino acid backbone, with the R group positioned on either the resulting second or third carbon atom. As a consequence, the side chain remains unaltered, yet the substitution results in a broad resistance to degradation by a wide range of proteases even with just a single substitution in a CTL epitope.[33] The authors and others have used sequential substitution of each individual residue with β-amino acids followed by monitoring for protease resistance, MHC binding, MHC thermal stability, and recognition by an epitope-specific CTL line as a screening strategy for vaccine components.[33] Results from these approaches have shown that changes introduced by the β-amino acid residue substitutions had independent effects on MHC binding and T-cell recognition but consistently engendered protease resistance. Likewise, Guichard et al. have applied a positional β-amino acid scan on the MART-1$_{27\text{-}35}$ melanoma epitope.[8] The optimal position for the β-amino acid was determined to be at the postulated

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

TCR contact residue Ile_{30}; interestingly, as a consequence, HLA-A2 binding was also enhanced.[8] Despite the success of these studies, none of the β-analogs described above have been tested *in vivo*. The only study so far to analyze this type of modification for *in vivo* immunogenicity has used the SIINFEKL epitope as a surrogate tumor antigen. By using a β-amino acid scan of this epitope, the MHC anchor residues were found to be the most efficacious site for β-amino acid replacement, with single substitutions at positions 5 and 8 conferring strong MHC binding and maintaining T cell recognition. Importantly, immunization of mice with the βPhe_5 analog generated crossreactive T-cells capable of lysing tumor cells expressing the native epitope.[33] Collectively, these studies suggest that β-amino acid-containing epitopes show promise as highly stable mimetics which, through careful manipulation, retain MHC binding and immunogenicity.

CONCLUSIONS

In this chapter, we have discussed the relevance of peptides to immune recognition and contrasted peptide vaccination with the processing and presentation of endogenous antigens. The advantages of peptides as vaccines have often been counterbalanced by their disadvantages, namely, poor bioavailability and the requirement to personalize vaccines because of the tremendous immunogenetic diversity in human populations. Relatively simple chemical modification of these peptides can overcome problems with bioavailability and generate potent immunogens. Moreover, the use of mass spectrometry to identify antigen-specific peptides both *in vitro* and *in vivo* will fast track the identification of tumor-specific epitopes from selected HLA haplotypes. In the near future, one can foresee where tumor biopsies may be probed by mass spectrometry using targeted approaches such as MRM to examine the actual presentation of tumor-specific epitopes on the surface of the patient's tumor and a cocktail of tumor peptides selected for immunotherapy. This will then allow chemically optimized forms of the peptide epitopes to be administered to patients. Thus, whether as a standalone treatment or used in combination with other antitumor strategies, there is a bright future for peptide-based vaccine in the treatment of cancer.

Chapter 80

Peptide Vaccine for Alzheimer's Disease

Beka Solomon

ABSTRACT

The pathology of Alzheimer's disease (AD) shows a significant correlation between β-amyloid peptide (AβP) deposition and severity of dementia. We have shown that antibodies toward the N-terminal region of β-amyloid peptide suppress *in vitro* and *in vivo* formation of toxic β-amyloid (Aβ). The epitope of these antiaggregating antibodies displayed on phage proved to be a potent antigen which induces antibodies against the whole AβP. In Alzheimer's diseased transgenic mice, these antibodies are delivered from the periphery to the CNS, preventing β-amyloid formation and/or dissolving such aggregates. Performance of such antigens offers possibilities for development of an efficient, long-lasting immunization for AD treatment.

INTRODUCTION

The pathology of AD is characterized primarily by extracellular senile plaques and intracellular neurofibrillary tangles.[26,27] The presence of amyloid in senile plaques and in cerebral blood vessels (amyloid angiopathy) has long been pathologically recognized. In 1984, Glenner and Wong were the first to sequence the deposits, showing them to be β-pleated sheets of amyloid (Aβ).[9] Soluble amyloid beta-peptide is a normal metabolite of approximately 4-kDa that is produced by processing a large transmembrane glycoprotein called amyloid beta-protein precursor (APP),[11,28] The pathological conditions and mechanisms that transform soluble beta-amyloid peptide into the fibrillary, toxic, beta-sheet form found in the plaques and vessels of patients with AD is not yet completely understood, but it is clear that the same amino acid sequence of beta-amyloid peptide can have both a fibrillar and soluble conformation.

Various theories have suggested that besides amyloid plaques, circulating amyloid, vascular amyloid and, more recently, soluble oligomeric species of amyloid may be responsible for the cognitive impairment and neural degeneration in AD.[12,14,26,27]

The most studied hypothesis, amyloid cascade,[14] states that overproduction of AβP, or failure to clear this peptide, leads to AD primarily through amyloid deposition, which is presumed to be involved in neurofibrillary tangles formation,[2,13] These lesions are then associated with cell death, which is reflected in memory impairment, the hallmark of this dementia.[12,13]

IN VITRO MODULATION OF β-AMYLOID FORMATION

Many investigators have studied the propensity of beta-amyloid peptide or its fragments to assemble into insoluble aggregates.[16,20] Beta-amyloid peptide can exist in two alternative conformations, depending on the secondary structure adopted by the N-terminal domain,[15,32] under various environmental conditions.[1] The N-terminal domain contains sequences that permit the existence of a dynamic equilibrium between the alpha-helix and the beta-strand conformations[32] (Fig. 1). The perturbations of the equilibrium of various conformational states of the beta-amyloid peptide can be caused by local pH changes, alterations of environmental hydrophobicity, or binding of other proteins.[17,32]

The involvement of the N-terminal region in conformational transformations of beta-amyloid peptide was confirmed by studies using synthetic peptides bearing the beta-amyloid peptide sequence in various solvents and in studies with synthetic beta-amyloid peptides containing single amino acid substitutions.[16] The polar domain of beta-amyloid peptide (1–28) is capable of stable self-association to form fibrils at acid pH, even in the absence of the stabilizing influence of the hydrophobic carboxyl terminus.[17] The importance of the N-terminal region in maintaining the solubility of the beta-peptide has been confirmed by studies showing that amino-terminal deletions within the (1–12) and (1–17) peptides enhance the aggregation of the beta-amyloid peptide *in vitro* in parallel with the neurotoxicity effect.[23]

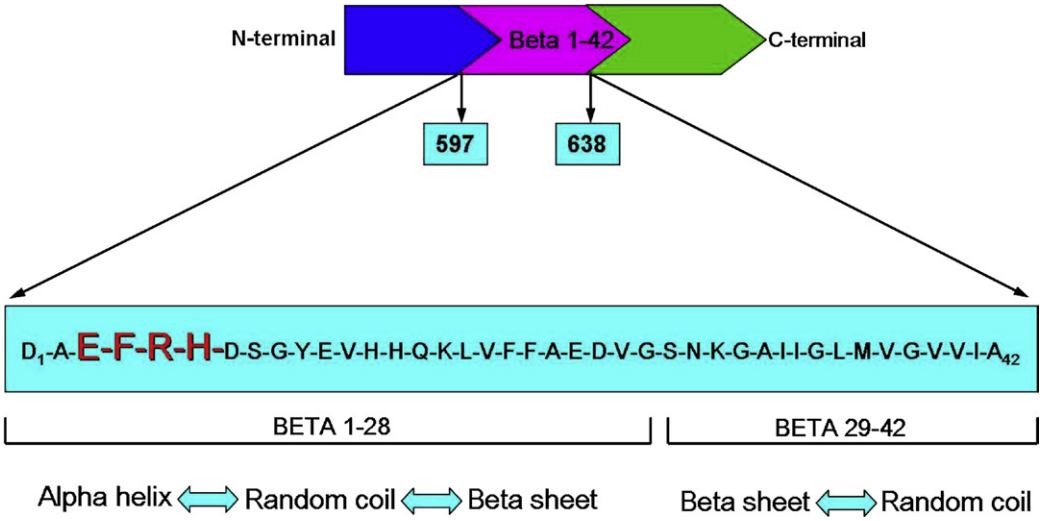

FIGURE 1

As beta-amyloid peptide might be critical for inducing the pathology seen in AD, its accumulation may result in a cascade effect, thereby allowing for intervention at multiple different points to slow disease progression. The treatment may be directed toward decreasing beta-amyloid peptide production, increasing its removal, and decreasing beta-amyloid aggregation.[3]

We showed for the first time that antibodies raised against the N-terminal region of the AβP peptide prevent amyloid formation and bind to preformed Aβ fibrils, leading to their disaggregation and inhibition of their neurotoxic activity.[29,30]

Antibodies interact at strategic sites where protein aggregation is initiated and are able to stabilize the antigen by preventing aggregation and resolubilizing already formed protein aggregates. For such an active role, the mAbs require a high binding constant to the "strategic" positions on the antigen molecule, and to be noninhibitors of the biological activity of the respective antigen.[31]

The ability of these antibodies to modulate βA formation *in vitro* and *in vivo* was found to be epitope dependent. We localized the epitope of antiaggregating antibodies in the N-terminal region of beta-amyloid peptide, which modulates amyloid formation,[4,5] using the phage libraries. The construction and application of several epitope libraries in which different peptides are expressed on the surface of filamentous phage (fd) has been described.[21,25] The minimal epitope for these mAbs was determined by using combinatorial phage-displayed six and/or fifteen peptide libraries. The immunopositive peptide-presenting phages were selected by AβP antiaggregating antibody according to the higher affinity binding, of about 10–9 M (half maximal binding). A consensus sequence of four residues, namely, EFRH (Glu–Phe–Arg–His), was found and this motif is sequentially located at positions 3–6 of the beta-amyloid molecule. The fact that the EFRH epitope is available for mAbs both when beta-amyloid peptide is either in solution or is an aggregate suggests that the N-terminal is exposed for antibody binding in both forms.[4,5]

We found that the epitope EFRH, which is located at the soluble tail of the N-terminal region, is involved in the aggregation process and acts as a regulatory site controlling both the solubilization and the disaggregation process of the beta-amyloid molecule. Locking of this epitope by antibodies modulates the dynamics of aggregation and resolubilization of already formed aggregates.

If the so-called pathological chaperones, such as ApoE and heparan sulfate, increase the extent of β-amyloid formation, we propose the use of site-directed monoclonal antibodies against β-amyloid peptides, which decrease β-amyloid formation as therapeutic chaperones.

Finding the "aggregating epitopes" as sequences that are related to the physiological protein regions where conformational changes are initiated, and preparation of antibodies against them, *are the bases of the immunological approach in treatment of conformational diseases, such as Alzheimer's disease*.

EFRH PHAGE ELICITS ANTIBODIES AGAINST β-AMYLOID PEPTIDE

We developed an immunization procedure for the production of effective antiaggregating AβP antibodies based on filamentous phages displaying on their surface the EFRH (Glu–Phe–Arg–His) peptide as the antigen,[6,7] which was found to be the main regulatory site for amyloid modulation.[5] Small synthetic peptides, consisting of antibody epitopes, are generally poor antigens and need to be coupled

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

to a large carrier, but even then they may induce only a low affinity immune response. The generation of antisera to define peptide sequences usually involves the chemical synthesis of a peptide and its conjugation to a carrier molecule.

Much effort has been made to circumvent the low affinity response with limited success. A novel turn has been accomplished by using filamentous bacteriophage as peptide carrier. Filamentous bacteriophages offer an obvious advantage over other immunocarriers.[35]

Filamentous bacteriophages have been used extensively in recent years for the "display" on their surface of large repertoires of peptides generated by cloning random oligonucleotides at the 5′-end of the genes coding for the phage coat proteins,[21,25] Filamentous phages are long thread-like single-stranded DNA phages, which infect bacteria via sex pili. The best known, the Ff phages, are a group of three phages (M13, fd and fl). The phage protein that is responsible for binding to the pilus tip, pIII, is present in four copies, encoded by gene 3. If foreign DNA that encodes a peptide or protein is inserted downstream of the leader sequence of gene 3, it will be translated and exposed at the N terminus of the mature pIII without compromising the ability of pIII to mediate infection via the F pilus. Although pIII is the protein most used for phage display, the major coat protein, pVIII, has also been used. The main difference between pIII and pVIII is the copy number of the displayed protein; although pIII is present in four copies, pVIII is found in 2700 copies.

Parenteral administration of filamentous phages in animals induced a strong immunological response to the phage proteins in all animals tested.[35] Mimotopes displayed on filamentous phages could be used as immunogens and form the basis for developing a wide range of vaccines.

Immunization with the EFRH phage of BALB/c mice may, in a short period of time (a few weeks), increase the high concentration of high affinity (IgG) antiaggregation antibodies. Seven days after each injection of 1011 phages displaying the epitope without the adjuvant, mice were bled, and their sera were tested by ELISA for antibody IgG reactivity against wildtype (WT) phage (not bearing the peptide EFRH on its surface) and against whole beta-amyloid peptide. Highly specific antibodies (IgG) against the beta-amyloid peptide were achieved after the first injection and the titers increased with the second and the third injection till 1:50,000.[7] Moreover, that specific IgA antibodies against the beta-amyloid peptide antiaggregation epitope EFRH were obtained seven days after only one boost through intranasal administration.[6] The level of antibody in the sera is related to the number of copies per phage. The high immunogenicity of filamentous phages enables the raising of antibodies against self-peptides or antigens. Immunization of guinea pigs with EFRH phage as antigen, in which the beta-amyloid peptide sequence is similar to that in humans, results in the production of antibodies against self-peptides. Although in mice there is a switch of one amino acid (glycine instead of arginine in position 5-EFGH), in guinea pigs, the amino acid sequences are identical to those in humans.[7]

Highly specific antibodies (IgG) against the AβP are achieved after the fourth injection effective in concentrations as dilute as 1:5000. Similar results are obtained after immunization with 1011 phage per intranasal injection without the adjuvant with an additional administration of antigen.

The antibodies resulting from EFRH phage immunization are similar regarding their immunological properties to monoclonal antibodies previously studied, and to the antibodies raised by direct injection with fibrillar toxic beta-amyloid.[6]

PEPTIDES AS VACCINES FOR THE PREVENTION AND/OR REDUCTION OF AMYLOID PLAQUES IN AD TRANSGENIC MICE

The abundant evidence that AβP aggregation is an essential early event in AD pathogenesis has prompted an intensive search for therapeutics that target amyloid β-peptide, especially after the development of animal models of the disease. Several laboratories have bred AD diseased models of transgenic mice that produce human AβP, which develop plaques and neuron damage in their brains, as reviewed.[34] Although they do not develop the widespread neuronal death and severe dementia seen in the human disease, they are used as models for the study of AD and putative treatments. With the development of transgenic mice (Tg), the immunological concept in the treatment of conformational diseases became immunization approaches being pursued to stimulate clearance of brain Aβ plaques.[30] They include both active and passive immunization techniques. Active immunization approaches use AβP epitopes and/or immunogenic AβP conjugates, as well as various routes of administration and types of adjuvants. Passive immunization approaches include monoclonal antibodies or specific antibody fractions (Fabs) directed against specific AβP epitopes.

The idea of eliciting an immune response to exogenously administered Aβ-peptide in humans was originally described in a 1990 U.S. patent by a physician and an experimental immunologist.[18] They proposed to parenterally administer low amounts (up to 10 μg/day) of Aβ-peptide to slow the development of amyloid plaques.

Later, Schenk et al.[24] showed that immunization with human synthetic fibrillar Aβ 42 in transgenic mice (PDAPP) harboring a mutant version of human APP770 (V717F) produces high serum antibody titers against Aβ 42 (1:10,000) and inhibits the formation of amyloid plaques and associated histopathologic lesions.

ACTIVE IMMUNIZATION OF HAPP TRANSGENIC MICE WITH EFRH PHAGE AS PEPTIDE VACCINE

We developed a series of antigens displaying the EFRH epitope on filamentous phages, which enabled modulating the immune response against AβP, according to the number of EFRH copies.[19]

APP[V717I] transgenic mice (16 months old) were immunized with the EFRH phage and analyzed at age 21 months.[8] Amyloid burden in the brain was significantly reduced in the immunized APP[V717I] transgenic mice that developed anti-AβP titers of at least 1:100, indicating that a relatively low antibody titer may be enough to reduce brain amyloid load.[8]

Another set of experiments was performed on transgenic mice which express human APP751 regulated by the neuronal murine Thy1 promoter. The hAPP gene carries both the London (717) and the Swedish (670/671) mutations, resulting in age-dependent increase in Aβ. Overexpression of the mutated human APP results in the development of typical AβP depositions as amyloid plaques in the neocortex and hippocampus. The mice were provided by JSW Research Co., Austria.[19]

hAPP transgenic mice were immunized with phages displaying EFRH sequences by intraperitoneal administration and analyzed at age 15 months. At this age, the amyloid plaque pathology is maximally and stably established.

Titer levels, although moderate, are positively correlated to the copy number of the EFRH epitopes displayed by the phage antigens. Titers obtained from sera of non transgenic mice or mice that were injected only with PBS are at background levels.

The amyloid burden in the brain is reduced in the immunized hAPP transgenic mice that developed anti-AβP titers of at least 1:100, similar to that in previous experiments,[6] showing a dose–response relationship between antibody titer and reduced amyloid load.

A considerable difference in plaque load content exists between treated and untreated mice. The reduction in total amyloid burden is related to the level of antibodies. We showed that a low but continuous titer of anti-EFRH is sufficient to reduce the amyloid burden.[19]

The development of AβP antiaggregating antibodies via immunization with phage-EFRH of AD models of transgenic mice show not only a considerable reduction of amyloid in the brains of the affected animals but also a considerable improvement in cognitive functions of the treated mice.[19]

The advantages of phage-EFRH antigen in raising antiaggregating β-amyloid antibodies versus whole β-amyloid can be summarized as follows:

1. The high immunogenicity of the phage enables production of high titers of IgG antibodies in a short period of weeks without need for adjuvant administration. Self-expression of the antigen led to long-lasting immunization.
2. The key role of the EFRH epitope in β-amyloid formation and its high immunogenicity leads to antiaggregating antibodies which recognize whole β-amyloid peptide and can substitute for whole toxic β-amyloid fibrils.

FUTURE OUTLOOK

In spite of uncertainty regarding the efficacy of AβP immunization in humans, the very promising results with APP Tg mice generated by several laboratories led ELAN/AHP to start human clinical trials after two and a half years of preclinical animal studies by injection of fibrillar Aβ 42 into participants in the clinical trials.

Patients with mild to moderate AD were immunized with AN1792 (fibrillar Aβ 1–42 plus adjuvant) in single- and multiple-dose Phase 1 safety studies, which were well tolerated and showed no significant safety concerns. Elan suspended inoculations in mid-January 2002 after some volunteers fell ill with what is called "clinical signs consistent with inflammation in the central nervous system."

Clinical trials showed stabilized cognition and slowed progression of dementia; however, there was neuroinflammation in some patients. Meningoencephalitis is not a feature of AD pathology and is probably a consequence of the immunotherapy. Vaccination seemed to have both beneficial and harmful effects, suggesting that the vaccine can have potent clinical utility if an appropriate immunological response can be generated.

An inflammatory reaction was probably triggered by T-lymphocyte activation after immune system stimulation with fibrillar Aβ 1–42. The adverse events observed in patients with AN1792 could reflect an autoimmune inflammatory response[22] because of T-cell epitopes to AβP 1–42, which reside in the mid-to-carboxy-terminal region of the beta-peptide.[10]

Improved immunotherapeutic strategies may be used to obtain a beneficial effect without untoward side effects. It is possible to induce AβP antibodies with no AβP T-cell response, as the N-terminal of AβP (1–15) contains the dominant B-cell epitopes that bind to Aβ plaques with no T-cell epitopes,[22] or with only small sequences from this region,[19] as described below.

In contrast, humans may develop self-antibodies when immunized with whole or fragments of AβP. These antibodies are capable of binding to a variety of Aβ species in the brain. Thus, immunization could have contradictory effects: the desired inhibition of amyloid fibril formation versus Fc microglial overactivation leading to neuroinflammation.[33]

How many antibodies are required for an effective immunization? No data are available on the quantitative decrease of AβP concentration necessary to reduce

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Aβ deposition. An increase of approximately 30% of Aβ concentration shifts the disease onset earlier by several decades.

Taking these arguments into consideration, the proposed EFRH sequence devoid of T-cell epitopes displayed on phage as antigens and able to provide a relatively low titer of AβP antiaggregating antibodies may become a real alternative for AD vaccination.

Despite the setbacks in the halted phase II Elan/Wyeth vaccination trial, amyloid immunotherapy strategies remain a novel and promising approach for the treatment and/or prevention of AD. To move forward, it will require considerable effort to determine whether immunotherapy will work in humans.

Amino acid sequence of β-amyloid peptide–C-terminal domain of AβP between 29 and 42 amino acids develops an β-strand structure in aqueous solutions independent of pH or temperature conditions, while the N-terminal region, 1–28 amino acids, can exhibit different conformations and solubility properties depending on environmental conditions. **EFRH** epitope of antiaggregating antibodies located at positions 3–6 is in bold.

Chapter 81

Peptide Vaccines for Myeloid Leukemias

Pratap Neelakantan and Katayoun Rezvani

ABSTRACT

Despite recent advances in the treatment of hematological malignancies, allogeneic stem cell transplant remains the only curative option for many patients with acute or chronic leukemias. The successful identification of many leukemia-associated antigen (LAA) and advances in understanding the fundamentals of tumor immunology have fostered the progress of immunotherapy. Preliminary results from many clinical studies suggest that vaccination using peptides derived from a number of LAAs is safe and induces immune responses, which may translate into clinical responses. In this chapter, we focus on the results of clinical trials of peptide vaccination in leukemia and discuss strategies to optimize the efficacy of immunotherapy in the future.

INTRODUCTION

Allogeneic stem cell transplant remains the only curative option for many patients with acute or chronic leukemia. Although the advent of tyrosine kinase inhibitors (TKIs) has significantly improved the outlook for patients with chronic myeloid leukemia (CML), the majority of patients continue to harbor residual disease. The potent graft versus leukemia effect (GVL), mediated by donor derived lymphocytes after allogeneic stem cell transplantation (SCT), supports a role for immunotherapy in leukemia. Evidence that the GVL effect plays a significant role in determining the risk of relapse after SCT came from studies reporting that relapse rates after allogeneic transplantation are markedly less in patients who developed graft-versus-host disease (GvHD) compared with those who did not. Further, the potential of allogeneic donor lymphocyte infusions to induce remissions in patients relapsing after SCT is strong evidence that T cells could destroy leukemia.[15] This realization led to efforts by many groups to generate leukemia-specific T cells for adoptive transfer in the treatment of leukemia relapse. Despite a successful demonstration of proof of principle, however, the approach has not been applied widely because of its cost and impracticability.[8] Meanwhile, other groups have explored the use of peptide vaccines derived from defined leukemia protein antigens, because of their potential to establish universal and practical vaccines for myeloid leukemias. In the last decade, a variety of proteins giving rise to leukemia-specific antigenic peptides have been characterized and several clinical peptide-based vaccine trials have been initiated in acute myeloid leukemia (AML), CML, and myelodysplastic syndrome (MDS) (Table 1).

LEUKEMIA-ASSOCIATED ANTIGENS (LAAs)

The successful identification of a range of LAAs that drive the GVL response in recent years has stimulated research in the development of vaccines to treat hematological malignancies.

LAA can be broadly categorized as: (1) unique leukemia-specific antigens or neoantigens, arising as a consequence of mutations or chromosomal translocations (e.g. BCR-ABL);[4] (2) aberrantly expressed or overexpressed self-antigens e.g. Wilms tumor (WT1)[9] proteinase-3 (PR3),[18,26] the receptor for hyaluronic-acid-mediated motility (RHAMM)[32] and preferentially expressed antigen of melanoma (PRAME);[24,30] (3) Viral antigens e.g. Ebstein-Barr virus (EBV); and 4) Allo antigens such as the minor histocompatibility antigens (mHAgs), HA-1 and HA-2.[10] An ideal target antigen for immunotherapy should be preferentially expressed on the leukemic progenitor cells, be intrinsic to leukemic survival so that viable tumor escape by down regulation of the antigen cannot occur and induce a strong cytotoxic T-cell (CTL) response.

Expression of LAA: Targeting neoantigens such as fusion proteins arising from specific chromosomal recombinations or mutated proteins for vaccination has the advantage that it is probably safe because of being restricted entirely to leukemia cells. However, the majority of LAAs identified to date are self-antigens that are also expressed by other normal tissues, raising concerns regarding the risk of autoimmunity. Interestingly, the requirement for exclusive expression by the leukemia is not absolute: the overexpressed self-antigen WT1, expressed on stem cells and at low levels on renal podocytes

TABLE 1 Summary of Peptide Vaccine Studies

Study, year	Vaccine	No. of patients	Diagnosis	Status before vaccination	Comments
BCR-ABL vaccines, phase I/II					
Bocchia et al.,[3] 2005	b3a2 breakpoint-derived peptides + QS21 + GM-CSF	16	CML CP	MCyR on imatinib or INF-α	Patients continued on imatinib or INF-α; 5/10 achieved CCyR (Imatinib group)
Bocchia et al.,[2] 2009	b3a2 breakpoint-derived peptides + GM-CSF	57	CML CP	CcyR on imatinib	Patients continued on imatinib; 67% had CD4+ T-cell proliferation. 0.5 log reduction in the BCR-ABL transcript level after 9 months
Rojas et al.,[31] 2007	PADRE-linked b3a2 breakpoint-derived peptides + GM-CSF	19	CML CP	MCyR on imatinib	Patients continued on imatinib. One log reduction in 13/14 patients in MCyR
Maslak et al.,[16] 2008	b3a2 or b2a2 breakpoint-derived heteroclitic peptides + Montanide + GM-CSF	13	CML CP	CcyR or MCyR on imatinib	CD8+ T cell responses. No objective responses
WT1 vaccines, phase I/II					
Oka et al,[20] 2004	WT1-235, heteroclitic + Montanide	20	MDS, AML	Measurable disease	12/20 had clinical responses + WT1 specific CTL response
Keilholz et al.,[14] 2009	WT1-126 peptide + KLH +GM-CSF	19	Breast, lung Ca AML (17), MDS (2)	PR, SD, PD	8/18 WT1-specific CD8+ T-cell responses; 6/10 objective responses
Maslak et al.,[17] 2010	Polyvalent WT1 peptide vaccine + GM-CSF	10	AML	CR	7/8 WT1-specific CD8+ T-cell responses. Median disease-free survival not reached at median follow-up of 30 months from diagnosis
PR1 vaccine, phase I/II					
Qazilbash et al.,[22] 2004	PR1 peptide + Montanide + GM-CSF	66	AML, CML, MDS	Measurable disease (53), CR (13)	Patients with immune response had better EFS: 8.7 vs 2.3 months ($P = 0.03$)
Combination of PR1 – Combined PR1 and WT1 vaccines					
Rezvani et al.,[27,28] 2008, 2011	PR1 + WT1-126 peptide + Montanide + GM-CSF	8	AML, MDS, CML	CR	PR1 or WT1-specific CD8+ T cells were associated with transient reduction in MRD
RHAMM vaccine – Phase I/II					
Schmitt et al.,[32] 2008	RHAMM/CD1 68-R3 peptide + Montanide + GM-CSF	10	AML, MDS, MM	PR, PD	5/10 immunological response, 3/10 objective response.

Abbreviations: CML CP: chronic myeloid leukemia in chronic phase, DTH: delayed type hypersensitivity, MCyR: major cytogenetic remission, IFN-α: interferon-alpha, CCyR: complete cytogenetic remission, AML: acute myeloid leukemia, MDS: myelodysplastic syndrome, Ca: cancer, PR: partial remission, PD: progressive disease, CR: complete remission, SD: stable disease, EFS: event-free survival, DC: dendritic cell, MRD: minimal residual disease.

and gonadal cells, behaves in a leukemia-restricted manner because only the malignant cells which overexpress WT1 are susceptible targets of T cell attack.[9] Similar concerns that immune reactions against proteins such as PR3 and neutrophil elastase (NE) may target not only the leukemia cells, which overexpress the protein but also normal tissues that express lesser amounts of the protein such as normal early myeloid precursors have so far been unjustified.[23,27,28]

There is an assumption that effective immunotherapy requires the target antigen to be expressed by the earliest

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

leukemic progenitor. Although this seems to be a reasonable criterion for antigen selection, it may not be a prerequisite in every case: individual leukemias have diverse hierarchical patterns of progenitor and progeny. CML progression, for example, seems to derive from the committed granulocytic progenitor.[12] We have delineated the spectrum of expression of mHAgs and candidate LAA including PR1, WT1, and PRAME, within the CD34+ primitive stem cell and the committed progenitor pool of CML cells.[35] We found heterogeneity in the expression of leukemia antigens, whereas mHAs are expressed in all CD34+ stem cell populations, the expression of LAA is varied depending on CML disease phase and CD34 progenitor maturity. WT1 and PRAME are preferentially expressed in the advanced stages of CML, whereas PR3 and NE are expressed in chronic phase CML.

Functional importance for the leukemic phenotype: It is possible for malignant cells to escape immune control by down-regulating antigen expression. Selecting antigenic targets that are intrinsic to the maintenance of the leukemic phenotype (e.g. BCR-ABL, WT1, PR3) may render it impossible for the leukemia cell to escape and still retain leukemic function.[5,21,34] It should be remembered, however, that it is possible for leukemic stem cells to evade immune surveillance by down regulating the appropriate major histocompatibility (MHC) molecules, allowing them to conserve essential leukemic features.

Immunogenicity: The ability of the LAA to elicit an immune response in the form CTLS is the key to successful immunotherapies. CTLs directed against mHAg and a number of LAA including PR1, WT1, RHAMM, and PRAME have been shown to selectively eliminate leukemic cells while sparing normal CD34+ cells.[18,24–26,29,30,32] Further, the presence of memory T cells directed against LAA further strengthens the evidence for *in vivo* immunogenicity of these antigens.[25,26]

VACCINATION

The increasing array of both allo antigens (mHAg) and LAA that can elicit antileukemia T-cell responses provides the basis for the development of vaccines for leukemia. Vaccination offers a less complicated alternative to the expense and technical complexity of alternative forms of immunotherapy such as adoptive T-cell transfer; however, little is known about the best approach for a successful vaccination strategy.

WHY PEPTIDES?

Peptide vaccines are attractive to use in clinical trials because they are relatively cheap, easily manufactured to clinical grade, and easy to administer. We will focus on clinical trials of peptide vaccination in leukemia.

BCR-ABL PEPTIDE VACCINE

BCR-ABL offers an attractive approach to vaccination, as BCR-ABL is central to leukemogenesis and expressed by leukemic cells only. A number of phase I/II studies have investigated the safety and immunogenicity of BCR-ABL peptide vaccination in patients with CML.[3,6,16,31] Pinilla-Ibarz and colleagues at the Memorial Sloan-Kettering Cancer Center developed the first BCR-ABL vaccine, composed of a pool of six peptide fragments derived from the b3a2 junctional region. The vaccine and its adjuvant, QS-21, were well tolerated and elicited T-cell immune responses to BCR-ABL with no major cytotoxicity.[6] In a subsequent phase 2 study involving 14 CML patients, delayed type hypersensitivity or CD4+ proliferative responses to the peptide vaccines were noted in all patients.[6] Reduction in marrow Philadelphia (Ph) positive chromosomes occurred in four patients, but three of these continued other treatments such as IFN-α or imatinib. Three patients with molecular relapse after SCT had transient molecular remissions, but two had also been treated with DLIs. These results, while promising, could not convincingly demonstrate the efficacy of the vaccine.

In a subsequent Italian study, 16 CML patients who had achieved stable residual disease after a minimum of 12 months' treatment with imatinib or 24 months with IFN-α received six vaccinations with a peptide vaccine derived from the b3a2 junctional region plus recombinant granulocyte macrophage colony-stimulating factor (GM-CSF) and QS-21 as adjuvant (CMLVAX100).[3] All patients had improvements in their cytogenetic response, with five patients achieving complete cytogenetic remission (CCyR). Three of these five patients also had negative polymerase chain reaction (PCR) for BCR-ABL. The interim analysis for a follow up phase 2 study in 57 CP CML patients who had achieved a CCyR on at least 18 months of imatinib treatment was presented at the Annual Meeting of the American Society of Hematology (ASH) in 2009. The investigators reported that 67% of 43 evaluable patients had a significant *in vitro* b3a2-peptide-specific CD4+ T-cell proliferation.[2] Fourteen of 29 evaluable patients who reached the ninth month evaluation had at least a 0.5 log reduction in the BCR-ABL transcript levels. It must be emphasized that patients continued with their imatinib therapy throughout the vaccination period.

Similarly, in a phase I/II study from the UK, Rojas et al. reported that the administration of peptides spanning the b3a2 junctional region, linked to the pan DR epitope (PADRE) to enhance CD4 T-cell responses, consistently induced T-cell response in vaccinated patients, as measured by IFN-γ ELISPOT and tetramer staining.[31] Of the 14 patients in major cytogenetic response (MCyR) at baseline, 13 developed at least 1 log fall in BCR-ABL transcripts, though this occurred several months after completing vaccination and no molecular

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

benefit was seen in five patients who were not in MCyR at baseline.

By contrast, in a pilot study of vaccination with heteroclitic class I and II peptides, modified to enhance their binding to HLA class I and class II molecules, despite the successful induction of CD8+ T-cell responses that cross-reacted with native junctional peptides, Maslak and colleagues failed to show a clinically relevant activity, even in the setting of minimal residual disease (MRD).[16]

Taken together, these studies support the immunogenicity and safety of BCR-ABL peptide vaccination in patients with CML, although in the setting of current treatments with TKIs, data on possible clinical responses to BCR-ABL peptide vaccination are difficult to interpret.

WT1 PEPTIDE VACCINE

WT1 is a zinc finger transcription factor that is normally expressed in the tissues of mesodermal origin during embryogenesis. In normal adult tissues, WT1 expression is limited to low levels in normal CD34+ve hematopoietic stem cells, myoepithelial progenitor cells, renal podocytes and some cells in testis and ovary. Although originally described as a tumor suppressor gene, the WT1 protein also seems to be involved in tumorigenesis, as WT1 is overexpressed in most cases of AML, CML, MDS and acute lymphoblastic leukemia (ALL), and in several solid tumors.[33] Further, expression increases as disease progresses, making WT1 an attractive vaccine candidate in otherwise untreatable advanced leukemias.[35] Several investigators reported the presence of both humoral and cellular immune responses to WT1 in patients with hematopoietic malignancies, indicating that WT1 is a highly immunogenic antigen *in vivo*.[7,25,26,29] These observations suggest that WT1 is an interesting vaccine candidate for hematological malignancies.

Oka et al. first reported the outcome of a phase I clinical study of WT1 peptide-based immunotherapy in patients with breast or lung cancer, MDS, or AML.[20] Patients received a heteroclitic HLA-A24 restricted 9-mer WT1 peptide (WT-235), modified to enhance its affinity binding to HLA class I. The vaccine was administered in Montanide adjuvant at 2 weekly intervals in a dose escalation study. The vaccine was well tolerated and 12 of 20 evaluable patients had clinical responses, including reductions in blood or marrow leukemic blasts, tumor size, or tumor markers, associated with increases in WT1-specific CTL frequencies.

In a similar study, Keilholz and colleagues in Germany investigated the safety and immunogenicity of vaccination with an HLA-A0201-restricted WT1 peptide (WT-126) with keyhole limpet hemocyanin (KLH) and GM-CSF as adjuvants. A total of 19 patients (17 AML and 2 with MDS) received a median of 11 vaccinations. Treatment was well tolerated. Clinical responses were seen in 6 of 10 patients, including 4 stable disease (SDs) with >50% blast reduction and 2 with hematological improvement. An additional four patients had clinical benefit after initial progression, including one complete remission (CR) and three SDs. WT1 transcripts as molecular disease marker decreased in 35% of patients.[14]

Maslak and colleagues at the memorial Sloan-Kettering investigated the immunogenicity of a polyvalent WT1 vaccine containing a cocktail of WT1 peptides to stimulate both CD8+ and CD4+ T-cell responses.[17] Ten AML patients in CR but with molecular evidence of WT1 transcript received six vaccinations plus immune adjuvants over 12 weeks. Of the nine evaluable patients, seven completed six vaccinations and WT1-specific T-cell responses were noted in seven of eight patients. Three patients who were HLA-A0201-positive showed significant increases in the frequency of WT1-tetramer-positive CD8+ T cells. The median disease-free survival for the group had not been reached at the time of publication.

Although the lack of a control group limits the analysis of these trials, the promising results indicate that WT1 vaccination can induce functional CTL responses, which may be associated with clinical improvement in some patients, and support further studies using WT1 as a target cancer antigen.

PR1 PEPTIDE VACCINE

PR1 is a nine amino acid, HLA-A0201-restricted peptide, shared by two myeloid LAAs, PR3, and NE. PR3 and NE are found in the primary (azurophil) granule proteins of normal granulocytes and are overexpressed in myeloid leukemia cells. PR1 induces powerful HLA-A0201-restricted CD8+ T-cell responses that selectively kill myeloid leukemia cells *in vitro*.[18] The detection of low frequencies of PR1-specific CD8+ T cells in patients with CML and at higher frequencies in patients entering molecular remission after allogeneic SCT supports the concept that there is natural immunity to PR1, which can be boosted further by vaccination.[19,26]

Highly encouraging preliminary data from a pilot study of PR1 peptide vaccination in patients with myeloid malignancies were first presented by Molldrem and colleagues at ASH in 2004[22] and updated at ASH in 2007.[23] A total of 66 HLA-A0201-positive patients with AML (42), CML (13) or MDS (11) received one of three dose levels of PR1 peptide vaccine: 0.25, 0.5, or 1.0 mg per vaccination every 3 weeks, together with Montanide adjuvant and GM-CSF. The vaccine was well tolerated. Of the 53 patients with active disease, 25 (47%) had an immune response. Clinical responses ranging from improvements in blood counts to CCyR were observed in nine of 25 responders (36%), compared with three of the 28 nonresponders (10%).

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Analysis of the effectiveness of this approach in a subgroup of 20 patients with myeloid leukemia vaccinated after SCT showed a PR1 response to the vaccine in 11/20 (55%) patients. Nine of 11 (82%) patients with a PR1 response compared with one of nine (11%) patients who failed to mount an immunological response to the vaccine had clinical responses ($P = 0.005$). Importantly, a significant PR1 response to the vaccine was associated with significantly better clinical response and longer event-free survival (EFS). These encouraging results have culminated in a Phase 3 multicenter study of PR1 vaccination in patients with myeloid malignancies.

COMBINED PR1 AND WT1 PEPTIDE VACCINES

Our group conducted a phase I study to assess the safety and immunogenicity of vaccination with a combination of PR1 and WT1-126 peptides in eight HLA-A0201-positive patients with low risk myeloid malignancies.[28] Five patients with AML in CR (one following a second unrelated donor SCT), two patients with MDS (refractory anemia and refractory anemia with ring sideroblasts) and one patient with CML in chronic phase (BCR-ABL negative on imatinib) were recruited. Patients received a single subcutaneous injection of PR1 (0.5 mg) and WT1-126 (0.2 mg) peptide vaccines in Montanide adjuvant, administered concomitantly with GM-CSF. Patients were reviewed weekly to monitor for toxicity and immunological responses. Toxicity was limited to grade 1–2. CD8+ T-cell responses against PR1 were detected in 7/8 and against WT1-126 in 5/8 vaccinated patients. Vaccine-induced T-cell responses were detected as early as 1–2 weeks postvaccination in most patients, but these responses were short-lived. Postvaccination, the emergence of PR1 or WT1-specific CD8+ T cells was associated with a significant but transient reduction in MRD as assessed by WT1 gene expression, suggesting a vaccine-induced antileukemia response.

These encouraging results led to the initiation of a phase II study of biweekly injections with PR1 and WT1 peptide vaccines in patients with myeloid malignancies. Again, the combination of PR1 and WT1 peptide vaccines was found to be immunogenic in all patients. However, repeated vaccination led to selective deletion of high avidity vaccine-induced T cells and additional boosting did not increase the frequency of PR1 or WT1-specific CD8+ T cells further. In four of six patients, the vaccine-induced T-cell response was lost after the fourth dose and in all patients after the sixth dose of vaccine.[27] Therefore, although these results support the immunogenicity of PR1 and WT1 peptide vaccination, novel approaches will be needed to induce long-term immune responses against these leukemia antigens.

RHAMM PEPTIDE VACCINE

RHAMM, also known as CD168, was first described as a soluble binding protein released by subconfluent migrating cells that interact with hyaluronic acid (HA) to promote cell motility and invasion.[32] Because RHAMM lacks a signal peptide, it interacts with CD44 to bind its ligand HA. RHAMM has been related to motility, transformation, adhesion, wound healing, metastasis, and growth. RHAMM is overexpressed in AML and CML and is immunogenic, making it an ideal LAA.

A phase I/II study investigated the safety and immunogenicity of vaccination using the HLA-A0201-restricted RHAMM/CD168-R3-peptide in ten patients with AML, MDS, or multiple myeloma.[32] Vaccination with 300 mg of R3 peptide induced immunological responses in five of ten patients. Clinical responses were observed in three patients; one patient with AML and one with MDS had a significant reduction in blasts in the bone marrow and one patient with MDS no longer required erythrocyte transfusions after four doses of vaccine. The study was therefore extended and further patients were vaccinated with an increased dose of 1000 mg of R3 peptide.[11] Nine patients were vaccinated, of whom four had positive immunological responses. However, higher doses of peptide did not improve the frequency and intensity of immune responses in this trial.

IMPLICATIONS AND FUTURE PERSPECTIVES

Taken together, these studies support the safety and immunogenicity of peptide vaccination in patients with leukemia. However, although encouraging antileukemia responses (mainly in the setting of MRD) have been reported, convincing results on sustained clinical efficacy are lacking. The current trials have so far failed to identify the best target antigen and the optimal schedule for vaccination.[20,22]

The transient immunological and clinical responses seen in many trials of peptide vaccination with CD8 epitopes may be partly explained by the lack of CD4+ T cell help in these studies. CD4+ T cells are essential for secondary CTL expansion and the induction of immunological memory.[13] It is therefore possible that inclusion of MHC class II binding peptides in a vaccine to elicit CD4+ T cells may improve the success of vaccination. The choice of adjuvant also seems to be very important in determining the peptide-specific immune response. Bijker et al. demonstrated that vaccination with CD8 epitopes derived from self-antigens mixed with oil-in-water adjuvants such as Montanide results in transient effector CD8 T-cell responses and fails to induce CD8 T cell memory in mice.[1] They proposed that the sustained systemic presentation of the peptides gradually

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

leaking out of the oil-in-water depot without systemic danger signals leads to tolerance induction. This hypothesis was further supported by the demonstration that vaccination with peptides admixed with PBS, resulting in relatively short duration of antigen presentation, induced memory CD8+ T cells that were able to expand on secondary antigen stimulation *in vitro*.

Although both the clinical setting in which vaccines are used as well as their design and mode of application (e.g. CD4 epitopes, adjuvants) clearly are important parameters, it is likely that this is an oversimplification. The fact that the majority of LAA under investigation are nonmutated self-antigens and as such are likely to induce immune tolerance further adds to the challenges of peptide vaccination. Well-designed multicenter clinical studies are imperative to improve the results of peptide vaccination by addressing basic questions such as the ideal target antigen, the optimal vaccine dose and vaccination schedule, the inclusion of CD4+ T epitopes and the role of novel immune modulatory agents to enhance the vaccine-induced T-cell response.

Chapter 82

Peptide Vaccines for Otitis Media

Laura A. Novotny and Lauren O. Bakaletz

ABSTRACT

Nontypeable *Haemophilus influenzae* (NTHI) is a predominant causative agent of bacterial otitis media (OM). Of interest for vaccine development are several conserved or semiconserved NTHI surface proteins. We have focused our efforts on two of the multiple adhesins expressed by NTHI, outer membrane protein P5 (OMP P5) and the Type IV pilus (Tfp). NTHI OMP P5 is a fimbrial structure shown to be expressed by 100% of clinical NTHI isolates recovered from children with chronic OM. This adhesin mediates bacterial binding to epithelial cells, mucin, CEACAM1, and ICAM-1. NTHI Tfp is a filamentous polymer that mediates adherence to epithelial cells, competence, twitching motility, and biofilm formation. Because of amino acid conservation within specific domains, surface location, and important biological functions, we targeted each adhesin for vaccine development, generating highly efficacious, synthetic peptide, and recombinant chimeric peptide immunogens.

DISEASE TARGET

Otitis media, both acute and chronic, are highly prevalent pediatric diseases worldwide. In 1990, 24.5 million physician office visits were made for OM in the U.S. which represented a >200% increase over those reported in the 1980s.[26] OM is the most frequently diagnosed illness in children less than 15 years of age and is the primary cause for emergency room visits.[11] It is estimated that 83% of all children will experience at least one episode of acute OM (AOM) by age 3 and that >40% of children will experience 3 or more episodes of AOM by this age.[32] Worldwide, it is reported that between 65 and 330 million children suffer from chronic secretory OM, a disease characterized by chronically draining ears and long-term hearing loss.[19] Shockingly, in 1990, approximately 28,000 childhood deaths were attributed to OM, primarily in developing countries.[26] Although in developed countries OM is rarely associated with mortality, the associated morbidity is significant. Hearing loss is the most common complication of OM with behavioral, educational, and language development delays being additional consequences of early onset OM with effusion, or OME.[32] The socioeconomic impact of OM is also significant, with direct and indirect costs of diagnosing and managing OM exceeding $5 billion annually in the U.S. alone.[3,15]

BACKGROUND OF AVAILABLE THERAPIES

To date, antibiotic use, both therapeutically and prophylactically has been largely relied upon for medical management of the spectrum of clinical entities known collectively as OM. With 20 million antibiotic prescriptions annually in the U.S., OM is the primary reason for a child to receive an antimicrobial.[1] Due to the emergence of multiple antibiotic resistant bacterial strains, clinical practice guidelines were revised in 2004 to implement a period of 'watchful waiting' for otherwise healthy children diagnosed with OM with effusion who were likely to resolve disease without treatment, versus immediate prescription of antibiotics for children with more severe acute OM.[2]

Surgical management of OM involves the insertion of tympanostomy tubes through the tympanic membrane (or eardrum) while a child is anesthetized. Although this procedure is commonplace and is highly effective in terms of relieving painful symptoms by draining the middle ear of accumulated fluids, it has been met with criticism because of the invasive nature of the procedure and the incumbent risks of putting a child under general anesthesia.

Clearly, there is a tremendous need to develop more effective and novel approaches to the management as well as prevention of OM. Vaccine development holds the greatest promise and would be the most cost-effective method to accomplish this goal. However, progress in terms of vaccine development for NTHI, the Gram-negative pathogen that predominates both in *chronic* OM with effusion, as well as being a significant etiologic agent of *acute* OM, is hampered by our incomplete understanding of the pathogenesis and immunobiology of OM, a polymicrobial disease caused by one or more of three predominant bacterial pathogens, whose ability to invade the tympanum is facilitated by virtually any upper respiratory tract virus and some enteroviruses. Thus, pathogenesis is dependent on interactions

FIGURE 1 Synthetic chimeric peptide immunogens, LB1 and LB2.

between microbes, within distinct microenvironments of the host, and the evolving innate and acquired immune responses to these microbes. Adding to the complexity is the ability of the bacteria that cause OM to form biofilms, communities of bacteria that are recalcitrant to standard therapies, and resistant to host defenses. As NTHI are an extremely heterogeneous group of microorganisms, identification of appropriate and conserved targets for vaccine development has proved to be quite challenging. Because adherence and colonization are of primary importance in the disease course of OM, we have focused our vaccine development efforts to date on two candidates that target two of several known NTHI adhesins.

WHY PEPTIDES?

In 1988, we made the observation that 100% of a panel of clinical NTHI isolates recovered from children with chronic OM expressed a filamentous OMP P5-homologous adhesin.[9] To begin to characterize the biological functions of this structure, we cloned and sequenced the gene that encodes the adhesin in NTHI strain 1128. The nucleotide sequence of OMP P5 encodes a mature protein of 338 amino acids with a calculated molecular mass of 36.4 kDa.[31] Expression of OMP P5 facilitates NTHI adherence to human oropharyngeal cells and nasopharyngeal mucin, as well as to CEACAM1- and ICAM-1-expressing cells.[4,10,28] Upon disruption of *ompP5*, the mutant shows reduced adherence to human oropharyngeal cells *in vitro*. In animal models of experimental OM, the OMP P5 mutant is cleared more rapidly from the chinchilla middle ears after direct challenge and is significantly less able to induce OM after intranasal inoculation.[31]

Although OMP P5 is an adhesin and a virulence factor for OM in chinchilla models, immunization with the whole native protein was only effective against challenge with the homologous isolate,[7,8,31] with no (or limited) protection conferred against heterologous challenge, as had been shown with many other NTHI OMPs when used in their entirety as an immunogen. To overcome this obstacle and identify a minimal region of the protein that could elicit a protective response, we subjected the translated amino acid sequence of OMP P5 to multiple algorithmic analyses and determined that there were two predominant putative B-cell epitopes of interest that resided within two of four predicted surface-exposed loops within this protein (loops 3 and 4).[35] With the rationale that inclusion of both B- and T-cell epitopes within the design of a synthetic peptide immunogen can induce antibodies of higher affinity to the incorporated B-cell epitope, combined with the knowledge that particular T-cell epitopes are broadly permissive in binding to human MHC class II molecules,[16] we synthesized two 40-mer peptides called 'LB1' and 'LB2' that comprised each B-cell epitope colinearly synthesized with a 'promiscuous' T-cell epitope from the fusion protein of measles virus[8] (Fig. 1). Sera obtained from immunized rabbits and chinchillas demonstrated significant reciprocal titers to LB1, and this antiserum also immunolabels native OMP P5 expressed by whole unfixed NTHI.[8] LB1 (but not LB2) induces significant protection against homologous and heterologous NTHI challenge in chinchilla and rat models of direct middle ear or lung challenge[7,8,18] as well as the prevention of ascending OM in a chinchilla passive transfer-superinfection model[17] compared to sham treated controls. Additionally, transcutaneous immunization of chinchillas with LB1 results in significantly earlier eradication of NTHI from the nasopharynx and middle ears of chinchillas when utilized in preventative and therapeutic immunization strategies.[23]

Although these were encouraging results, we wanted to determine the relative amino acid conservation within the B-cell epitope incorporated within LB1 as an indicator for potential breadth of protective coverage this immunogen might provide. To do so, a panel of 99 strains from the U.S. and Europe were subjected to PCR amplification and nucleotide sequence analysis of the 19-mer B-cell epitope incorporated into the peptide immunogen, LB1. Upon alignment of sequences (each 13–22 amino acids long), strains segregated into three groups based on at least 75% identity to the consensus sequence of that group. Approximately 76% of the NTHI strains clustered into majority Group 1, 16% to Group 2 (limited, but consistent sequence differences further divide this group into subgroups 2a and 2b) and 8% to Group 3 (Table 1).[8] Therefore, an immunogen that incorporated the B-cell epitope derived from majority Group 1 could be predicted to induce antibodies that would potentially crossreact with approximately 76% of circulating NTHI isolates.

Although LB1 is highly efficacious against OM resulting from NTHI in animal models, the incorporation of a T-cell promiscuous epitope was considered potentially problematic for a pediatric vaccine against OM, although its inclusion could be useful for older patient populations and/or other diseases of the respiratory tract due to NTHI. We

therefore sought to replace the measles virus fusion protein moiety without reducing the overall efficacy observed for LB1. In 2005, ongoing efforts within the laboratory to identify novel NTHI virulence determinants revealed that NTHI strain 86-028NP possesses a four-gene cluster, *pilABCD*, which is highly homologous to gene loci in other bacterial species that express Type IV pili (Tfp).[6] Upon further interrogation, the *comABCDEF* competence gene cluster was also identified, one gene of which encodes the ComE secretin, a protein required for passage of an assembled pilus through the cell membrane. Thus, NTHI 86-028NP possesses the genetic material required to assemble and express functional Tfp. However, as Tfp had not yet been described for NTHI, we first confirmed that the bacterium produced this structure. When cultured under defined nutrient conditions and at an alkaline pH, >80% of NTHI express several Tfp-like structures of an approximately 6- to 7-nm diameter, localized to a slightly off polar location.[6] Further, no Tfp are observed upon disruption of the gene that encodes the majority subunit of the pilus, PilA. Functionally, Tfp are involved in competence, adherence, biofilm formation, twitching motility, and colonization. Upon disruption or deletion of *pilA*, NTHI is unable to take up exogenous DNA, shows reduced adherence to normal human bronchial epithelial cells, forms a biofilm of diminished height and density and is attenuated in its ability to twitch on solid medium, compared to the parent strain.[6,14,33] Moreover, the *pilA* mutant is compromised in its ability to maintain long-term colonization (>10 days) within the chinchilla nasopharynx and forms a biofilm within the middle ear with reduced structural integrity, compared to the parent strain.[14]

We therefore focused on developing a novel chimeric immunogen wherein NTHI PilA could serve as both a carrier peptide for the OMP P5 B-cell epitope and a powerful co-immunogen. Toward that end, we confirmed that within a panel of 24 clinical NTHI isolates recovered from patients in the U.S. and Europe with a variety of acute or chronic respiratory tract diseases that a single *pilA* gene was present within the genome of each strain.[6] Moreover, alignment of the deduced amino acid sequences of the PilA proteins revealed >81% homology among the strains with only two regions of limited diversity (Fig. 2) (unpublished observations).[6] Antibodies against an approximately 14 kDa N-terminally truncated and recombinant soluble form of PilA, 'rsPilA', recognize native Tfp expressed by viable NTHI *in vitro*.[21] Moreover, rsPilA affords significant protection against NTHI-induced OM in the chinchilla passive transfer–superinfection model[21] and as observed with LB1, transcutaneous immunization of chinchillas with rsPilA was significantly efficacious in both preventative and therapeutic immunization regimes.[23] As a result of these findings, we designed and expressed a novel

chimeric immunogen in which rsPilA served as a unique immunogenic protein that carries the slightly larger (24-mer) OMP P5 B-cell epitope at its N-terminus (Fig. 3C). The resultant chimeric recombinant immunogen, called 'chimV4,' thus has the potential to simultaneously induce the formation of protective antibodies directed against two key NTHI virulence determinants within a single, approximately 18-kDa protein.

In support of this premise, we showed that serum from animals immunized with chimV4 contains antibodies that recognized both rsPilA and the OMP P5 B-cell epitope individually.[21] Passive transfer of serum raised against chimV4 to adenovirus-compromised chinchillas by cardiac puncture, followed by NTHI challenge, confers significant protection against ascending NTHI-induced OM.[21] No statistically significant differences were observed between cohorts that received anti-rsPilA or anti-chimV4 serum pools; however, this chinchilla model of experimental OM may not be sensitive enough to detect an additive effect. Interestingly, immunization with chimV4 by transcutaneous immunization (TCI) results in significantly fewer NTHI detected within directly challenged middle ears and complete eradication of bacteria within 10 days after challenge.[23] Moreover, after a therapeutic immunization regime, receipt of chimV4 by TCI induces a significant reduction or eradication of NTHI biofilms already resident within the middle ear. Although no statistically significant differences in resolution of OM is observed after transcutaneous immunization after preventative or therapeutic strategies between cohorts that received either rsPilA or chimV4, receipt of chimV4 is associated with a greater reduction in the number of NTHI within the middle ear and enhanced resolution of signs of active disease compared to immunization with rsPilA.

OUR CONTRIBUTIONS TO THE AREA

Active immunization with either isolated native OMP P5 or with the P5-derived synthetic peptide immunogen LB1 induces significant protection in chinchilla models against homologous challenge. However, to assay for potentially greater breadth of protective efficacy, we conducted a passive protection study in which antiserum directed against LB1 was now assayed for ability to confer protection against heterologous challenge using NTHI strains representing majority Group 1 but also a minority Group 2 and 3 isolate as well.[17] We found that passive immunization of chinchillas with serum specific for LB1 before challenge with heterologous NTHI isolates significantly inhibits the signs and incidence of OM ($p \leq 0.01$) induced by all three challenge isolates (Fig. 4). These results suggest that the approximately nine-residue N-terminal portion of the 19-mer sequence that is shared among all three NTHI groups (Table 1) and is incorporated into LB1 [RSDYFK(L)YE(N,D)D(K,N) is potentially an immunodominant region of this epitope or that it perhaps comprises a key protective epitope.[17]

In addition to noting the ability of anti-LB1 antiserum to provide significant crossprotection relevant to induction of culture-positive OM, in this study, we also observed that the ability of this antiserum pool to induce total eradication of NTHI from the nasopharynx was not equivalent among challenged cohorts despite the noted protection against development of OM. Importantly, these data thus suggested that while early, complete eradication of NTHI from the nasopharynx (as seen in the homologously challenged cohort) was highly protective against OM, reduction of the bacterial load to below a critical threshold level (as seen in the heterologously challenged cohorts) seemed to be equally protective. This observation has very important clinical implications, in that induction of sterilizing immunity did not seem to be necessary for protection against ascending OM, and instead, by immunizing in a manner that simply reduced the load of bacteria present in the NP, one could have a similar protective effect against disease. Given the serotype replacement issues that are currently confounding the efficacy of multivalent pneumococcal capsular-conjugate based vaccines posteradication of vaccine types of pneumococci from the NP after immunization,[29,34] this was a valuable piece of information to have and keep in mind as we moved forward with our vaccine development efforts.

Having now shown that LB1 could induce the formation of antibodies that were protective against both homologous and heterologous challenge in chinchilla models after parenteral immunization, variants of this vaccine candidate were then blindly evaluated in a rat model of mucosal immunization.[18] For this study, the 18-mer B-cell epitope contained within LB1 was conjugated to either keyhole limpet hemocyanin or bovine serum albumin and delivered to rats via direct immunization of the Peyer's patches followed 14 days later by an intratracheal boost. All immunogens tested induced a high-titered and specific response in the rat. Clearance of NTHI, measured 4 hours after challenge, occurred significantly earlier from the lungs of rats immunized with a combination of three LB1 peptides (representing each of the groups, see Table 1) than from sham-immunized controls. Clearance of NTHI from the middle ears of rats challenged intrabullarly also occurred

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

significantly earlier for those rats administered the combination of three LB1-derived peptides. The efficacy shown for LB1 in a second, independent rodent model lent strong support to the merits of its continued development and evaluation as a component of a vaccine directed against NTHI-induced OM.

Given the significant protective efficacy of LB1, delivered parenterally in chinchilla models and mucosally in rat models of OM, we now wanted to examine the response induced when LB1 was delivered intranasally to chinchillas. We also wanted to determine the optimal prime-boost regimen for this immunogen when admixed with the adjuvant monophosphoryl lipid A (MPL). Thereby, we immunized cohorts of chinchillas with either 30 μg of LB1 plus MPL, 10 μg LB1 plus MPL, or MPL alone. Formulations were administered as either three intranasal (IN) doses via microaerosolized spray, or as one subcutaneous (SQ) dose followed by two IN doses, all at biweekly intervals. Chinchillas were then challenged IN with first adenovirus, then NTHI to better mimic the polymicrobial nature of natural OM where children typically develop OM approximately 1 week after having a viral URT infection.[5]

Clearance of NTHI from the NP occurred most rapidly in the cohort immunized mucosally with 10 μg LB1/dose. In the directly challenged middle ear, significantly earlier clearance of NTHI ($p<0.01$) occurred in cohorts immunized with either 10 μg LB1 delivered IN/IN/IN or with 30 μg LB1 delivered SQ/IN/IN. Immunization via either regimen induced LB1-specific serum antibody in all cohorts except those that received MPL only. We also detected immunogen-specific immunoglobulins in effusions recovered from the middle ears of chinchillas after NTHI challenge, with greatest levels occurring in those that cleared bacteria most rapidly. Although total serum antibody was greatest in cohorts receiving 30 μg LB1/dose, regardless of the immunization regime, based on induced augmented clearance observed among cohorts, LB1-specific immunoglobulins available locally seem to also play a key role in mediating bacterial clearance from both the NP and middle ears.

Antibody levels induced by IN immunization with LB1 were modest compared with parenteral immunization strategy, yet significant efficacy against NTHI-induced OM was achieved. Both characteristics of the immunogen itself and antigen processing by dendritic cells (DCs) can influence vaccine efficacy, as upon migration to lymphoid tissues, DCs present antigen in the context of MHC molecules to naive T-cells, thus serving to initiate an immune response or induce T-cell tolerance. The gene that encodes NTHI OMP P5 shares homology with *E. coli ompA*.[31] It is reported that OmpA proteins induce dendritic cell maturation and activation, and this has led to the designation of this family of proteins as a new pathogen-associated molecular pattern (PAMP).[13] As NTHI OMP P5 protein is an OmpA protein homolog, we wanted to determine whether OMP P5-derived LB1 showed similar properties of those of a PAMP (i.e., the ability to interact with and induce the maturation of DCs), thereby providing a mechanism for the observed efficacy afforded by IN administration. Briefly, we identified that chinchilla bone marrow-derived DCs exhibit phenotypic and functional activation on incubation with LB1, including preferential binding and uptake of LB1, greater expression of costimulatory markers and ability to effectively present antigen to T-cells, compared with a control peptide of comparable size.[25] Collectively, these results suggest that the 19-mer motif derived from OMP P5 and incorporated within LB1 may serve as a PAMP and that preferential processing and presentation of LB1 by DCs probably underlies the efficacy achieved by immunization with this peptide.

At the time we made the above observations, research within the laboratory had identified that NTHI expressed Tfp. As the majority subunit of Tfp is highly conserved among diverse NTHI clinical isolates and Tfp are located on the bacterial surface where they are involved in multiple key biologic functions, we targeted PilA in the design of a second novel vaccine candidate. Moreover, as described earlier, we sought to replace the potentially problematic T-cell promiscuous epitope within LB1 with PilA to serve as both a carrier for the OMP P5 B-cell epitope and immunogenic partner. To do so, several iterations of a chimeric immunogen were designed to determine the optimal location within PilA to incorporate the P5 epitope. Two chimeric recombinant immunogens were successfully expressed, 'chimV3' in which rsPilA carries the OMP P5 B-cell epitope at its C-terminus, and 'chimV4,' in which the epitope is positioned at the truncated N-terminus (Fig. 3). Disappointingly, antiserum against chimV3 does not confer protection against NTHI-induced OM in a chinchilla model and is less protective than either rsPilA or the B-cell epitope individually. Ongoing epitope mapping studies reveal that the C-terminus of PilA and the N-terminus of the P5 B-cell epitope are immunodominant and thereby within the context of chimV3, these moieties are blocked and potentially unavailable for presentation by antigen-presenting cells.[21,24] Within chimV4, however, the critical regions of both immunogens were exposed. The improvement of this design strategy is evident as significant protective efficacy against NTHI-induced OM is achieved in the chinchilla model upon immunization with chimV4 ($p<0.001$).

Finally, our most recent work examines transcutaneous immunization (TCI) as a noninvasive but potentially equally efficacious strategy to immunize against OM. This route targets the numerous dendritic cells within the skin and incorporation of a novel adjuvant to induce both mucosal and

systemic immune responses. The immunization regimen is performed as follows: both pinnae of alert chinchillas were hydrated with saline to facilitate adsorption of formulations through the barrier of the *stratum corneum*. Vaccine formulations are then applied, the pinnae folded in half and opposing surfaces gently rubbed together. Formulations consist of our three most promising immunogens LB1, rsPilA, and chimV4 delivered either alone or admixed with a potent adjuvant, a double mutant of *E. coli* heat-labile enterotoxin, called dmLT.[20] Animals are immunized either before NTHI challenge to examine the ability of TCI to *prevent* OM, or after direct inoculation of the middle ear to determine the resolution of active OM induced by a *therapeutic* regime. TCI with LB1, rsPlA or chimV4 delivered with dmLT before bacterial challenge induces a rapid reduction in the bacterial load within the NP of immune animals, with the cohort that received LB1+dmLT eradicating NTHI from this site within 10 days of challenge (Fig. 5A).[23] Within middle ears although an increase in bacterial concentration is typically observed after direct challenge because of initial bacterial replication, only a modest increase in CFU NTHI is observed in cohort that receive any of the three antigens plus dmLT and is followed by rapid elimination of NTHI from the middle ear (Fig. 5B). Strikingly, beginning 3 days after direct challenge of the middle ear, significantly fewer NTHI are detected in animals that received chimV4+dmLT, with complete eradication within 10 days, compared with receipt of adjuvant alone.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

The chronicity and recurrence of OM is a consequence of biofilms established by NTHI within the middle ear. Based on the efficacy afforded by TCI with LB1, rsPilA and chimV4 before bacterial challenge when used in a standard preventative regime, we then wondered whether TCI after challenge might also effectively resolve OM by eradicating an already established biofilm from the middle ear. Notably, immunization via a therapeutic regimen results in a reduction in the signs of OM based on a clinically relevant scoring system, in addition to the overall resolution of an established NTHI biomass in the middle ear (Fig. 5C). Moreover, only cohorts that received rsPilA or chimV4 admixed with adjuvant show a significant reduction in signs of disease as determined by video otoscopy and tympanometry. The strategy to resolve active disease by therapeutic vaccination is highly promising.

Collectively, our results show that a protective immune response could be elicited after delivery of LB1 or the combined Tfp- and OMP P5-targeted immunogen, chimV4 via multiple immunization strategies. Whether or not the efficacy shown for LB1 and chimV4 in animal models will translate into similar protection in children awaits clinical evaluation.

FUTURE OUTLOOK

Despite their limitations, peptide-based vaccines have the potential to direct the immune response against prespecified immunodominant or protective epitopes of native proteins.[12] Reports from several laboratories, including ours, show that the inclusion of both B- and T-cell epitopes in synthetic peptide immunogens can induce antibodies of higher affinity for the incorporated B-cell epitopes.[27,30] The orientation, number, and secondary character of peptide sequences included in these immunogens influence antigen processing and presentation to T-cells, thus affecting the specificity and affinity of the antibodies produced for native proteins.[12,27,30] Using this epitope-targeted, peptide-based strategy to develop the immunogens LB1 and chimV4, we have shown in multiple preclinical trials that this approach to the rational design of vaccine candidates is highly successful.

Chapter 83

Therapeutic Peptides Targeting HER-2/*neu* and VEGF Signaling Pathways in Breast Cancer

Kevin Chu Foy, Daniele Vicari and Pravin T.P. Kaumaya

ABSTRACT

HER-2/*neu* is a member of the epidermal growth factor receptor family and is overexpressed in 30% of breast cancers. Trastuzumab and Pertuzumab are humanized monoclonal antibodies that target the extracellular domain of the HER-2, but limitations still exist with these treatments due to its high cost and short half-life of the drugs. The overexpression of HER-2 leads to overexpression of VEGF, which turns on angiogenesis, causing increased blood flow to the tumors. This chapter is mainly centered on the use of peptides that are cost effective, specific and nontoxic to target both HER-2 and VEGF signaling pathways. We have designed conformational peptides of the pertuzumab epitope and also peptides that mimic the VEGF binding sites. With the use of *in vitro* assays and two *in vivo* tumor models, we have shown that combination treatment aimed at targeting the HER-2/*neu* and VEGF signaling pathways produces additive effects with no cardiotoxicity.

PEPTIDES AS THERAPEUTIC CANDIDATES

Peptides are small protein-like chains of amino acids, and a peptide mimic is a peptide or a peptide-like molecule that intends to mimic one portion of the entire protein. In most cases, the region of interest is biologically active such as the binding sites or active site of enzymes.[20] Protein–protein interactions play a key role in the activation of several mechanisms such as viral replication, cellular growth, and differentiation. Thus, it is the great interest in the development of peptides that would retain the protein binding ability, acting as an antagonist or agonist.[28] Smaller molecules such as peptides can be chemically synthesized and easily modified to such molecules. Synthetic peptides that disrupt protein–protein interaction inhibit HIV-1 proteases, HIV-1 reverse transcriptase, herpes simplex virus ribonucleotide reductase, and thymine synthase. Peptides that can block receptor–ligand interaction can be obtained by the screening of combinatorial libraries of compounds but the most preferred approach is to use a structure-based design. The spatial configuration of side-chain groups is the key for recognition and biological activity. The aim is to maintain the conformational space and orientation of the bioactive surface while retaining sufficient flexibility to bind cooperatively with a given receptor.[16] Peptide mimics offer the benefits of being water soluble, nonimmunogenic, and the ability to easily cross tissue barriers.[30] Natural peptides such as insulin, vancomycin, oxytocin, and cyclosporine and synthetically produced ones such as Fuzeon® (enfuvirtide) and Integrilin® (eptifibatide) are among the FDA-approved peptide-based drugs. Fuzeon® is a peptide derived from the HIV-1 envelope glycoprotein transmembrane subunit gp41 C-terminal heptad repeat (CHR) region and blocks the entry of HIV into cells,[32] whereas Integrilin® is an antiplatelet drug that selectively blocks the platelet glycoprotein IIb/IIIa receptor. Peptide-based therapy has the inconveniency that frequent doses need to be administrated because of proteosomal degradation *in vivo* of the peptides.[9] However, this problem can be overcome by the use of retro-inverso D-amino acid peptides.

HER-2 SIGNALING PATHWAYS, CANCER, AND STRATEGY FOR THE DESIGN OF HER-2 PEPTIDE MIMIC

HER-2/*neu* is a self-antigen that is overexpressed in different types of epithelial tumors including breast and is associated with a worse prognosis in several malignancies. Overexpression of HER-2 has been reported in about 30% of all breast cancers[29] and seems to predict a decreased disease free and overall rates of survival. Many therapeutic strategies targeting the HER-2 receptor have been devised, and most outstanding among them are a group of humanized monoclonal antibodies which include Trastuzumab and Pertuzumab. Trastuzumab is a growth inhibitory monoclonal Ab that binds the extracellular domain (ECD) of the HER-2 receptor and blocks

Copyright Elsevier 2024

intracellular signaling. Pertuzumab also binds the ECD of HER-2 thereby preventing dimerization of the receptor, and it is currently being evaluated in human clinical trials. HER-2 is an attractive therapeutic target for several reasons. The amount of HER-2 expressed on cancer cells is much higher than in normal adult tissues potentially reducing the toxicity of HER-2 targeting drugs.[5] Tumors with a high expression of HER-2 often show homogenous intense IHC staining,[4] signifying that HER-2 targeted therapy will target most cancer cells in a given patient. HER-2 is always observed in metastatic disease suggesting its implication in most aggressive tumors though it is not observed in benign tumors. However, evidence suggesting the continuous use of this humanized Abs is lacking because of their instability, repeated administration, and effects of cardiotoxicity, poor penetration across tissue barriers and their high cost of treatment with potential immunogenicities associated with them.[21] Prediction of novel B-cell epitopes from the ECD of HER-2 has been the focus of our laboratory for the past decade. Through such an approach, we have identified two novel HER-2 vaccine candidates that were translated into a Phase I clinical trial thereby validating our overall strategy. A subset of the patients (6 out of 24) showed clinical responses, and some of these patients were given more doses of the vaccine because of their clinical responses.[17] After the publication of the crystal structure of HER-2 in complex trastuzumab[3] and HER-2 in complex with pertuzumab,[11] we synthesized a second generation of peptide vaccines based on the interaction of these abs with the ECD of the HER-2 receptor. We have extensively showed the efficacy of these new vaccine candidates in preclinical studies.[1,12] Two of the vaccine candidates are currently being evaluated in a Phase Ib NCI funded clinical trial at the James Cancer Hospital. Pertuzumab bind to different epitopes in the extracellular domain near the junction of domains I, II, and III of the HER-2 extracellular domain amino acids **266–333**. This interaction of pertuzumab with HER-2 was shown to sterically hinder the association of HER-2 with other receptors such as HER3[11] sterically blocking a binding pocket necessary for receptor dimerization and signaling. Based on these studies, we have selected one HER-2 peptide mimic pertuzumab-like sequence 266–296, which has been shown to be a good candidate for a neutralizing, blocking peptide.[1] The B-cell peptide epitope alone can therefore be used to inhibit HER-2 dimerization just like pertuzumab. We showed that the HER-2-266–296 peptide mimic is able to prevent tumor growth and development in a transplantable mouse model of breast cancer. Peptide treatments caused a significant delay in the onset of tumor growth and also significantly increased the tumor-free survival rates when compared with mice in the untreated groups or groups treated with the irrelevant peptide. Also the peptide interrupts many HER-2 signaling pathways *in vitro* like inhibition of proliferation, dimerization, and cell viability in a dose-dependent manner.[10]

VEGF, CANCER, AND THE DESIGN OF VEGF PEPTIDE INHIBITOR

VEGF is the most proangiogenic factor studied because of its specificity and important role in the activation of all steps of angiogenesis in the endothelium vasculature,[7] and it is upregulated in the tumor microenvironment by hypoxia or activation of altered oncogenes like HER-2.[24] Examples of FDA-approved cancer treatments with anti-angiogenic agents targeting VEGF pathway include monoclonal antibody bevacizumab (Avastin®), small tyrosine kinase inhibitors SU11248 (Sunitinib®), and BAY 43-9006 (Sorafenib®).[6] Although the clinical applications of these drugs in cancer therapy are promising, drug resistance development and long-term side effects such as hypertension and endothelium dysfunction remain a concern. VEGF binds with higher affinity to VEGFR-1, in the endothelial cells, but the majority of angiogenesis signaling (proliferation, migration, and survival) occurs via the interaction between VEGF and VEGFR-2.[18] The VEGF binding site to its receptors and neutralizing antibodies has been characterized by crystal structure analysis as well as alanine scanning, revealing overlapping regions located at the poles in each homodimer. VEGF: VEGFR-2 interaction has been extensively targeted by antibodies that bind VEGF and the extracellular domain of VEGFR-2. These studies have identified VEGF sequences in the binding region that inhibit VEGF activated pathways. The interaction between VEGF and VEGFR-2 comprises residues within the loop region formed by the antiparallel β-sheets β5–β6 in the VEGF protein and blockade of receptor–ligand interaction offers a validated and proven approach in drug development because receptor:ligand interaction is usually confined to a defined portion of the ligand and the receptor, and recent technologies have allowed the accurate identification of these binding regions. In an attempt to block the VEGF and VEGFR-2 interaction, we designed several peptides that mimic the VEGF loop region containing the binding sites residues. Our hypothesis is that inhibiting binding of the VEGFR-2 and in activating the tyrosine kinase activity can be achieved by blocking the binding site of the receptor using peptide mimics containing the structural binding region of VEGF. To confirm the effect of the VEGF peptide mimics as angiogenesis inhibitors, we used several *in vitro* angiogenic assays such as the scratch wound (migration), Matrigel (tube formation) and HUVEC proliferation assay (proliferation). All three VEGF peptide mimics are able to inhibit cell migration in the presence of exogenous rhVEGF at the wound assay, showing that they can block migration induced by rhVEGF, throughout blocking VEGF: VEGFR-2 interaction. We tested whether the VEGF peptide mimics could inhibit the tube formation in Matrigel. All three peptide mimics inhibit tube formation with

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

VEGF-P3(CYC) displaying the largest inhibition. Proliferation of endothelial cells is essential in the formation of new blood vessels, and inhibition of HUVEC proliferation occurs in a dose-dependent manner with VEGF-P3(CYC) being the most potent inhibitor. The conformational peptide VEGF-P3(CYC) shows the best inhibitory effects and the highest binding affinity, suggesting that the loop stabilization by the disulfide bond between the extra cysteines, may be responsible for this effect. Our biochemical and *in vitro* experiment results are in agreement and confirm that VEGF-P3(CYC) has the best potential of inhibiting angiogenesis. To investigate whether these results would be reproduced *in vivo*, we tested the VEGF peptide mimic as a potential treatment in VEGF overexpressing mice. The *in vivo* studies were performed in the double transgenic mice VEGF$^{-/+}$/Neu2–5$^{-/+}$, which has acceleration (resulting from VEGF overexpression) of spontaneous mammary gland tumor development (resulting from the *neu* mutation).[23] The delay in tumor burden seen in the VEGF-P3(CYC)-treated mice indicates that the conformational loop designed structure may be necessary for blocking VEGF and its receptor interaction and consequently, delaying the tumor growth. Combining *in vitro* and *in vivo* results VEGF-P3(CYC) is the best candidate for the development of angiogenesis peptide inhibitors. The design of the peptide, VEGF-P3 (CYC) that would mimic a structural binding site of VEGF to its receptor is important in obtaining a better inhibitory molecule in several *in vitro* assays. The conformational peptide mimic VEGF-P3 (CYC) also shows better affinity to the receptor and is efficient in delaying tumor burden in a VEGF overexpressing animal model.[31] These findings motivate the development and potential of using VEGF-P3 (CYC) as a peptide therapeutic drug to inhibit angiogenesis. Still, future analysis involving other animal models more specific to angiogenesis will give an insight into the efficacy of these peptides in inhibiting angiogenesis given the complexity of the tumor microenvironment.

ADDITIVE/SYNERGISTIC EFFECTS OF TARGETING BOTH HER-2 AND VEGF PATHWAYS IN CANCER

The upregulation of HER-2 is associated with increased expression of vascular endothelial growth factor, or VEGF at both the RNA and protein level in human breast cancer cells and exposure of HER-2 positive cells to Trastuzumab significantly decreases VEGF expression.[26] Shc, a downstream adaptor protein of the HER-2 signaling pathway has been identified as a critical switch for VEGF production[15] showing that VEGF is a downstream target of the HER-2 signaling pathway. This shows that, the effects of HER-2 on tumor cell behavior may be mediated in part through the stimulation of angiogenesis. Angiogenesis is the growth of new blood vessels from preexisting ones and contributes to the development of numerous types of tumors and their metastasis. VEGF, a well-known proangiogenic factor is secreted by most tumor cells.[25] VEGF expression is increased in many different types of cancer and most tumor cells secrete VEGF.[7] It is also believed that VEGF is a key promoter of metastasis.[27] VEGF is a 34- to 42-kDa, homodimeric, heparin-binding, disulfide-bonded glycoprotein that has several isoforms arising from splice variants.[8] Therefore, VEGF and its receptors VEGFR-1 and VEGFR-2 are prime targets for antiangiogenic intervention, which is believed to be one of the most promising approaches in cancer therapy. Blocking angiogenesis is an attractive strategy to inhibit tumor growth, invasion, and metastasis. Bevacizumab has been tested in several cancer clinical trials and showed some promising results in a phase II clinical trial for breast cancer.[26] Other VEGF inhibitors in clinical trials in progress today include several receptor tyrosine kinase inhibitors, VEGF-Trap, and anti-VEGF-R2. VEGF stimulates angiogenesis by binding to its receptor VEGFR-2, which is expressed by both endothelial and tumor cells.[2] A two-pronged approach to target cancer by coimmunizing with defined tumor-associated antigens and angiogenesis associated antigens have been shown to have synergistic effects. All these show that combination treatment targeting both HER-2 and VEGF is a promising strategy because angiogenic therapy alone will only delay tumor growth[19] and targeting HER-2 and VEGF will destroy two different tumor-dependent subpathways. In a study, we evaluated the effects of combination treatment with both HER-2 and VEGF peptide mimics, and the results obtained showed that targeting these two proteins seems to be a promising strategy for treating HER-2-positive cancers. Combination treatments with both peptides causes superior antitumor and antiangiogenic effects *in vitro* and *in vivo*. This dual therapeutic benefit is clearly shown by the increased proliferation and phosphorylation inhibition as well as by a decrease in cell viability. Combination treatment also causes a greater delay in tumor growth and development in a transplantable tumor model. These results are indicative that the selected inhibitory peptides have great therapeutic effects in targeting both HER-2 and VEGF by eliciting potent antitumor and antiangiogenic effects.

CONCLUSIONS

Drug therapies, which target specific tumor cell types of different signaling pathways, have been the mainstay of pharmaceutical companies. Development of monoclonal antibodies and small tyrosine kinase inhibitors has been the spotlight of cancer therapeutics, bringing huge revenue to biotech companies. R&D investments to develop such novel drugs are really enormous because it involves a long way between discovery and implementation of the drug, with the entire

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

process being covered under patents.[14] This reflects the cost of treatment using target therapeutic drugs and difficulties in broad utilization. Also, these drugs did not eliminate high-risk long-term toxicity and development of drug resistance. These obstacles combined with economical stagnation have put pressure on biotech companies to decrease drug development costs and increase productivity. Also, many companies have turned their attention to the use of peptides as alternatives to the development of therapeutic drugs. Advances in the peptide synthesis technology have allowed the application of peptides as antimicrobial agents or antagonists in protein–protein interaction.[13] We decided to evaluate rationally designed peptides as cancer and angiogenesis inhibitors. VEGF peptide mimics designed in our laboratory show potential in inhibiting angiogenesis. Many studies have shown the beneficial effects of using a combination strategy to target cancer cells and *in vitro* studies have shown that a combination of pertuzumab and trastuzumab synergistically inhibit the survival of breast cancer cells.[22] The combination of these peptide mimics could be translated into the clinic to investigate the efficacy of targeting both HER-2 and VEGF in HER-2 positive cancers. Additionally, future studies could be performed to investigate possible combination of our peptide mimics with low doses of chemotherapy.

Chapter 84

Use of Positional Scanning Libraries to Identify Immunologically Relevant Peptides

Mireia Sospedra, Valeria Judkowski, Jon R. Appel and Clemencia Pinilla

ABSTRACT

Many receptor–ligand interactions in biology involve the binding of peptidic molecules to complex surface receptors. Among these, the immune system is a particularly interesting example, because peptides are the main targets for T lymphocytes and can also be recognized by antibodies. The systematic identification of ligands for biologically relevant receptors has been greatly facilitated by the introduction of combinatorial peptide chemistry. Here, we introduce the underlying principles of the use of positional scanning libraries and report their application to elucidate the specificity of antibody, T cell, and MHC molecules. The first reports as well as representative work from different research groups and recent contributions are presented.

DEFINITION OF MIXTURE-BASED LIBRARIES

Mixture-based libraries are synthesized in a combinatorial manner and are made up of mixtures having one or more positions defined with a given amino acid, while other positions have amino acids incorporated as mixtures. These libraries represent a very large number of compounds—in this case synthetic peptides. They are generated by the use of the simultaneous multiple peptide synthesis method known as the "tea bag approach."[7] Then, they are cleaved from the solid support and assayed in solution; this allows each peptide within each mixture to freely interact with a given receptor and thus these libraries can be used in virtually all existing assay systems. Two different deconvolution methods can be used to identify individual active compounds from these mixture-based libraries. The first described method, the iterative approach,[9] uses a selection and enhancement process to identify individual compounds. After the identification of active mixtures having defined positions, the remaining positions are defined, one diversity position at a time, through a synthesis and selection process, until individual compounds are identified. The second deconvolution approach, the positional scanning method,[22] simultaneously addresses each position of the library by testing at the same time individual sublibraries in which each diversity position is defined by a single amino acid, while the remaining positions are composed of mixtures of amino acids. The assay data derived from each position provide information about the most important amino acid for every diversity position of the positional scanning library.

An illustration of the positional scanning library using a tripeptide combinatorial library is shown in Fig. 1. Four different amino acids are incorporated at each of the three diversity positions resulting in a diversity of 64 individual peptides. When the same diversity is arranged as a positional scanning library, only 12 peptide mixtures (4 amino acids × 3 positions) need to be synthesized. Each of the three positional sublibraries, namely, OXX, XOX, and XXO and the same diversity of peptides, is synthesized, and they differ only in the location of the defined amino acid position. The O positions represent one of the four amino acids, whereas the remaining two diversity positions are mixtures (X) of the same four amino acids. Shown below each mixture contains the 16 peptides (4^2) that make up that mixture. Assuming that ART is the only active tripeptide in this library that is recognized, the ART tripeptide (outlined below each sublibrary in Fig. 1) is present in all three positional sublibraries. Thus, the only mixtures with activity are AXX, XRX, and XXT because the ART tripeptide is present only in those mixtures. The combination of these amino acids in their respective positions yields the tripeptide ART, which would then be synthesized and tested for its activity against the receptor. The activity observed for each of the three mixtures (AXX, XRX, and XXT) results from the presence of

Tripeptide Positional Scanning Library

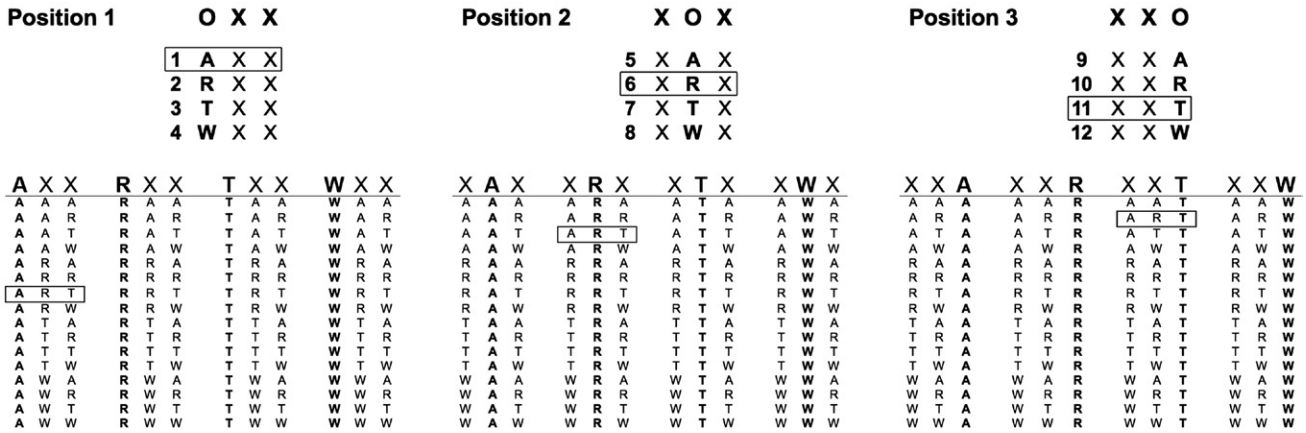

FIGURE 1 Conceptual illustration of a tripeptide positional scanning library.

the tripeptide ART within each mixture and not from the individual amino acids (A, R, and T) that occupy the defined positions. In more complex libraries, more than one mixture is often found to have activity at each position. Selection of the amino acids for the synthesis of individual peptides is based first on activity and then on differences in the chemical character. Although the above example is a simple representation of the arrangement and use of positional scanning libraries, the same concept applies to all types of mixture-based libraries having defined and mixture positions. To give an estimate of the complexity of these libraries, a hexapeptide library using 20 amino acids represents a total diversity of approximately 50 million (19^6) (cysteine is not included in the mixture positions) individual peptides, while a decapeptide library using the same number of amino acids represents a total diversity of approximately 6 trillion (19^{10}) individual peptides, a number of peptides that could clearly not be synthesized or tested individually. A hexapeptide positional scanning library can be formatted into 120 mixtures (20 amino acids × 6 positions) and a decapeptide library into 200 mixtures (20 amino acids × 10 positions).

Positional scanning libraries provide an invaluable resource for characterizing the molecular interactions that underlie many biological processes and for identifying novel sequences that have a desired biological activity. In this chapter, we describe the use of positional scanning libraries in the elucidation of antibody, T cell, and MHC specificity. The first report of their use for each of these molecular interactions, contributions by different research groups and some of the most recent reports are presented.

USE OF POSITIONAL SCANNING LIBRARIES TO DETERMINE ANTIBODY SPECIFICITY

Antibodies are glycoproteins synthesized and secreted by B cells that mediate humoral immunity. Monoclonal antibodies are identical antibodies produced by one type of B cell that recognizes antigens with high affinity and

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

specificity. The remarkable specificity of antibodies makes them very valuable for protection against disease organisms and also attractive candidates to target other types of molecules found in the body and promising agents for human therapy. Furthermore, antibodies have an important medical application in the diagnosis of infectious diseases and autoimmune disorders. In this context, the identification of antibody ligands is of great interest. Despite the high specificity that characterizes antibodies, it is important to notice that crossrecognition of peptides by single antibodies also exists. The identification of synthetic mimics recognized by an antibody is also very interesting in the development of more effective immunodiagnostics and synthetic vaccines.

The epitopes recognized by antibodies can be classified as either continuous or discontinuous. It is believed that antibodies mainly recognize native discontinuous or conformational epitopes, and therefore, linear peptides might represent part of the complete epitope. In addition, it has been described that antibodies that recognize discontinuous epitopes can crossreact with linear peptide fragments, indicating that peptides can be used effectively to determine antibody specificity. The classical approach used to identify antibody ligands involves the synthesis and testing of overlapping peptides. Although this methodology allows the identification of ligands, it requires substantial time and resources. Several different peptide combinatorial library approaches, including synthetic and phage display, have emerged as more straightforward and useful approaches for mapping antigen–antibody interactions. Among these approaches positional scanning libraries offer an important advantage because no prior information regarding the specificity of the antibody is needed.

The first use of positional scanning libraries in immunology was for the identification of high-affinity peptides recognized by monoclonal antibodies of known specificity. In 1992, Pinilla et al.[22] showed that the antigenic determinants recognized with high affinity by two antibodies could be correctly identified upon a single screening using hexapeptide positional scanning library. In 1994, Pinilla et al.[23] extended the practical range to decapeptide libraries. With a decapeptide library, the known six-residue antigenic determinant sequence recognized by an antibody was found, with the most specific residues appearing to "walk through" the 10 positions of the peptide library. Interestingly, the antibody recognition in this system was stronger when the antigenic determinant was located at the C-terminus of the decapeptide library. Individual decapeptides corresponding to sequences derived from the most active peptide mixtures at each position were synthesized to confirm the results of the screening. Four peptides were 5–10 times more active than the known control peptides. Additional studies were performed using hexa- and decapeptides by us and others to identify the antigen determinants of antibodies (reviewed in Refs. 8,24).

One of the main advantages of the use of positional scanning libraries for the study of antibody specificity is that no previous specificity information is required. In 1996, two studies reported the use of positional scanning libraries to determine the epitope determinant for antibodies for which the target protein was known, but not the epitope. The first study, Appel et al. reported the identification of high-affinity, crossreactive peptides recognized by a monoclonal antibody (mAb 12) known to recognize the surface antigens of hepatitis B virus (HBsAg). The binding specificity of mAb 12 was studied with a hexapeptide library that was screened by competitive enzyme-linked immunosorbent assay (ELISA). This led to the identification of the peptides STTSMM (IC50 = 170nM) and SVGPPH (IC50 = 165nM), which specifically inhibited the interaction between HBsAg and mAb 12. Because motifs from these two hexapeptides, –STTS– and –GP–, are located in the primary sequence of the protein (residues 114–120), overlapping hexapeptides of this region were used to identify the most active hexapeptide, TTSTGP (IC50 = 2.3μM), which is 10-fold less active than either hexapeptide found from the library (included in review[24]). In the second study, Gao et al. reported on the identification of an epitope for a monoclonal antibody 201/9, raised against betafactor XIIa, which was determined with octapeptide mixture–based libraries including some in positional scanning format (reviewed in Ref. 24).

One important observation was that highly active peptide sequences having little or no resemblance to the known immunogen were identified for some antibodies. Park et al. in 1997 using a hexapeptide library identified peptide sequences that inhibit the binding of IgG antibodies specific of thyroid-stimulating-hormone receptor (TSHR) obtained from patients with Graves' disease. Interestingly, these peptides do not resemble the linear sequence of TSHR and thus may mimic a spatial arrangement of the key antigenic residues (reviewed in Ref. 24). The structural basis for the molecular mimicry shown by monoclonal antibodies remains unclear. It has been suggested that the flexible hypervariable loops of antibodies and the fact that they recognize functional conformation rather than identical structures can facilitate crossrecognition.

It is often assumed that crossreactive antigens share some structural similarity that is specifically recognized by a monoclonal antibody. Antibody crossreactivity was further explored by Pinilla et al. in 1998 for a monoclonal antibody (mAb HGAC 39.G3), which binds to *N*-acetyl-D-glucosamine (GlcNAc) on a polyrhamnose backbone. Hexapeptide positional scanning libraries consisting of all-L or all-D amino acids were screened and the inhibitory activity by mixtures from the all-D hexapeptide library is much greater than the activity from the all-L libraries. The sequence Ac-yryygl-NH_2 is specifically recognized by mAb HGAC 39.G3 with a relative affinity of 300nM when

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

measured in a competitive binding assay. This peptide shares little homology with the carbohydrate antigen, suggesting that the peptide might interact differently with the antibody (reviewed in Ref. 24).

USE OF POSITIONAL SCANNING LIBRARIES FOR T CELL EPITOPE MAPPING

T lymphocytes play a central role in controlling the acquired immune response orchestrating both the "cellular" and "humoral" (helping B cells) arms of acquired/specific immunity. Like B lymphocytes, T cells express a clonal antigen-specific receptor that recognizes fragmented, linear antigenic peptides when these are bound to proteins encoded by major histocompatibility complex (MHC) genes. There are two major subsets of T lymphocytes that differ in effector function and MHC restriction. $CD8^+$ T cells recognize peptides bound to MHC class I molecules and act as effector cells during viral infections through antigen-specific cytotoxic activity. $CD4^+$ T cells recognize peptides bound to MHC class II molecules and act as inducers of T and B cell functions producing cytokines. Although T cell recognition was previously considered exquisitely specific for single peptides or close homologs with similar sequence, it is now clear that T cell recognition is very flexible and crossreactivity is a common phenomenon.

T lymphocytes play important roles in infectious diseases, autoimmunity, and also immune responses against tumors. For many of these disorders, the relevant target antigens are not known. Designing effective methods that allow the search for T cell epitopes is therefore an important goal, and several approaches have been applied with variable success. Epitope mapping with series of overlapping peptides can be applied only when the antigenic protein is known. Biochemical analysis of pools and peptides eluted from MHC molecules is another approach but requires sophisticated instrumentation. Molecular biology approaches using expression libraries or the search of epitopes using MHC-binding motifs are biased because they require the previous selection of an organism or tissue of interest.

Several studies have shown the efficacy of using positional scanning libraries for identifying target antigens and highly active peptide mimics and naturally occurring peptides for both $CD4^+$ and $CD8^+$ T cells of known and unknown specificity. Initially $CD8^+$ T cells received more attention not only because they often show higher antigen affinities but also because the class I-binding groove accommodates shorter peptides (8–10 amino acids) and less complex peptide libraries can be used to determine their specificity. In 1996, Gundlach et al.[3] presented the use of a nonapeptide positional scanning library to elucidate the specificity of cytotoxic T cells (CTL). Sequences for potential T cell epitopes were deduced from scan profiles by the use of combinations of the active amino acids. An octapeptide positional scanning library was successfully used by this group to identify self-MHC-restricted antigenic peptides crossrecognized by an allo-MHC-specific CTL clone and also by Udaka et al. in 1996 to study the specificity and degeneracy of H-3-specific, H-2K(b)-restricted CTL clones (reviewed in Refs. 1, 24).

The identification of defined human tumor antigens recognized by autologous CTL opened new opportunities for the development of antigen-specific cancer vaccines. In 2000, Linnemann et al. (reviewed in Ref. 1) used a nonapeptide library in a standard chromium release assay to identify a synthetic epitope for the My-La CTL specific for cutaneous T cell lymphoma. The response toward this epitope was comparable with the response toward their natural target My-La. The identification of synthetic epitopes for tumor-specific CTL clones that are recognized in an MHC-restricted manner can be used for the development of vaccines for immune therapies of cancer.

Positional scanning libraries can also be used to improve vaccines, for example, enhancing the activity of peptide ligands to reduce the amount of peptide vaccine needed to obtain a clinical CTL response in an immunization strategy. In this context, the study by La Rosa et al. 2001, using a nonapeptide library identified a series of peptide analogs for the cytomegalovirus (CMV)-specific T Cell Clone 3-3F4 that were recognized better than the native peptide sequence reviewed in Ref. 1. Moreover, the study by Lustgarten et al. in 2006 reported the use of a decapeptide positional scanning library to identify optimal amino acids substitutions in the native peptide. This strategy led to the identification of superagonist peptides that expand antitumor T cells with higher killing efficiency than the native peptide.[19]

The identification of the specificity of $CD4^+$ class II-restricted T cell clones seemed more difficult because the affinity of these cells is lower than described for $CD8^+$ T cells and peptides bound to class-II molecules are longer (typically 12–15 amino acids). $CD4^+$ class II-restricted T cells specific for self-antigens are thought to be involved in the pathogenesis of most human autoimmune diseases, and molecular mimicry between foreign and self-ligands has been implicated as a possible mechanism for their activation. The identification of peptide mimics for these autoreactive $CD4^+$ T cells is crucial to understand the autoimmune process and to develop future therapies. In 1997, Hemmer et al.[4] showed that a 11-mer library could be used to identify crossreactive artificial peptides for a $CD4^+$ T cell clone (TCC) TL5G7, specific for the myelin basic protein peptide (MBP) (86–96) and derived from the peripheral blood of a patient with multiple sclerosis. Interestingly, these artificial peptides induced proliferative responses at much lower concentrations than the original peptide MBP (86–96) used to generate the TCC. In addition stimulatory

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

ligands derived from protein sequences of self and microbial proteins were identified, some of them more potent agonists than MBP (86–96). A more extensive study was performed with a decapeptide library to study the specificity of two additional MBP (86–96)-specific TCC, also established from peripheral blood lymphocytes of MS patients: TL5F6 that is DR2b restricted, and TL3A6 that is DR2a restricted.[6] The use of positional scanning libraries allowed the identification of TCR motifs and stimulatory antigenic peptides. In this study, the authors suggested for the first time that each amino acid residue contributes to the overall potency of the antigenic peptide ligand. The decapeptide library was also successfully used to identify peptide mimics for CD4+ T cell clones of known specificity in two additional studies. The first study published in 1999 by Wilson and colleagues showed that the use of a 10-mer library to identify peptide epitopes is more effective than the native peptide in stimulating proliferative responses in a CD4+ T cell clone derived from transgenic mice. This TCC expresses a TCR specific for the 88–104 peptide fragment of pigeon cytochrome c and the Ek class II molecule, reviewed in Ref. 1. A second study showing the power of positional scanning libraries in identifying epitopes for CD4+ T cell clones was published in 2001.[12] Nonobese diabetic (NOD) mice spontaneously develop destruction of the insulin-producing pancreative islet beta cells similar to type-1 diabetes mellitus in humans. The diabetogenic NOD CD4+ T cell clone BDC2.5 adoptively transfers disease after being activated *in vitro* with syngeneic islets cells. The identity of the islet cell antigen responsible for pathogenicity is not known. Positional scanning libraries were used to identify decapeptides able to stimulate BDC2.5 cells and transfer disease to NOD-scid mice. Surprisingly, some of these peptides include sequences similar to residues 528–539 of glutamic acid decarboxylase 65, a candidate autoantigen in diabetes.

An enormous step forward was achieved in the use of positional scanning libraries to identify T cell epitopes when Hemmer et al.[5] incorporated biometrical analysis to this approach. The positional scanning libraries based biometrical analysis developed as a strategy that systematically compares the data derived from the screening with the library with all peptide fragments present in protein databases. The response of T cell clones to positional scanning synthetic combinatorial libraries is analyzed with a mathematical approach that is based on a model of independent contribution of individual amino acids to peptide antigen recognition. This biometric analysis compares the information derived from these libraries consisting of trillions of decapeptides with all the millions of decapeptides contained in a protein database to rank and predict the most stimulatory peptides for a given T cell clone. In chronic infectious diseases such as Lyme disease, immune-mediated damage may add to the effects of direct infection by means of molecular mimicry to tissue autoantigen. Using this strategy, the authors effectively identified both microbial epitopes, from *Borrelia burgdorferi*, and candidate autoantigens, from the host, recognized by TCC CSF-3 of unknown specificity that was established from the cerebrospinal fluid (CSF) of a patient with chronic neuroborreliosis using *Borrelia burgdorferi* lysate. The positional scanning libraries based biometrical analysis was analyzed in detail by Zhao et al.,[35] and its predictive power was shown with CD4+ TCC GP5F11 that was established from the peripheral blood of a patient with multiple sclerosis using influenza virus hemagglutinin (HA) peptide 309–318 as antigen. The experimental data from the screening of the library was used to generate a matrix, which was used to score all the decapetides in all the viral proteins in the Genpept database. The information obtained was a list of peptides ranked by their score, and the native peptide ranked sixth. The selected peptides were synthesized and tested, and their stimulatory capacity from TCC GP5F11 recognition was confirmed. More recently, the crossreactivity of this TCC against 14 Flu-HA variants, 11 viral, 15 human, and 3 myelin-derived naturally occurring peptides was reported.[20] Six of these peptides have higher stimulatory potency than the native ligand, showing that high crossreactivity can be a feature even of virus-specific memory TCC. Furthermore, positional scanning libraries in combination with protein database analyses were used to identify the specificity of TCC of completely unknown specificity that were generated from a relevant compartment and expanded using a universal T cell stimulus such as phytohemagglutinin. Using this strategy the specificity of CSF infiltrating and *in vivo* expanded TCC from an untreated MS patient[29] and of CSF infiltrating TCC from a Lyme disease's patient[18] was successfully identified. In addition, the use of positional scanning libraries in combination with B cell lines expressing only a single class II restriction element as APC was used to study the promiscuous restriction of T cell recognition.[27] The ability of T cells to recognize peptides in the context of more than one HLA class II molecule is a feature of some T cells, and this crossrecognition seems to be behind the low predictive capacity of this approach for some T cell clones.[28] The use of B cell lines expressing single HLA class II molecules as antigen-presenting cells instead of autologous peripheral blood mononuclear cells to test the mixtures of the positional scanning libraries markedly improves the capacity to identify target peptides for this type of T cells. In addition, Judkowski et al. reported in 2004 the use of the screening data obtained with the BDC2.5 T cell clone together with the biometrical analysis for the identification of viral and bacterial peptides that are capable of activating BDC2.5 CD4+ T cells and transfer diabetes in NOD-scid mice.[13]

Recent studies have extended the use of positional scanning libraries together with the biometrical analysis

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

to determine the specificity of the CD4+ T cell response upon smallpox vaccination in humans. Using a single *in vitro* stimulation of PBMC with vaccinia virus and PHA stimulation, CD4+ T cell clones from vaccinated donors were generated. A comprehensive analysis of the cytokine expression profile by vaccinia specific CD4+ T cells showed that GM-CSF is produced at high levels in the supernatant of pathogen stimulated cultures. Based on this observation, GM-CSF was used as readout of CD4+ activation and was shown, for the first time, to be an excellent cytokine to measure the response to mixtures of positional scanning libraries. The biometrical analysis was performed with a custom Western Reserve vaccinia protein database and all clones were found to respond to the first or second vaccinia ranked predicted peptide. Interestingly, analysis of the performance efficacy of the T cell driven strategy presented in this study showed that this approach is very efficient in the identification of immunogenic and predominantly recognized proteins. Because the analysis of the whole pathogen proteome to identify relevant antigens might not be feasible for larger pathogens (>1,000 proteins), there is a clear advantage in using positional scanning libraries to elucidate the antigen specificity upon infection or vaccination in humans.[11] Finally, it is clear that further efforts on the development of miniature T cell activation assays will be extremely beneficial to reduce the number of clonal CD4+ T cells required to test combinatorial peptide libraries and to be able to define the spectrum of specificities with higher throughput.

The effectiveness of positional scanning library-based biometrical analysis has also been shown with tumor antigen-specific $CD8^+$ clones of known (Melan-A, Pinilla et al., 2001 and Tyrosinase, Rubio-Godoy et al., 2002) and unknown specificity (SSX-2, Rubio-Godoy et al., 2002). These studies as well as an overview of the positional scanning library-based biometrical analysis of the study of T cell specificity and crossreactivity are reviewed in Refs. 1, 21. In addition, positional scanning libraries in combination with motif analysis have also been used to study the specificity of CD8+ T cells. Anderson et al. published in 1999 a study in which nonapeptide mixtures were designed to have the $H\text{-}2K^d$ or $H\text{-}2D^b$ anchor residues fixed at positions 2 and 9 or 5 and 9, respectively. Screening of the $H\text{-}2K^d$ library derived in the identification of a mimotope targeted by diabetogenic 8.3-CD8+ T cells reviewed in Ref. 1. Screening of the $H\text{-}2D^b$ restricted positional scanning library led to the identification of a set of active peptides, including a natural occurring sequence within the widely expressed dystrophia miotonica kinase for the A14-pathogenic CD8+ T cell clone. In addition, the analysis of the screening results using both libraries with A14 T cells was used to confirm that the A14 TCR is highly promiscuous having the capacity to interact with both the $H\text{-}2K^d$ and $H\text{-}2D^b$ Class I MHC molecules.[17]

USE OF POSITIONAL SCANNING LIBRARIES TO IDENTIFY MHC-BINDING MOTIFS

$CD8^+$ and $CD4^+$ T lymphocytes recognize peptides bound to class I or class II MHC molecules, respectively. These complexes are assembled intracellularly during the biosynthesis and trafficking of MHC molecules. MHC class I and class II molecules have different peptide binding sites. MHC class I molecules have a closed groove that only allows short peptides of 8–10 amino acids in length. In contrast MHC class II molecules bind peptides that are 10–25 amino acids in length. Considerable interest has been focused on understanding how MHC specificity is generated with the ultimate goal of predicting peptide binding.

Positional scanning libraries have emerged as a highly efficient, universal and unbiased approach to address MHC specificity. In the first report in 1995, Udaka et al.[32] identified patterns of amino acid preferences from testing an octapeptide library against the mouse MHC-I molecule H2-Kb using stabilization experiments. A year later, Stryhn et al.[30] used an octapeptide library and competitive binding assays to describe peptide binding motifs for class I molecules, including primary and secondary anchor residues. The quantification of the effect of any amino acid in each position also allowed the identification of disfavored residues very important in shaping MHC class I specificity. In 1996, Pridzun et al. reported on the determination of the impact of the amino acids in every sequence position of octapeptides using stabilization experiments for the mouse MHC class I molecule H2-Ld (reviewed in Ref. 24). Later, Udaka et al.[31] also used this approach to determine the specificities of three mouse major MHC class I molecules, Kb, Db, and Ld. The results of this study was used to create a scoring program to predict MHC-binding peptides in proteins. However, the authors frequently found MHC-binding peptides with incomplete or no anchor amino acid(s) suggesting a substantial bias that is introduced by natural antigen processing in peptide selection by MHC class I molecules. More recently, the efficacy of the positional scanning libraries was shown for 15 human and 4 class I alleles for the definition of the binding specificity and the identification of high-affinity-binding peptides.[25] In addition, a novel matrix similarity derived from these studies was used to develop a new MHC Class I prediction method.[16] Also, the characterization of the peptide binding to MHC alleles in rhesus macaques was reported for frequently expressed allele, namely, Mam-A*02201.[26]

Positional scanning libraries have also been used to study the binding characteristics of MHC class II molecules. In 1996, Fleckenstein et al.[2] used an undecapeptide library to estimate the influence of every amino acid on the binding to human MHC-DRB1*0101 molecules (HLA-DRI) and to identify new peptide ligands. The amino acids favorable or

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

unfavorable for DR1-binding at every sequence position were defined and individual peptides were identified. The same research group using an undecapeptide library elucidated the specificity of HLA-DRB1*0301.[14] More recently, the use of nonapeptide libraries for the identification of ligands for two human MHC alleles, namely, HLA-DQ4[33] and HLA-DQ2[15] has been reported. Also, the predictive performance of a 13 amino acid long positional scanning peptide library, having alanine residues in positions 1, 2, 12, and 13 and the central nine residues in positional scanning format, was compared with several other predicting algorithms. The authors concluded that positional scanning libraries are an efficient approach to derive MHC class II binding profiles.[34]

CONCLUSIONS

This chapter presents a summary of the use of positional scanning libraries to elucidate the specificity of a number of immunologically relevant receptor–peptide interactions. These receptors include antibody, T cell receptors, and MHC molecules. Peptide libraries have also been successfully used for the identification of the substrates of several proteases relevant in immunology such as human caspases and granzyme B (reviewed in Refs. 8,10). Furthermore, nonpeptidic and small molecule positional scanning libraries represent a source of diversity for the identification of protein–protein or protein–receptor interactions in which inhibitors or modulators of nonpeptidic composition would be favorable. The authors and others have successfully used these libraries for the identification of highly active agonists and antagonists of G protein-coupled receptors, antimicrobials, enzyme inhibitors, and other biological targets.[8,10]

Chapter 85

Anaphylatoxins

De Yang

ABSTRACT

Anaphylatoxins, namely, C3a and C5a, are complement-derived, cationic, inflammatory peptides that can cause anaphylactic reaction. C3a and C5a are generated on the enzymatic cleavage of complement C3 and C5 during the course of complement activation through classic, lectin, or alternative pathways. C3a and C5a mediate diverse biological actions by interacting with their receptors that are G protein coupled receptors differentially expressed by many subsets of leukocytes. Anaphylatoxins play important roles in inflammation and immunity and are implicated in the pathogenesis of numerous diseases.

HISTORICAL PERSPECTIVE AND SCOPE

Anaphylatoxin is a substance derived from complement activation that causes smooth muscle contraction, capillary leakage, and even anaphylactic shock. Historically, the development of our knowledge of anaphylatoxin is closely linked with the advancement in the understanding of complement system, which parallels the history of immunology. In the late ninteenth century, two theories on the mechanisms involved in protecting the host from microbial attack emerged: the "cellular theory," based on the existence of blood cells capable of ingesting bacteria, and the "humoral theory," based on the capacity of cell-free serum to cause bacteriolysis. Toward the end of the ninteenth century, Bordet, working at the Pasteur Institute, found that the serum from guinea pigs immunized with cholera organisms lost its bacteriolytic activity after heating but that the activity could be fully restored by the addition of nonimmune serum.[4] Bordet hypothesized that two humoral factors were involved, one of which was heat liable and the other a thermostable substance present in immune serum. Later, the thermostable factor present only in immune serum was identified as antibody and the heat-labile factor present in both nonimmune and immune sera was termed complement because it 'complemented' the activity of antibody in bacteriolysis. At the beginning of the twentieth century, anaphylatoxin was first described by Friedberger, who showed that the treatment of fresh serum with immune precipitates resulted in the formation of a substance that elicits anaphylactic shock in animals and speculated that the substance was derived from complement.[13] In the first half of the twentieth century, it was established that the complement contains more than one proteinaceous component. The 1960s and 1970s witnessed the purification and characterization of the individual components of the complement system including the identification of anaphylatoxic peptides, the establishment of the classic and alternative pathways of the complement activation cascade, as well as the biochemical characterization of the receptors used by complement components including the anaphylatoxins.[21,25] The genes for the complement components, anaphylatoxin, and their receptors were cloned in the 1980s and 1990s.[30]

Anaphylatoxins include C3a and C5a. Although C4a is also considered an anaphylatoxin,[21,25] C4a has only been shown to bind to the C3a receptor (C3aR) with low affinity and no C4a-specific receptor has been identified. In addition, human C4a has no agonistic effect on human C3aR despite showing anaphylactic activity in guinea pigs.[23]

PRECURSOR mRNA/GENE STRUCTURE, EXPRESSION, AND REGULATION OF ANAPHYLATOXINS

The genome organization, transcription, translation, and processing of human C3 and C5 are schematically illustrated in Fig. 1. Human C3 and C5 genes are located on chromosome 19p13.3–p13.2 and 9q33, respectively.[32,33] Although C3 (41 kb) and C5 (79 kb) genes are quite different in size, their intron–exon organization is very similar, with each consisting of 41 exons.[7,11] Transcription of the genes leads to the generation of C3 and C5 mRNAs of approximately 5.0–5.4 kb, which contain C3- and C5-coding sequence of 4992 and 5031 bases (including three bases of the stop codon), respectively.[10,17]

The major site for both C3 and C5 synthesis is hepatocytes; however, many other cell types, such as monocytes/macrophages, dendritic cells, and alveolar type II epithelial cells, can also produce C3 and C5.[2,12,25,30] Translation of

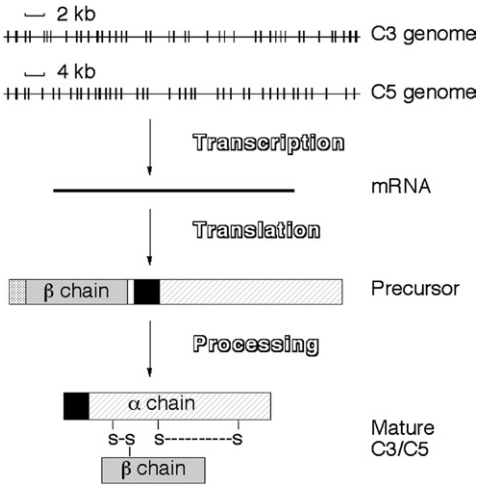

FIGURE 1 Schematic of the genome, synthesis, and processing of the precursors of human anaphylatoxins. The vertical bars in the genome represent exons.

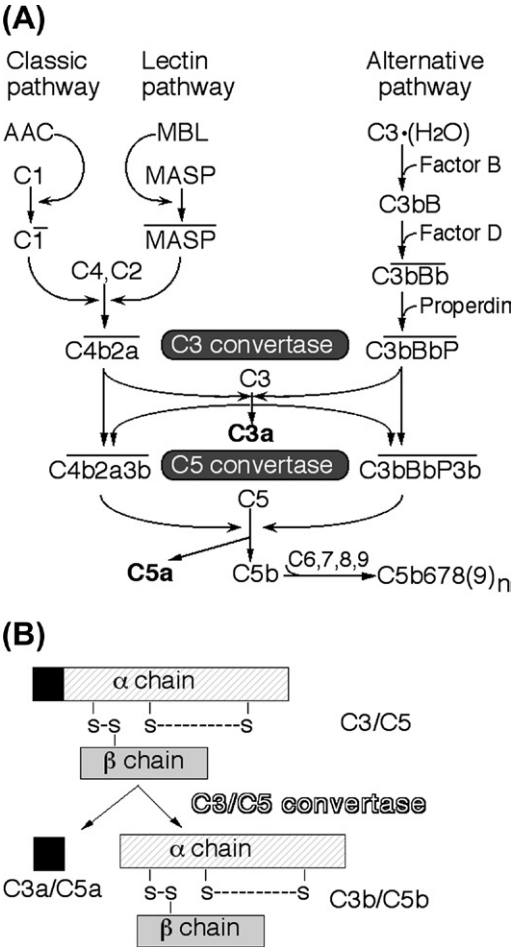

FIGURE 2 Generation of anaphylatoxins. (A) Outline of the complement activation cascade. Overlined components represent activated enzymes. AAC, antigen–antibody complex; MBL, mannose-binding lectin; MASP, MBL-associated serine protease. (B) cleavage of the α chain of C3 or C5 by respective convertases leads to the release of C3a or C5a anaphylatoxin.

C3 mRNA gives rise to a single-chain C3 precursor of 1663 amino acid (aa) residues consisting of a 22 aa leader peptide, a 645 aa β chain peptide, a 4 aa (Arg–Arg–Arg–Arg) linker sequence, and a 992 aa α chain peptide.[10] Similarly, C5 mRNA is translated into a single-chain procursor of 1676 aa including an 18 aa leader peptide, a 655 aa β chain peptide, a 4 aa (Arg–Pro–Arg–Arg) linker sequence, and a 999 aa α chain peptide.[17] Both the leader peptide and the linker sequence are removed during intracellular processing, leading to the generation of mature C3 or C5, which possesses a similar two-chain structure held together by one interchain disulfide bond and noncovalent interactions.[10,17,25,30]

Mature C3 and C5 are secreted into the extracellular fluids. In the serum, C3 is the most abundant complement component with a concentration ranging from 1 to 1.5 mg/ml, whereas C5 is present at approximately 70–80 μg/ml.[12,25,30]

The expression of C3 by many types of cells can be upregulated by inflammatory stimuli such as proinflammatory cytokines (e.g., TNFα, IL-1, IL-6, and IFNγ) and microbial products (e.g., LPS).[30] Therefore, C3 is considered to be one of the prominent acute response proteins. The expression of C3 is regulated at both transcriptional and posttranscriptional levels. By contrast, proinflammatory cytokines and LPS do not modulate the hepatic expression of C5.

GENERATION OF C3A AND C5A ANAPHYLATOXINS

C3a and C5a are generated in the course of complement activation.[12,21,25,30] The complement system is activated through three different pathways: classic, lectin, and alternative, as illustrated in Fig. 2A [Reviewed in detail in Ref. 30]. Although initiated uniquely and differing in the generation of C3 and C5 convertases, the three activation pathways converge on the activation of C5. The classic pathway is initiated by the formation of antigen–antibody complex (AAC), which activates C1 by binding C1q through the exposed CH2 region of certain antibodies (IgG1–3 and IgM). By contrast, the lectin pathway is initiated by the activation of mannose-binding lectin associated serine proteases, which is triggered by the binding of mannose-binding lectin to mannose-containing carbohydrate moieties on the microbial cell surfaces. Activated C1 and MASP sequentially cleave C4 and C2, leading to the generation of C4b2a C3 convertase. The alternative pathway is initiated by many microbial cell wall components, such as zymosan and LPS. The exact mechanism of initiation of this pathway is not completely understood; however, the most probable explanation is the "tickover" hypothesis.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Based on this hypothesis, C3 is believed to be constantly hydrolyzed [C3?(H_2O)] at a low-rate ("tickover") to form C3b, which is extremely unstable unless it binds to targets such as bacteria. Subsequently, factor B is recruited to the bound C3b and followed by factor D that cleaves factor B to form C3bBb, which is further stabilized by properdin to form C3bBbP, the C3 convertase of the alternative complement activation pathway. Once C3 is cleaved by C3 convertases, C3b binds with C3 convertase to form a complex termed C5 convertase [either C4b2a3b or C3bBbP3b], which, in turn, cleaves C5. C5b continues the complement activation cascade by binding to C6–8 and multiple C9 to ultimately form a cylindrical transmembrane channel, C5b678$(9)_n$, which is termed the membrane attack complex, for the destruction of target cell membrane.

In the complement activation cascade, cleavage of either C3 or C5 by C3 or C5 convertases occurs at a site close to the N-termini of their α chains,[12,21,25,30] leading to the generation of a big fragment, C3b or C5b, and a small peptide fragment, C3a or C5a (Fig. 2A and B). C3b and C5b continue the complement activation cascade on the surface of microbial or cell surfaces, whereas C3a and C5a are released into the fluid phase to act as anaphylatoxins. The life span of C3a and C5a *in vivo* is limited by carboxypeptidase N, an enzyme in the plasma that cleaves off the C-terminal Arg residue from both C3a and C5a, leading to the formation of desArg derivatives, C3adesArg and C5adesArg. Although C3adesArg is inactive, C5adesArg retains about 1% of the anaphylactic activity of C5a.

STRUCTURE OF ANAPHYLATOXINS

Anaphylatoxins purified from many vertebrate species are 74–77 aa residue peptides, highly cationic (with pIs of 8.6–9.6), and characteristically contain six cysteine residues.[21,25,30] The primary sequences of human C3a (77 aa) and C5a (74 aa) are shown in Fig. 3A. Elucidation of the tertiary structures of C3a and C5a by X-ray crystallography and nuclear magnetic resonance spectroscopy has revealed that both C3a and C5a adopt a compact globular folding, which consists of four antiparallel α-helices connected by three peptide loops,[27,35] as illustrated by the structure of human C5a (Fig. 3B). The globular core of four antiparallel α-helices is stabilized by three intrachain disulfide bonds, whereas the C-terminal tail is relatively disordered and flexible (Fig. 3B).

For both C3a and C5a, the C-terminal tail, particularly the C-terminal pentapeptide (LGLAR for C3a and MQLGR for C5a), plays an important role in mediating both binding and activation of their receptors.[16,20,21,24,25,35] However, other regions of surface of the globular core, such as the first and second loops, also participate in receptor binding.[8,16,20,24,27,35]

RECEPTORS FOR ANAPHYLATOXINS

C3a and C5a exert their biological actions by binding to their receptors. To date, one C3a receptor (C3aR) and two C5a receptor (C5aR, also known as CD88, and C5L2) have been cloned and characterized.[3,5,6,9,15] As illustrated by Fig. 4, all three receptors belong to the family of G-protein-coupled receptors (GPCRs), which share a common structural motif of seven transmembrane domains joined together by three extracellular and three intracellular hydrophilic loops. These receptors also have an extracellular N-terminal portion that contains an N-glycosylation site, and an intracellular C-terminal tail that harbors multiple Ser/Thr phosphorylation sites. C3aR contains a large second extracellular loop.

C3aR is expressed by many tissues including those of the central nervous system and by myeloid leukocytes such as neutrophils, eosinophils, basophils, mast cells, and monocytes/macrophages.[3,9,21,25,30] C5aR is expressed by many leukocytes such as neutrophils, eosinophils, basophils, mast cells, monocytes/macrophages, dendritic cells, and certain subset of lymphocytes, as well as nonleukocytes such as endothelial, epithelial, glial, and blood vessel smooth muscle cells.[5,15,20,21,25,30,34]

FIGURE 4 Sequence alignment of human C3aR (NCBI accession no. = Q16581), C5aR (NCBI accession no. = P21730), and C5L2 (NCBI accession no. = NP060955). The seven transmembrane domains (I–VII) are underlined. Residues involved in ligand-induced receptor activation in C5aR and conserved in C3aR and C5L2 are boxed. The "DRY" motif residues are bold-faced. The intracellular loop 3 Ser/Thr-containing motif in C3aR and C5aR is both boxed and bold-faced. The extra residues of large extracellular loop of C3aR are shown as a budding out loop for appropriate alignment.

contribute to the binding of their respective ligands.[6,8,20,30] Binding of ligands to C3aR and C5aR, in particular through interacting with the boxed residues (Fig. 4), triggers the conformational change of the receptor, which leads to the activation of heterotrimeric G proteins. Subsequently, multiple intracellular kinases (e.g., PLCs, PI-3Ks, PKC, PKB, MAPKs) and small G proteins (e.g., Ras, Rac, Rho, Cdc42) are activated, which ultimately lead to diverse biological actions. Although it can bind with both C5a and C5adesArg with high affinity, C5L2 does not elicit the biological actions that C5aR does,[6,14] raising the possibility that C5L2 may act as a decoy receptor for C5a.

BIOLOGICAL ACTIONS OF ANAPHYLATOXINS

Binding and activation of C3aR and C5aR by their respective ligands have diverse effects on various target cells, which play important roles in inflammation and immunity.

Anaphylatoxic Effect

C3a and C5a can cause smooth muscle contraction, increase in capillary permeability, vasodilation, and anaphylactic shock if systemically generated or applied. This anaphylatoxic effect is predominantly due to the activation of anaphylatoxin receptors on mast cells and basophils, which leads to their degranulation and release of histamine and other vasoactive or inflammatory mediators such as arachidonic acid metabolites (prostaglandins, leukotrienes, lipoxins), lipid mediators (e.g., platelet-activating factor), and the nucleoside adenosine.[12,21,25,30] Together with the direct action of anaphylatoxins on smooth muscle and vessel endothelial cells, these mediators elicit the constriction of bronchial, intestinal, and uterine smooth muscles, promote local vasodilatation, augment capillary permeability, and induce mucous secretion from bronchial, gastric, and intestinal epithelial cells.

Chemotactic Effect

Anaphylatoxins are potent chemoattractants and can induce the migration of leukocytes expressing their receptors.[8,12,15,20,21,25,30,34] C5a is more potent than C3a, and is actually one of the most potent peptide chemoattractants that are active at concentrations as low as 0.1 nM. Both C3a and C5a are chemotactic for granulocytes (neutrophils, eosinophils, and basophils), monocytes/macrophages, and mast cells. In addition, C5a is also chemotactic for dendritic cells (DCs), germinal center B cells, and T cells.[22,26,34] Thus, anaphalatoxins participate in the recruitment of various leukocytes into sites of inflammation during infection and tissue injury.

Phagocyte-activating Effect

Anaphylatoxins act as strong activators for neutrophils and monocytes/macrophages.[12,21,30] Activation of neutrophils by anaphylatoxins increases their adhesiveness, causes neutrophil aggregation, triggers the release of antimicrobial substances such as lysozyme, defensins, and cathelicidns, and remarkably stimulates neutrophil oxidative metabolism and the production of toxic reactive oxygen species. Activation of monocytes or macrophages by anaphylatoxins augments their cytotoxic activity and stimulates their production of inflammatory mediators such as cytokines and chemokines.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Immunoregulatory Effect

Interaction of C3a and C5a with their receptors on antigen-presenting cells (APCs) such as macrophage or DC promotes APC recruitment, surface upregulation of MHC and costimulatory molecules, and production of inflammatory cytokines.[28,29,34] C3a and C5a modulate the activation of APCs induced by various Toll-like receptor ligands, and hence altering the subsequent polarization of T cells.[28] C3aR and C5aR expressed by T cells on interacting with C3a and C5a can provide a survival signal. Therefore, anaphylatoxins modulate both innate and adaptive immune responses.

PATHOPHYSIOLOGICAL IMPLICATIONS OF ANAPHYLATOXINS

Based on their multiple biological actions, it is clear that the physiological function of anaphylatoxins is participation in immune defense and inflammation of the host.[21,25,28,30] During infection, anaphylatoxins contribute to the establishment of inflammatory responses with the ultimate goal of elimination of invading pathogens by facilitating bacterial killing or the induction of adaptive immunity. Therefore, it is not unexpected that individuals genetically deficient in either C3 or C5 display severe recurrent bacterial infection, likely due to the lack of both terminal membrane attack complex and anaphylatoxins. The critical role of C5a in host antimicrobial immune defense and inflammation has been clearly demonstrated by the use of C5aR knockout mice that, in comparison with wild-type mice, exhibit elevated susceptibility to mucosal bacterial challenge and an impaired inflammatory response in experimental reverse Arthus reactions.[18,19]

Anaphylatoxins are associated with nearly all types of inflammation.[14,21,25,30,31] Their inflammatory effects, particularly when excessive, are harmful and play a role in the pathogenesis of many diseases such as anaphylaxis, adult respiratory distress syndrome, acute transplant ejection, ischemia reperfusion, sepsis, brain inflammation, and many autoimmune diseases such as psoriasis, rheumatoid arthritis, and systemic lupus erythematosus.[30,31] Blockade of anaphylatoxins by neutralizing antibody or antagonists ameliorates the pathogenesis and symptoms of these diseases in experimental animal models. Therefore, great effort has been made to develop effective antagonists for anaphylatoxins.[1,31] Thus, anapylatoxic peptides have moved from gross observation to the understanding of their genomic complexity, regulation at the molecular level of their expression and action, as well as roles in inflammation and immunity in the twentieth century, and finally culminating in the twenty-first century with the development of molecularly targeted antagonists for the potential treatment of various inflammatory diseases.

Chapter 86

Annexin-A1 Peptide Ac2–26

M Perretti, F D'Acquisto and R.J. Flower

ABSTRACT

Annexin A1 *N*-Acetyl 2–26 (m.w. 3089.5 kDa; empirical formula $C_{141}H_{210}N_{32}O_{44}S$, hereafter referred to as Acetyl 2–26), is a peptide sequence derived from the N-terminus of the glucocorticoid-regulated protein Annexin (Anx) A1. Although it does not occur naturally as such, longer peptides containing this sequence are found in inflammatory exudates and other biological fluids. The significance of the peptide is that it seems to contain the major Anx-A1 pharmacophore and can reproduce many of the biological properties of the full-length protein. The peptide is available commercially and is commonly used in many experimental systems in its capacity as an Anx-A1 mimetic, albeit with less potency.

DISCOVERY

The discovery of the 37-kDa protein Annexin A1 (Anx-A1; formerly macrocortin, Lipocortin 1) arose from investigations into the mechanism by which anti-inflammatory glucocorticoids suppressed eicosanoid synthesis in intact but not disrupted cells. In the authors' own laboratory, it was determined that glucocorticoids, acting on cells through a receptor-dependent mechanism, promoted the synthesis and release of a proteinaceous factor that, when partially purified, was found to duplicate the glucocorticoid-like activity in other untreated cells. Although originally observed in guinea-pig lung tissue, further sources were soon discovered. The unknown protein was found to possess anti-inflammatory properties in rodent models of acute inflammation. Similar factors (renomedullin, lipomodulin) were reported by other laboratories and were, in due course, found to be structurally or immunologically related.[13]

Anx-A1 itself was subsequently[32] purified to homogeneity from peritoneal lavage fluid obtained from glucocorticoid-treated rats,[23] cloned and sequenced. The mammalian native protein is acetylated after removal of the N-terminal Met residue.

A comparison of the Anx-A1 sequence with several other partially purified proteins led to the recognition that all these species formed part of a much larger family of proteins, subsequently dubbed the "Annexin super-family."[21] This embraces some thousand proteins distributed throughout most eukaryotic (but not prokaryotic) phyla although it seems to be largely absent from yeasts.

Family members are characterized by the presence of four (eight in the case of Anx-A6) homologous domains of approximately 70 residues (the "core") that usually harbor "type 2" calcium-binding sites but distinguished by a unique N-terminal region believed to confer individual properties upon each member of the family. These N-termini are of variable length with the shortest being that of Anx-A5 (six amino acids) and the longest, Anx-A7 (100 amino acids).

The early history of the discovery of Anx-A1 has been documented,[13] and there are several reviews relating to its action as an anti-inflammatory agent,[10,26] as a mediator of glucocorticoid feedback in the HPA axis[3] and as a regulator of other cell functions.[15] The detailed information in these reviews will not be reiterated here, but Table 1 shows the main actions of Anx-A1 as established by experiments using transgenic mice, neutralizing anti-Anx-A1 antibodies and antisense agents.

SCOPE OF THIS CHAPTER

This review restricts itself to a discussion of the usage of Acetyl 2–26 as a pharmacologically active agent. Other peptides based on the Anx-A1 structure have been used and some have been found to have anti-inflammatory or other biologically active properties. These include Anx-A1 1–188 (which includes the Acetyl 2–26 sequence) and peptides from some other regions of the protein including the antiflammins such as AF2, which is derived (His^{246}-Glu^{254}) from the core domain of Anx-A1.[2] These will not be discussed further in this chapter.

DISCOVERY OF IMPORTANCE OF THE N-TERMINAL PEPTIDE

The notion that the N-terminal domain was of particular significance to the biological activity of Anx-A1 originally arose from the work of Cirino et al.[6] who observed that an N-terminal truncated form of native Anx-A1 (~33 kDa),

TABLE 1 A Summary of Some Biological Actions of Native Anx-A1

System	Inhibits	Promotes
In vitro	• $cPLA_2$ activation • Eicosanoid production • Superoxide production • Phagocytosis • Th2 cell differentiation • Anterior pituitary hormone release • Cell (e.g. A549) growth and differentiation	• L-selectin shedding • PMN apoptosis • Efferocytosis • T-cell proliferation • TCR downstream signaling • Th1 cell differentiation
In vivo	• PMN trafficking • PMN adherence • Histamine release • Cytokine generation • Acute inflammation (some models) • Chronic inflammation (some models) • Hyperalgesia/ nociception • Fever (some pyrogens) • NMDA-induced neuronal damage	• T-cell dependent inflammatory responses

These were established by experiments using recombinant Anx-A1, Anx-A1 null mice, specific neutralizing antibodies, or antisense agents. The results are collected from a variety of sources as reviewed in Refs 3,10,13,26.

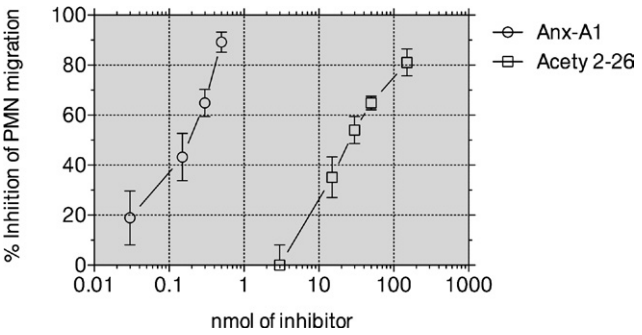

FIGURE 1 Anti-inflammatory action of acetyl 2–26 in comparison with the full-length Anx-A1 protein. The model used is a murine air pouch model in which neutrophil emigration is stimulated with IL-1β. Anx-A1, or its acetyl 2–26 N-terminal peptide are administered 15 min before the cytokine and the neutrophil emigration in the pouch counted 4 h later. The ED_{50} doses are approximately 5.2 and 88 μg per mouse, respectively. In this experiment, a longer N-terminal peptide (1–188) seemed to have an intermediate (ED_{50} 38 μg per mouse) potency although a full dose-response curve could not be established. Acetyl 2–26 has a potency of some 200-fold less than the native protein although it evidently has the same efficacy. From Perretti et al.[24]

prepared by plasmin cleavage of the native protein, was biologically inactive while a synthetic peptide corresponding to the first 26 amino acids retained activity in three different models of acute rodent inflammation, although it was at least an order of magnitude less active. In a related article,[24] the same group showed using a murine air pouch technique that Acetyl 2–26 shows a similar efficacy to the full-length recombinant protein in murine peritonitis, neutrophil migration, and skin inflammation models. The authors observed that the efficacy of the peptide was similar that of the native protein but that it was some 200-fold less potent (Fig. 1).

The conclusive demonstration that this fragment was responsible for much of the observed biological actions of Anx-A1 came from a study using a chimeric protein. Anx-A5, another member of the annexin family with a very short N-terminus, lacks the biological activity associated with Anx-A1, but a fusion protein comprising the Anx-A5 "core" domain and the Anx-A1 N-terminus exhibited very similar biological activity to the intact Anx-A1 protein itself.[18]

THE STRUCTURE OF ANX-A1 AND ACETYL 2–26

Anx-A1 itself is a monomeric amphipathic protein comprising 346 amino acids. The crystal structure has been determined at the 1.8 Å level[29] and reveals the protein to exist in a lenticular configuration with a central pore. The N-terminus (44 amino acids) is folded into the core domain on the concave surface, but can "flip" out in the presence of calcium. On the convex aspect of the protein, six calcium-binding sites may mediate the binding to negatively charged phospholipids in a pH-dependent fashion.

The peptide itself has a complex predicted structure (Table 2) in aqueous solution with a strong tendency to form a helical structure in residues Ala^2-Ile^{14} a potential "turn" in the structure at residues Glu^{15}-Glu^{18} and a propensity to form a sheet structure from residues Gln^{19}-Thr^{24}. The majority of the peptide consists of hydrophobic sequences interspersed with a strongly hydrophilic region at residues Asn^{16}-Tyr^{21}. It is likely that the actual structure adopted by the peptide in biological solutions will depend on the presence of lipids such as phosphatidyl serine.

Biochemistry of the Anx-A1 N-Terminus Domain

The full-length N-terminal domain contains several Ser, Thr, His, and Tyr phosphorylation sites. Several protein kinases including PKC and the EGF and other receptor tyrosine kinases have been implicated in the widespread occurrence of phosphorylated species in biological fluids

Hydrophobic			2	4	6				8	8	8	8	2								1	4	4		

The propensity of the Acetyl 2–26 to form helices, sheets, turns, or coils in aqueous solution is shown. These parameters were calculated using conventional algorithms. The upper case and lower case letters indicate the approximate likelihood of these structures occurring. The relative hydrophilicity/-phobicity of the sequence is represented numerically on a scale of 1–20 where 1 represents the least, and 20 the most hydrophobic/-philic residues. From Croxtall et al.[8]

and cell extracts. Acetyl 2–26 itself has many residues that are putative phosphorylation targets (Ser^3, Thr^{24}, and Tyr^{21}).

Consensus sequences for glycosylation (Asn^{43}-Ser^{45}) and transglutamination (Glu^{19}, Gln^{23}) are also found within the N-terminal domain. Both glycosylated and transglutaminase-linked species have been reported in the placenta and elsewhere, although these species are not apparently widespread.

The N-terminus also contains several proteolytic motifs. An N-terminal truncated moiety is commonly encountered in inflammatory fluids probably as a result of cleavage at Lys^{26}-Lys^{29}, or Val^{36} by serine proteases such as neutrophil elastase or PR3.[10] Proteolysis in the N-terminal domain profoundly modifies the physical properties of the protein and is probably associated with the inactivation given the dramatic reduction in potency of Acetyl 2–26 when compared with that of the native protein.

The N-terminal domain of Anx-A1 is important for another reason. Certain annexins, including Anx-A1, can form heterotetramers with members of the S100 family of EF-hand calcium-binding proteins. It is believed that the Anx-A1 1–12 sequence is the region involved in binding to these proteins.[21]

The significance of these observations is that Acetyl 2–26 could have secondary actions by blocking one or more of these interactions in addition to its chief, receptor mediated, effect (see below).

RECEPTORS FOR ANX-A1 AND N-ACETYL 2–26

Native Anx-A1 and its bioactive N-terminal peptides exert extracellular actions on cells to mimic some of the effects of glucocorticoids both *in vivo* and *in vitro*. It was therefore a reasonable assumption that there was a cell surface receptor for the proteins.

The first experimental evidence for such a receptor arose from the observation that there were discrete, saturable binding sites for human recombinant Anx-A1 on the surface of human peripheral blood monocytes and neutrophils,[10] which disappeared during the inflammatory response and which coprecipitated with Anx-A1 from membrane extracts. Receptor-like proteins were later described in the endocrine pituitary cells.[5]

A key article from Walther et al.[33] led the field in a different direction by implicating the formylated peptide (f-Met-Leu-Phe; FMLP) receptor (FPR) in the transduction of the Anx-A1 signal in leukocytes. FPR is a member of a family of G-protein-coupled receptors expressed in migratory cells and many other tissues. In humans, there are three known species: FPR itself (now known as FPR1), FPRL-1 (FPR-like-1, also termed FPR2 or ALXR) and FPRL-2 (now known as FPR3). Although FPR1 probably mediates the proinflammatory effects of the bacterial tri-peptide FMLP, FPR2/ALX is more promiscuous binding lipoxin A_4, an anti-inflammatory mediator generated from arachidonic acid, as well as serum amyloid A, a liver-derived acute phase protein.[4]

Anx-A1 and the peptide Acetyl 2–26 induce calcium transients in human neutrophils suggesting that their effects are mediated through FPR1 itself.[33] However, unlike FMLP, Anx-A1-related peptides do not stimulate superoxide generation at concentrations that provoke calcium fluxes and L-selectin shedding, and FMLP does not compete with Anx-A1 binding in cells transfected with the human FPR1.

"Boc" antagonists (Boc-Met-Leu-Phe and Boc-Phe-D-Leu-Phe-D-Leu-Phe) of the FPR family of receptors inhibit Anx-A1-induced calcium fluxes and L-selectin shedding by PMN and also prevent the Acetyl 2–26 induced inhibition of leucocyte adhesion and emigration in murine inflammatory models and elsewhere.[17] However, these antagonists lack specificity between members of the FPR family making it difficult to determine which subtype is being used. Acetyl 2–26 also retains anti-inflammatory activity in FPR1 null mice[14] suggesting that although the FPR family mediates some Anx-A1 effects the receptor responsible is unlikely to be FPR1 itself.

Of the three products of the FPR gene cluster in humans, only FPR2/ALXR binds the anti-inflammatory lipoxin A_4. This binding can be displaced by SAA, and high concentrations of FMLP or the synthetic peptide MMK1.[4] Both Anx-A1 and Acetyl 2–26 also bind FPR2/ALX in human PMN and compete specifically with lipoxin A_4. Endogenous Anx-A1 and FPR2 co-immunoprecipitate from human and murine PMN.[25] Like lipoxin A_4, Acetyl 2–26 retains the ability to promote the detachment of adherent leucocytes in FPR1 null mice, again suggesting that the receptor for Anx-A1 is not FPR1 but a further subtype.[14]

In the mouse, the fpr gene cluster has undergone differential expansion and six genes have been identified.[11] Two are not expressed, and another is found only in the skeletal muscle. The remaining three genes (now termed Fpr1, Fpr2, and Fpr3) are expressed in leucocytes, spleen and lung and are therefore potential candidate murine receptors for Anx-A1. In mouse, however, the functions of human FPR2/ALX seem to be split between Fpr2 and Fpr3. It is probable that the mRNA for Fpr2 and Fpr3 is formed by differential transcription of the same gene.

Dufton et al.[11] generated an Fpr2/3 null mouse strain and used this to assess the role of these receptors in the action of Anx-A1 and Acetyl 2–26. These transgenic mice fail to respond to the N-terminal peptide Acetyl 2–26 and other agonists at these receptors and exhibit an enhanced inflammatory response when compared with that in WT control animals. These results are reminiscent of the behavior of the Anx-A1 null mouse and taken, together with other results,[2]

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

point to the existence of an anti-inflammatory loop centered upon this receptor.

BIOLOGICAL PROPERTIES OF THE ACETYL-26 PEPTIDE

After the discovery that the biological activity of Anx-A1 could be reproduced by *N*-acetyl 2–26, and by some shorter peptides, it has become a common practice to use these instead of the full-length recombinant molecule which, despite its greater potency, exhibits more instability in use and can prove difficult to prepare in a correctly folded and endotoxin-free manner. Acetyl 2–26 does exhibit a slightly different affinity profile for the FPR family of receptors but nevertheless possesses very similar anti-inflammatory properties to the full-length molecule.[2] Tables 3 and 4 give an idea of the different systems in which this peptide has been tested and found to be effective.

TABLE 3 Some *In Vitro* Systems in Which Acetyl 2–26 Has Biological Properties

Year	Species	System	Concentration	Comments	Refs
1995	Rat	Release of prolactin from the anterior pituitary gland.	3 pM–3 nM	Inhibition of prolactin release in a stimulus dependent fashion.	Taylor et al.[31]

2005	Human	Phagocytosis of neutrophils by monocyte-derived macrophages.	32 μM	Stimulated phagocytosis through an FPR-dependent mechanism.	Maderna et al.[20]
2005	Rat	Ischemic damage to cardiac myocytes.	0.3 μM	Cardio-protective effect through an FPR-mediated mechanism.	Ritchie et al.[28]
2006	Human	Neutrophil–endothelium interaction under flow conditions.	3–30 μM	Attenuated capture and rolling but not adhesion to endothelium.	Hayhoe et al.[16]
2007	Human	Growth of Hep-2 larynx cancer cells.	2 μM	Inhibition of cell growth.	Silistino-Souza et al.[30]
2010	Equine	Blood neutrophil superoxide production.	10–50 μM	Stimulation at higher concentration: inhibition at lower concentration. Through an FPR-dependent mechanism.	Pickles et al.[27]

TABLE 4 Some *In Vivo* Systems in Which Acetyl 2–26 Has Biological Activity

Year	Species	System	Dose	Comments	Refs
1993	Mouse	Models of inflammation: air pouch, skin edema and zymosan peritonitis	88–200 μg per mouse	Anti-inflammatory actions in all models.	Perretti et al.[24]
1997	Rat	Ischemia reperfusion injury of intestine	0.125–0.5 mg/kg	Reduced GI damage and cardiovascular disturbances.	Cuzzocrea et al.[9]
2001	Rat	Myocardial ischemia-perfusion injury	0.5–1.0 mg/kg	Cardioprotective in an FPR dependent fashion.	La et al.[17]
2005	Rat	Allergic response	50–200 μg topically	Inhibition of mast cell histamine release and cell accumulation.	Bandeira-Melo et al.[1]
2007	Rat	Spinal cord injury	5–20 μg topically	Neuroprotective	Liu et al.[19]
2011	Rat	Asthma	1.0 mg/kg	Inhibited eosinophil migration and the release of cytokines and PGD in lungs. Effect reversed by PGD administration.	Wang et al.[34]

Some *in vivo* systems in which Acetyl 2–26 has biological activity.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

In Vitro Systems

Table 3 shows a representative (though necessarily incomplete) selection of *in vitro* systems, drawn from the literature, in which Acetyl 2–26 has been found to possess biological activity. The examples illustrate the wide range of biological activities achieved by this peptide, which includes inhibition of hormone release from neuroendocrine tissues, cardioprotection, inhibition of cell growth, and PMN and monocyte activation. The peptide is active across a wide range of species including human, mouse, rat, and horse.

In general, the peptide displays FPR-mediated biological activity in the 1 μM range, although there are exceptions. Of importance is the finding by several groups of the concentration-dependency of the actions of the peptide. Several groups[27] have observed, for example, that high concentrations of the peptide can activate neutrophil superoxide production, whereas low concentrations can inhibit the response. This is most probably because Acetyl 2–26 (unlike full-length Anx-A1) is not specific for the FPR2/ALXR subtype and can also activate other FPR family receptors at concentrations of 10–100 μM.[12,16]

The question of which portion of the Acetyl 2–26 structure interacts with the FPR1 receptor to activate PMN NADPH oxidase has been addressed by Movitz et al.[22] with the suggestion that the sequence Acetyl Gln^{10}–Phe^{13} is the minimum sequence required to activate the receptor and to block the action of FMLP.

In Vivo Systems

Table 4 shows a selection of systems drawn from the literature, in which the peptide has been used *in vivo*, mainly as an anti-inflammatory agent. Of necessity, most work has been performed in rodents but the range of models used is wide, including allergic disorders, cardioprotection, and neuroprotection. Routes of administration, vary but the peptide is effective systemically in doses in the general range of 0.1–5.0 mg/kg and topically in the range 5–200 μg. The frequency of dosing varies, but most investigators have deployed a single administration given before the inflammatory stimulus.

STRUCTURE–ACTIVITY RELATIONSHIPS

The structure–activity relationships between different fragments of Acetyl 2–26 have been investigated by several authors, but there are some anomalies and gaps in the results that make definitive conclusions regarding the minimum active sequence, difficult at this time.

One problem has been that some of the peptides tested have been N-acetylated, while others have not. Additionally, it has not been established in every case whether or not the FPR receptor system is involved in the action of the peptide in all test systems. As explained above, it is conceivable that Acetyl 2–26 may have a secondary pharmacology through its ability to interfere with heterodimerization, phosphorylation, or proteolysis of the native Anx-A1 and such factors may account for some of the discrepancies.

Generally speaking, the results from *in vivo* models seem fairly straightforward. As Table 5 shows, not only Acetyl 2–26 but also the fragment Acetyl 2–12 is biologically active in models of reperfusion injury *in vivo* through an FPR mechanism, whereas the fragments Acetyl 2–6 and 9–25 are not. This would imply that the key sequence for achieving bioactivity *in vivo* is located somewhere in the region of Glu^{6}–Trp^{12}. This sequence is similar to the sequence proposed by Movitz et al.[22] to be the highly hydrophobic core sequence required to bind to the transmembrane binding pocket of FPR1, Gln^{10}–Phe^{13}. Although the FPR receptors are not identical, there is a high degree of homology between them, so this could be a significant region for interaction with all the FPR family.

In vitro however, the situation is more complex. Croxtall et al.[7,8] examined the activity of a range of peptides drawn from the N-terminal domain for their effect on A549 cell growth, proliferation, arachidonic acid, and eicosanoid release under either resting or EGF-stimulated conditions. Native Anx-A1 is highly active in this assay (EC_{50} ~50 nM) and (unacetylated) Met^{1}–Trp^{12} is inactive, whereas Phe^{13}–Val^{25} is fully active (although ~1000 less potent than the native protein) through an effect that depends on the inhibition of $cPLA_2$ activation. The role of Tyr^{21} seems crucial for the inhibition of cell growth as replacement with a Phe residue, or methoxylation, abolishes activity of the peptide. However, these peptides retain inhibitory activity when EGF proliferation is measured instead as does Met^{1}–Trp^{12}, which is inactive on cell growth per se.

When a range of 25 (nonacetylated) peptides derived from the sequence Phe^{13}–Val^{25} is systematically tested, the sequence common to all active peptides is Glu^{18}–Val^{22}, and the minimum sequence that is required for biological action is Glu^{18}–Val^{25}. This sequence contains important phosphorylation sites and is at least partially homologous to several other peptides such as middle T antigen, MT peptide and the amphibian anti-inflammatory peptide sauvagine all of which that have been shown to exert similar biological effects in some systems.

The most probable possibility is that the activity of these peptides in this particular system is not dependent on FPR receptor occupation but rather on some secondary interference with signal transduction systems by, for example, acting as decoy substrates for kinases. Tyr^{21} is a substrate for EGF receptor kinase and these sequences contain other

phosphorylation sites also (e.g. Thr^{24}). Because many of the peptide fragments used in these experiments are generally hydrophilic and have a tendency to form helical structures in solution, it may be the conformation of the peptide rather than its sequence that is crucial to the effects seen in this type of assay. Some kinases such as $PP60^{v\text{-}src}$ have a strong preference for substrates in this conformation.In summary, it is possible that the effects of short peptides in this system reflect a capacity to interfere with cell signaling downstream from G protein activation rather than the FPR-mediated effects that probably account for most of their biological actions.

The structure of the Acetyl 2–26 is highly conserved between humans and common laboratory species (Table 6) particularly in the region Ala^2–Ala^{11}. Only in the horse was there an "unfavorable" substitution for Glu at Ala^6. This does not affect the activity of Acetyl 2–26 in equine cells (Table 4). Elsewhere, the overall homology is very high with the overwhelming number of substitutions being "favorable" replacements.

SUMMARY

Acetyl 2–26 is a convenient and readily obtained peptide with which to explore the functionality of the Anx-A1—FPR2/ALX anti-inflammatory system *in vivo* and *in vitro* and there is a substantial literature on the subject. The main mode of action of its anti-inflammatory action is through the activation of FPR2/ALX receptors and in this respect the key sequence seems to be Ala^2–Trp^{12}. The peptide is not, however, specific for this receptor especially at higher concentrations. Activation of other FPR receptors may complicate interpretation of results if it is not used with care. Further, the peptide may have secondary pharmacology through its ability to interfere with signal transduction systems, at least under defined conditions *in vitro*.

Chapter 87

Immunoregulatory Neuropeptides

Mario Delgado

ABSTRACT

The immune system is faced with the daunting job of defending the organism against invading pathogens, while at the same time maintaining tolerance to the body's own tissues, thereby preserving its integrity. Multiple mechanisms act in concert to ensure self-tolerance. Loss of immune tolerance compromises immune homeostasis and results in the onset of autoimmune disorders. Identification of the endogenous factors that control antigen-specific tolerance and inflammation is a key goal in the field of immunology. In the last decade, various neuropeptides that are produced by immune cells with potent anti-inflammatory actions have been found to participate in the maintenance of immune tolerance at multiple levels, especially in immunological disorders. Here, I review the most recent advances in this field and highlight the therapeutic potential of using neuropeptides in a wide range of inflammatory/autoimmune situations.

INTRODUCTION

The immune system is a protective device perfectly designed to recognize and respond to a wide variety of foreign pathogens and injuries. However, because foreign and self-proteins are chemically similar, strict discrimination between self and non-self is neither possible nor desirable. The inflammatory process is vital to the survival of all complex organisms and although it is a localized protective response that serves to destroy the injurious agents, once the pathogen is eliminated, cells participating in innate and adaptive immunity have to be deactivated or eliminated, to reestablish tissue homeostasis.[20] The accumulation and subsequent activation of leukocytes are central events in the pathogenesis of virtually all forms of inflammation. Uncontrolled activation of the immune system and the sustained production of inflammatory mediators lead to serious consequences for the host, such as tissue destruction, organ failure, even death if it is systemically disseminated (i.e., septic shock) (Fig. 1A). A further damage arises from potential autoimmune responses occurring during chronic inflammatory responses.[20] Most of the immune-mediated destruction of self-tissues occurs via specific recognition of self-antigens, followed by a typical effector immune response, and/or occasionally as a byproduct of unchecked nonspecific inflammation or overly vigorous responses to chronic infections (Fig. 1A). In addition, genetic predisposition and environmental factors are critical triggers of self-reactive responses in a chronic inflammatory scenario. Generally, autoimmunity is initiated by differential processing of self-antigens/peptides, which occurs under inflammatory conditions, in which cytokines activate proteases that increase the processing and presentation of previously cryptic self-antigens. Alternatively, the activation of crossreactive lymphocytes that recognize the original pathogen antigen and self-antigen leads to release of cytokines and chemokines, which enhance local inflammation, activate antigen-presenting cells, and indirectly or directly cause tissue destruction and spreading of the autoimmune process (Fig. 1A). The initial stages of the autoimmune disease take place in peripheral lymphoid organs, are associated with initiation and establishment of autoimmunity to self-components, and involve the development of self-reactive T helper 1 (Th1) and Th17 cells by dendritic cells (DCs) presenting self-antigens. Moreover, Th1 cells promote the secretion of IgG2 autoantibodies by self-reactive B-cells and the deposition of immune complexes in the target tissue where they activate complement, neutrophils, and mast cells (Fig. 1A). Progression of the autoimmune response involves the entry of self-reactive Th1/Th17 cells into the affected organ or organs (if systemic), release of proinflammatory cytokines and chemokines, and subsequent recruitment and activation of inflammatory cells (macrophages and neutrophils). Later events are associated with the evolving immune and destructive inflammatory responses, where inflammatory mediators (cytokines, oxygen and nitrogen reactive species, and free radicals) produced by infiltrating cells and resident cells participate in tissue destruction (Fig. 1A).

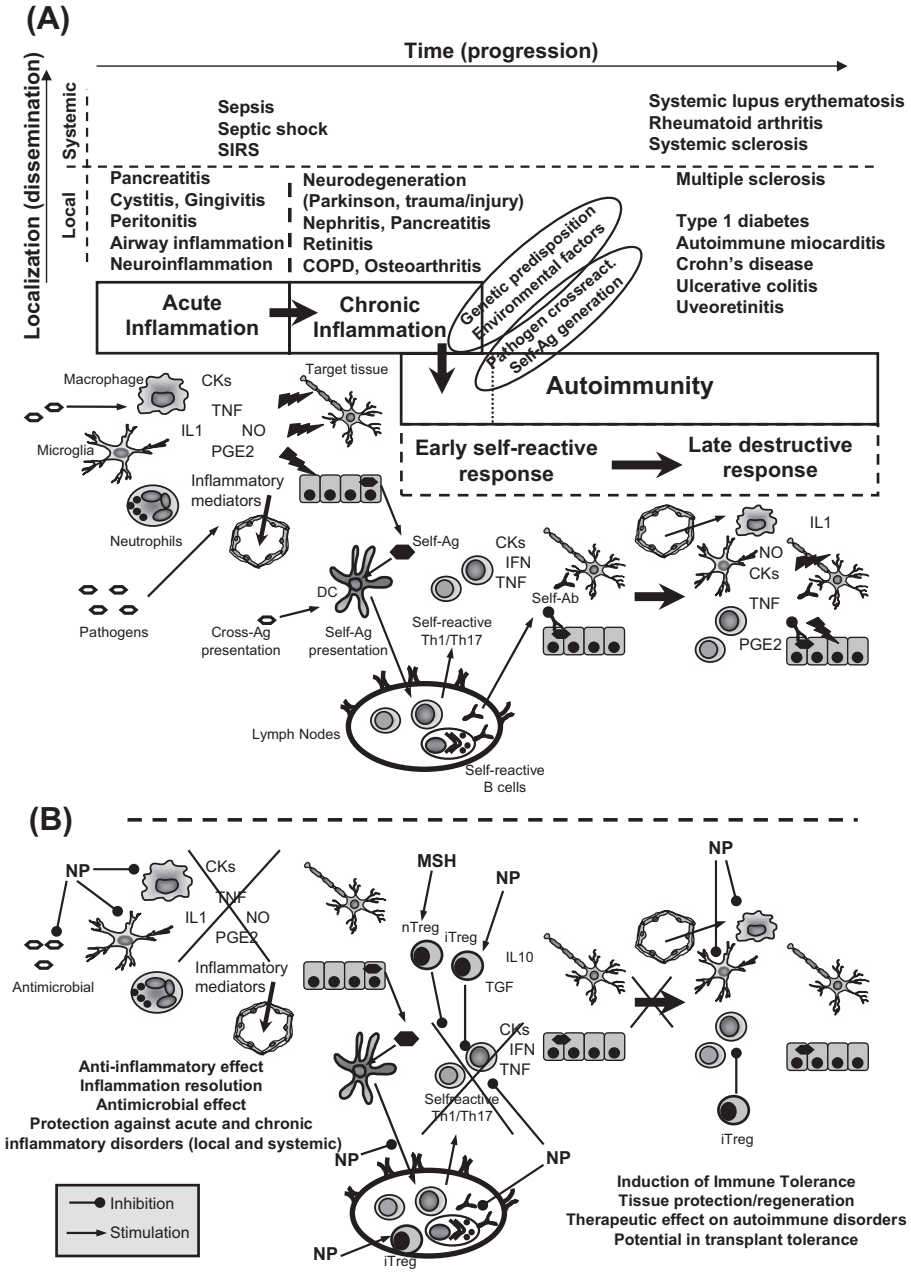

FIGURE 1 Mechanisms involved in the protective effect of neuropeptides on autoimmunity. (A) Inflammation is a necessary process for the elimination of pathogens, but it can lead to serious deleterious effects in the host if left unchecked. A sustained inflammatory response causes tissue damage, which is especially serious in some tissues/organs such as the central nervous system with limited regenerative capacities (i.e., neurodegenerative disorders). Systemically disseminated inflammatory mediators could cause sepsis, septic shock, systemic inflammatory response syndrome (SIRS), and eventually death. Besides, autoimmunity is the result of the progression from acute to chronic inflammation, is initiated by aberrant immune responses against self-antigens (self-Ag), and genetic predisposition and environmental factors play a role in its triggering. (B) To reinstate tolerance on inflammatory and autoimmune disorders, certain neuropeptides (NP), including VIP, PACAP, ghrelin, cortistatin, αMSH, urocortin, and adrenomedullin, reinforce various mechanisms. (**1**) Neuropeptides inhibit the production of a plethora of inflammatory cytokines, chemokines (CK), and free radicals (NO: nitric oxide) by macrophages and resident cells (i.e., microglia and synovial cells), avoiding the perpetuation/dissemination of the inflammatory response and its cytotoxic effect against self-tissue components. (**2**) Through a direct cell-independent antimicrobial action, neuropeptides eliminate pathogens and subsequently avoid chronic inflammation and self-antigen crosspresentation. (**3**) If autoimmune responses occur, neuropeptides can decrease Th1/Th17 cell functions through direct actions on differentiating T-cells, or indirectly by regulating DC functions in the peripheral lymphoid organs and locally in the affected tissue. Consequently, the inflammatory and autoimmune responses are inhibited because the infiltration/activation of neutrophils and macrophages and deposition of immune complexes (self-Ab) are avoided. (**4**) Neuropeptides induce the new generation of peripheral Treg (iTreg) that suppress the activation of self-reactive T-cells, expand naturally occurring Treg (nTreg), and indirectly generates iTreg through the differentiation of tolerogenic DCs. COPD: chronic obstructive pulmonary disease.

To protect against autoimmunity without inhibiting its ability to mount effective responses to pathogens, the immune system has evolved several mechanisms to maintain tolerance to self-tissues that normally operate at multiple and successive layers of regulation.[20] Central clonal deletion, effector T-cell balance, regulatory T-cells (Treg), and cytokine deviation are some of the multiple mechanisms that act in concert to ensure self-tolerance (Table 1). Despite the plethora of safeguards that exists to ensure that tolerance is enforced in the immune system, they can occasionally be overcome, and autoimmune diseases develop.

Because the maintenance of this tolerance is critical for the homeostasis of the immune system and at the end the survival of the organism, it is logical to assume that the immune system must produce endogenous factors involved in such a role to accomplish this task. For example, inflammatory responses are self-controlled by anti-inflammatory mediators secreted during the ongoing process. Although traditional anti-inflammatory and/or immunosuppressive cytokines and interleukins (i.e., IL-10, TGFβ, and IFNα) are the immediate candidates,[20] numerous researchers have lately focused their effort in the identification of these endogenous inductors of tolerance on mediators nontraditionally classified as immune factors. In this sense, considerable evidence indicates that the immune system is not totally autonomous in generating an immune response and that the neuroendocrine system communicates with the immune system mounting a variety of coordinated responses to the "danger" of pathogen infection, injury, or inflammation.[29] This communication is bidirectional and is based in a mutual biochemical language. Thus, cytokines/interleukins produced by immune cells are recognized by receptors expressed on neuroendocrine cells, and vice versa, cells of the immune system recognize neurotransmitters, neuropeptides, and hormones produced by the nervous system. In this scenario, the immune system acts as sixth sense signaling the brain to respond to danger, orchestrating the febrile response and its subsequent effects on behavior. The nervous system conversely regulates the immune system in response to physical or psychological stress. Glucocorticoids and adrenergic neurotransmitters secreted by the hypothalamic-pituitary-adrenergic axis and sympathetic nervous system are the classical example of endogenous immunosuppressive agents produced in response to stress or systemic inflammation.[13,29] Besides, peripheral endings of sensory and efferent nerves release various neuropeptides capable of acting on nearby immune cells in response to various danger signals.[14,29]

From the growing list of about 40 neuropeptides currently thought to posses immunomodulatory actions, some of them (i.e., opioids and galanin) show a clear anti-inflammatory profile, acting on macrophages, microglia, and neutrophils, in an attempt to keep under control the innate inflammatory response; other neuropeptides (i.e., substance P and neurokinins) contribute to the inflammatory response, especially associated with neurogenic inflammation and hyperalgesia; and more limited is the number of neuropeptides that modulates the acquired immune response.[14,25] Most of these neuropeptides have been addressed in detail by Dr. Zhang in another chapter in this section of the book.

TABLE 1 Mechanisms of Induction of Immune Tolerance

Mechanism	Definition
Central deletion	Developing self-reactive lymphocytes generated by the random genetic recombination, with a high affinity to ubiquitously expressed self-antigens, are eliminated in the central lymphoid organs (thymus for T-cells, bone marrow for B-cells) by apoptosis. Before being clonally deleted, the self-reactive B-cell might be rescued by further gene rearrangements that replace the light chains of the self-reactive receptor with a new receptor that is not autoreactive, a mechanism termed receptor editing.
Anergy and ignorance	T-cells that recognize a self-antigen in the periphery in the absence of sufficient costimulatory signals or in the presence of coinhibitory (e.g., CTLA4) signals are functionally inactivated. Persistent and repetitive stimulation with a self-antigen also causes inadequate T-cell responses.
Regulatory T-cells (Treg)	Various T-cell populations that can functionally suppress an immune response by influencing the activity of effector autoreactive cells. Several phenotypically distinct regulatory T-cell populations exist: thymus-generated natural $CD4^+CD25^+FOXP3^+$ Treg, peripherally induced $CD4^+CD25^+FOXP3^+$ Treg, IL-10-producing type 1 regulatory cells induced by tolerogenic dendritic cells and transforming growth factor-β1-producing Th3 cells.
Cytokine deviation	Inflammatory responses are counteracted by anti-inflammatory mediators secreted during the ongoing process. The ability to control an inflammatory state depends on the local balance between proinflammatory and anti-inflammatory factors. An insufficient response can be life threatening, but an excessive response may lead to pathological conditions. Differentiation of T-cells that express noninflammatory Th2 cytokines and inhibit the generation of self-reactive Th1 cells that produce inflammatory cytokines contributes to this immune modulation.

This chapter only covers the neuropeptides that have been shown to be clearly involved in the maintenance of immune tolerance and that regulate the autoimmune response. Autoreactivity, by definition, designates a specific immune response to self-antigens. Therefore, antigen-non-specific responses such as inflammation and innate immune processes should not be considered autoimmune in the strict sense, although they may accompany, enhance, or even trigger adaptive autoimmune responses. Thus, I will focus on the neuropeptides showing a prominent role in the regulation of the self-antigen-specific T- or B-cell immunity, which underlie the genuine autoimmune disorders.

ANTI-INFLAMMATORY NEUROPEPTIDES THAT REGULATE THE AUTOIMMUNE RESPONSE

With the exception of VIP and pituitary adenylate cyclase-activating polypeptide (PACAP), the sequence and structure of the neuropeptides, melanocyte-stimulating hormone (MSH), urocortin, adrenomedullin, cortistatin, ghrelin, and neuropeptide Y (NPY) are not related to each other, and their source and main actions in the body generally differ (see other chapters of this book). However, from an immunological point of view, they have some characteristics in common that make them attractive as potential regulators of immune tolerance: they are produced by immune cells, generally in response to inflammation, antigen stimulation, or injury; their receptors are expressed on various immune cells; besides their potent anti-inflammatory effects, they show diverse regulatory effects on T-cell–mediated responses (Table 2).

Recent studies examining these neuropeptides have shown their relevance to health, proving a crucial clinical significance in autoimmune diseases. Treatment with VIP, MSH, NPY, urocortin, adrenomedullin, cortistatin, or ghrelin decreases disease frequency/severity in various experimental models of rheumatoid arthritis, inflammatory bowel disease, type I diabetes mellitus, multiple sclerosis, Sjogren's syndrome, and uveoretinitis (Table 2).[4,8,15] The therapeutic effects of these neuropeptides are associated with the reduction of the two main phases of these diseases. They downregulate early events that are associated with the initiation and establishment of autoimmunity to self-tissue components and later phases that are associated with the evolving immune and destructive inflammatory responses (Fig. 1B). These neuropeptides impair the development of self-reactive Th1 and Th17 cells, their entry into the target organ, the release of inflammatory cytokines and chemokines, and the subsequent recruitment and activation of macrophages and neutrophils. This results in a decreased production of destructive inflammatory mediators (cytokines, nitric/oxygen radicals, and matrix metalloproteinases) by infiltrating and resident (i.e., microglia or synoviocytes) inflammatory cells.[8,15]

Various *in vitro* and *in vivo* studies indicate that some of these neuropeptides regulate the inflammatory response by directly acting on inflammatory cells. Thus, VIP, PACAP, MSH, urocortin, adrenomedullin, cortistatin, and ghrelin downregulate the production of a wide spectrum of inflammatory mediators, including inflammatory cytokines (i.e., TNFα, IL-12, IL-6, and IL-1β), various chemokines, PGE2 (by decreasing cycloxygenase 2), nitric oxide (by inhibiting the induced form of nitric oxide synthase), and the late inflammatory mediator high mobility group box-1 (Table 2, Fig. 1B) by macrophages, microglia, synovial cells, and DCs.[5,8,9,15–17,21,23] At the same time, they stimulate the production of anti-inflammatory cytokines such as IL-10 by macrophages, microglia, and DCs.

Although the mechanisms involved in the suppressive effects on Th1-cell responses of most of these neuropeptides are not fully elucidated, most results coming from VIP studies show that neuropeptides may regulate Th1/Th2 balance through various nonexcluding mechanisms with direct actions on differentiating T-cells and indirect regulation of functions of antigen-presenting cells (Table 2). Thus, they directly reduce the proliferation of activated Th1 cells, inhibit the production of the Th1-associated cytokine IL-12, inhibit the transcription factor T-bet, which is required for Th1 differentiation, and impair the recruitment of Th1 cells by inhibiting the secretion of CXC-chemokine ligand 10 by DCs and macrophages.[8,9] VIP also induces a sustained anergic state in human T-cells at multiple levels by inducing cell cycle arrest, inhibiting IL-2 secretion, and increasing the immunosuppressive molecule CTLA4.[2] Some evidence indicates that the induction of Th2 responses by VIP, PACAP, cortistatin, and ghrelin could contribute to the impairment of Th1-mediated responses. For example, VIP and PACAP induce CD86 expression in resting DCs, which is important for Th2 differentiation, promote specific Th2 recruitment by increasing CC-chemokine ligand 22, inhibit FasL- and granzyme B-mediated apoptosis of Th2 but not of Th1, and finally, induce the Th2 master transcription factors c-MAF, GATA-3, and JUNB in differentiating CD4 T-cells.[8,9]

Although the inhibitory effect of VIP, PACAP, urocortin, cortistatin, adrenomedullin, and ghrelin on Th17-cell response is evident *in vivo*, no results exist *in vitro* about the mechanisms involved in such effect and whether it is simply a consequence of an impaired recruitment of these cells to the target tissue and lymphoid organs resulting from the inhibitory effect exerted by these neuropeptides in the production of inflammatory chemokines by macrophages and inflammatory resident cells.

Another important issue that contributes to the amelioration of the destructive responses on the target tissue after the treatment of autoimmunity with these neuropeptides is the decrease in the levels of autoantibodies (especially IgG2a antibodies),[8,15–17] because this isotype of antibodies

is involved in the activation of complement and neutrophils. It is still unknown whether neuropeptides could affect B-cell responses directly, but some results with VIP and PACAP indicate that this action could be indirectly exerted through the inhibition of self-reactive Th1-cell responses.[8]

On the other hand, another interesting effect of some neuropeptides that could limit the perpetuation and/or dissemination of chronic inflammatory responses and the triggering of an autoimmune response is the recently discovered antimicrobial properties exerted by VIP, αMSH, ghrelin, and adrenomedullin against a wide variety of gram-positive and gram-negative bacteria, essentially present in the gastrointestinal tract.[5,12] This is especially important in autoimmune disorders of the bowel, such as Crohn's disease, where an imbalance between commensal and pathogenic bacteria seems to be related to the initiation of the autoimmune response. Based on their amphipathic design, amino acid composition and cationic charge, these neuropeptides form pores on the plasma membrane of the bacteria compromising its viability. VIP, PACAP, urocortin, and adrenomedullin have also shown significant antiparasitic actions against tropical protozoa[7] that are frequently related to the initiation of myocardial autoimmune disorders.

INDUCTION OF IMMUNE TOLERANCE BY GENERATING REGULATORY T-CELLS

Considerable evidence indicates that the generation of Treg plays a major role in the beneficial effect of αMSH, VIP, ghrelin, PACAP, urocortin, adrenomedullin, and cortistatin in several models of autoimmune diseases, including experimental autoimmune encephalomyelitis (EAE), experimental colitis, experimental uveoretinitis, and experimental arthritis.[15–19] These neuropeptides induce the peripheral expansion of new antigen-specific $CD4^+CD25^+FoxP3^+$ Treg that suppresses the activity of self-reactive T- and B-cells and tissue-localized inflammatory responses.[2] With the exception of αMSH, all of them promote the differentiation of $CD4^+CD25^+$ Treg from the $CD4^+CD25^-$ T-cell repertoire.[15–19] αMSH seems to expand the thymus-occurring natural Treg.[32] The suppression of self-reactive effector T-cells by neuropeptide-induced Treg involves direct cellular contacts dependent on CTLA-4 and/or the production of the immunosuppressive cytokines IL-10 and/or TGFβ. In addition, αMSH, VIP, and PACAP induce the differentiation of tolerogenic DCs (tolDCs) from bone marrow precursors or monocytes.[6,18,24] The tolDCs induced by these neuropeptides have the ability to generate antigen-specific Treg with suppressive actions on effector T-cells and to transfer antigen-specific tolerance *in vivo*. As far as I know, the effect of NPY on Treg has not been reported yet. Although results from human studies are scarce, recent results show that it is possible to induce alloantigen-specific human Treg with VIP-differentiated tolDCs[18] and to convert conventional human $CD4^+CD25^-$ lymphocytes into antigen-specific $CD4^+CD25^+FoxP3^+$ Treg in the presence of VIP.[2] Importantly, the VIP-converted human Tregs show a potent suppressive capacity on effector antigen-specific T-cells. More definitive are the results obtained in a recent phase I/II clinical trial performed in patients with sarcoidosis, a chronic inflammatory/Th1-driven disease, showing that inhalation of VIP for four weeks increased the number and activity of Treg in the lung of these patients, and at the same time, decreased the levels of inflammatory and Th1 cytokines and chemokines in the bronchoalveolar fluid.[27]

On the other hand, various reports have described in experimental models of autoimmunity the beneficial effects of Treg and tolDCs generated *ex vivo* with neuropeptides.[6,18,19] The therapeutic application of this strategy has been also extended to other immune disorders, such as allogeneic transplantation, in which the induction of tolerance against alloantigens is required,[18] and to neurodegenerative diseases, such as Parkinson's disease,[28] in which the neuroprotective effect of VIP-induced Treg is antigen specific, as occurs in autoimmune disorders.

REDUNDANT AND PLEIOTROPIC EFFECTS ON IMMUNE HOMEOSTASIS: A MATTER OF RECEPTOR SPECIFICITY AND SIGNALING

Now, the obvious question is, how do VIP, α-MSH, urocortin, NPY, adrenomedullin, ghrelin, and cortistatin regulate this plethora of inflammatory and immunomodulatory mediators? The answer could lie with the cAMP/PKA pathway that is the major intracellular signaling pathway involved in most of the effects exerted by all these neuropeptides, including the downregulation of inflammatory mediators.[17] cAMP-inducing agents have been described as potent anti-inflammatory factors, inhibitors of the Th1 response, and inducers of Treg function.[17] These neuropeptides, through the elevation of intracellular cAMP, downregulate the activation of several signal transduction pathways and transcription factors essential for the transcriptional activation of most of the inflammatory cytokines, chemokines, and costimulatory factors, including nuclear factor-κB (NFκB), mitogen-activated protein kinases (MAPK), interferon regulatory factor 1 (IRF1), and the activator protein 1 (AP1).[9,17,23] Moreover, they can also affect common upstream elements located very early in the signaling of these pathways, such as inhibition of the expression of Toll-like receptors (TLRs) and associated proteins (i.e., endotoxin-binding factor CD14), or of proximal intracellular signaling molecules of TLR4 such as IRAK-1 in macrophages.[17] A cAMP/PKA-dependent inhibition of NFκB, AP-1, NF-AT, and Akt pathways seems to be critically involved in the induction of T-cell anergy, the generation of Treg cells, and the induction of tolDCs by VIP.[2,15,18] Most

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

of these findings have been reported for VIP, PACAP, and αMSH. However, studies in other cell types show that urocortin, NPY, adrenomedullin, and ghrelin regulate a number of the described pathways, suggesting that they can also be involved in their immunosuppressive effects.[17]

That most of the modes of action of these neuropeptides in inflammation primarily depend on the activation of the cAMP/PKA pathway translates a relevant importance to the differential expression of the specific receptors for these neuropeptides in different immune cells, as well as their regulation by inflammatory and antigenic stimuli. The differential expression and signaling of these receptors in immune cells, the dimerization with other receptors, or the association with certain receptor-activity-modifying proteins (RAMPs) have also shed light on the existing controversy about the emergence of new antinflammatory neuropeptides, such as urocortin, adrenomedullin, and cortistatin, which show more potent, in some cases contrary actions on immune tolerance compared with their respective structurally related peptides, corticotropin-releasing hormone (CRH), calcitonin gene-related peptide (CGRP), and somatostatin.

For example, although the anti-inflammatory action of urocortin is well documented,[8,15–17] CRH regulates the immune and inflammatory responses in two antithetical ways, depending on the site of secretion (central vs. peripheral).[21] The different relevance of CRH and urocortin in the CNS and periphery might result from the differential expression of specific receptors for both neuropeptides in immune cells. CRH and urocortin bind to two receptors: CRH receptor type 1 (CRHR1) and CRHR2. In general, CRHR1 is expressed abundantly in the CNS with limited expression in peripheral tissues, whereas CRHR2 is more widespread in the periphery, including in most immune cells (Table 2). Urocortin binds to CRHR2 with much higher affinity than CRH. CRHR1 and CRHR2 signal through cAMP/PKA, but only CRHR1 stimulates the proinflammatory p38MAPK pathway, whereas only CRHR2 inhibits ERK signaling.[17] Indeed, specific CRHR2 agonists have shown a clear antinflammatory action *in vivo*.[17] Therefore, the fact that urocortin is produced by immune cells, and that CRHR2 is the predominant receptor in immune cells, indicates that urocortin can act peripherally in the immune system as an anti-inflammatory factor.

Another example of differential effects between two structurally related neuropeptides is the case of CGRP and adrenomedullin. CGRP has been traditionally considered a neuropeptide with a general anti-inflammatory effect, although others have described the contrary.[14] By contrast, adrenomedullin clearly acts as an anti-inflammatory and immunosuppressive factor.[15,17] Indeed, although CGRP fails to prevent sepsis, inflammatory bowel disease and arthritis and to downregulate the inflammatory and T-cell-mediated responses in these disorders, adrenomedullin shows striking therapeutic effects.[15,17] Interestingly, although CGRP induces inflammatory response by stimulating NFκB, adrenomedullin deactivates the NFκB and p38MAPK pathways in target cells.[17] The difference in responses induced by adrenomedullin and CGRP might reside in the differential binding of both neuropeptides to different binding complexes, which are formed by the calcitonin-related-like receptor (CRLR) and various RAMPs (RAMP1, RAMP2, and RAMP3). The RAMP subtype associated with CRLR determines the binding specificity for the ligand and the activity of the receptor: CGRP specifically binds to the CRLR–RAMP1 complex, whereas adrenomedullin preferentially binds to CRLR associated with RAMP2 and RAMP3 and coupled to the cAMP/PKA pathway. Macrophages specifically express the adrenomedullin-specific CRLR-RAMP2/3 complexes (personal communication). This partially explains the higher potency of adrenomedullin versus CGRP in the inflammatory response.

Finally, cortistatin shows a high homology with somatostatin and binds to all five somatostatin receptor subtypes (SST1–5), sharing many of the functional properties of somatostatin, including the suppression of neuronal activity and cell proliferation. However, cortistatin has many properties distinct from somatostatin in the nervous system (induction of slow-wave sleep and reduction of locomotor activity) and in the immune system. Although contradictory results exist about the production of somatostatin by immune cells, cortistatin expression by immune cells is well established,[15] suggesting that cortistatin might be a major endogenous immunoregulatory factor. Somatostatin and different SST agonists have emerged as attractive anti-inflammatory factors, in some cases with clinical validation. However, cortistatin downregulates inflammation more efficiently than somatostatin, and cortistatin, but not somatostatin, induces antigen-specific Treg.[8,15] This might reside in its capacity to activate different receptors and signal transduction pathways. Although somatostatin only binds to SST, cortistatin can also activate other receptors, including the ghrelin receptor (GHSR).[17] Ghrelin binding to GHRS and activation of the cAMP/PKA pathway are associated with antinflammatory and immunosuppressive actions.[15,17] Therefore, cortistatin might exert its immunoregulatory effect through both SST- and GHSR-mediated signaling pathways, one GHSR-mediated cAMP-dependent and one SST-mediated cAMP-independent.

A HEALTHY IMMUNE SYSTEM REQUIRES A PHYSIOLOGICALLY FUNCTIONAL NEUROPEPTIDE SYSTEM

In view of this plethora of actions mediated by these neuropeptides, an important issue is related to the physiological role played by endogenous neuropeptides in the maintenance of immune homeostasis. Previous evidence, obtained

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

primarily in animals deficient in one of these neuropeptides or their receptors, indicates that the absence of adrenomedullin, VIP, urocortin, or some of their receptors results in higher susceptibility to endotoxemia and airway inflammation.[8,15] Adaptive immune response is also affected, and mice deficient in the VIP receptor VPAC2 show exacerbated Th1-mediated responses *in vivo*, and conversely, animals overexpressing this receptor show eosinophilia, elevated IgE and IgG1 levels, and increased cutaneous anaphylaxis.[9] PACAP-deficient mice support these findings in an autoimmune scenario, because they show a higher incidence and severity with EAE, increased inflammatory/Th1-driven encephalitogenic responses, and decreased numbers of antigen-specific Treg than wild-type mice.[31] Interestingly, mice deficient for NPY-receptor Y1 reveal a bimodal effect of NPY on the immune system, in which signaling through Y1 in T-cells results in T-cell deactivation and through Y1 in DCs results in antigen-presenting cell activation.[34] These results could explain why NPY treatment shows a beneficial effect on EAE,[4] whereas paradoxically, Y1-KO mice are resistant to Th1-mediated inflammatory responses and colitis.[34] Similarly, VIP-KO mice show resistance to EAE, although they show an increased number of encephalitogenic T-cells[1] and improved survival after viral infections associated with a marked increase in MHCII and CD80, increased Th1/Tc1 cells, and fewer IL-10 producing T-cells.[22] Finally, ghrelin seems to play a major role on the function and evolution of the thymus, because mice deficient in ghrelin or its receptor have compromised the thymic stromal cell microenvironment, which plays a critical role in the education/selection of T-cells in the thymus (central tolerance and generation of natural Treg).[35]

Even more interesting is the biological relevance of the neuropeptides produced by one's own immune cells. Various studies reported the capacity of the VIP and ghrelin secreted by T-cells to decrease, in an autocrine and paracrine way, the production of inflammatory Th1 and Th17 cytokines by murine and human T-cells.[9,11,22] Similarly, NPY secreted by lymphocytes and antigen-presenting cells actively regulates T-cell activation.[34] Various studies with VIP suggest that similar conclusions can be made in human conditions. Monocytes, synovial cells, and T-cells isolated from patients with rheumatoid arthritis, osteoarthritis, and multiple sclerosis express lower VPAC1 levels and respond poorly to VIP.[10,26,30] The altered expression of VIP receptors is probably related to an aberrant autoreactive Th1-driven inflammatory response in these patients. Moreover, there is a genetic association between multiple-marker haplotypes of the VIP receptor VPAC1 and susceptibility to suffer rheumatoid arthritis and ankylosing spondylitis[10,26] and also a correlation between reduced VIP levels and high amounts of autoantibodies with VIPase activity in patients with autoimmune thyroiditis and systemic lupus erythematosus.[3]

CONCLUSIONS

Because there are no particular molecular signatures of self, autoimmunity is the inevitable evolutionary price of being able to make effective responses against a wide variety of pathogens by the immune system. Without the various phenomena referred to as immune tolerance, the organism would surely self-destruct. The findings discussed in this chapter indicate that various endogenous neuropeptides play a major role in the education of our immune system to be self-tolerant. That neuropeptides regulate, with apparent redundancy as cytokine-like factors, various layers involved in maintenance of tolerance, balancing proinflammatory and antinflammatory responses and decreasing self-reactive Th1/Th17 cells versus Treg/Th2 cells, makes them attractive candidates for the development of new therapies for the treatment of inflammatory and autoimmune disorders. Once the problems of instability inherent in their peptidic nature are solved (i.e., aminoacid substitutions, cycling structure, gene therapy, combination with endopeptidase inhibitors, biocompatible and degradable depots), interest by the pharmaceutical industry for neuropeptide-based therapies in immune disorders will be high because of their potency and minimal side effects. In addition, the possibility of manipulating Treg generation and/or expansion raises the possibility of a cell-based strategy to treat autoimmunity by providing long-term tolerance to self-antigens. This is tremendously attractive from a therapeutic point of view, because the translation of important biological findings about Treg to a clinic setting has been limited by the scarcity of circulating Treg. Beside their therapeutic potential, recent evidence suggests that neuropeptides and their receptors are intrinsic regulators of immune tolerance and that a defect in their signaling system affects the maintenance of immune homeostasis. Even if neuropeptides are not commonly used under normal circumstances, they could come into play when the immune system is trying to adapt to various types of challenges (e.g., autoimmunity), representing, together with other cytokines, the language of the stressed immune system.

ACKNOWLEDGMENTS

The authors thank the many researchers and laboratories that have contributed to our current understanding of the fundamental roles that neuropeptides play in immunology. This work was supported by grants from the Spanish Ministry of Health and Junta de Andalucia.

Chapter 88

Chemerin

Marc Parmentier

ABSTRACT

Chemerin is a 16 kDa polypeptide containing a cystatin-like fold and a disordered C-terminus required for bioactivity. It is secreted as an inactive precursor (prochemerin) requiring processing by various proteases to become a high affinity ligand for its main receptor ChemR23. Chemerin binds two other receptors, GPR1 and CCLR2, with high affinity, promoting only weak signaling through GPR1, and no signaling through CCRL2. Chemerin promotes chemotaxis of leukocyte populations expressing ChemR23, including monocytes, macrophages, myeloid and plasmacytoid dendritic cells (pDC), and NK cells. Bioactive chemerin is generated in inflammatory conditions, and ChemR23-positive cells are recruited to affected tissues in a number of inflammatory diseases in humans. In animal models, chemerin displays both pro- and anti-inflammatory properties. Chemerin is also an adipokine secreted by adipocytes, and its serum concentratons are correlated with body mass index (BMI) and other parameters of the metabolic syndrome. It regulates lipid and glucose metabolism in different tissues.

DISCOVERY

Tazarotene-induced gene 2 (Tig2) was first described as a gene induced by retinoic acid and synthetic analogs in keratinocytes.[23] The protein encoded by this gene was not recognized initially as a secreted factor and its function remained unknown. The Tig2 product was subsequently purified as a natural ligand stimulating the orphan G protein-coupled receptor (GPCR) ChemR23, starting from ascitic fluid secondary to ovary cancer.[30] The requirement for proteolytic processing of the protein was shown, and the processed ligand displayed chemotactic properties for leukocyte populations expressing ChemR23. The bioactive processed product of the Tig2 gene was therefore named chemerin. Chemerin displays weak similarity with a set of extracellular proteins sharing the so-called "cystatin" fold. These include the cysteine protease inhibitors cystatins type 2, the bactericidal peptide precursors cathelicidins, and kininogens. All these proteins share four conserved cysteines per cystatin domain, which form two disulfide bonds in the crystal structures that have been determined (e.g. chicken cystatin, 1CEW; human cystatin D, 1ROA; porcine protegrin 3, 1PFP). Chemerin contains two additional cysteines, suggesting the existence of an additional disulfide bond, and some variation from the classical cystatin fold. An NMR assignment of human chemerin was published, although the tridimensional structure of the protein was not reported.[2]

STRUCTURE OF THE mRNA/GENE

The gene encoding preprochemerin (RARRES2) is located on 7q36.1 in human and 6B2.3 in mouse. The human gene spans 3357 base pairs (2973 in mouse) from the transcriptional start site to the poly-adenylation site. It contains six exons and five introns, and the length of the mature transcript is 741 nucleotides (excluding the poly-A tail). Three of the introns split the coding region, while one exon is located in the 5′-untranslated region and another in the 3′-untranslated region. The location of the exons is similar to that found in other genes encoding proteins sharing with chemerin the cystatin fold. The position of the three introns splitting the open reading frame is conserved relative to codons (between codons for all three), and relative to the conserved cysteines involved in the disulfide bonds that stabilize the cystatin fold. The promoter of the mouse chemerin gene was shown to contain a DR-1-type PPAR response element between −61 and −49.[22] A binding site for the sterol regulatory element-binding protein 2 (SREBP2) transcription factor was also reported in the chemerin gene, potentially explaining the induction of chemerin expression by free fatty acids.[5]

PROCESSING OF THE PRECURSOR

The Tig2 gene product contains a signal peptide of 20 amino acids, which is cleaved during biosynthesis (Fig. 1). Chemerin is generated as a precursor, prochemerin (21-163), displaying very poor activity toward its receptors. To become an agonist of its main receptor, ChemR23, prochemerin requires precise proteolytic processing at its C-terminus. Several proteases activate or inactivate (pro)chemerin by cleaving at specific sites of the protein C-terminus (Fig. 2).

FIGURE 1 Alignment of preprochemerin amino acid sequences from a set of mammalian and non-mammalian species. A set of preprochemerin sequences was aligned. The signal peptides are displayed as italic lowercase letters. Cleavage sites were predicted on the SignalP 4.0 server (http://www.cbs.dtu.dk/services/SignalP/). For human preprochemerin, the cleavage site of the signal peptidase was confirmed by mass spectrometry analysis of bioactive chemerin purified from natural sources.[30] The cysteines stabilizing the core structure of chemerin, presumably adopting a cystatin-like fold, are indicated in bold. The nonapeptides characterized in human and mouse as displaying nanomolar potencies toward ChemR23 and GPR1 are indicated in bold and underlined. The sequence of human chemerin-9 and mouse C15, two peptides described in the text, are also indicated.

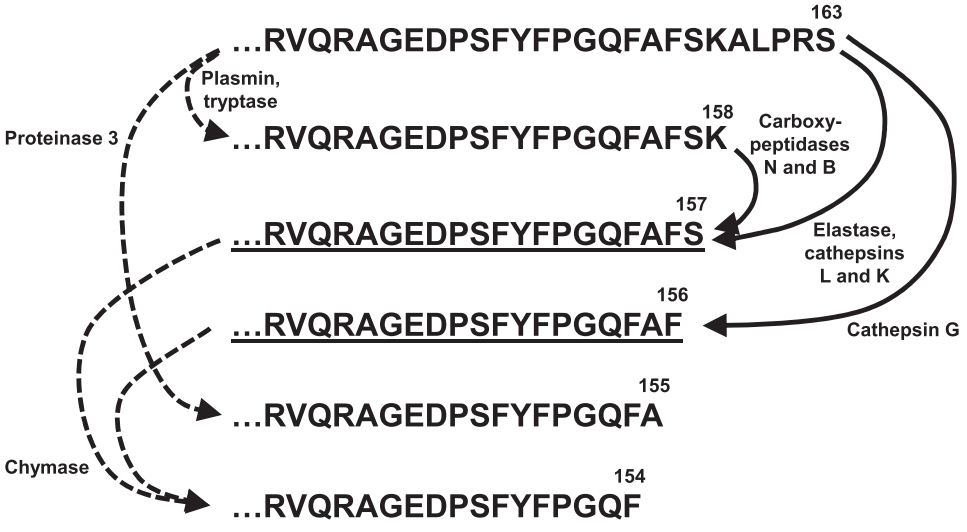

FIGURE 2 Multiple proteases regulate human (pro)chemerin bioactivity. The C-terminal sequence of known human chemerin variants is displayed, with numbering of the last amino acid relative to the full preprochemerin sequence (see Fig. 1). The two active forms are underlined. On the right, proteases generating bioactive forms of chemerin are indicated, while on the left, proteases resulting in inactive (or poorly active) forms of chemerin are displayed.

Two neutrophil serine proteases, elastase and cathepsin G, remove respectively the last 6 and 7 amino acids from prochemerin.[31] The two resulting forms of chemerin (21-157 and 21-156) are bioactive, although the longer form is slightly more potent, according to the pharmacological characterization of peptides derived from chemerin C-terminus. Serine proteases of the coagulation and fibrinolytic cascades, other cathepsins, and mast cell tryptase were also described as activators of prochemerin.[34] Plasmin and tryptase remove the last 5 amino acids (generating an inactive form), while carboxypeptidases N and B efficiently remove the resulting carboxy-terminal lysine, generating the active chemerin 20-157 form.[13] Cathepsins L and K generate the 20-157 form directly from prochemerin.[20] Urokinase and tissue plasminogen activator (TPA) as well as factor XIIa at high concentrations activate prochemerin, but the precise cleavage sites were not reported.[34] Staphopain B, a cysteine protease from *Staphylococcus aureus*, also activates plasma

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

prochemerin. Other proteases inactivate bioactive chemerin or compete for prochemerin with the activating proteases. Mast cell chymase targets chemerin 21-157 and chemerin 21-156 (but not prochemerin) and generates the inactive variant chemerin 21-154. Neutrophil proteinase three cleaves prochemerin (but not the bioactive chemerin forms), generating the inactive 21-155 form.[17]

Short peptides derived from chemerin C-terminus retain significant bioactivity *in vitro* (Fig. 1). A chemerin nonapeptide (Y^{149}FPGQFAFS^{157}, chemerin-9) displays an EC_{50} of 5 nM for ChemR23. This is at least 10-fold higher than that of full-size chemerin, which has an EC_{50} of 0.1 to 0.2 nM in the same assays. Y^{149}, F^{150}, G^{152}, F^{154}, F^{156} and the terminal carboxyl group were shown as essential moieties for the bioactivity of these peptides. These C-terminal peptides were used for generating binding tracers, such as ^{125}I-YHSFFPGQFAFS, but the stability of these peptides in plasma, cell cultures and *in vivo* is very short (half-life < 10 min[26]), as a result of proteolytic degradation. The requirement for C-terminal proteolytic processing is identical in human and mouse, and the C-terminal nonapeptide of mouse chemerin, although slightly different (L^{148}FPGQFAFS^{156}), displays properties similar to that of human chemerin-9.[21,26] A peptide analog was developed (D-Tyr^{147}-[D-Ser^{151}, D-Ala^{154}, Tic^{155}] mouse chemerin 148-156), displaying good potency (EC_{50}: 22 nM) and a considerable improvement of stability in biological media (half-life > 240 min in plasma).[26] Another peptide derived from the mouse chemerin C-terminus, C15 (A^{140}GEDPHGYFLPGQFA^{154}), was described to display anti-inflammatory properties *in vitro* and *in vivo* through ChemR23.[9,10] However, this peptide was later shown to be devoid of any biological activity toward ChemR23 (see below), using either binding or functional assays.[21,26]

DISTRIBUTION OF THE mRNA/PEPTIDE

Prochemerin is expressed by most tissues. The transcript is detected at high levels in liver, white adipose tissue and placenta, but is also present in skin, adrenal gland, all parts of the gut, pancreas, the airways, and the kidney. Epithelial cells, endothelial cells and fibroblasts were shown to express prochemerin. The precursor is present at relatively high concentrations in plasma. Immunoassays, measuring all (active and inactive) forms of chemerin in serum, have provided averages of 100–200 ng/ml in control subjects according to studies, corresponding to 6–12 nM. Concentrations of bioactive chemerin forms are more troublesome to measure, and rarely assayed. Liver and adipose tissue probably constitute the main contributors to serum (pro)chemerin, and it was suggested that modifications of these levels might arise mostly from production by adipocytes.[15,22] Prochemerin transcripts were also detected in platelets, and chemerin is stored in platelet granules and released after activation by thrombin, collagen or ADP, partially in an activated form.[13]

RECEPTORS AND SIGNALING CASCADES

Three GPCR have been described so far to bind chemerin with high affinity (K_D around 1 nM). The first of these receptors, ChemR23 (also known as CMKLR1), is expressed by a number of leukocyte populations, including monocytes, macrophages, immature myeloid (mDC) and plasmacytoid dendritic cells (pDC) and NK cells. ChemR23 expression is significantly higher in pDCs than in mDCs, and ChemR23 is one of the few functional receptors in pDCs.[28] Chemerin may therefore play an important and nonredundant role in the recruitment of pDCs, which are professional type I interferon producers involved in antiviral responses. Epidermal Langerhans cells do not express ChemR23. ChemR23 is down regulated during maturation of dendritic cells and after stimulation of macrophages by proinflammatory cytokines and TLR ligands, while TGF-β upregulates the receptor in macrophages.[30,28] ChemR23 expression was also described in adipocytes, endothelial cells, osteoclasts, and vascular smooth muscle cells [reviewed in Ref. 33].

ChemR23 was reported to bind another ligand, resolvin E1 (RvE1). RvE1 is an anti-inflammatory lipid mediator, derived from eicosapentaenoic acid, that promotes the resolution of inflammation. RvE1 was described as an agonist of ChemR23, using an assay based on the inhibition of TNF-induced NF-κB activation in HEK293 cells. Subsequent studies have failed to confirm the activity of RvE1 on ChemR23, using binding and diverse functional assays.[21] Besides, ChemR23 is not expressed by neutrophils, the main target of RvE1, while another receptor (BLT1, a leukotriene B4 receptor), was later shown to respond to RvE1[3] and is present in neutrophils. Furthermore, blockade of neutrophil recruitment by RvE1 in a model of zymosan-induced peritonitis was abrogated in BLT1 knockout mice,[3] suggesting that BLT1 is indeed the sole relevant receptor of RvE1.

ChemR23 is coupled to the G_i family of G proteins. In cells expressing this receptor, chemerin inhibits accumulation of cAMP, promotes phospholipase C activation, IP_3 release and calcium mobilization, and activates the PI3K and MAPK pathways, with EC_{50} values in the low or subnanomolar range.[30] All these activities are blocked by Pertussis toxin.

GPR1 was described as a second receptor for chemerin, using a β-arrestin recruitment screening assay (Tango).[4] GPR1, which is structurally related to ChemR23, binds chemerin with high affinity, but signaling is inefficient. Chemerin promotes relatively modest mobilization of Ca^{2+} and MAPK activation in cell lines expressing the receptor, and no signaling mediated by GPR1 has so far been

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

described in primary cells. GPR1 is not present in leukocytes, but expressed in the central nervous system, adipose tissue, skeletal muscle and skin. As a receptor poorly signaling through classical intracellular pathways, but able to bind chemerin with high affinity and internalize as a result of this binding, GPR1 might be considered as a decoy receptor or chemerin scavenger. However, the demonstration of such role has not yet been demonstrated.

A third receptor, chemokine (C-C motif) receptor-like 2 (CCRL2, also called CKRX, HCR or CRAM in human, and L-CCR in mice), was described to bind chemerin with a K_D of about 1 nM.[35] CCRL2 is an atypical receptor belonging to the chemokine receptor family, with an unusually high variability across species (51% identity between human and mouse). Chemerin does not seem to promote any signaling pathway through CCRL2, nor internalization of the ligand-receptor complex. It was therefore suggested that CCRL2 might increase local concentrations of chemerin and present the protein to other nearby cells displaying ChemR23 on their surface.[35] CCRL2 is expressed by human monocytes, macrophages, DCs, neutrophils, T cells, NK cells, mast cells and $CD34^+$ bone marrow precursors.[33] The receptor is generally upregulated upon activation of these cells, by LPS or TNF-α.

BIOLOGICAL ACTIONS

Chemerin was first described as a chemoattractant agent, promoting chemotaxis of leukocyte populations that express ChemR23. Macrophages, immature mDCs and pDCs, and NK cells from human and mouse respond to chemerin in chemotaxis assays ex vivo, including in transmigration assays across endothelial monolayers.[30,28,25,21] These cells are also responsive to chemerin in other functional assays, such as calcium mobilization or MAP kinase activation. Maturation of mDCs and pDCs abrogates their functional response to chemerin, which is partially explained by the down regulation of ChemR23 in these cells.[28] Chemerin stimulates adhesion of macrophages to VCAM-1 and fibronectin, through a pathway involving G_i proteins, PI3K, Akt, and p38, and the clustering of the VLA-4 and VLA-5 integrins at the cell surface.[18] Despite its cystatin-like structure, chemerin does not seem to inhibit cysteine proteases.[20] *In vivo*, chemerin was reported to display both pro- and anti-inflammatory actions (see below), depending on the animal model studied. ChemR23 expression in endothelial cells was reported to be upregulated by inflammatory cytokines (TNF-α and IL-6), and chemerin was described to promote angiogenesis.[19]

Chemerin was more recently described as an adipokine regulating adipogenesis and adipocyte metabolism.[15] As stated above, both the protein and its main receptor, ChemR23, are expressed by adipocytes, and upregulated during differentiation from bone marrow mesenchymal stem cells (BMSC) or 3T3-L1 cells. The chemerin/ChemR23 autocrine/paracrine stimulatory loop plays an important role during the early clonal expansion phase of BMSC differentiation into adipocyte precursors, as knock down of chemerin or ChemR23, as well as blocking antibodies, inhibit differentiation of adipocytes in culture. Chemerin upregulation during adipocyte differentiation from BMSCs is correlated to that of the PPARγ transcription factor, the master regulator of adipogenesis.[22] Chemerin synthesis and secretion is increased by TNF-α in 3T3-L1 cells, primary human adipocytes, and mouse fat tissue *in vivo*.[24] Chemerin expression is also promoted by IL-1β in 3T3-L1 cells and brown fat adipocytes, through a pathway involving NFκB and ERK1/2, and free fatty acids were reported to upregulate chemerin expression in adipocytes, through the transcription factor SREBP2.[5]

In mature adipocytes, chemerin regulates key effectors of the glucose and lipid metabolism, including the glucose transporter GLUT4, diacylglycerol acyltransferase (DGAT2), an enzyme involved in triglyceride synthesis, and the adipokines leptin and adiponectin.[15] Chemerin was reported to both promote and inhibit basal or isoproterenol-evoked lipolysis in 3T3-L1 adipocytes or primary cultures of mouse white adipocytes.[15,26] Similarly, the effect of chemerin on glucose metabolism is a matter of debate. On 3T3-L1 adipocytes, a moderate increase of insulin-promoted glucose uptake and IRS-1 phosphorylation was reported after a short stimulation by low concentrations (nM) of chemerin, while longer stimulation by higher chemerin concentrations (μM) decreased insulin-promoted glucose uptake in the same cells.[15] Inhibition of glucose uptake by chemerin was also reported in primary muscle cells, and a moderate increase in glucose intolerance was observed after chemerin treatment in *ob/ob* and *db/db* mice, as a result of decreased glucose uptake in adipose tissue, liver and skeletal muscle.[14,15] Further studies will therefore be required to clarify the discrepancies regarding the effects of chemerin on lipid and glucose metabolism.

ChemR23 is also expressed in endothelial cells and upregulated following stimulation by proinflammatory cytokines, including TNF-α, IL-1β and Il-6.[19] Chemerin promotes proliferation of endothelial cells and the release of metalloproteases (MMP-2 and MMP-9), suggesting a contribution of the chemerin/ChemR23 system in angiogenesis. In fibroblast/endothelial cell cocultures, chemerin promotes the formation of endothelial tubules in a MAPK-dependent manner.[8]

PATHOPHYSIOLOGICAL IMPLICATIONS

As stated above, chemerin is generated as an inactive precursor requiring activation by proteolysis. Prochemerin-processing enzymes are activated during inflammation

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

(neutrophil proteases), coagulation, fibrinolysis, and cancer. High levels of bioactive chemerin were therefore found in inflammatory conditions, and ChemR23-expressing cells are recruited in a number of chronic inflammatory diseases.

The presence of chemerin was reported by immunohistochemistry in the endothelium of dermal blood vessels in lupus erythematous skin lesions, and in high endothelial venules of secondary lymphoid organs, suggesting that it is involved in the recruitment of leukocyte populations, particularly pDCs in this disease.[28] Infiltration by ChemR23-expressing pDCs was further reported in the kidney of patients with severe lupus nephritis.[12] Chemerin was found in epithelial cells from proximal tubules and lymphatic endothelium from lupus-affected kidneys, but not in normal kidneys.

The presence of chemerin was also shown in fibroblasts, mast cells and endothelial cells in prepsoriatic skin adjacent to active lesions, and early psoriatic lesions, which are strongly infiltrated by neutrophils and pDCs.[1] Low chemerin expression and low pDC infiltration occurs in chronic plaques. Cultured fibroblasts from psoriatic skin lesions release bioactive chemerin, and elevated serum chemerin concentrations occur in psoriatic patients. These observations support the involvement of the chemerin/ChemR23 system in the early phases of psoriasis development, which are characterized by pDC recruitment and the production of type I interferons. In oral lichen planus, expression of chemerin in dermal endothelium is associated with the co-recruitment of pDCs and NK cells, suggesting that chemerin might promote the important cross-talk between these two cell populations in inflammatory diseases.[25]

Chemerin was described to inhibit the production of inflammatory cytokines by mouse peritoneal macrophages after stimulation by LPS and IFN-γ. Similar inhibition of macrophage activation (but inefficient chemotaxis) was observed with the mouse C15 peptide.[9] C15 was also described to display anti-inflammatory activities at surprisingly low doses in a zymosan-induced peritonitis model in mice, preventing the recruitment of neutrophils and monocytes and the expression of proinflammatory cytokines.[9] The absence of effects of C15 in ChemR23$^{-/-}$ mice suggested a specific activity through this receptor. The same group reported that C15, but not full-size chemerin, could enhance phagocytosis of microbial particles and apoptotic cells by ChemR23$^{+/+}$ (but not ChemR23$^{-/-}$) macrophages.[10] C15 was however shown to be devoid of biological activities toward recombinant ChemR23-expressing cells (using functional and binding assays) and native leukocyte populations expressing the receptor in the hands of other groups, up to μM concentrations,[21,26] casting doubt on the biological activities attributed to this peptide. Although the anti-inflammatory role assigned to chemerin on the basis of these experiments seem to fit with some later studies *in vivo* (see below), the observations made with C15 need to be clarified.

In a model of acute lung injury promoted by lipopolysaccharide instillation into the airways, chemerin displays anti-inflammatory properties in a ChemR23-dependent manner. Co-administration of chemerin with LPS reduces the number of neutrophils recruited to the lung, as well as the production of chemokines (CXCL1) and cytokines (TNF-α, IL-1β, IL-6). Chemerin has no effect in ChemR23 KO mice, and the number of recruited neutrophils is higher than in wildtype mice, suggesting that endogenous production of chemerin dampens the inflammatory response in ChemR23$^{+/+}$ mice.[21] ChemR23$^{-/-}$ mice were also tested in a mouse model of viral pneumonia.[6] Pneumonia virus of mice (PVM) is considered as the mouse counterpart of the human respiratory syncytial virus (RSV), which is a major cause of acute bronchiolitis in infants and young children. ChemR23$^{-/-}$ mice displayed a higher mortality, a severe impairment of lung function, and increased neutrophilic infiltration in the lung. Lower recruitment of pDCs, reduction in type I interferon production and delayed viral clearance were observed in these mice, showing that the chemerin/ChemR23 system is involved in the recruitment of pDCs *in vivo*. Adoptive transfer of ChemR23$^{+/+}$ pDCs restored the type I interferon response, but increased further the morbidity and mortality. Similar observations were made in chimeric mice expressing ChemR23 in bone marrow-derived cells. These observations suggest therefore an anti-inflammatory role of the chemerin/ChemR23 system, which is independent from marrow-derived leukocyte populations. Although the cells and precise mechanisms involved in this process are still unknown, chemerin and its receptor appear to play important roles in the physiopathology of viral pneumonia, and might be considered as a therapeutic target for anti-inflammatory strategies in this frame.

By contrast, chemerin and ChemR23 contribute to the pathogenesis of experimental autoimmune encephalomyelitis (EAE), a model for multiple sclerosis induced by immunization with the myelin oligodendrocyte glycoprotein (MOG). ChemR23 expression is found in microglial cells and infiltrating myeloid DCs, and chemerin upregulation is observed in mice with EAE. ChemR23$^{-/-}$ mice are partially protected, displaying lower leukocytic infiltration of the brain and less clinical signs.[16] Adoptive transfer of MOG-reactive lymphocytes between ChemR23$^{+/+}$ and ChemR23$^{-/-}$ mice show that ChemR23 is involved both in the induction and effector phases of the disease.

The chemerin/ChemR23 system was also studied in a model of chronic obstructive pulmonary disease (COPD) secondary to cigarette smoke exposure.[11] Acute and chronic exposure of mouse airways to cigarette smoke increase the levels of chemerin in the bronchoalveolar lavage (BAL) fluid, while chemerin and ChemR23 transcripts are down regulated in the lung of these mice. In ChemR23$^{-/-}$ mice, proinflammatory chemokine levels in BAL, and recruitment of neutrophils,

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

DCs and CD4+ T cells to the lung are decreased after exposure to cigarette smoke. These observations suggest that the chemerin/ChemR23 system contributes significantly to the recruitment of innate and adaptive immune cells to cigarette smoke-exposed lungs and plays a proinflammatory role in this context.

Obesity is frequently associated with a chronic systemic inflammatory state. As adipocytes enlarge, they start to secrete a number of cytokines (TNF-α, IL-6) that are found elevated in the bloodstream, while the adipose tissue becomes infiltrated by various leukocyte populations, particularly macrophages, but also T cells, NK cells and immature mDCs and pDCs. Macrophages also contribute to the production of proinflammatory cytokines that in turn interfere with insulin signaling and promote insulin resistance. Chemerin, as an adipokine able to promote chemotaxis of most leukocyte populations found in adipose tissue from obese individuals, might therefore constitute a link between obesity and inflammation, although this role is not yet formally established. Proteases known to activate prochemerin have been described in adipose tissue,[15] but it is not known presently which forms of chemerin predominate in fat tissue, and whether these forms evolve with the development of obesity.

Chemerin concentrations in human serum are elevated in obese and type 2 diabetic patients, and in a number of studies correlate positively with body mass index (BMI), fasting glucose, fasting insulin, triglycerides, and total cholesterol, and negatively with HDL cholesterol.[15] Serum chemerin concentrations also correlate with levels of TNF-α, IL-6, and C-reactive protein (CRP), it was suggested that they may reflect more the inflammatory status associated with obesity than obesity itself.[29] Serum chemerin does not correlate with the extent of atherosclerosis lesions, but local production of chemerin was suggested to play a role by promoting the recruitment of macrophages to atherosclerotic plaques.[27] Circulating chemerin levels are also increased in nonalcoholic fatty liver disease.[32] In animal models, obesity and diabetes are associated with increased chemerin concentrations in serum.[14] High chemerin levels are found in genetically obese *ob/ob* and *db/db* mice, which are characterized by high TNFα production in adipose tissue,[15,24] and chemerin is also overexpressed in adipose tissue of obese *Psammomys obesus*.[7]

Chapter 89

Chemokines

Sunny C. Yung and Joshua M. Farber

ABSTRACT

Chemokines belong to a family of phylogenetically related, small inducible proteins that recruit leukocytes to sites of inflammation and infection. Their name is derived from *chemo*tactic cyto*kines*. In addition to promoting host defense and mediating inflammation, some chemokines can affect tissue repair and organ development, and many can be shown to have antimicrobial properties.

ORGANIZATION OF CHEMOKINES

Chemokines belong to the largest subgroup of cytokines, with approximately 45 present in humans. Chemokine genes are found in vertebrates from teleost fish to humans. Chemokines are classified according to the number and arrangement of conserved cysteine residues. All but two chemokines contain four conserved cysteine residues, and disulfide bonds link C1–C3 and C2–C4[20] (Figure 1). In the four-cysteine group, the first two are adjacent (CC motif, $n=24$), or separated by one amino acid (CXC motif, $n=16$), or by three amino acids (CX3C motif, $n=1$). The XC chemokines ($n=2$) have only two cysteines, without the paired arrangement close to the N-terminus. Sequence identity is <30% between members of different classes, but within the same class, sequence identity ranges from approximately 30% to 99% within species. Most chemokines are cationic with basic isoelectric points and approximately 7–12 kDa in molecular weight.

The CXC chemokines can be divided into ELR positive and ELR negative. ELR denotes glutamatic acid–leucine–arginine amino acids that are N-terminal to C1 in these CXC chemokines. They have >40% amino acid sequence identity, are the principal chemokines for recruiting neutrophils, are angiogenic, and share a receptor, CXCR2.

STRUCTURE OF CHEMOKINES

Tertiary structures of chemokines are similar because of the conserved disulfide bonds. Structural analysis of chemokines reveals a flexible N-terminal region, an N-terminal loop, three antiparallel beta sheets, and a C-terminal alpha helix (Figure 1). Chemokines are believed to interact with their receptors through two domains.[19] The N-region loop of chemokines interacts with the receptor N-domain residues (receptor Site-I), and the N-terminal flexible region of the chemokine associates with the extracellular loops and/or transmembrane residues of the receptor (receptor Site-II).

Although homodimers and aggregation of chemokines are often observed in structural studies, functional analysis of chemokines by *in vitro* assays (calcium flux, chemotaxis, internalization of receptor) shows that at least some chemokines can function as monomers to activate their receptors.[5] Nonetheless, it has been reported that oligomerization is required for binding glycosaminoglycans (GAGs), which is in turn required for recruiting leukocytes *in vivo*. GAGs such as heparan sulfate are highly expressed on cell surfaces and extracellular matrix, and by binding to GAGs, chemokines can form high local concentrations. Site-directed mutagenesis in CCL2, CCL3, and CCL5 showed that mutants incapable of binding GAGs or incapable of forming oligomers could not recruit leukocytes into the peritoneum of mice.[2]

CHEMOKINE RECEPTORS

Chemokines signal by activating seven-transmembrane-domain receptors, and the responses of leukocytes to particular chemokines is determined by their repertoire of chemokine receptors. The chemokine system shows bidirectional promiscuity: Some chemokines can activate more than one chemokine receptor, and many chemokine receptors can be activated by more than one chemokine. In general, however, a receptor binds chemokines within only a single class. Chemokine receptors are denoted by the motif of their ligands (e.g., CXC, CC) + R (for receptor) + a number in approximate order of discovery.[20] One consequence of receptor activation is a change in integrin conformation that leads to the arrest of leukocytes on endothelium and subsequent transendothelial migration. In addition, in the presence of a concentration gradient of chemokine in tissue, signals are produced that lead to cell polarization and directional migration up the gradient of

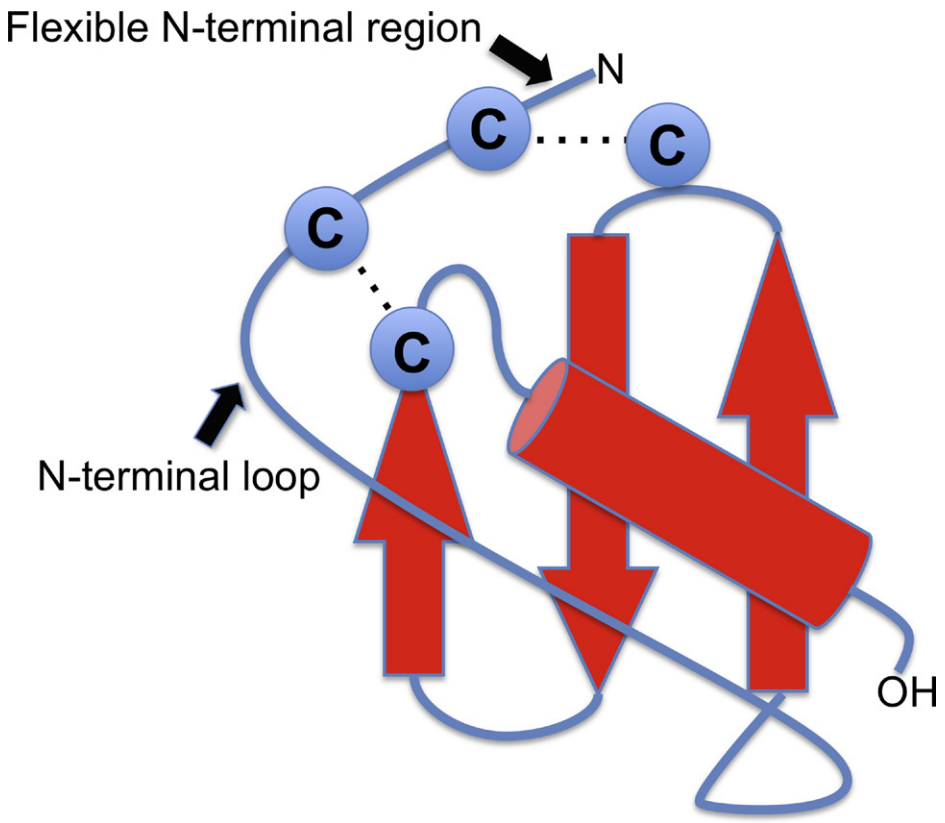

FIGURE 1 Tertiary structure of chemokines. For chemokines with four conserved cysteines, intramolecular disulfide bonds connect cysteines one and three and two and four. The first two cysteines are either adjacent (in CC chemokines) or separated by one residue (in CXC chemokines). The disulfide bonds (dotted lines), flexible N-terminal region, and the N-loop are important for receptor binding and activation. The amphipathic alpha helix (cylinder) is probably important for structural stability and antimicrobial properties. The large arrows represent antiparallel beta sheets. Adapted from Kohidai L. http://en-wikipedia.org/wiki/File:ChtxCheminStr2.png

chemoattractant. In neutrophils, chemokines can also induce the exocytosis of granules.

BIOLOGY OF CHEMOKINES

The principal biological function of the chemokine system is to coordinate the homing and trafficking of hematopoietic cells under homeostatic and inflammatory conditions. However, some chemokines can also regulate the migration of nonhematopoietc cells, affecting organ development and angiogenesis, and chemokines may have activities beyond the control of cell movement. In addition, several chemokines have antimicrobial properties that affect viruses, bacteria, and fungi.

In one commonly used scheme, chemokines are denoted as either homeostatic or inflammatory depending on whether they are constitutively expressed or induced during inflammation—although the distinctions are not absolute.[27] Homeostatic chemokines are important in hematopoiesis and immune surveillance, and, based on experiments in mice, include CXCL12, CXCL13, CCL2, CCL7, CCL19, CCL21, and CCL25. CXCL12 is made constitutively in the bone marrow by stromal cells and is important in myelopoiesis and B cell development. Mice genetically deficient in CXCL12 die close to birth with abnormalities in the cardiac ventricular septum and major vessels to the gastrointestinal tract, as well as in the architecture of the cerebellum. The CCR2 ligands, CCL2 and CCL7, which have prominent roles in recruiting cells to inflammatory sites, are also important for monocyte homeostasis by controlling the movement of monocytes from bone marrow to blood. The CXCR5 ligand, CXCL13, and the CCR7 ligands, CCL19 and CCL21, are important for immune system homeostasis by helping to establish the B and T cell compartments, respectively, within secondary lymphoid organs. CCL25, the ligand for CCR9, is unusual in serving a homeostatic role in a specific peripheral tissue, namely in recruiting cells to the small bowel.

Although CXCL12 is the only chemokine that has a role in vasculogenesis during development, several chemokines also have activity in assays of angiogenesis, such as the rat corneal micropocket assay. ELR$^+$ CXC chemokines (CXCL1, CXCL2, CXCL3, CXCL5, CXCL6, CXCL7, CXCL8) have scored as proangiogenic, whereas

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

ELR⁻ CXC chemokines (CXCL4, CXCL4L1, CXCL9, CXCL10, CXCL11, CXCL14) have angiostatic activities. Blockage of CXCR2, a receptor for all the ELR⁺ CXC chemokines, results in the inhibition of angiogenesis and impaired wound healing. CC chemokines such as CCL2, CCL11, and CCL16 may also participate in angiogenesis.[14]

Effects on angiogenesis is one of the mechanisms proposed for the activities of the chemokine system in cancer, although there are many other ways in which chemokines could influence malignancies. The most extensive result for chemokine receptors in cancer is, again, for CXCR4, which is expressed in >23 human cancers and has been implicated in enhancing tumor cell survival and/or growth and/or metastasis. In general, the expression levels of CXCR4 on cancer cells are correlated with resistance to therapy and poor prognosis. Other chemokine receptors expressed on cancers of hematopoietic and nonhematopoietic origin, such as CCR6 and CCR7, are also believed to influence patterns of metastasis. Given the roles for leukocytes in tumor stroma as both: (1) promoters of cancer in the context of chronic inflammation, and (2) agents of immunologically mediated antitumor activity, the chemokine system is certain to play a broad role in cancer biology.[22]

The majority of chemokines are inducible under inflammatory conditions, often in response to pleiotropic cytokines. These chemokines are involved in host defense (both innate and adaptive immunity), and in acute and chronic inflammation.

CHEMOKINES IN HOST DEFENSE

Host defense against pathogens can be divided into innate and adaptive immune responses. Chemokines are involved in the development and recruitment of immune cells in both systems.

Innate Immunity

Neutrophil Activation and Trafficking

The ELR⁺ CXC chemokines attract and activate neutrophils. There are seven members in this family (CXCL1, 2, 3, 5, 6, 7, and 8). Separate chemokine domains were found to be critical for different aspects of neutrophil activation. Such observations probably stem from roles for these domains in the activation of different chemokine receptors. For example, CXCL8, in contrast to other ELR⁺ CXC chemokines, can bind and activate both CXCR1 and CXCR2 (although affinities for the two receptors differ). Mutational analysis of CXCL8 shows that the ELR domain is critical for neutrophil degranulation (an effect mediated by CXCR1) but not neutrophil chemotaxis (an effect mediated by CXCR2). The C-terminal domain probably also participates in receptor binding, because C-terminal truncation of CXCL8 decreases receptor affinity. Interestingly, a sequence that includes the GP dipeptide and is found just N-terminal to the third conserved cysteine in most ELR+ positive chemokines is active as a chemoattractant and resembles a proteolytic fragment of collagen, PGP, that is able to recruit neutrophils via both CXCR1 and CXCR2.[28]

Monocyte and Macrophage Activation

Historically, CC chemokines were first identified as having chemotactic activity for monocytes and macrophages. Monocyte chemoattractantants (CCL2, CCL7, CCL8, and CCL13) recruit monocytes to sites of trauma, infection, toxin exposure, and ischemia.

Within the blood, there exist subpopulations of monocytes expressing different chemokine receptor profiles. Classical or "inflammatory" monocytes ($CD14^{high}CD16^{-}$ cells) preferentially express CCR2, whereas "resident'' monocytes ($CD14^{low}CD16^{+}$ cells) preferentially express CX3CR1.[11] CCR2 is activated by CCL2, CCL7, and CCL13, and these chemokines recruit inflammatory monocytes to the sites of inflammation. By contrast, the resident-monocyte subset is thought to replace tissue-resident macrophage and dendritic cell populations. The only ligand for CX3CR1 is CX3CL1, an unusual chemokine that is membrane bound and contains a mucin-like stalk.

One "nonimmunologic" process that depends on cells of the innate immune system is wound healing, which involves inflammation, cell proliferation, and tissue remodeling. These steps require the coordinated movement and activities of neutrophils, monocytes, and macrophages. As such, chemokines have an important role in tissue repair. CXCL1 and CXCL8 along with their receptor, CXCR2, are expressed in the human epidermis during inflammation. These chemokines as well as CCL2 and CX3CL1 are involved in leukocyte recruitment and neovascularization during wound repair.[22]

Adaptive Immunity

T cells

Chemokine receptors CCR9, CCR7, and CXCR4 are important in the development of α/β T cells in the thymus. T cells begin as $CD4^{-}CD8^{-}$ and go through a $CD4^{+}CD8^{+}$ stage before becoming mature $CD4^{+}CD8^{-}$ or $CD4^{-}CD8^{+}$ cells. During the double-negative stage, T cells undergo rearrangement of the TCRβ gene and formation of the pre-T cell receptor (TCR), a developmental checkpoint known as β-selection. CXCR4 serves to localize T cell precursors within the thymus during this process and serves as an essential costimulator of pre-TCR signals.[26] CCR9 is a receptor expressed on late double-negative and on

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

double-positive T cells. However, as double-positive T cells transition to mature single-positive T cells, CCR9 is downregulated. This regulated expression of CCR9 may be critical for T cell development, because forced transgenic expression of CCR9 resulted in fewer double-positive and single-positive cells. CCL19 and CCL21 are highly expressed in the medulla of the thymus,[30] and their receptor, CCR7, is important for the inward migration of T cells from the cortex to medulla, which occurs during maturation and before the single-positive cells leave the thymus.

Naive T cells migrate through the T cell zones of secondary lymphoid organs, and as discussed above, localization in T cell areas requires CCL19/CCL21/CCR7. After the activation of a naive helper ($CD4^+$) T cell, some progeny migrate to B cell follicles (so-called T_{FH}, or follicular helper cells), which depends on CXCL13 and its receptor CXCR5. Other activated T cells will traffic to peripheral sites. For activated $CD4^+$ T cells, some will differentiate into "lineages" of effector/memory cells defined by patterns of cytokine production—Th1, Th2, and Th17 cells. Each of these subpopulations is associated with certain chemokine responses and chemokine receptors.

Th1 cells, whose signature cytokine is IFN-γ, all express CXCR3. Not all $CXCR3^+$ $CD4^+$ T cells are Th1 cells, however, so that the Th1 population is a subset of the $CXCR3^+$ cells. Analogous relationships pertain for the other lineages. Th2 cells, whose signature cytokine is IL-4, form a subset within the $CCR4^+$ cells, and Th17 cells, whose signature cytokine is IL-17, form a subset within the $CCR6^+$ cells. Of additional interest, the chemokine ligands for these receptors are inducible by the subsets' signature cytokines. CXCL9, CXCL10, and CXCL11, the ligands for CXCR3, are inducible by IFN-γ; CCL17 and CCL22, the ligands for CCR4, are inducible by IL-4; and CCL20, the ligand for CCR6, is inducible by IL-17. These relationships suggest that the chemokine/receptor groups can serve as components of positive feedback loops to establish Th1 or Th2 or Th17 cell accumulations that yield type-specific inflammatory environments.[15,24,25]

B Cells

CXCL12 (ligand for CXCR4) is important for B cell development in the bone marrow. Mice deficient in CXCL12 are defective in B lymphopoiesis in the fetal liver and bone marrow.[21] Naive B cells express high levels of CXCR4 and are attracted to secondary lymphoid organs via CXCL12 (and CCR7 ligands). CXCL13 is crucial for defining B cell follicles, and both B cells and T_{FH} are recruited to the follicles by signaling through CXCR5. In the germinal centers, CXCL12/CXCR4 is again important for the localization of centroblasts to the dark zones, where these antigen-activated B cells are undergoing proliferation and somatic hypermutation important for generating high-affinity antibodies. Finally, CXCL12/CXCR4 is important for the localization of plasma cells to the bone marrow.[1]

CHEMOKINES IN INFLAMMATORY DISEASES

Many diseases, such as rheumatoid arthritis, atherosclerosis, diabetes, chronic obstructive pulmonary diseases, asthma, psoriasis, and multiple sclerosis have major inflammatory components, and, not surprisingly, the chemokine system is involved in each.[4,27] Some of the chemokine activity is through the recruitment of cells of innate immunity. For example, macrophage-rich plaques in atherosclerosis exhibit high expression of CCL2 and deletion of CCL2 decreased diet-induced atherosclerosis in mice. Further, higher transcription of CCL2 resulting from a mutation in the promoter is associated with an increased risk for coronary artery disease. Chemokines are also involved in the autoimmune component of these diseases, because effector/memory T cells, such as the $CD4^+$ T cell subsets discussed above, can express as many as 15 different chemokine receptors in combinatorial fashion to mediate trafficking toward inflammatory chemokines.

CHEMOKINES AS ANTIMICROBIAL PEPTIDES

Certain chemokines have intrinsic antimicrobial properties *in vitro* (Table 1). At micromolar concentrations, and at low salt concentrations, these chemokines can inhibit bacterial and fungal growth. The mechanism is believed to involve the cationic chemokine binding to the negatively charged membrane of the pathogen to disrupt membrane integrity, and electron microscopy shows membrane damage after chemokine exposure. However, as the salt concentration is increased, the antimicrobial effect of chemokines is greatly diminished or disappears. In some respects, chemokines resemble β-defensins, a group of host antimicrobial peptides that are active at mucosal surfaces. Both are cationic peptides with intrachain disulfide bonds and amphipathic regions, and both have antimicrobial and immunomodulatory activities.[29] α- and β-Defensins have been reported to attract leukocytes by acting on chemokine receptors.[23]

In addition to the reports of antimicrobial properties *in vitro*, there is also some recent evidence that these antimicrobial effects can be important in host defense *in vivo*. For example, the related, IFN-γ-inducible chemokines CXCL9, 10, and 11 protect mice against pulmonary infection with *B. anthracis* through a receptor-independent mechanism.[8]

Chemokines have also been reported to block viral infection. The most celebrated example is in the inhibition of cell entry by HIV-1. The experiments identifying the chemokines CCL3, CCL4, and CCL5 as agents able to inhibit

Gram-positive organisms (methicillin-resistant ***S. aureus*** (MRSA), ***Staphylococcus coagulase*** negative species***, S. pyogenes, E. faecium, B. subtilis, L. monocytogenes***) are arranged on the left side, followed by Gram-negative organisms (***E. coli***, ***P. aeruginosa***) and fungi (***C. neofomans***, ***C. glabrata***, ***C. albicans***). Only for assays with MRSA and ***E. coli*** do the following symbols of inhibition apply: ++++, >80%; +++, 60–79%; ++, 40–59%; +, 20–39%; –, <20%. For all other organisms "+, –/+, and –" denote >50%, 20–50%, and <20% antimicrobial activity, respectively. The "–, +" and "++, ++++" symbols represent discrepancies in antimicrobial properties from the literature. Most antimicrobial assays were performed at low salt concentration (10 mM). The CXCL7 cleaved peptide "(cleaved)" with antimicrobial properties was purified from platelet granules and is a C-terminal processed form. The pI of each chemokine is also shown.

Copyright Elsevier 2024

some strains of HIV-1 contributed to the discovery that chemokine receptors, and in particular CCR5, are essential coreceptors for HIV-1 entry.[3,6] There have been suggestions that increased production of the HIV-blocking chemokines may be effective against the virus *in vivo*, because higher production of CCL3, CCL4, and CCL5 by HIV-antigen-stimulated peripheral blood mononuclear cells has been associated with a more favorable clinical status in HIV/AIDS.[10] There are also recent results for antiviral activity of CXCL10, again by blocking viral entry. CXCL10 binds to heparan sulfate on cell membranes and can prevent dengue virus from infecting cells. Deletion of the *Cxcl10* gene makes mice more susceptible to dengue virus infection.[13]

In summary, the chemokines are a group of phylogenetically and structurally related proteins with diverse biological properties. Both the innate and adaptive immune systems use chemokines to regulate specific leukocyte populations, and chemokines are critical for host defense and inflammation. In addition, chemokines may have more direct effects against pathogens. Given these activities, chemokines could be used to optimize host defense or for immunotherapy, or could be targeted to block inflammatory damage.

Chapter 90

DP IV/CD26 Effector Peptides

Siegfried Ansorge and Dirk Reinhold

ABSTRACT

Many biologically active peptides of the immune system like cytokines and chemokines and also a number of neuropeptides are generated or inactivated by a concerted action of proteolytic enzymes. One of the most prominent peptidases is the dipeptidyl aminopeptidase IV (DP IV, CD26, EC 3.4.14.5), which is expressed as an ectoenzyme on all lymphocytes and that plays a crucial role in the regulation of the immune response. In this chapter, we describe the activities of biologically active peptides that are regulated by soluble and membrane-bound DP IV/CD26 and that themselves may specifically act on this peptidase and thereby modulate the immune response. Recent results show that the cellular role of DP IV/CD26 is regulated not only via its active site but much more by its newly discovered binding site in the antechamber of the central pore of this peptidase.

INTRODUCTION

The ectoenzyme dipeptidyl peptidase IV (DP IV, E.C. 3.4.14.5) is identical to the leukocyte surface antigen CD26 and belongs to the group of postproline dipeptidyl aminopeptidases, which consist of the gene family of DP IV, FAP (fibroblast activation protein), DP8 and DP9, and DPII (E.C.3.4.14.2). DP IV is a homodimeric Type II transmembranic glycoprotein with a total molecular mass of 220–240 kD. It seems that DP IV is associated with glycolipid- and cholesterol-rich microdomains known as "rafts."[25] FAP (Seprase) is also a dimeric peptidase expressed in the plasma membrane, whereas DP8 and DP9 are soluble, monomeric cytoplasmic proteins.[3,34]

DP IV/CD26 is a serine exopeptidase catalyzing the release of N-terminal dipeptides from oligopeptides and polypeptides preferentially with proline, hydroxyproline, and, with less efficiency, alanine or serine in the penultimate position (Fig. 1). The postproline cleaving substrate specificity makes DP IV/CD26 and the related peptidases relatively unique among other proteases. The crystal structure of DP IV homodimers has been published recently (cf. Refs 2, 34).

Each subunit consists of two domains: an α/β-hydrolase domain and an eight-bladed ß-propeller domain. The active site is accessible via two openings from which the central pore opening in the center of the propeller domain, opposite to the cell membrane, is playing a crucial role in the function of cellular DP IV.[2]

DP IV is ubiquitously distributed and highly expressed in the intestine, kidney, and liver. Lower expression is detectable in nearly every tissue.[1] Functionally relevant is also its localization on the endothelial cells of all organs examined and on intestinal epithelial cells.

Membrane-bound DP IV on the surface of cells is embedded in a number of other membrane proteins, and the activation of cells as T lymphocytes leads to a recruitment of DP IV/CD26 to detergent-insoluble glycolipid-enriched domains or lipid rafts.[25] This raft distribution results in an association of raft-associated signal-transducing molecules (cf. Ref. 2). It is highly probable that, in contrast to the soluble DP IV, the access for peptide substrates to the side pore of membrane DP IV is restricted. Consequently, the main central access in the propeller domain could be the only access to the active site of the enzyme for those substrates. By the use of docking approaches and computational techniques, surprisingly, a special binding site within an antechamber of this central access was identified in our laboratory.[2] This binding site was named "central pore-binding site," which is located approximately 20Å from the active site. It is capable of interacting with a number of peptide substrates and DP IV inhibitors. By using docking approaches, it was found that the most frequent amino acids involved in interaction with inhibitors/ligands are Glu361, Pro362, His363, and Glu 408.[2] By the use of central pore-binding site-selective ligands, it could be shown that the central pore-binding site seems to be the sterical control and binding point that regulates the access of substrates to the active site and DP IV-mediated signal pathways.[2,14]

The unique enzymatic substrate specificity of DP IV results in the peptidase playing a key role in the catabolism

of a number of neuropeptides, immunopeptides, and peptide hormones, discussed elsewhere in this book, containing the X-Pro or X-Ala amino-terminal sequences, such as substance P, neuropeptide Y, peptide YY, enterostatin, glucose-dependent insulinotropic polypeptide (GIP), and glucagon-like peptide-1 (GLP-1).[9,31] Recently, the emphasis of the research related to DP IV has been concentrated on its ability to cleave a dipeptide from the N-terminus of the GLP-1 (see chapters in Ingestive Peptides and Gastrointestinal Peptides sections). This incretin seems to play an important role in the management of glucose levels. Therefore, GLP-1–based therapies are of potential use in the treatment of Type II diabetes.[9,31] As described in detail above, in addition to the active site of DP IV, which is directly involved in enzymatic hydrolysis of peptides, the central pore-binding site in the antechamber of the central access to the active site of cellular DP IV is involved in the regulation of its cellular function.[2] This holds true particularly for the immune functions of DP IV/CD26.

DP IV/CD26 IN THE IMMUNE SYSTEM

Within the immune system, DP IV/CD26 is expressed on the surface of resting and activated T-cells, activated B-cells, and activated NK cells.[2,14] DP IV/CD26 expression is upregulated after the stimulation of T-cells with mitogen, antigen, anti-CD3 antibodies, or IL–2, after B-cell stimulation with staphylococcal proteins and IL-2 stimulation of NK cells. Thus, activated antigen-specific CD4+T-cell clones express high levels of DP IV/CD26.[24] In 1985, Schön et al.[26] showed for the first time that the inhibitor N-Ala-Pro-O-(nitrobenzoyl)-hydroxylamine, which irreversibly inhibits DP IV, is capable of suppressing the proliferation of human peripheral blood mononuclear cells (PBMCs) stimulated with mitogens. This was the first evidence that DP IV/CD26 plays a critical role in the regulation of DNA synthesis of immune cells and that the enzymatic activity of DP IV is involved in this process.

In the meantime, a multitude of biochemically distinct synthetic compounds inhibiting DP IV and/or DP IV-like enzymes have been studied under different stimulation conditions with a variety of target cells. The most frequent reversible inhibitors used were Lys[Z(NO_2)]-thiazolidide, -piperidide, and -pyrrolidide, which cause a 50% inhibition of DP IV in the range of 0.2–0.5μM. The inhibitory effects of these substances on leukocyte proliferation and cytokine production were confirmed in different mitogen- or antigen-stimulated T-cells and T-cell clones from human and mouse.[24,27,28] Besides their influence on DNA synthesis, inhibitors of DP IV enzymatic activity also exhibit strong suppressive effects on the production of various cytokines. It was shown that Lys[Z(NO_2)]-thiazolidide, -piperidide, and -pyrrolidide inhibit the production of IL-2, IL-5, IL-10, IL-17, IL-12, and IFN-γ of mitogen-stimulated PBMCs and purified T-cells[1,2] as well as the production of IL-2, IL-6, and IL-10 of PHA (phytohemagglutinin)-stimulated mouse splenocytes and Con A (concanavalin A)-stimulated mouse thymocytes (cf. Ref. 14). These inhibitors also reduce in a dose-dependent manner IFN-γ, IL-4, and TNF-α production of myelin basic protein (MBP)-stimulated T-cell clones from MS patients.[24] DP IV inhibitors, on the other hand, elicit the enhanced production and secretion of latent transforming growth factor-ß1 (TGF-ß1), which partially explain the suppressive effects on DNA synthesis and cytokine production.[14,24]

In vivo, the administration of DP IV inhibitors suppresses antibody production in mice after stimulation with bovine serum albumin,[16] and hind paw swelling in an arthritis model in rats,[29] acute rejection in a rat cardiac transplantation model,[15] and experimental autoimmune encephalomyelitis in mice.[28] In all, the results convincingly demonstrate the involvement of DP IV or DP IV-like proteolytical activity in immune functions.

It should be mentioned that in addition to DP IV, lymphocytes do express the cytosolic peptidases DP8 and DP9, which have similar substrate specificity as DP IV. Both are also inhibited by a number of typical DP IV inhibitors and also by ligands that selectively interact with the central pore-binding site but not with the active site of DP IV.[1,2] This means that many DP IV inhibitors are selective for the DP IV family rather than DP IV itself. However, a functional relevance of the cytosolic DP8 and DP9 in regulating growth and cytokine production is difficult to explain.[3] Moreover, it is highly probable that the newly discovered central pore-binding site of DP IV/CD26 is the most crucial target site in the regulation of growth and cytokine production of immune and other cells. Recent results show that combined targeting of DP IV/CD26 and the alanyl-aminopeptidase N (APN/CD13) have much stronger synergistic anti-inflammatory effects compared with DP IV inhibition alone.[1]

DP IV EFFECTOR PEPTIDES

Although the detailed molecular mechanism of DP IV action in the immune system is not known yet, the most probable explanation for its role lies in the processing of immunorelevant bioactive oligo- and polypeptides and/or the inhibitory effects of DP IV-binding peptides, that is, peptides with N-terminal X-Pro- or X-Ala- motifs, on the enzymatic activity of DP IV itself. During the past years, a number of bioactive peptides were experimentally identified as substrates of DP IV. Most of them belong to the group of chemokines and endocrine factors (Table 1). However, the group of potential DP IV effector peptides is much larger. A number of bioactive polypeptides like cytokines have the N-terminal X-Pro or X-Ala sequence required for cleavage by DP IV but are not processed by soluble DP IV (Table 2). Probably their N-terminus is not susceptible under *in vitro* conditions. The N-terminal peptides of some, if not all, of them are, however, susceptible to DP IV cleavage after endoproteolytical processing of the native peptide.

Moreover, potential DP IV substrates can be also generated from any proteins or peptides, which express the -X-Pro sequence within the peptide chain, namely, via endo- or exo-proteolytical processing. One example is the endogenous peptide hemorphin-7 belonging to the family of atypical opioid peptides released from hemoglobin B-chain sequence 35-41.[4] From this, one can conclude that the DP IV substrate scenario is characterized by a vast number of oligo- and polypeptides, which potentially can act either as substrates, as competitive inhibitors or as ligands for the central pore-binding site.

PRIMARY DP IV EFFECTOR PEPTIDES

In vitro studies on processing of immunorelevant peptides by soluble DP IV have identified a number of candidates where DP IV plays a critical role in regulating their bioactivity (Table 1). *In vivo*, bioactive peptides are acting in nanomolar or picomolar concentration ranges. The physiological relevance of *in vitro* inactivation of such peptides is defined by the physiological efficiency or selectivity constant kcat/Km. Substances with higher kcat/Km values are better substrates than those with lower values.

Chemokines play a fundamental role in the immune system, particularly in traffic and homing of lymphocytes

and other immune cells. They bind to specific receptors on the surface of endothelial or immune cells or to the extracellular matrix. Many chemokines exhibit a DP IV susceptible N-terminal sequence, and some of them have been found in a DP IV truncated form in blood and tissues. Therefore, it is highly probable that DP IV-mediated truncation is an important mechanism of regulating chemokinesis.

One of the most rapidly DP IV-processed chemokine **is CXCL12 (stromal-derived factor–1α and -1ß)**. The CXCL12 form found in blood is predominantly the truncated form generated by DP IV cleavage.[5] CXCL12 is also a ligand of the HIV coreceptor CXCR4 and inhibits infection of macrophages by special HIV strains.[7,11,17,18]

CCL11/Eotaxin is a significant factor for the recruitment of eosinophils to inflammatory sites, particularly in allergic reactions. DP IV-mediated processing of CCL11 results in a clear loss of its biological activity.[7] Coincubation of CCL11 with human T-cells shows a processing of full-length CCL11 to CCL11(3–74) reflecting the specific cleavage of CCL11 by DP IV. Intravenous administration of CCL11 in wild-type Fischer 344 rats leads to the mobilization of eosinophils into the blood, peaking at 30min. This mobilization is significantly increased in DP IV–deficient Fischer 344 mutants. This result clearly underscores the role of DP IV in controlling eosinophilia.[11]

Neuropeptide Y (**NPY**) and **peptide YY** (**PYY**) belong to the best natural substrate of DP IV. Several lines of evidence suggest that NPY exerts regulatory effects in local inflammatory response. Lymphocytes express NPY Y1 receptor. It was shown that NPY, PYY, and an NPY Y5 receptor agonists potentiate Con A-induced paw edema in the rat. The DP IV inhibitor Ile-thiazolidide exerted synergistic and potentiating effects *in vivo*. This clearly shows an involvement of DP IV in NPY- and PYY-mediated immune response.[8] Recent data showed that NPY has a bimodal role as a negative regulator of T-cells and as an activator of antigen-presenting cell function[23] and is capable of promoting the production of the immunosuppressive cytokine TGF-β1.[35]

Hemorphins are endogenous peptides belonging to the family of atypical opioid peptides released from sequentially hydrolyzed hemoglobin. Hemorphin-7 (heptapeptide (35–41) of human hemoglobin) has been shown to be capable of inhibiting the inflammatory response in acute but not chronic injury conditions. Inhibition kinetic studies conducted with purified DP IV demonstrated that hemorphin-7 constitutes a good substrate for this enzyme but could also act as a selective competitive inhibitor by substrate binding site competition. Therefore, this group of blood peptides could represent endogenous regulators of DP IV activity.[4]

Substance P (SP) is an undecapeptide that is secreted by nerves and inflammatory cells such as macrophages, lymphocytes, and dendritic cells. It has proinflammatory effects in immune and epithelial cells and plays a crucial role in inflammatory diseases.[21,22] Besides the neutral endopeptidase (NEP) and the angiotensin converting enzyme (ACE), DP IV is one of the most important peptidases involved in the degradation of SP.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

In many studies, it has been reported that **vasoactive intestinal peptide (VIP)** could play an important role in the modulation of the immunological response. VIP can be produced by immunological cells, and the receptors for this neuropeptide are also present in many of these cells. Recent work has demonstrated that VIP is produced by Th2 cells, and that through specific receptors, it exerts immunological functions typically ascribed to Th2 cytokines in nervous and immune systems. VIP strongly reduces the inflammatory response under different conditions. Thus, it was added to the list of endogenous anti-inflammatory agents.[22]

The **pituitary adenylate cyclase-activating polypeptide (PACAP)** is a neuropeptide belonging to the VIP/secretin glucagon family of peptides produced by immune cells, which exerts a wide spectrum of immunological functions controlling the homeostasis of immune system through different receptors expressed on various immunocompetent cells. Like VIP, PACAP has been identified as a potent anti-inflammatory factor that exerts its function by regulating the production of both anti-inflammatory and proinflammatory mediators.[6] DP IV inhibitors are presumed to protect both PACAP and VIP from inactivation and thereby to favor the anti-inflammatory status.

The tetradecapeptide **gastrin-releasing peptide (GRP)** is the mammalian homolog of bombesin and has been shown to affect cytokine production and release from various immune cells. It is present in joint fluids in rheumatoid arthritis and correlates clearly with proinflammatory cytokines.[12]

Procalcitonin (PCT), a protein of 116 amino acids, was discovered as a prohormone of calcitonin produced by C-cells of the thyroid gland. Circulating levels of PCT in healthy subjects are below the detection limit. Blood concentration of PCT is increased in systemic inflammation, especially when this is caused by bacterial infection, such as sepsis.[10] Recently, it was found that not PCT(1–116) but only the truncated form, lacking the dipeptide Ala–Pro, PCT (3–116), is present in the serum of patients with bacterial sepsis and that this DP IV-catalyzed processing of PCT can be imitated also *in vitro*.[32]

SECONDARY IMMUNORELEVANT DP IV PEPTIDE SUBSTRATES

A number of cytokines, chemokines, endocrine factors, and other bioactive peptides exhibit X-Pro or X-Ala sequences at the N-terminus (Table 2) but were not processed by soluble DP IV under *in vitro* conditions.[13,14]

A number of candidates are yet to be studied with respect to their DP IV susceptibility *in vitro*. In the context of DP IV action, it is of interest that biological activity is changed strongly by short deletions and mutations at the N-terminal part of the bioactive peptide [cf. Ref. 13]. Using IL-2 oligopeptides with different chain lengths, it was shown that the soluble DP IV-catalyzed hydrolysis rate was negatively correlated to their chain length.[13] Similar effects were observed with IL-6 and other peptides.[13] Obviously, the free and flexible N-terminus of the peptide is required. Probably, binding of the bioactive peptide to the receptor could change conformation and susceptibility.

It should be mentioned, however, that all data on hydrolysis of these peptides available as yet were generated with soluble DP IV, which represents <1% of the total DP IV and not with the cellular DP IV.

Moreover, it is also not known how strong native peptides do interact with the central pore-binding site of cellular DP IV/CD26 and whether these interactions have a direct effect on cellular functions after binding to this site. Docking results from our laboratory show the binding of shorter N-terminal hexapeptides of some of these peptides to the central pore-binding site of DP IV/CD26, which suggests a functional role of these natural peptides via this binding site. This would be a totally new mechanistic aspect on the role of DP IV/CD26 in the regulation of growth and inflammatory processes.

Nevertheless, it should be taken also into consideration that, in any case, soluble DP IV-resistant bioactive peptides can be processed by endoproteases *in vivo* to suitable substrates for DP IV, which are then capable of acting as competitive inhibitors and immune suppressors. The large number of such peptides makes them a powerful natural tool in the regulation of immune response via DP IV/CD26 *in vivo*.

PEPTIDE INHIBITORS OF DP IV

In contrast to the increasing number of nonpeptide inhibitors of DP IV,[9,31] the examples of natural peptide inhibitors already studied are limited (Table 3). One should remember, however, that the above-discussed peptide substrates of DP IV can principally act also as competitive inhibitors of this peptidase. This means that the number of potential DP IV inhibitors with proline in the second position is much larger. A special feature of DP IV inhibition is the finding that peptides with proline in the third position can also act as potent inhibitors of DP IV particularly if tryptophan is present in the second position of the N-terminus (Table 3). Examples are Tat protein and its derivatives of the human immunodeficiency virus 1.[33]

Peptides described in this chapter probably represent only a small portion of the total number of peptide candidates related to DP IV. Future work will show that the number of immunorelevant peptides that are actively (DP IV inhibitors as suppressor peptides) or passively (cytokines and chemokines as instructor peptides) involved in DP IV/Cd26-mediated immune regulation is much larger.

Chapter 91

FPR Ligands

Ying Liu, Keqiang Chen and Ji Ming Wang

ABSTRACT

Formyl peptide receptors (FPRs) belong to the classical G protein-coupled chemoattractant receptor family. They are mainly expressed in mammalian phagocytic leukocytes and play important roles in inflammatory and immune responses. *N*-formyl peptides produced by Gram-negative bacteria were among the first chemotactic factors identified for two FPRs in human beings: FPR1 (originally termed FPR) and FPR2 (originally termed FPRL1). During the past few years, a variety of novel pathogen- and host-derived agonists as well as antagonists for the FPR family have been identified, indicating a broader spectrum of the biological significance of these receptors. Activation of FPRs in leukocytes by agonists induces cell chemotaxis, phagocytosis, release of proinflammatory mediators and gene transcription. Despite these new developments, the *in vivo* functions of FPRs and their ligands in disease states are not yet fully understood. This chapter summarizes the pharmacological characterization of FPR ligands and their implications in pathophysiological conditions.

INTRODUCTION

Inflammation is essentially a protective attempt by the organisms to remove the injurious stimuli and to initiate the healing process. The migration of leukocytes is crucial in the progression and resolution of inflammation and is tightly regulated. Leukocytes accumulate at the sites of inflammation by responding to pathogen- and host-derived chemotactic factors named chemoattractants. Numerous chemoattractants have been described including chemokines, activated complement fragments, lipid mediators, and pathogen-derived molecules.[32]

Most chemoattractants use G protein-coupled receptors (GPCRs) classified as GPCRs for chemokines and for classical chemoattractants. Formyl peptide receptors (FPRs) belong to the family of classical GPCRs. These receptors are named based on their capacity to recognize the *N*-formyl methionine motif in synthetic neutrophil chemotactic peptides and in peptide fragments released into the culture supernatants by *Escherichia coli.*[32] The FPR family members are coupled to pertussis toxin (PTX)-sensitive Gi proteins and mediate neutrophil and monocyte chemotaxis and activation.[11] Although FPRs were identified and cloned in the early 1990s,[19] the biological function of these receptors remains poorly understood. However, with the identification of a number of novel nonformylated and host-derived agonists for FPRs, it is becoming evident that these receptors and their peptide ligands play important roles in innate and adaptive immune responses.

FORMYL PEPTIDE RECEPTORS (FPRs)

The prototype human FPR was cloned from differentiated HL-60 myeloid leukemia cells.[32] Two additional human FPRs were subsequently cloned and were named as FPR like-1 (FPRL1) and FPRL2. Recently, these GPCRs were renamed as FPR1, FPR2/ALX (FPRL1), and FPR3 (FPRL2). FPR1 and FPR2 share 69% identity at the amino acid level, whereas FPR3 has 56% amino acid sequence identity to human FPR1 and 83% to FPR2.[32] Both human FPR1 and FPR2 are expressed in many cell types, such as myeloid cells including monocytes/macrophages, neutrophils and immature dendritic cells (DCs), endothelial cells, hepatocytes, astrocytes, microglial cells, and fibroblasts.[32] The expression of human FPR3 is more restricted and is detected in monocytes/macrophages and DCs but not in neutrophils.[32] FPR3 is also expressed in plasmacytoid DCs and is upregulated on cell maturation.[10] The signal transduction pathways of FPRs have been more extensively studied with FPR1 in phagocytic cells and in cell lines transfected with cloned receptor. The interaction of FPR1 with its agonist peptide fMLF uncouples trimeric G proteins to elicit a signaling cascade that activates phospholipase C (PLC), protein kinase C (PKC) and PI3 kinases (PI3Ks), which are translated into biological functions of receptor-bearing cells including chemotaxis and mediator release. FPR1 and FPR2 also crosstalk with some receptor tyrosine kinases, such as nerve growth factor (NGF) receptor TrkA and the epidermal growth factor receptor (EGFR).[12,15]

In the mouse FPR gene family, there are at least eight members, *Fpr1* and *Fpr-rs1* to *Fpr-rs7*.[32] *Fpr1* encodes mFPR1, which is the ortholog of human FPR1 and binds fMLF with a relatively high affinity, whereas both *Fpr-rs1* and *Fpr-rs2* encode receptors most similar to human FPR2.[32] The gene product of mouse *Fpr-rs2*, mFPR2, is a

low-affinity receptor for fMLF.[19] The biological functions of other six mouse *Fpr* gene homologs have not been characterized.[32] The high sequence divergence between species orthologs (~25–30% between human and mouse) indicates the complicated evolution of the FPR gene family.[32] *In vivo*, mFPR1-KO mice were more susceptible to infection by *Listeria monocytogenes*, indicating the role of FPR1 in antibacterial defense.[32] More recently, FPR1 (mFPR1) was shown to mediate trauma reaction in severe inflammatory response syndrome[34] and neutrophil accumulation in the necrotic center of the liver injury, presumably by responding to N-formylated mitochondrial peptides released by ruptured cells.[24] mFPR2-KO mice have also been generated recently and show diminished allergic airway inflammation and accompanying immune responses.[2] FPR2 (mFPR2) expressed in human and mouse neutrophils interacts with an acute-phase protein serum amyloid A (SAA) produced by liver and also by melanoma cells to promote the release of the anti-inflammatory cytokine IL-10, which increases the interaction of neutrophils with invariant natural killer (NK) T cells. These NKT cells limit the immunosuppressive activity of neutrophils by decreasing IL-10, but increasing IL-12 production, thereby enhancing the anti-melanoma host responses.[8] These new developments highlight the critical function of FPR1 and FPR2 in innate and adaptive host responses.

FPR AGONISTS

FPRs recognize many agonists including peptides and nonpeptides. The peptides comprise three subtypes, pathogen-derived, host-derived and synthetic. The nonpeptides are either synthetic or derived from the host[32] (Table 1).

TABLE 1 The Agonists of FPRs

Agonists	Origin	Receptors
Peptides		
Bacteria-derived *N*-formyl peptides		
N-formyl-MLF	*E. coli*	FPR1, FPR2
N-formyl-MIFL	*S. aureus*	mFPR1
N-formyl-MIVIL	*L. monocytogenes*	FPR1, FPR2
N-formyl-MIGWI	*L. monocytogenes*	FPR1, FPR2
N-formyl-MIVTLF	*L. monocytogenes*	FPR1, FPR2
N-formyl-MIGWII	*L. monocytogenes*	FPR1
N-formyl-MFEDAVAWF	*M. avium*	FPR1
Mitochondria-derived *N*-formyl peptides		
N-formyl-MMYALF	Mitochondria, ND6	FPR1, FPR2
N-formyl-MLKLIV	Mitochondria, ND4	FPR1, FPR2
N-formyl-MYFINILTL	Mitochondria, ND1	FPR2
N-formyl-MFADRW	Cytochrome *c* oxidase subunit	FPR1, FPR2
N-formyl-Nle-LF-Nle-YK	Synthetic	FPR1, FPR2
Mitocryptide-2 (MCT-2)	Mitochondria cytochrome b	FPR2
Microbe-derived peptides		
Hp (2–20)	*H. pylori*	FPR2, FPR3
T20 (DP178)	HIV-1 gp41 aa. 643–678	FPR1
T21 (DP107)	HIV-1 gp41 aa. 558–595	FPR2
V3 peptide	HIV-1 gp120, V3 loop	FPR2
N36 peptide	HIV-1 gp41 aa. 546–581	FPR2
F peptide	HIV-1 gp120 aa. 414–434	FPR2
gG-2p20	Herpes simplex virus type 2	FPR1
N-formyl HKU-1 coronavirus peptide	Respiratory syndrome coronavirus	FPR1

TABLE 1 The Agonists of FPRs—*Cont'd*

Agonists	Origin	Receptors
Host-derived peptides		
CKβ8–1 (human CCL23)	Chemokine	FPR2, CCR1
SHAAGtide	CCL23 *N*-terminal 18 aa.	FPR2, CCR1
Humanin (HN)	Neuroprotective peptide	FPR2, FPR3
F2L	Heme-binding protein	FPR2, FPR3
SAA	Acute-phase protein	FPR2
Annexin 1 / lipocortin 1	Glucocorticoid-regulated protein	FPR1
Ac1-25	Annexin 1	FPR1, FPR2, FPR3
Ac2–26	Annexin 1	FPR1, FPR2, FPR3
Ac9–25	Annexin 1	FPR1, FPR2
Antiflammin-2 (AF2)	Annexin 1	FPR2
Aβ (1–42)	Amyloid precursor	FPR2
D2D3	uPAR (88–274)	FPR2
SRSRYp	D2D3	FPR1
LL-37	Cathelicidin	FPR2
PrP (106–126)	Prion protein	FPR2
Temporin A	*Rana temporaria*	FPR2
PACAP27	Pituitary adenylate cyclase activating polypeptide	FPR2
Agonists from peptide library		
WKYMVm	Peptide library	FPR1, FPR2, FPR3
WKYMVM	Peptide library	FPR2, FPR3
MMK-1	Peptide library	FPR2
MMWLL, formyl-MMWLL	Peptide library	FPR1
CGEN-855A	Peptide library	FPR2
Nonpeptides		
Host-derived nonpeptides		
Lipoxin A4 and aspirin-triggered lipoxins	Eicosanoids	FPR2, AhR
Agonists from nonpeptide library		
Quinazolinone derivative (Quin-C1)	Combinatorial library	FPR1, FPR2
Pyrazolone, 4-iodo-substituted, no. 43	Combinatorial library	FPR1, FPR2
AG-14	Drug-like molecule library	FPR1
Compound 1 and 2	Arylcarboxylic acid hydrazide derivatives	FPR2
Others		
PD168368	Gastrin-releasing	FPR1, FPR2,
PD176252	peptide/neuromedin B receptors (BB1/BB2)	FPR1, FPR2, FPR3
Trp-and Phe-based analogs	PD168368/ PD176252	FPR1, FPR2, FPR3
Related nonpeptide/nonpeptoid analogs	PD168368/ PD176252	FPR1, FPR2
A-71623	Cholecystokinin-1 receptor agonist

Peptides

Microbial Peptides

Synthetic or *E. coli*-derived fMLF is most widely used to characterize the function of FPR1 and FPR2. The chemotactic activity of fMLF for neutrophils is increased by an oligoethylene glycol substituent.[16] In addition to its chemotactic activity for myeloid cells, fMLF also induces intestinal epithelial cell migration and participates in epithelial restitution and wound closure.[32] The activity of fMLF on intestinal epithelial cells is attributed to FPR1, which is located along actin filaments in lamellipodial and filopodial extrusions associated with activated PI3K, Rac1, and Cdc42.[32] In human mesenchymal stem cells, fMLF stimulates signaling pathways coupled to FPR1 that drive phospholipase C (PLC)/phospholipase D (PLD)-Ca^{2+}-calmodulin-dependent kinase II-ERK-CREB during osteogenic differentiation. By contrast, fMLF inhibits the expression of PPARγ1 and suppresses adipocytic commitment during differentiation.[28] Thus, FPR1 and its agonist fMLF also display important functions in nonhematopoietic cells. In addition to fMLF, there are other *N*-formyl peptides derived from bacteria. For example, a pentapeptide fMIVIL from *L. monocytogenes* and a tetrapeptide fMIFL from *Staphylococcus aureus* preferentially activate mFPR1.[32] fMFEDAVAWF derived from *Mycobacterium avium* also activates FPR1.[32]

Although formylated peptides are believed to be mainly of bacterial origin, three hexapeptides fMLKLIV, fMMYALF, and fMFADRW corresponding to the N terminus of mitochondrial NADH dehydrogenase subunits 4 and 6 and cytochrome *c* oxidase subunit I[32] are also potent chemotactic agonists for FPR1 and FPR2. Other mitochondrial *N*-formyl peptides (e.g. mitochondrial transcription factor A (TFAM) released during cell necrosis) also activate monocytes to release IL-8 (CXCL8), a neutrophil specific chemokine.[4]

Mitochondria are considered to be evolutionary endosymbionts derived from bacteria and may thus contain bacterial molecular motifs. On cell injury, mitochondrial "damage"-associated molecular patterns (DAMPs) are released into the circulation and elicit neutrophil-mediated organ injury. The effect of mitochondrial DAMPs (MTDs) containing formyl peptides on neutrophils is mediated by FPR1, while mitochondrial DNA in MTDs activates Toll-like receptor (TLR) 9.[34] Some functional "cryptic" peptides hidden in protein structures are termed "cryptides," one of which, mitocryptide-2 (MCT-2) in mitochondrial cytochrome *b*, was a specific agonist for FPR2 and may play a role in inflammatory host responses.[27]

Non-formylated Peptides

Many peptides without *N*-formyl group have been identified as agonists for FPRs. A *Helicobacter pylori* peptide Hp (2–20) activates FPR2 and FPR3 and may contribute to the development of pyloritis by the recruitment of monocytes and basophils to the gastric mucosa in response to bacterial infection.[19] Hp (2–20) also induces the migration, proliferation, and the expression of vascular endothelial growth factor (VEGF) in gastric epithelial cells, suggesting that this *H. pylori* peptide may promote gastric mucosal healing.[32]

HIV-1 envelope proteins contain segments capable of interacting with either or both FPR1 and FPR2, including at least three domains in gp41, as well as two sequences from gp120. Although T20/DP178 from gp41 specifically activates human FPR1 *in vitro*[19] and the murine FPR1 homolog mFPR1 *in vivo*, T21/DP107 from gp41 uses both FPR1 and FPR2 with higher efficacy on FPR2. N36 from gp41, which partially overlaps with T21/DP107, solely signals through FPR2.[32] Two peptide domains in HIV-1 gp120 are potent chemoattractants and activators for FPR2, but not for FPR1, in human phagocytic leukocytes.[3] One peptide domain, F peptide, consists of 20-amino acid residues and is located in the C4–V4 region of gp120 of the HIV-1 LAI strain. Another peptide of 33 amino acids (V3 peptide) is derived from a linear sequence of the V3 region of the HIV-1 MN strain.[3] However, despite the existence of peptide domains in HIV-1 envelope proteins that interact with FPRs, it remains unclear whether such domains are released by enzymatic cleavage of the envelope proteins *in vivo* during HIV-1 infection.

In addition to peptides from HIV protein, there are also some other viral proteins containing sequences that act as FPR ligands. gG-2p20, derived from *Herpes simplex* virus type 2 (HSV-2), is a chemoattractant for both monocytes and neutrophils by activating FPR1.[32] It is noteworthy that an HKU coronavirus peptide, MYVKWPWYVWL, is a potent antagonist, but *N*-formyl-MYVKWPWYVWL is a potent agonist for FPR1,[32] suggesting the importance of N-terminal modification in the biological activity of a synthetic peptide.

Host-Derived Peptides

Peptides Associated with Amyloidogenic Diseases

At least 3 amyloidogenic polypeptides associated with chronic inflammation and amyloidosis have been identified as agonists for FPR2. They are serum amyloid A (SAA), β amyloid peptide $A\beta_{42}$, and $PrP_{106–126}$.

SAA, an acute-phase protein, increases in serum by as much as 1000-fold in inflammatory diseases, e.g. trauma, infection, and other environmental stress.[32] Recombinant human SAA as the first mammalian host-derived peptide ligand identified for FPR2[19] is chemotactic for myeloid cells and T lymphocytes. In synovial tissues of patients with rheumatoid arthritis (RA), highly expressed SAA promotes the proliferation of human fibroblast-like synoviocytes (FLS)

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

and induces the expression of matrix metalloproteinases by FLS.[32] SAA also protects RA FLS from apoptotic death induced by serum starvation, anti-Fas IgM, and sodium nitroprusside[32] by interacting with FPR2. In addition, SAA stimulates CCL-2 production via FPR2 by human umbilical vein endothelial cells and monocytes contributing to the progression of atherosclerosis.[21,22] SAA also stimulates M-CSF and CCL-2 expression in human and mouse hepatocellular carcinoma cells.[23] SAA may interact with other receptors; the nucleotide receptor P2X7 was reported to mediate the protective role of SAA in human neutrophil apoptosis.[1]

$A\beta_{42}$ is a 42-amino acid cleavage product of the amyloid precursor protein in the brain and a pathogenic factor for Alzheimer's disease (AD).[19] FPR2 mediates the migration and activation of monocytic phagocytes, including macrophages and brain microglia, induced by $A\beta_{42}$. FPR2 also promotes the endocytosis of $A\beta_{42}$ by macrophages and microglia in the form of receptor and ligand complexes. If the exposure of macrophages to $A\beta_{42}$ is transient, the internalized $A\beta_{42}$ is degraded and FPR2 is rapidly recycled back to the cell surface. However, prolonged exposure results in accumulation of $A\beta_{42}$ and FPR2 complexes in macrophages, which culminates in progressive fibrillary aggregation of $A\beta_{42}$ and the macrophage death.[3] These observations suggest that FPR2 not only mediates the proinflammatory activity of $A\beta_{42}$ but it may also play an important role in the fibrillary deposition of $A\beta_{42}$, a typical pathologic feature of AD.[3]

$PrP_{106–126}$ is a prion protein fragment that is produced in human brains with prion disease.[19] $PrP_{106–126}$ induces the migration and activation of human myeloid cells through FPR2 and may thus contribute to the inflammatory responses seen in the prion disease.

Although the interaction of FPRs with peptide agonists in general elicits proinflammatory responses, FPR2 may exert a neuroprotective effect by recognizing a small peptide, humanin (HN), which was identified through a functional expression screening based on its ability to suppress neuronal cell death seen in familial AD.[32] HN is chemotactic for monocytes through the use of FPR2 and by competitive blockage of FPR2 abrogates the intracellular fibrillary aggregation of $A\beta_{42}$. In neuronal cells, HN protects the cells from apoptosis induced by $A\beta_{42}$. Thus, FPR2 may transduce life and death signals in neuronal cells depending on the nature of the agonists it encounters and may determine the outcome of AD. However, it has also been reported that HN-mediated protection of F11 neurohybrid cells is mediated through tyrosine kinases and STATs which are unlikely coupled to FPR2.[32]

Peptides Associated with Inflammatory and Antibacterial Responses

Urokinase-type plasminogen activator[18] is a serine protease known for its ability to regulate fibrinolysis. uPA is required for leukocyte trafficking to sites of inflammation *in vivo*, and it indirectly activates FPR2 through the liberation of a chemotactic peptide $D2D3_{88–274}$ from uPA receptor (uPAR) (CD87).[19] Consistent with this, the presence of both uPAR and FPR2 on the cell surface is required for the chemotactic activity of uPA, whereas FPR2 alone is sufficient for the effect of $D2D3_{88–274}$. Thus, uPAR may facilitate fibrinolysis and serve as a source of chemotactic proinflammatory peptides necessary for host defense. SRSRY, a peptide corresponding to residues 88–92 in uPAR is an agonist of FPR1.[32] In addition, $uPAR_{84–95}$ induces basophil migration by interacting with both FPR2 and FPR3 and mobilizes hematopoietic stem cells by activating FPR1 by desensitizing the chemokine receptor CXCR4.[32]

FPRs interact with some bactericidal peptides contained in human neutrophil granules. LL37, an enzymatic cleavage fragment of neutrophil granule protein cathelicidin and its mouse homolog CRAMP (see the Cathelicin Chapters in Bacterial/Antibiotic Peptides section of this book), activate FPR2 to promote myeloid cell chemotaxis.[32] LL-37 also induces angiogenesis via FPR2 expressed on endothelial cells. In CRAMP-deficient mice, neovascularization is decreased during cutaneous wound repair.[32] Another antibacterial neutrophil granule protein, cathepsin G, is a serine protease (see the Peptide Biosynthesis/Processing section of this book) and a specific agonist for FPR1.[32] It is therefore conceivable that the capacity of antimicrobial neutrophil granule peptides to interact with FPRs may aid in the recruitment of phagocytic leukocytes to the sites of infection and thus accelerate the killing and clearance of the invading bacteria.

FPR2 has also been reported to interact with a chemokine variant (CKβ8) that activates phagocytic leukocytes. CKβ8 (CCL23/MPIF-1) uses a typical GPCR, CCR1, for its leukocyte chemotactic activity. However, an N-terminal truncation product of the CKβ8 splice variant CKβ8-1 (22–137 aa) activates myeloid cells and FPR2-transfected cell lines at low nanomolar concentration range and is thus considered one of the most potent FPR2 agonists identified so far.[3] However, the cell sources of CKβ8 and the circumstances for its release *in vivo* remain unclear. Interestingly, an 18-amino acid peptide from CKβ8, SHAAG, activates FPR2 activity but not CCR1, revealing a structural basis for the receptor specificity of CKβ8.[25]

Annexin I (Anx A1) and its N-Terminal Peptides

It is intriguing that some FPR agonists have dual roles in inflammatory responses. Anx A1, also named lipocortin I, is a glucocorticoid-regulated, phosphorylated-binding protein possessing both proinflammatory and anti-inflammatory activity mediated in part by FPR1. Expressed in a variety of cell types, Anx A1 is particularly abundant in neutrophils where it is located on the outer cell surface and serves to inhibit neutrophil transendothelial migration. At low

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

concentrations, Anx A1 and its N-terminal peptides (Ac2–26 and Ac9–25) elicit Ca^{2+} transients through FPR1 to desensitize neutrophils and inhibit its transendothelial migration induced by the chemokine IL-8 (CXCL8).[32] At high concentrations, the Anx A1 peptides activate neutrophils as potent proinflammatory stimulants. The antimigratory activity of exogenous and endogenous Anx A1 has been shown in both acute and chronic models of inflammation. More recent studies revealed that Anx A1 peptides may also use FPR2 and, to a lesser extent, FPR3, suggesting a complex role for FPRs in Anx A1–mediated regulation of host responses. In addition to neutrophils, Anx A1 also regulates T cell receptor[30] signaling. Stimulation of T cells via TCR leads to the secretion of endogenous Anx A1 and a simultaneous externalization of its receptor FPR2 on the plasma membrane, highlighting a "coordinated" signaling of "Anx A1_FPR" system.[5] In the presence of Anx A1, naive T cells differentiate toward Th1 cells, whereas Anx-A1-deficient T cells produce high levels of Th2 cytokines.[5,7] Also, in Anx A1-deficient T cells, the production of IL-17 as well as FPR2 signaling is impaired during differentiation in Th17-skewing conditions.[6] In addition, tumor growth and metastasis are markedly decreased in Anx A1-KO mice, whereas the survival and tumor necrosis are significantly increased, due to impaired angiogenesis.[33] These observations demonstrate a complex role of Anx A1 and FPR2 in multiple pathophysiological processes.

Frog Skin Peptides (see Amphibian/Skin Peptides Section of this Book)

Temporin A (TA) is a frog-derived antimicrobial peptide that was found to induce the migration of human monocytes, neutrophils, and macrophages.[32] Characterization of the signaling characteristics of TA in monocytes and the use of receptor transfected HEK293 epithelial cell line revealed that this peptide uses FPR2 as a receptor. TA is also chemotactic *in vivo*, because it elicited infiltration of neutrophils and monocytes into the injection site in mice. Another temporin peptide Rana-6 is chemotactic for human phagocytes also by using FPR2. Thus, frog-derived temporins have the capacity to chemoattract phagocytes through human FPR2 and the mouse homolog mFPR2, suggesting the participation of amphibian antimicrobial peptides in host innate immunity. Because the expression of FPR homolog(s) has not been reported in species other than mammals, it will be interesting to clarify whether such receptor exists in amphibians and other species such as insects, which normally rely on the secretion of antimicrobial peptides as a natural host defense.[3]

Other Host-Derived Peptides

It is important that highly efficacious agonist peptide for FPR3 has been isolated from spleen extracts. F2L, an acetylated amino-terminal 21-amino acid peptide, is derived from the cleavage of the human heme-binding protein, an intracellular tetrapyrolle-binding protein. F2L chemoattracts and activates monocyte-derived DCs, thus seems to be a novel and unique natural chemoattractant peptide for FPR3 in DCs and monocytes, in agreement with the selective expression of FPR3 in these cells,[32] suggesting its role in linking innate and adaptive immune responses by activating antigen-presenting $FPR3^{+}$ DCs, which express reduced levels of FPR1 and FPR2. In mice, mouse F2L activates neutrophils by using mFPR2, a homolog of human FPR2, because neutrophils from $mFPR2^{-/-}$ mice lost all responsiveness to F2L. These results suggest that mFPR2 in mice is likely a homolog of both human FPR2 and FPR3.[2]

Agonists from Peptide Library

Random small peptide libraries are rich sources of FPR agonists and have yielded a number of potent chemotactic stimulants for leukocytes. For instance, WKYMVm, a hexapeptide representing a modified sequence isolated from a random peptide library, was initially reported to be an efficacious stimulant of human B lymphocytes, monocytic cell lines, as well as peripheral blood neutrophils. It was subsequently found that WKYMVm uses both FPR1 and FPR2, and is by far the most potent peptide agonist for FPR2 to chemoattract and activate human phagocytic cells.[32] The WKYMVm analog, produced by converting the D-amino acid methionine at the C-terminus into to an L-amino acid, becomes a more selective agonist of FPR2 and also a weaker activator of FPR3.[3] Another peptide, MMK-1, which is also derived from a random peptide library, is a potent and very selective chemotactic agonist for FPR2. Although FPR agonists identified in random peptide libraries seem not to be pathophysiologically relevant to diseases, they nevertheless constitute useful pharmacological tools for the studies of FPR signaling pathways, structural basis of the ligands versus receptors, and identification of receptor antagonists that could be valuable in conditions resulted from receptor overactivation.

Nonpeptides

Host-derived Nonpeptide FPR Agonists

LXA4, biosynthesized from arachidonic acid metabolism, is the first described endogenous lipid ligand for FPR2. However, despite the original observation of LXA4 being a chemotactic agonist for FPR2, this lipid metabolite has been shown to mainly exert inhibitory activities on a variety of inflammatory responses. LXA4 inhibits the production of inflammatory cytokines by epithelial cell lines in response to TNFα and LPS, while it simulates the expression of the anti-inflammatory cytokine IL-10.[32] In DCs, LXA4/ATL activates the suppressor of cytokine signaling (SOCS)-2 and

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

in T cells, LXA4 attenuates TNFα release by impairing ERK signaling.[32] LXA4 also prevents renal fibrosis by inhibiting PDGF-induced TGF-β production in mesangial cells.[32] In addition, LXA4 attenuates inflammation-induced pain and displays proresolution properties in various disease models, including dermal inflammation, ischemia/reperfusion injury, peritonitis, colitis, cystic fibrosis, asthma, parasitic infection and glomerulonephritis.[32] The multiplicity of the anti-inflammatory activity of LXA4 raises the question of how this lipid mediator shares FPR2 with other peptide agonists that trigger a proinflammatory signaling pathway. One plausible explanation was that LXA4 binds to an FPR2 domain, which is different from the domains utilized by peptide agonists. However, because LXA4 has been reported to interact with multiple receptors depending on the cell types, it remains to be clarified whether the biological function of LXA4 is the consequence of interaction with more than one receptor.

Agonists from Small Compound Library

In addition to recognizing peptide agonists and the lipid agonist LXA4, nonpeptide small compounds may also be recognized by FPRs. For instance, a quinazolinone derivative Quin-C1 was reported as a highly selective agonist for FPR2.[32] High-throughput screening of compound library has yielded compound 43 that reduces inflammation in an ear swelling model in mice through FPR2, but it was later shown as a preferential agonist for FPR1 that activates neutrophils.[14] In addition, AG-14 was found to activate neutrophils by using FPR1.[32] Compounds 1 and 2, arylcarboxylic acid hydrazide derivatives, are agonists for FPR2 that induce the production of TNFα by macrophages.[32]

Others

PD168368 and PD176252, antagonists of gastrin-releasing peptide/neuromedin B receptors (BB1/BB2), are potent agonists of both FPR1 and FPR2.[26] Their Trp-and Phe-based analogs and related nonpeptide/nonpeptoid analogs are also agonists of FPRs.[26] In addition, the cholecystokinin-1 receptor agonist A-71623 activates both FPR1 and FPR2.[26] These physiologically relevant nonpeptide agonists for FPRs may contribute to the regulation of inflammation and immune responses. The similarities and divergence of their binding domains in FPRs and signal transduction pathways as compared with that of peptide agonists will be of great pathophysiological and pharmacological interests.

FPR ANTAGONISTS

The importance of FPRs in microbial infection and host immune responses suggests that these GPCRs may be targets of pharmacological intervention to attenuate complications associated with undesirable receptor overactivation. This consideration leads to the search and development of FPR antagonists, which have yielded many molecules as listed in Table 2.

Microbial FPR Antagonists

Cyclosporin H (CsH) produced by a fungus is an inverse agonist (negative antagonist) that suppresses the constitutive activity of FPR1.[19] Similar to CsH, CsA also inhibits fMLF-induced neutrophil degranulation and cell activation, although the inhibitory effect is less potent than CsH. FPR2-inhibitor protein (FLIPr), a staphylococcal anti-inflammatory protein, directly binds to FPR1 and FPR2 and attenuates fMLF-induced cell activation.[32] At low concentrations, FLIPr selectively inhibits the binding of some FPR2 agonists including MMK-1, WKYMVM, PrP (106–126), and $A\beta_{42}$. At high concentrations, it reduces fMLF binding to FPR1.[32] Iodinated chemotaxis inhibitory protein of *S. aureus* (CHIPS) is a potent peptide antagonist of FPR1.[32] LDLLDL is an immunosuppressive hexapeptide derived from retroviral trans-membrane envelope protein p15E and is a specific FPR1 antagonist.[20] Peptides derived from the membrane proximal region of fusion proteins from HIV 1 and 2, Coronavirus 229 E, severe acute respiratory syndrome (SARS) coronavirus and Ebola virus are all potent antagonists of FPR1.[32] These observations suggest the capacity of microbia to produce molecules that inhibit FPR-mediated function of host cells that are directly involved in antimicrobial responses.

Host-derived Antagonists

Several "endogenous" FPR antagonists have been reported. Deoxycholic acid (DCA) and chenodeoxycholic acid (CDCA) identified as antagonists for FPR1 with unclear pathophysiological significance. CDCA also partially inhibits FPR2 agonist-induced myeloid cell activation. Spinorphin (LVVYPWT), which belongs to the family of hemorphins, is a peptide antagonist for FPR1.[32] In addition, Quin-C7, a synthetic nonpeptide compound, is a highly selective antagonist for FPR2. Interestingly, Quin-C7 is derived from FPR2 agonist Quin-C1 through chemical modification.[32]

Synthetic Peptide Antagonists

Boc1 (t-Boc-MLF) and Boc2 (t-Boc-FLFLF) were originally found as antagonists for FPR1.[11] However, a recent study shows that at low micromolar concentrations, both Boc1 and Boc2 are selective for FPR1; at high micromolar concentrations, Boc2 also partially inhibits the function of FPR2.[32] The WRW4 obtained from hexapeptide library is a more selective antagonist for FPR2.[29] Further, a cell permeable peptide PBP10, which is derived from a PIP2-binding

TABLE 2 FPR Antagonists

Antagonists	Origin	Receptors
Microbial antagonists		
Chemotaxis inhibitory protein of *S. aureus* (CHIPS)	*Staphylococcus aureus*	FPR1
FPRL1-inhibitor protein (FLIPr)	*Staphylococcus aureus*	FPR1, FPR2
Cyclosporin A (CsA)	Fungi	FPR1
Cyclosporin H (CsH)	Fungi	FPR1
HKU coronavirus peptides	Coronavirus	FPR1
Coronavirus 229E peptides	Coronavirus	FPR1
SARS coronavirus peptides	Coronavirus	FPR1
HIV-1 peptides	HIV-1	FPR1
HIV-2 peptides	HIV-2	FPR1
Ebola peptide	Ebola virus	FPR1
LDLLDL	Retrovirus	FPR1
Synthetic peptide antagonists		
i-Boc-MLF	Synthetic peptide	FPR1
t-Boc-MLF (Boc1)	Synthetic peptide	FPR1
t-Boc-FLFLF (Boc2)	Synthetic peptide	FPR1, FPR2
Trp-Arg-Trp-Trp-Trp-Trp (WRW4)	Random peptide library	FPR1
PBP10	Gelsolin	FPR2
Host-derived antagonists		
Spinorphin	Bovine spinal cord	FPR1
Chenodeoxycholic acid (CDCA)	Endogenous (bile acid)	FPR1, FPR2
Deoxycholic acid (DCA)	Endogenous (bile acid)	FPR1
Others		
Piroxicam	Nonsteroid anti-inflammatory drugs (NSDAIDs)	FPR1
SDS	Amphiphile	FPR1

domain of the cytoskeleton protein gelsolin, displays FPR2 antagonist activity by its ability to penetrate cell membrane to act on the intracellular domains in FPR2.[13]

Other Antagonists

The nonsteroidal anti-inflammatory drug (NSDAID) piroxicam, a nonselective cyclooxygenase (COX)-inhibitor, can reduce neutrophil superoxide production induced by FPR1 agonists but had no significant effect on FPR2-mediated responses. However, piroxicam inhibits WKYMVm-induced neutrophil intracellular calcium mobilization and superoxide release when the drug was combined with the FPR2 specific antagonist WRW4.[32] The inhibitory effect of piroxicam is dependent on its binding to the receptor, therefore seems to be FPR specific.

PERSPECTIVES

In this chapter, we attempted to provide a comprehensive overview of FPR ligands including agonists and antagonists. It is now clear that FPRs play important roles in the regulation of inflammatory and immune responses. The process of understanding of the biological roles of FPRs has been

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

considerably prompted by the identification of a variety of ligands from different sources, in particular, from microbes and human. In addition to the evidence that the FPRs are involved in antimicrobial defense and inflammation, they are also implicated in the progression of cancer. For example, FPR1 is selectively expressed by highly malignant human glioma cells and increases the motility, growth, and angiogenesis of human glioblastoma by interacting with host-derived agonist(s) released by necrotic tumor cells.[35] An effort to identify potential FPR1 agonist(s) in glioma cell supernatant revealed Anx A1 as a major component.[31] Therefore, FPR1 and Anx A1 axis may constitute targets for novel antiglioma therapy. Human FPR2 is also expressed in astrocytoma cell line,[9] hepatocellar carcinoma,[23] and breast cancer[17] with yet unclear pathophysiological implications.

It is intriguing that FPR1 and FPR2 exhibit a promiscuity to interact with a broad range of ligands that do not share significant primary or tertiary structure similarities. How a single FPR could bind such a diverse array of ligands, from small peptides to nonpeptide compounds, remains to be elucidated, possibly through classical receptor chimera approaches and site-directed mutagenesis. Further investigation should not only benefit better understanding of the role of FPRs and their ligands in disease states but also the identification of pharmacological targets for the development of therapeutic agents.

Chapter 92

Neuroimmune Peptides

Ning Zhang, Hua Geng and Joost J. Oppenheim

ABSTRACT

Increasing evidence has shown that many neuropeptides modulate immune responses in addition to their well-documented function in the central and peripheral nervous systems. Surprisingly, RT-PCR, Western blotting, and functional assays reveal the production of these neuropeptides by the immune system and the expression of their receptors on leukocyte surface. This chapter will provide a brief summary of the immunological activities of neuropeptides.

INTRODUCTION

The nervous and immune systems are tightly integrated and orchestrated to serve the complicated tasks of host sensation and response. A disturbance in one system often has a profound effect on the other. For example, activation of the hypothalamic–pituitary–adrenal (HPA) axis by long-term stress often elicits suppression of both innate and adaptive immunities.[6] Conversely, inflammatory immune responses activate central nervous system sensory pain pathways.[34,35] Increasing evidence suggests that a family of immunoactive neuropeptides provides key signals between these two systems. Beyond their well-characterized effects in the nervous system, these neuropeptides also interact with their receptors on leukocytes, thus modulating the function of these pivotal mediators of host defense. Further, leukocytes are also capable of producing many of these peptides in the peripheral immune system. The structure, properties, and roles of neuropeptides in the central and peripheral nervous systems are discussed in other chapters of this book. This section will briefly describe the immunological effects of these neuropeptides as summarized in Table 1. Other actions of these peptides are discussed elsewhere in this book.

Neuropeptides influence host immune defenses based on two mechanisms. First, these peptides indirectly regulate the immune response by acting on the different axis of the central nervous system. For example, Met-enkephalin, an endogenous opioid, stimulates the HPA-axis-mediated production of corticosterone, a potent immunosuppressive hormone.[19] Opioids also activate the sympathetic nervous system, resulting in an increase in the level of circulating epinephrine from the adrenal medulla and secretion of the norepinephrine by sympathetic nerve terminals. Increased catecholamine levels have been linked to the suppression of natural killer cell and lymphocyte function. Second, all the peptides listed in Table 1 are able to directly regulate the functions of receptor expressing leukocytes, independent of their neuronal activities. Studies using reverse transcription-polymerase chain reaction (RT-PCR) or western blotting analysis reveal the expression of a wide variety of neuropeptide receptors on various types of leukocytes. For example, all three subtypes of opioid receptors, μ-, δ-, and κ-receptors, have been detected on T cell, B cells, monocytes, neutrophils, and natural killer cells.[23] Stimulation of these neuropeptide receptors can modulate leukocyte production of proinflammatory cytokines. Interestingly, most neuropeptide receptors are seven-transmembrane domain-containing receptors, which exert their function by activating heterotrimeric G proteins.

Neuropeptides are mainly expressed and active in the central and peripheral nervous systems. However, these peptides can also be unexpectedly produced and are functional in other peripheral tissues. For example, adrenocorticotropic hormone/corticotropin (ACTH) is not only produced by pituitary cells but also to a limited extent by leukocytes.[2] Endogenous opioids are expressed by leukocytes and play an important role in peripheral analgesic effects.[29] In addition to being produced in the pituitary gland, α-melanocyte-stimulating hormones (αMSH) are also highly expressed in the skin and the gastro intestinal (GI) tract cells.[21] Substance P mRNA and protein have been detected in the thymic medulla and purified CD5+ thymocytes.[27]

The neuropeptides of the HPA axis play a profound role in inflammation. Stressful stimuli activate the HPA axis through the release of a sequential series of neuropeptide hormones, beginning with the production of hypothalamic corticotropin-releasing hormone (CRH) and followed by pituitary derived ACTH, culminating in the secretion of glucocorticoids, potent anti-inflammatory hormones produced by the adrenal cortex.[6] Vasopressin (AVP) potentiates

TABLE 1 Neuropeptides Regulating Receptor Expressing Leukocytes

Neuropeptides	Size	Receptors in immune system	Immune effects	Nonimmune effects
CRH	41aa	Neutrophils, eosinophils, thymus, spleen	Enhances the production of immunosuppresive glucocorticoids through the HPA axis, enhances peripheral inflammation. Urocortin (Ucn), UcnI, and UcnII share similar properties.	Endocrine-signaling peptide involved in the stress response
Urocortin (Ucn)	40aa	Monocytes, macrophages, dendritic cells, polymorphonuclear cells, T cells	Inhibits inflammatory cytokines and chemokines production, T cell proliferation, and TH1 response; enhances IL-10/transforming growth factor (TGF)-β1 production; induces regulatory T cells.	Regulates vasodilatation, bronchodilatation, cardiac output, smooth muscle relaxation, food intake, and ACTH secretion.
Somatostatin	14aa, or 28aa	T cells, monocytes	Inhibits the secretion of proinflammatory cytokines and antibodies by immune cells; inhibits lymphocyte proliferation.	Inhibits secretion of numerous growth hormones.
Cortistatin	17aa	Monocytes, macrophages, dendritic cells, T cells	Inhibits inflammatory cytokines and chemokines production, T cell proliferation, and TH1 response; induces regulatory T cells.	Inhibits locomotor activity, regulates growth hormone.
Vasopressin (AVP)	9aa	T cells, B cells, monocytes	Enhances production of immunosuppresive glucocorticoids through the HPA axis, enhances secretion of IFN-γ by T-cells.	Potentiates CRH effects, responds to osmotic and hemodynamic stress.
Gastrin-releasing peptides (GRP)	27aa	Macrophage, T cells, natural killer cells	Stimulates phagocytic activities of macrophages, inhibits Con-A induced proliferation of lymphocytes. Bombesin and neuromedin C share similar properties.	Activates the sympathetic nervous system to modulate stress, fear, and anxiety responses.
Met-enkephalin and endorphins	5aa	T cell, B cells monocytes, neutrophils, natural killer cells	Induces heterologous desensitization of chemokine receptors, inhibits natural killer cell activity, suppresses IL2 and IFNγ production.	Analgesic peptides, induces the secretion of corticosterone.
ACTH	39aa	T helper cells, B cells, macrophages	Enhances production of immunosuppresive glucocorticoids through the HPA axis.	Endocrine-signaling peptides involved in the response to stress.
αMSH (melanocortin)	13aa	Monocytes, macrophages, natural killer cells, T helper cells, B cells, and dendritic cells	Downregulates the production of proinflammatory cytokines, downregulates the expression of costimulatory molecules (CD86, CD40, ICAM-1) on antigen-presenting dendritic cells, upregulates IL-10. inhibits cutaneous inflammation, inhibits T cell proliferation, and induces regulatory T cells.	Regulation of energy homeostasis.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY

Copyright Elsevier 2024

Neuropeptide Y	36aa	Monocytes, T cells, B cells, natural killer cells	Elicits neurogenic inflammation by inducing the secretion of substance P, contributes to colitis, potentiates paw edema; enhances T cell adhesion to fibronectin; increases release of oxidative reagents by neutrophils, suppresses NK cell activity; enhances phagocytosis by monocyte.	Regulates energy balance, food intake, and antihyperalgesia, antimicrobial peptide, affects skin color, antipyretic effects.
VIP/PACAP	28aa	T cells, mast cells, macrophages, monocytes, dentritic cells, polymorphonuclear cells	Inhibits leukocyte recruitment, cytokine production; polarizes TH2 responses, induces T lymphocyte adhesion and chemotaxis, inhibits TH1 response and recruitment, enhances tolerogenic DC generation. PACAP possesses similar anti-inflammatory activities.	Neurotransmitter, secretagogue, neuroprotective, neurotrophic, and vasodilator.
Substance P (neurokinin1, tachykinin 1)	11aa	T cells, macrophages, dendritic cells	Contributes to neurogenic inflammation, involves in various respiratory diseases and pancreatitis. Substance K (neurokinin A) possesses similar proinflammatory activities.	Induces hyperalgesia
CGRP	37aa	T cells, B cells, dendritic cells	Contributes to neurogenic inflammation, involves in various aspiratory diseases.	Induces vasodilatation
Bradykinin	9aa	Monocytes, neutrophils, eosinophils, T cells	Induces chemotaxis of neutrophils, stimulates the secretion of superoxide radicals, exacerbates infection, contributes to ischemia reperfusion, involved in respiratory diseases.	Induces hyperalgesia; vasodilator.
Adrenomedullin (AM)	52aa	Monocytes, macrophages	Inhibits inflammatory cytokines and chemokine production, T cell proliferation, and TH1 response; induces regulatory T cells; Stimulates IL-10/TGF-β production.	Regulates vasodilatation, bronchodilatation, cardiac output, and smooth muscle relaxation.
Ghrelin	28aa	Monocytes, macrophages, dendritic cells, T cells	Inhibits inflammatory cytokines and chemokine production; suppresses T cell proliferation, and TH1 response (IL-2 and IFN-γ production); induces regulatory T cells	Regulates cardiac output, appetite, adiposity, vasodilatation; enhances GI secretion, and gastric motility.

CRH: corticotropin-releasing hormone; αMSH: alpha-melanocyte-stimulating hormone; ACTH: adrenocorticotropic hormone/corticotropin; CGRP: calcitonin-gene-related peptide; VIP: vasoactive intestinal polypeptide.

Copyright Elsevier 2024

the capacity of CRH to activate the HPA axis. The resultant elevated glucocorticoid concentrations in the circulation contribute to stress-induced immunosuppression. Surprisingly, CRH and AVP are also produced by leukocytes, and their receptors are expressed by leukocytes. Although hypothalamic CRH and AVP have indirect anti-inflammatory effects through the stimulation of glucocorticoids, these peptides seem to have direct proinflammatory effects in the peripheral tissues. AVP stimulates the secretion of interferon-γ by T-lymphocytes.[18] CRH elicits the production of interleukin (IL)-1 by human monocytes and enhances mouse *natural killer* (NK) cell activity.[5] CRH and its family members, urocortin (Ucn), UcnI, and UcnII have been shown to exacerbate symptoms of experimental autoimmune encephalomyelitis and toxin A-induced inflammatory diarrhea.[1] The expression of Ucn is upregulated during inflammation.[17] Ucn induces apoptosis of macrophage during inflammation, suggesting its important anti-inflammatory effect.[31] Regarding innate immunity, Ucn inhibits the production of several proinflammatory cytokines, such as *tumor necrosis factor* (TNF)α, IL-6, and IL-12, and further *in vivo* disease-associated (i.e. sepsis and inflammatory bowel disease) studies support the anti-inflammatory role of Ucn.[14] Thus, their antagonists have been tested as therapeutics for arthritis and preliminary results are encouraging.[33]

Inflammation induces hyperalgesia. This is in part attributable to the chemokine receptor-induced desensitization of analgesic opioid receptors and concomitant sensitization of algesic vanilloid receptors transient receptor potential vanilloid (TRPV)1 on neurons.[34,35] Conversely, opioid receptors on leukocytes have immunosuppressive effects. Met-enkephalin, an endogenous opioid, is an analgesic peptide of 5 amino acids.[3] It exerts immunosuppressive effects by heterologous desensitization of chemokine receptors and enhancing the secretion of corticosteroids.[23] TRPV1 is also expressed by leukocytes, but its immune function remains unknown.

Painful stimuli activate peripheral neurons to release several immunostimulatory peptides, including substance P and calcitonin-gene-related peptide (CGRP). These peptides have proinflammatory effects and are associated with neurogenic inflammation. Substance P, a hyperalgesic peptide, belongs to the tachykinin family. It stimulates the influx of neutrophils and eosinophils into the human dermis, induces the secretion of TNFα by macrophages, and it enhances leukocyte adhesion to endothelial cells, which may contribute to its proinflammatory effects in various respiratory diseases, pancreatitis, and inflammatory bowel disease.[24] Substance K, another peptide in the tachykinin family, possesses similar proinflammatory effects. CGRP is also involved in neurogenic respiratory diseases such as asthma, chronic obstructive pulmonary disease, or chronic cough.[28] Adrenomedullin (AM) could function as an endogenous anti-inflammatory immune modulator with a high structural homology to CGRP.[11] Unlike CGRP, AM could effectively prevent arthritis and sepsis through inhibiting the inflammatory response in these autoimmune/inflammatory diseases.[12,14] Neuropeptide Y (NPY), a key peptide regulating energy balance and food intake in *central nervous system* (CNS), also induces the secretion of substance P by peripheral neurons, contributing to colitis and paw edema in animal models of inflammation.[10] Further, NPY directly enhances T cell adhesion to fibronectin[20] and plays a major role in the regulation of Th1 responses.[26] Bradykinin, another hyperalgesic peptide, facilitates septic shock, exacerbates ischemia reperfusion, and enhances airway inflammation based on its vasodilatory effects.[4]

There several other neuropeptides that downregulate immune responses. Vasoactive intestinal polypeptide (VIP) has immunosuppressive effects based on its capacity to inhibit leukocyte recruitment to inflammatory sites. VIP also induces polarization to the T helper (TH)2 type of antibody-based allergic responses.[25] In addition, VIP induces the differentiation of tolerogenic dentritic cells that promote generation of antigen specific Treg cells.[15] αMSH downregulates the production of proinflammatory cytokines, inhibits the expression of costimulatory molecules (CD86, CD40, and intercellular adhesion molecule (ICAM)-1) on dendritic cells, and upregulates IL-10, resulting in immunosuppression.[22] An increasing body of evidence shows that VIP and αMSH could regulate TH1/TH2/Treg immune homeostasis and induce immune tolerance and inhibit autoimmune response through inhibiting the production of inflammatory cytokines and chemokines, polarizing the differentiation of T cells toward TH2 or Treg, and suppressing the activation of autoreactive T cells by IL-10 and TGFβ.[11,13] Moreover, both VIP and αMSH inhibit phagocytic activity as well as the migration and adherence of macrophages and neutrophils.[9] Ghrelin is one of the anti-inflammatory neuropeptides with an immunomodulatory role through binding to its receptor *growth hormone secretagog receptor* (GHSR), and subsequently activating the cyclic adenosine monophosphate-protein kinase A signaling pathway that is associated with anti-inflammatory actions.[13] Somatostatin inhibits the secretion of interferons (IFN)-γ and *cerebrospinal fluid*, enhances the secretion of IL-10 and IL-4, downregulates the secretion of antibodies by B lymphocytes, and impairs lymphocyte proliferation.[30] Cortistatin has a strong structural similarity to somatostatin. Cortistatin is expressed in various immune cells, including monocytes, macrophages, lymphocytes, and dentritic cells, with its expression upregulated on cell differentiation and activation, suggesting that cortistatin may act as a major immune regulator.[11] In addition, both *in vitro* and *in vivo* studies show that cortistatin functions more efficiently than somatostatin in its anti-inflammatory responses, probably because of the capacity

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

of cortistatin to activate different receptors and signaling pathways.[7,16] Cortistatin cannot only bind to somatostatin receptor subtypes (SSTs), but also to GHSR, thus leading to the activation of both cAMP-independent (SST mediated) and -dependent (GHSR-mediated) signaling.[13,32] Gastrin-releasing peptide (GRP) and neuromedin C belong to the bombesin peptide family. They stimulate phagocytic activities of macrophages but inhibit concanavalin-A induced proliferation of lymphocytes.[8]

In summary, increasing evidence has confirmed the production of neuropeptides and the expression of their receptors by cells of the immune system. Further, neuropeptides directly contribute to a wide range of diseases, such as stress-induced immunosuppresion, asthma, and inflammatory bowel disease. However, many more studies are needed to connect *in vitro* observations, based on the use of isolated leukocytes, to the *in vivo* systemic effects of neuropeptides in disease. Further, it is critical to understand that the anatomical and temporal distribution of these peptides may determine their overall effects on immune responses. For example, CRH acts as an anti-inflammatory agent when it exerts its effects in the CNS to stimulate the production of ACTH and then glucocorticoids. However, in the peripheral tissues, CRH is proinflammatory, and its antagonists can be used to treat arthritis in animal models. Experiments from various animal models with knockout of VIP, AM, VIP/PACAP receptors, or Ucn result in endotoxemia and lung inflammation as well as Th1-mediated responses *in vivo*, and further highlight the physiological relevance of these neuroimmune peptides in certain inflammatory and autoimmune conditions. In summary, a broad range of neuropeptides is capable of influencing immune responses. They may serve to integrate a host's immune and nervous system response to injurious environmental stimuli. The physiological relevance of immunoregulatory activity of these neuropeptides needs further investigation.

Chapter 93

Peptide Loading of MHC

Melissa J. Call

ABSTRACT

The proteins of the major histocompatibility complex (MHC) are central to the ability of an organism to protect itself from foreign invasion, be it viral, bacterial, or parasitic. This "protection," unfortunately for many, also mediates transplant rejection and, when mistakenly directed, results in autoimmune pathology. The two classes of MHC molecules source peptides in different ways and use different strategies to promote peptide loading. This chapter focuses on how immunogenic peptides are generated and the molecules that mediate peptide loading onto MHC proteins.

INTRODUCTION

There are two main classes of MHC molecules that display peptide epitopes. Their roles in immunity are distinct and perhaps the simplest way to illustrate their function is to consider some of the roles each plays during the course of a viral infection. A viral infection begins when infectious viral particles penetrate protective barriers such as the skin or mucosal membranes. Once in contact with a cell that supports viral entry, invasion followed by viral replication within the cytoplasm can begin. Any given cell has many countermeasures available to respond to infection, but MHC-mediated responses are particularly important in efficient pathogen clearance and the generation of lasting immunity. In almost all cells of the body, MHC-class I molecules are constitutively expressed and loaded with peptides derived from proteins being synthesized and degraded within the cell, and thus, it is extremely challenging for a virus to replicate using host machinery without supplying viral peptides to the MHC-class I loading pathway. This provides an elegant system for cells to display a "snapshot" of the proteome at the cell surface for perusal by circulating lymphocytes. The role of $CD8^+$ T-cells is to lyse cells that show signs of infection through the display of foreign peptides on surface MHC-class I molecules. Although this drastic response is extremely effective in limiting viral replication, it also has the potential to create catastrophic tissue damage if inappropriately deployed, and therefore, $CD8^+$ T-cell responses are highly regulated. Before a $CD8^+$ T-cell can kill an infected cell it must first become activated in the lymph node by dendritic cells (DCs).

Conventional migratory DCs are found with high frequency in peripheral tissues near protective barriers to sense when these are disrupted and to direct T-cell responses accordingly.[33] These sentinels straddle the innate and adaptive immune responses. DCs in the periphery are highly phagocytic and responsive to innate "danger signals"[22] that warn of infection. Dying cells and virions are rich sources of antigen for DCs, and once activated by the danger signals, DCs undergo changes to initiate an immune response. They alter their chemokine and cytokine expression profiles, leading to the recruitment of other immune cells to the site of infection. They migrate to the draining lymph node and can pass antigen on to other specialized DC subsets that reside there or interact directly with a large population of naïve T-cells. Costimulatory molecules that are required for the productive stimulation of T-cells are upregulated. Antigen processing within the lysosomal pathway is also upregulated, as is MHC-class II, which is loaded with peptides from endocytic compartments before export to the cell surface. In a specialized mechanism of "crosspresentation" that occurs efficiently in certain DC subsets, the peptides from the phagocytic pathway are also loaded onto MHC-class I molecules. The end result of these processes yields a potent antigen-presenting cell that can present peptides to both $CD4^+$ and $CD8^+$ T-cells. Unlike $CD8^+$ T-cells, $CD4^+$ T-cells do not generally lyse the infected cells through direct cytotoxicity, but rather exert their important effects by directing the quality of the adaptive immune response. Through recognition of peptides displayed on MHC-class II molecules, $CD4^+$ T-cells provide positive feedback in the form of cytokines to the DC, enhancing its ability to provoke long-lived and sustainable activation from naïve $CD8^+$ T-cells, which then traffic to the site of infection to lyse infected cells. Activated $CD4^+$ T-cells also promote antibody producing B-cell activation[21] through recognition of MHC-class II-peptide complexes generated from processed antigen acquired through surface immunoglobulin receptors. Subsequent antibody class-switching and affinity maturation is critical to the ability of the host to generate sterilizing immunity.

Although this simplistic overview of some MHC-directed processes only touches on a few of the events required for viral clearance, it highlights the features of the MHC system that share critical information among the many cell types that must cooperate to generate a successful immune response. In this context, MHC-class I is available to all cell types to display fragments of proteins currently being synthesized within the cell, while MHC-class II is reserved for the "professional" antigen-presenting cells and endows them with the special ability to display foreign epitopes without being directly infected. DCs are the most efficient antigen-presenting cells and have the ability to transfer the peptides derived from extracellular antigens into the MHC-class I pathway, representing an important link in the crosstalk between MHC-class I and MHC-class II mediated responses. In the following sections, I will go into more detail on how the peptides that are presented by MHC-class I and MHC-class II are generated and the sources from which they are derived.

THE MHC LOCUS

The MHC locus, located on chromosome 6 in humans and chromosome 17 in mice, is a clustering of around 150 genes that are largely involved in immune regulation and encode many different proteins including both MHC-class I and MHC-class II molecules. In humans, the classical MHC-class I genes are extremely polymorphic and are encoded by HLA-A, HLA-B and HLA-C, the gene products of which dimerize with β2 microglobulin to form functional MHC-class I proteins. More than a thousand polymorphisms have been reported for each gene and many more will probably be found. There are currently 5400 distinct sequences reported for MHC-class I molecules. An individual possesses two alleles at each MHC-class I gene locus, one maternal and one paternal. Thus, an individual expresses up to six different classical MHC-class I gene products at the cell surface.

MHC-class II proteins are formed by hetero-dimerization of α- and β-chains. Humans have three classical MHC-class II proteins, HLA-DR, HLA-DP, and HLA-DQ. The most polymorphic gene encodes the HLA-DR β-chain and the products of this gene combine with an invariant α-chain to make HLA-DR molecules. In HLA-DP and HLA-DQ both chains are polymorphic. There are currently around 1600 alleles reported for MHC-class II α- and β-chains, although the number of productive combinations that can form functional proteins is more difficult to estimate. Discussion of the nomenclature and diversity of MHC molecules is complex and beyond the scope of this chapter, and the reader is directed to this reference for further information.[28]

MHC-CLASS I

The MHC-Class I Peptide-Binding Site

MHC-class I gene products are type I membrane proteins. Each has a short cytoplasmic sequence, transmembrane domain, a membrane-proximal immunoglobulin domain and a membrane-distal peptide-binding groove. This groove is formed by an eight-strand antiparallel β-pleated sheet "floor" supporting two α-helices that flank the bound peptide. The folded protein is joined by β2-microglobulin which assumes a membrane-proximal position next to the class I immunoglobulin domain, underneath the floor of the peptide-binding groove[2] (Fig. 1A).

The α-helices that line the MHC-class I peptide-binding groove are closely apposed at both ends and MHC-class I molecules are therefore only able to "comfortably" bind peptides of 8–10 amino acids in length. The peptide is maintained in an extended conformation through a series of interactions. The N- and C-termini of the peptide are bound through a conserved network of hydrogen bonds, and key "anchor" residues have their side-chains buried in pockets found along the peptide-binding groove (Fig. 1B). The interactions mediated by the N- and C-termini represent the bulk of the peptide-binding energy[4] and this sequence-independent feature allows MHC-class I to bind extremely diverse peptides (each allele is estimated to have the ability to bind many thousands of different sequences). The series of pockets in the floor of the peptide-binding groove (Fig. 1C) provide distinct chemical environments that favor certain residues over others, and the polymorphisms in MHC-class I are concentrated in these regions to endow each MHC allele with a unique peptide specificity.[10] These pockets place restrictions on size, charge, and polarity of anchor residues and can stabilize the peptides through hydrogen bonds, electrostatic interactions, hydrophobic packing, and van der Waals forces. Importantly, in most human MHC-class I alleles, the pocket that houses the peptide C-terminal residue favors hydrophobic residues and allows basic residues, but is incompatible with peptides that have an acidic residue at this position.

MHC-Class I Peptide-Loading Complex

MHC-class I proteins are directed to the endoplasmic reticulum (ER) on synthesis for folding and secretion to the cell surface. MHC-class I molecules are unable to reach the cell surface until they are loaded with peptide. Immediately after synthesis, MHC-class I heavy chain associates with calnexin, a molecular chaperone that resides in the ER (Fig. 2a). Calnexin is associated with ERp57, a protein thiol oxoreductase that influences disulfide bond formation in the nascent MHC-class I heavy chain. Through interaction with these proteins, the heavy chain is folded

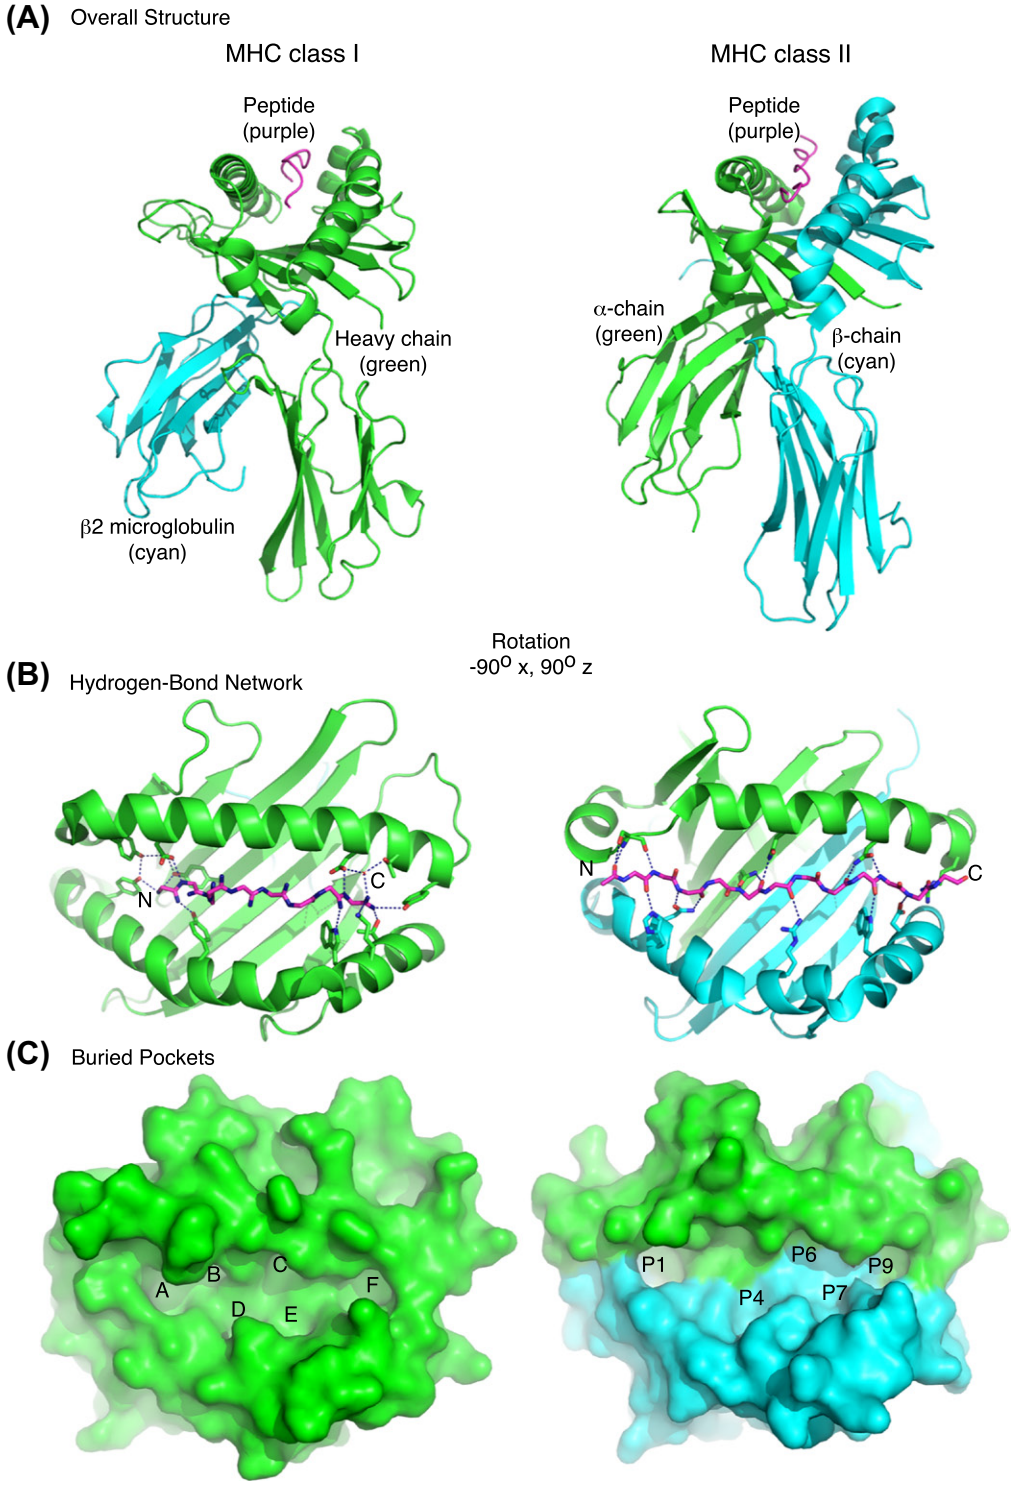

FIGURE 1 (A) Side view of MHC-class I (left) and MHC-class II (right) showing the peptide-binding site at the top and the membrane proximal immunoglobulin domains at the bottom. (B) Looking down on the peptide-binding site, which is formed by α-helices that flank the peptide and supported by an eight-strand β-sheet. Conserved hydrogen bonds that stabilize the peptide backbone are indicated as dashed lines in each structure. Note that in MHC-class II, the α- and β-chains together combine to form the groove, and peptide extends out of the peptide-binding site. The peptide N- and C-termini are indicated with N and C respectively. (C) The same view as (B), but in surface rendering with the peptide removed. The pockets that serve as anchor points for peptide side chains are labeled A–F for MHC-class I and P1–P9 for MHC-class II. PBD files 1S9Y and 1DLH were used to generate this figure. See color plate 23.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

allowing recruitment of β2-microglobulin, signaling that the MHC-class I molecule is ready for peptide loading (Fig. 2b). In humans, the folded MHC-class I – β2-microglobulin heterodimer then dissociates from calnexin and joins the peptide-loading complex containing calreticulin, transporter associated with antigen processing (TAP), tapasin, and ERp57 (Fig. 2c).[19] ERp57 is covalently linked to tapasin through a disulfide bond and this complex bridges the empty MHC heavy chain to TAP and calreticulin. In addition to its structural role in the peptide-loading complex, biochemical studies suggest that tapasin-ERp57 can modulate the quality of the peptide repertoire by favoring the loading of high-affinity peptides and promoting dissociation of prebound, low affinity peptides.[34]

TAP is an ATP-dependent transporter that delivers peptides from the cytosol to the ER lumen and comprises two

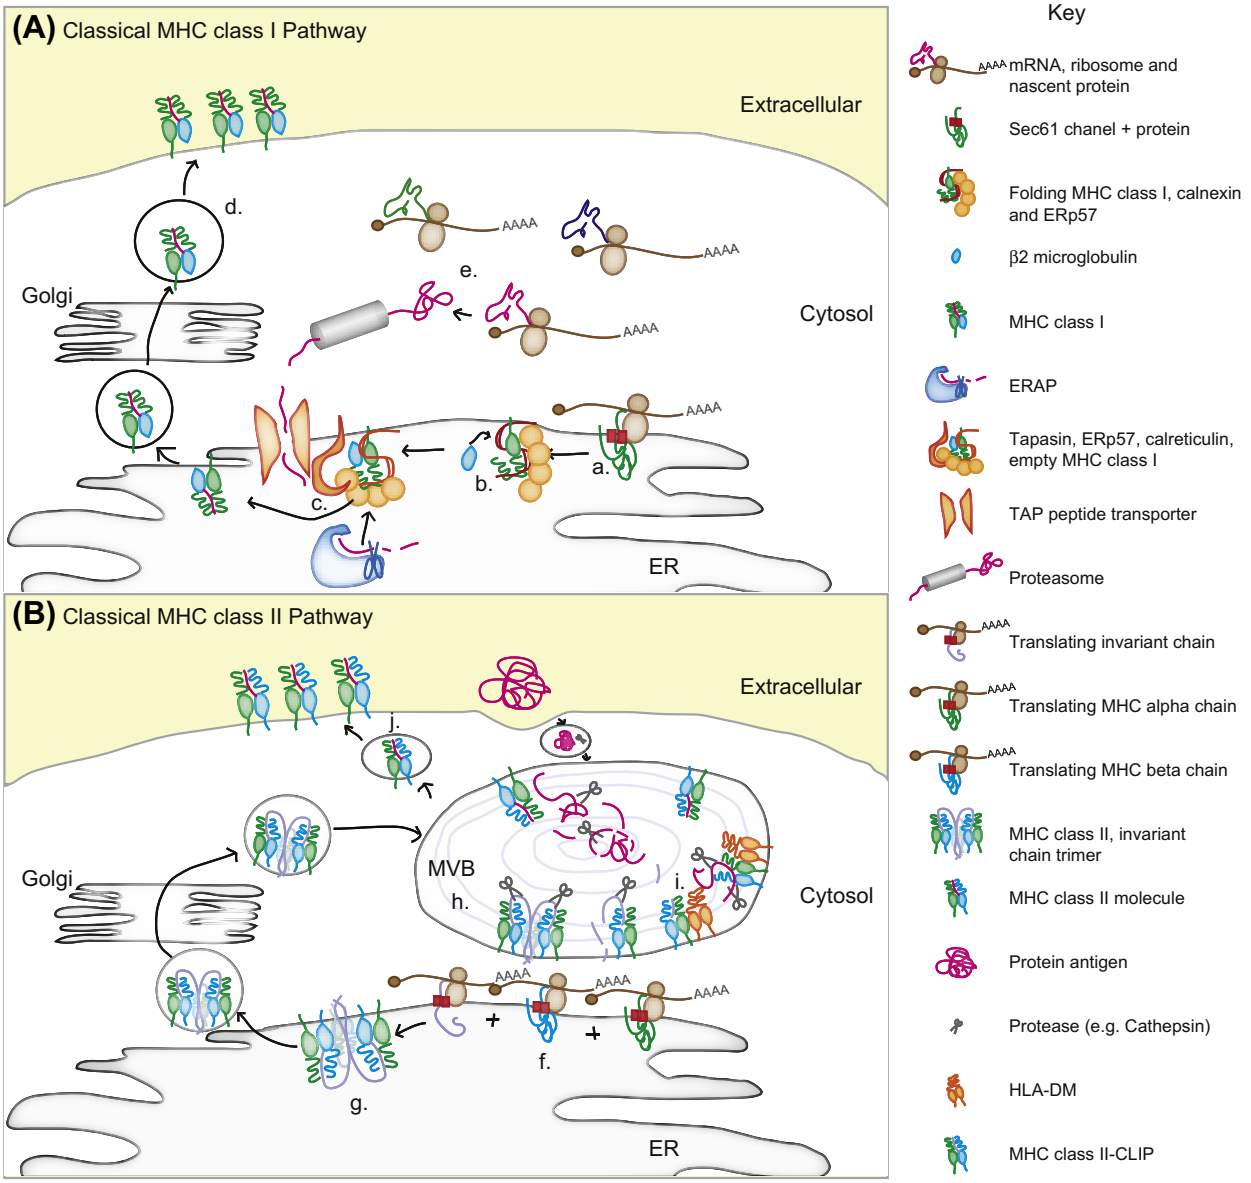

FIGURE 2 (A) MHC-class I heavy chains are synthesized in the ER (a) and then partially folded with assistance from calnexin and ERp57 (b). After β2 microglobulin joins the MHC-class I heavy chain the heterodimer is incorporated into the peptide-loading complex and loaded with peptides transported from the cytoplasm to the ER lumen by TAP and trimmed to the correct size by ERAP family proteases (c). Peptide-loaded MHC-class I is then transported via the Golgi to the cell surface (d). Proteasomes cleave proteins in to peptides, which can be selected by TAP for transport into the ER (e). (B) MHC-class II chains and invariant chain are synthesized in the ER (f) and fold together into a nonameric complex with 3 invariant chains, and 3 MHC-class II molecules (g). A region of the invariant chain (CLIP) occupies the peptide-binding groove of MHC-class II. This complex is exported via the Golgi to multivesicular bodies in the endocytic compartment (h). Proteolytic cleavage of invariant chain occurs to release MHC-class II molecules and allow HLA-DM mediated release of CLIP and replacement with peptides from endocytozed proteins (i). MHC-class II molecules are transported to the cell surface for display to CD4+ T-cells (j). See color plate 24.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

proteins, TAP1 and TAP2.[27] Like MHC-class I, TAP exhibits selectivity for peptides that have hydrophobic or basic C-terminal residues and are between 8 and 16 amino acids in length.[13] TAP has the ability to transport peptides that are longer than those preferred by MHC-class I, and proteases that trim the N-terminus are present in the ER lumen to ensure peptides of optimal length can be generated. In humans, ERAP1 and ERAP2 fulfill this role. Studies with ERAP1 have determined that this protease exhibits selectivity for peptides between 9 and 16 amino acids in length and displays little activity for peptides longer or shorter than this. A model has been proposed that suggests the peptide C-terminal residue is bound by ERAP1 in a pocket distinct from the active site and that the distance between these two sites determines the selectivity of ERAP1 for peptide length. If accurate, it would suggest that peptide trimming occurs before loading into MHC-class I.[20]

The Classical MHC-Class I Pathway

The source of peptides displayed by classical MHC-class I molecules and the pathways that generate them have been topics of intense research. Initially, it was assumed that peptides were simply "borrowed" from natural turnover processes, but because proteins often have half-lives of hours to days within a cell, the kinetics of this process did not seem to be congruous with the observation that viral peptides could be displayed by MHC-class I molecules in less than an hour after infection. Although natural turnover processes do account for some of the peptides displayed by MHC-class I, it is now thought that the bulk of peptides are acquired through the cleanup of incomplete synthesis products. Estimates indicate that up to 40% of the products generated by protein synthesis are rapidly degraded because of errors that might include early termination, misfolding, missplicing, and frameshift errors. Whether protein synthesis is simply a messy business or whether these errors are made specifically to generate peptides for the MHC-class I pathway is not known and remains a matter of debate.[9]

Proteins are targeted to the proteasome after becoming tagged with poly-ubiquitin chains, the reasons for which are diverse and include normal protein turnover, the destruction of improperly synthesized proteins described above, as well as regulatory proteins controlling cell cycle progression and intracellular signaling. The proteasome is a multisubunit complex[11] with a cylindrical catalytic core that is gated at each end by regulatory cap particles that are defined by their sedimentation values. The addition of the 19S regulatory caps to the 20S proteasomal core constitutes the 26S proteasome. Poly-ubiquitin chains of the proteins to be degraded are recognized by proteins in the 19S regulatory cap and, in an ATP-dependent process, ubiquitin is removed and the protein unwound to allow entry into the 20S proteasomal core. It is here that cleavage occurs, generating peptide fragments between 2 and 25 amino acids in length[18] (Fig. 2e). In humans the cylindrical 20S proteasomal core is made up of four heptameric rings. The alpha subunits, α1–-7, flank each end of the cylinder and form narrow openings that are modulated by the 19S regulatory cap. Sandwiched between the α rings are two antiparallel β rings made up of β1–β7 subunits.[11] Only three of these contain catalytically active sites, but between them they are able to cut after almost any amino acid: β5 is chymotrypsin-like, cleaving after bulky hydrophobic residues; β2 is trypsin-like and prefers to cleave after basic residues; and β1, which is caspase-like, cleaves after acidic and branched amino acids.

The pattern of cleavage for a particular protein is not random, and the same fragments are generated each time a protein is processed because the activity of the catalytic triad in each β subunit is sensitive to the sequence context around a cleavage site. The combination of limited time within the proteasome chamber and preferred sequences determining initial cleavage sites results in consistent, though difficult to predict, peptide products for any given protein. Peptides that are longer than seven amino acids in length are potential ligands for MHC-class I molecules, but most do not survive exposure to cytosolic proteases. A nine amino acid peptide in the cytosol has a half-life of less than 10 s, and therefore only peptides that are rapidly transported into the ER lumen have the opportunity to fold with MHC-class I heavy chains awaiting export to the cell surface.

The Immunoproteasome

Almost all cells in the body have the ability to express interferon (IFN) α/β in response to infection. This hallmark of stress, among others, is recognized by natural killer (NK) cells, which in turn secrete IFNγ. IFNγ has potent effects on antigen processing in both the MHC-class I and II pathways and is particularly important in antiviral responses.

Under normal cellular conditions, the proteasome is actually quite poor at generating peptides suitable for MHC-class I binding because most products are smaller than the minimal length required for ER import and MHC-class I loading. Additionally, all MHC-class I molecules studied to date prefer hydrophobic or basic anchors at the peptide C-terminus and acidic residues in particular seem to be excluded. This means that peptides generated by β1 cleavage, which occurs after acidic residues, are essentially lost from the MHC-class I repertoire. However, IFNγ exposure causes expression of three new β subunits, β1i, β2i, and β5i, which replace β1, β2, and β5 in the 20S proteasome catalytic core and all but eliminate the caspase-like activity. Thus most peptides processed by this alternative proteasome, termed the "immunoproteasome," contain suitable C-terminal anchor residues for MHC-class I binding. In addition to replacement of three β subunits, the immunoproteasome also uses an alternative regulatory cap known

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

as PA28, REG, or 11S Activator, which is IFNγ-inducible and significantly increases the maximal velocity of peptide hydrolysis compared with the normal 26S proteasome.[6] Interestingly, although the expression of the immunoproteasome is IFNγ dependent in most cell types, the alternative subunits are constitutively expressed in some cells of hematopoietic origin, including DCs and lymphoid cells, emphasizing their specialization for antigen processing and presentation. Mice lacking all three alternative catalytic subunits exhibited alterations in the MHC-class I peptide repertoire that were significant enough to cause the rejection of splenocytes transferred from wild type mice despite being matched at all MHC loci.[17]

A Specialized Thymic Proteasome

Within the thymus, the organ where T-cells reactive to the self are deleted to prevent autoimmunity, the cells that mediate this "negative selection" express both the proteasome and the immunoproteasome. Interestingly, there is a third "thymoproteasome" that uses an alternative β5 subunit in a distinct population of thymic stromal cells responsible for "positive selection," a process that ensures T-cells receive tonic stimulation by MHC for survival in the periphery. The thymoproteasome generates peptides that display significantly reduced affinity for MHC-class I, and it has been noted that mice deficient in this alternative β5 subunit have severe defects in positive selection.[26] The mechanism behind this observation is not yet understood, but it has been proposed that unstable MHC-class I peptide complexes may be somehow required for this process or that the thymoproteasome generates unique stimulatory peptides to drive positive selection.

Crosspresentation

MHC-class I is expressed ubiquitously and, for the most part, displays peptides derived from intracellular sources, with the notable exception of certain specialized cell types such as CD8αα$^+$ DCs that have the ability to load proteins derived from extracellular sources onto MHC-class I. This specialized pathway, termed crosspresentation, allows priming of cytotoxic CD8$^+$ T-cells by professional antigen-presenting cells that are not directly infected. Endocytic receptors seem to be critical regulators of crosspresentation, with antigens targeted to DEC205, for instance, being efficiently processed for MHC-class I loading, while those targeted to DCIR2 are not. Although it was initially assumed that these markers simply distinguished cells with different inherent abilities to crosspresent, follow-up experiments determined that introduction of DEC205 into the CD8$^-$ DC subset that does not normally cross-present, is sufficient to enable cross-presentation to occur.[16] The evidence suggests that crosspresentation is proteasome dependent, and therefore a mechanism by which antigen can escape the phagolysosome to reach the cytoplasm must exist. It is considered unlikely that antigens access the cytoplasm through permeabilized phagosomal membranes and research has instead focused on channels that have the ability to translocate proteins to the cytoplasm. The process of ER associated protein degradation (ERAD), which translocates misfolded proteins from the ER to the cytoplasm for degradation by the proteasome provides an attractive solution to this problem, but requires either the recruitment of ER membrane, or more controlled delivery of ERAD components to the phagosomal pathway. Once antigen has reached the cytoplasm it may intersect with the classical MHC-class I loading pathway, but evidence suggests that peptide loading during crosspresentation may actually occur in the phagocytic compartment itself, with the recruitment of proteasomes and peptide-loading machinery directly to the vesicles.[15] Although the mechanics of cross-presentation remain controversial, it is clear that this process is extremely important for CD8$^+$ T-cell function.

Nonclassical MHC-Class I

Although the products of the classical MHC-class I alleles HLA-A, -B, and -C have a crucial role in binding peptides for display to cytotoxic T-cells, the nonclassical HLA-E, -F, and -G alleles have more poorly defined roles. These proteins do bind peptide, but they are much less polymorphic than HLA-A, -B, and -C, and this is reflected in their restricted peptide repertoire. The best studied of these alleles is HLA-E, which is recognized by the CD94/NKG2 receptor system and seems to have a major role in regulating NK cell activity.[32] HLA-E primarily binds peptides that are derived from the signal sequences of other MHC-class I molecules and is believed to convey information about normal MHC biosynthesis to NK cells. NK cells are reactive to alterations in the MHC-class I pathway that are commonly caused by viral proteins evolved to inhibit MHC-mediated immune responses. Normal operation of the pathway results in peptide-loaded HLA-E binding to inhibitory receptors on NK cells and suppression of cytotoxicity, but loss of this signal in virally infected cells can trigger killing. In a striking evolutionary "tit-for-tat," human cytomegalovirus encodes a homolog of the MHC-class I leader peptide to maintain HLA-E at the cell surface while other virulence factors downregulate classical MHC-class I expression.[31]

MHC-CLASS II

MHC-Class II Peptide-Binding Site

Nascent MHC-class II molecules form from α- and β-chains that are assembled in the ER. Like the MHC-class I heavy chain, the β-chain forms a membrane-proximal immunoglobulin domain, but unlike its class I counterpart,

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

only contributes to half of the peptide-binding domain. The α-chain helps complete the peptide-binding domain and also contributes a membrane-proximal immunoglobulin domain so that, unlike MHC-class I, MHC-class II does not require β2 microglobulin (Fig. 1). Although the overall fold of MHC-class II molecules resembles that of MHC-class I, there are significant differences that endow these closely related structures with very different peptide-binding properties.[5] The peptide is accommodated in the groove in an extended conformation similar to that of a type II poly-proline helix and importantly, because the helices in MHC-class II molecules do not close together at each end of the peptide-binding groove as with MHC-class I proteins, MHC-class II molecules can bind much longer peptides. This means that polar contacts cannot always be made to free N- and C-termini of the peptide and interactions are instead dominated by a conserved network of hydrogen bonds to polar backbone atoms along the entire length of the peptide (Fig. 1B). Structural and biochemical studies indicate that the strongest binding energy is contributed by hydrogen bonds concentrated at the N-terminus of the bound peptide. These sequence-independent interactions are further complemented by anchoring pockets that, like MHC-class I, favor peptides with compatible amino acids (Fig. 1C). The register that any given peptide binds to MHC class II is defined by the residue that binds in the P1 pocket. The peptide residues are sequentially numbered in an N- to C-terminal direction. P1, P4, P6, and P9 residues interact with the major pockets in MHC, while P2, P5, and P8 are major TCR contact points. The P1 and P4 pockets of HLA-DR molecules contribute the most to peptide stability. A natural polymorphism at residue 86 of the HLA-DR β-chain influences the size of the P1 pocket. A glycine at this position provides a large pocket that can accommodate bulky hydrophobic residues while a valine at this position presents a shallower pocket that prefers smaller aliphatic residues.

Invariant Chain Processing and HLA-DM-Mediated Peptide Exchange

Each MHC-class II heterodimer assembles in the ER with the invariant chain, a trimeric chaperone that is exported through the Golgi and trans-Golgi network to intersect with the endosomal pathway in multivesicular antigen-processing compartments (Fig. 2f–h).[30] The invariant chain serves a number of purposes. A fragment of the invariant chain is embedded in the peptide-binding site to prevent opportunistic binding of proteins/peptides in the ER[29] and to stabilize the MHC-class II peptide-binding site, which is prone to collapse and aggregation if left unoccupied. The invariant chain cytoplasmic domain also contains trafficking signals that target MHC-class II to the appropriate subcellular location for peptide loading to occur.

As the invariant chain occupies the peptide-binding groove, it must be dislodged from MHC-class II to allow new peptide acquisition, and two important processes ensure that this is achieved. First, proteolytic degradation of invariant chain occurs which releases MHC-class II from all but the invariant-chain-derived fragment protecting the peptide-binding site. This fragment is termed CLIP and typically corresponds to residues approximately 80–105 depending on the fine mapping of protease cleavage sites. Degradation of invariant chain involves a number of proteases that are sensitive to the protease inhibitor leupeptin,[3] and although the complete pathway has not been elucidated, two proteases in particular play nonredundant roles in the latter steps of invariant chain processing: these are cathepsin S (in the periphery) and cathepsin L (in the thymus).[14] Attempts to identify proteases that have a nonredundant role in early steps of invariant chain processing have failed, and this no doubt reflects the susceptibility of the invariant chain to cleavage by multiple enzymes.

HLA-DM ensures that the protective CLIP peptide is then exchanged for exogenously derived peptides from the endocytic pool. HLA-DM is a heterodimeric MHC-class II protein that does not itself bind peptides.[23] HLA-DM resides in late endosomal compartments and is responsible for "editing" the peptide repertoire to promote formation of high-affinity complexes with very stably bound peptides. To achieve this, HLA-DM binds to MHC-class II molecules that contain suboptimal P1 anchor residues and stabilizes the empty groove to encourage bound peptides to leave and give new peptides access to sample the site. Peptides that supply optimal P1 anchor residues then cause HLA-DM to dissociate from MHC-class II and are protected from further editing by stable P1 interactions between peptide and MHC that block HLA-DM binding.[1] HLA-DM is negatively regulated by HLA-DO in a process that is thought to be mediated by competitive binding to HLA-DM in a way that prohibits interaction with MHC-class II complexes. HLA-DO expression depends on cell type and activation state, and is thought to be an important regulatory pathway in B-cells.[8]

Properties of CLIP

The CLIP peptide binds promiscuously to many MHC-class II alleles, albeit with widely variable affinity. For instance, the half-life of a MHC-class II allele that is associated with susceptibility to rheumatoid arthritis (DRB1*0401) in complex with CLIP is in the order of minutes, while another common allele (DRB1*0101) forms complexes that are stable for days. These differences in stability are unsurprising given that MHC-class II is highly polymorphic and those polymophisms are concentrated within the peptide-binding groove. In this context, perhaps what is more surprising is that there exists a single peptide that seems to interact

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

with most of the MHC-class II molecules. Only one crystal structure of an MHC-class II molecule in complex with CLIP has been determined. In this structure, methionine 90 of the invariant chain occupies the P1 pocket of the class II molecule HLA-DR3 (DRB1*0301). Almost all of the MHC-class II alleles analyzed thus far through mutagenesis studies appear to bind CLIP in this register, with the notable exceptions of two HLA-DQ alleles associated with celiac disease in which threonine 94 occupies the P1 pocket.[35] The peptide-binding site of MHC-class II molecules is open at each end, giving peptides the ability to shift register in the binding site. This, no doubt, allows different alleles to select different segments of the CLIP sequence according to variable motif preferences.

Generation of Peptides for MHC-Class II Loading

Antigen that is taken up by phagocytosis, receptor-mediated endocytosis or pinocytosis must traverse the endocytic pathway before loading onto MHC-class II molecules can be accomplished. The endocytic pathway has distinct compartments. Early endosomes are the principal sorting organelles where decisions are made as to whether molecules are exported back to the cell surface (recycling endosomes) or delivered to late endosomes. Early endosomes are mildly acidic and while MHC peptide complexes exhibit extraordinarily long half-lives, under acidic conditions peptide release is accelerated and therefore recycling endosomes are a possible site of peptide exchange. Late endosomes, however, are the principle location of MHC-class II loading (pH ~5.5) (Fig. 2h). There is some debate as to whether there are distinct late endosomes that are specialized for MHC-class II loading (typically referred to as MIIC) or whether the components required for loading are distributed throughout all late endosomes in antigen-presenting cells.[25] The final destination in the endocytic pathway is the lysosome. Lysosomes are highly acidified and even MHC-class II molecules, which are acid resistant, are unable to survive for long in this environment. In immature DCs, MHC-class II is targeted to lysosomes for degradation until maturation signals are encountered. MHC-class II is then directed to the late endosomes for peptide loading and then to the cell surface for peptide display.

The proteases with the largest role in generating antigenic peptide fragments for MHC-class II are the cathepsins. Cathepsins are primarily cysteine proteases with pH- and redox-dependent activity and are distributed throughout the endosomal compartment.[14] Expressed as proforms, they require proteolytic cleavage themselves to become activated. Although some cathepsins can accomplish their own activation through autocatalytic proteolysis, others require a second protease, which itself might display pH dependence. In this manner, the activity of certain cathepsins can be restricted to different parts of the endocytic pathway, and this is believed to influence the rate of proteolysis to ensure large enough protein fragments reach the compartments where peptide loading takes place.

MHC-class II molecules bind peptides in extended conformations, and for this to occur, denaturation of secondary structure must take place. In the endosomal pathway proteins are denatured by a combination of events: acidification interferes with salt bridges and hydrogen bonds; IFNγ-inducible lysosomal thiol reductase (GILT) reduces cysteine-mediated disulfide bonds;[12] and endoproteases such as cathepsins B, D, F, G, H, K, S, or asparagine endopeptidase (AEP) cleave exposed flexible areas of proteins to cause catastrophic destabilization.[14] It is probable that MHC-class II molecules then bind to large polypeptide fragments, which are trimmed from the C- and N-termini by cathepsins with carboxy and amino proteolytic activity, respectively. This allows MHC-class II, which is assisted by HLA-DM, to bind securely to a peptide epitope and protect it from further proteolysis.[7]

Model antigens have been used in an attempt to determine the relative contribution of proteases to the generation of epitopes recognized by T-cells. Each cathepsin's activity destroys some epitopes while creating others, but mice that are deficient in individual cathepsins (with the exception of Cathepsin S and L, which are required for invariant chain processing) show only minor defects in antigen presentation, indicating a high degree of redundancy in the system. It has been particularly difficult to ascribe unique roles to individual proteases in the generation of defined peptide-MHC-class II complexes because effects on the MHC-class II pathway may be caused by impaired invariant chain processing, impaired epitope generation, or impaired activation of proteases involved in these processes.

Autophagy and MHC-Class II

Autophagy, which means to "eat oneself," is the mechanism by which cells break down and recycle intracellular contents and is important for the maintenance of cellular homeostasis. Normally, autophagic activity is low, but during starvation, cellular stress, or infection, autophagy is upregulated and provides a source of peptides to the MHC-class II pathway. Autophagy is initiated by the recruitment of membrane, probably from the ER, to encircle a large volume of cytosol and its organellar contents. Initiation of this process in response to starvation is controlled by mTOR, which is released from its inhibitory complex when energy levels in the cell fall below a certain threshold. The recruited membrane then fuses to generate a double-membrane vesicle that is targeted to the lysosomal pathway. Access to the lysosomal pathway not only allows the contents to be degraded into building blocks that can be used by the cell to form new proteins and lipids, but also delivers

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

them to the MHC-class II loading pathway described above. Autophagy by macrophages and DCs in response to infection can be mediated by pattern recognition receptors in the cytoplasm and at the cell surface. Almost all the toll-like receptors studied to date influence the autophagic pathway, and this represents an important defense mechanism for the cell to rid itself of intracellular bacteria and parasites that might otherwise evade detection.[24]

CONCLUDING REMARKS

The MHC system and the peptides it presents to T-cells are at the heart of the adaptive immune response, and while we understand the basics of peptide processing and acquisition, there is much left to be learned. The outcome of a thorough and detailed understanding of these processes should provide the ability to manipulate the timing and location of peptide presentation. The ability to do this has implications in vaccine development, tumor immunity, transplant rejection, and autoimmunity.

Chapter 94

Peptide Recognition by T Cells

Malte Mohme and Roland Martin

ABSTRACT

Adaptive immune responses are mediated by either soluble immunoglobulin molecules or thymus-mediated, antigen-specific immune recognition, and orchestrate almost every aspect of physiological and pathological immune responses including the destruction of virus-infected cells, the differentiation of antibody-forming B cells, the lysis of tumor cells, and also allergic responses, autoimmune diseases, transplant rejection, and graft-versus-host disease. During the last three decades, a large proportion of research in immunology has been devoted to understanding T cell specificity. After the description that T cells recognize antigen in the context of self-major histocompatibility complex (MHC) molecules, which was coined "self-MHC restriction of T cells," the nature of the antigen was studied in detail. As is briefly described in this chapter, T cells respond with their clonotypic T cell antigen receptor to short peptides that are generated by the antigen-processing machinery of antigen-presenting cells and displayed on the surface of these in the context of self-MHC molecules.

INTRODUCTION

Different from antibodies that are largely specific for conformational determinants of macromolecules, T cells do not recognize antigen derived from, for example, a foreign pathogen itself, but only in the context of self-major histocompatibility complex (MHC; in humans also referred to as human leukocyte antigen; HLA) molecules on the surface of antigen-presenting cells (APC) such as dendritic cells (DC), B cells, or macrophages. This central observation by Zinkernagel and Doherty,[35] Bevan,[3] and others is now referred to as MHC/HLA-restriction of T cells. There are many subtypes of T cells that are characterized by specific surface molecules such as differentiation markers or by their functional phenotype such as the secretion of cytokines or chemokines. However, recent work has shown that especially with respect to secretion of soluble mediators T helper cells are more plastic than was previously believed. For the purpose of this chapter, only the two main populations will be mentioned, and these are defined by the expression of either one of the two coreceptors, the cluster of differentiation (CD) markers CD4 or CD8. CD4+ T cells are also referred to as T helper cells, whereas CD8+ T cells are often referred to as cytotoxic T cells. The subdivision into these two main categories of T cells is important not only because of their differing functions, but also because they recognize antigen in the context of different MHC/HLA (from here on these abbreviations will be used interchangeably) molecules. CD8+ T cells are restricted by MHC-class I molecules, and CD4+ by MHC-class II molecules with very few exceptions to these rules. Both CD4+ and CD8+ T cells express on their surface a clonotypic T cell receptor (TCR), a heterodimeric transmembrane receptor composed of an alpha (TCR-α) and beta-chain (TCR-β) with remarkable homologies to immunoglobulin molecules with respect to genetic organization of the genes that form the TCR-α/β chains and their molecular structure.[21] The site-specific recombination of the variable (V-), diversity (D-), and joining (J-) gene segments during thymic maturation of T cells results in the random reassortment of a limited number of germ-line encoded complementary determining region (CDR) 1 and 2 loops of their TCR together with a large number of somatically encoded CDR3 loops.[16] Generation of T cells in the thymus results in a T cell repertoire expressing a diverse set of clonally distributed TCR and in the first step of positive selection, only a few thousands of self peptides seem to be enough to generate a fully functional TCR repertoire. In both, positive and negative selection, survival of a T cell is determined by multiple variables within the trimolecular complex, like MHC surface-expression, TCR affinity, peptide abundance, -processing and -binding to MHC. Although the theoretical number of different TCR molecules has been estimated to be in the range of 10^{14}, thymic negative and positive selection processes eliminate the majority of TCR molecules with the propensity to recognize self-antigens in the context of self-MHC, and the resulting peripheral T cell repertoire is much smaller, in the order of 10^7 or even less different specificities.[1] As a consequence TCR crossreactivity

has to be an intrinsic feature of the physiological T cell repertoire.

After the observation that cytotoxic, virus-specific T cells recognize short overlapping peptides of viral proteins,[32] a combination of cell biology-, cellular immunology-, biochemical-, and later structural biology-techniques led to the discovery that CD8+ cytotoxic T cells recognize with their TCR nonamer or decamer peptides embedded in the antigen binding groove of MHC-class I molecules, whereas CD4+ T cells recognize longer, usually 12–20-mer, peptides in the binding groove of MHC-class II molecules.[25] The restriction of CD8+ T cells by MHC-class I molecules and vice versa CD4+ T cells by MHC-class II results from the observation that the coreceptors CD4 and CD8 interact with MHC-class I and II, respectively, independent of the interaction of the TCR with the MHC–peptide complex. They serve a pivotal role in stabilizing TCR–peptide:MHC engagement and therefore in initializing the immunological synapse, which can be seen as the most important interface, not only triggering but also regulating effector functions of the adaptive T cell response.[18]

It is impossible to summarize here the many studies and reviews on the general subject of T cell antigen recognition, details as to how exogenous proteins or endogenously synthesized antigens are processed, loaded onto nascent MHC molecules, and later displayed at the surface, or details on the structural interactions between TCR and MHC–peptide complex. Instead this chapter highlights a few aspects that are important, particularly the MHC molecules and peptides that are involved in T cell recognition.

MAJOR HISTOCOMPATIBILITY COMPLEX CLASS I AND CLASS II MOLECULES

The human HLA complex is encoded on the short arm of chromosome 6 (6p21.1–21.3), representing the densest area in the human genome by harboring >150 genes in an area of approximately 3500 kbp. 60% of those genes are being expressed, and most of them serve immunological functions.[4] HLA-class I molecules are heterodimeric transmembrane molecules consisting of the invariant β_2-microglobulin together with either of the HLA-class I heavy chains encoded by the polymorphic HLA-A, -B, or -C genes. Around 4500 allelic HLA-class I gene variants have been described so far, including HLA-B as the most polymorphic human gene. HLA-class II molecules are also heterodimers consisting of either a nonpolymorphic (DRα) or a polymorphic (DQα, DPα) alpha chain that pairs with a polymorphic beta chain encoded by the HLA-DRβ, -DQβ, and -DPβ genes. Thus, being expressed at the surface level, approximately 80% of HLA-class II molecules are represented by HLA-DR heterodimers. If an HLA-class I or -class II molecule is mentioned below, the respective heterodimer is meant (e.g. DR15 as the dimer of DRα and the beta chain encoded by DRB1*15:01); if a specific allele is referred to, the gene designation will be mentioned in parentheses (e.g. DRB1*15:01 as the DR-β1 chain gene number 1501). To give an impression of the complexity of HLA-class II allelic polymorphisms, there are currently 126 different HLA-DRB1*04 alleles listed by the American Society of Histocompatibility and Immunogenetics (ASHI), and there are hundred more polymorphic DR alleles. Most HLA-class II haplotypes encode for two DR heterodimers, one encoded by DRα together with the DRB1* gene product and the other by DRα paired with the DRB3*-, -B4*, or -B5* gene product. Hence, in humans each chromosome 6 codes for a set of three different class I molecules (HLA-A, -B, -C), and up to four different HLA-class II molecules (two different DR-, one DQ-, and one DP-molecule). If the individual is heterozygous, full HLA-typing will show six HLA-class I and eight class II molecules, and, because HLA genes are expressed codominantly, all corresponding HLA molecules are expressed as proteins on the cell membrane. This enormous complexity explains the difficulties in finding an unrelated organ transplant donor who fits in all HLA loci. For details on HLA typing and nomenclature, the reader is referred to the periodic update of the International HLA Workshops or the ASHI website (http://www.ashi-hla.org or http://www.ebi.ac.uk/imgt/hla/).

The main functional role of MHC/HLA molecules is to display antigenic peptides to T cells. Under physiological conditions the majority of surface HLA molecules on APC are occupied by self-peptides. Self-peptides in the context of the immune system refers to the peptides derived from proteins of the host organism in distinction from peptides that are derived from foreign agents such as viruses, bacteria, fungi, or proteins from other organisms. The repertoire of self-peptides that is continuously presented to T cells serves two major roles. During T cell development in the thymus, recognition of complexes of self-MHC that display a broad selection of self-peptides ensures that the emerging T cell repertoire is tolerant to self-proteins. As mentioned above, this is achieved by processes referred to as positive and negative selection.[2] T cells expressing TCR with high affinity for self-MHC/self-peptide complexes would pose the risk of T cell reactivity against the body's own tissue and organs, and hence they are deleted by activation-induced cell death. T cells with very low affinity for self-MHC/self-peptide complexes fail to be sufficiently stimulated in the thymus to undergo further maturation, and as a result they die of neglect. Only T cells recognizing self-MHC/self-peptide complexes within a range of intermediate affinities are positively selected,[2] mature, and leave the thymus to populate the peripheral lymphoid compartments. Although these rules generally apply, there are peptides from, for example, splice variants of certain proteins such as proteolipid protein (PLP), a major myelin component, that are not expressed in the thymus.[17] As a result, relatively

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

higher numbers of T cells with specificity for such peptides can be found in the periphery, and these T cells also express higher-affinity TCR. Beyond thymic T cell development, the constant exposure of peripheral T cells to self-MHC/self-peptide complexes guarantees a degree of low-level stimulation required for homeostatic proliferation that increasingly shapes and replenishes the peripheral repertoire during physiological thymic involution of the maturing immune system or also during lymphopenia. Therefore, the recognition of self-MHC/self-peptide complexes in the thymus will select for a broad set of T cells that do not cause harm to the host's own tissues in the periphery. However, these T cells are ready to be activated as soon as the complexes of self-MHC with peptides derived from an infectious agent, that is, nonself or foreign peptides, are recognized with higher affinity during, for example, a viral infection. Transplantation of histo-incompatible or allogeneic cells or tissue—cells that express a different set of MHC molecules—also leads to the strong activation of T cells and consequently organ rejection. Thymic selection processes take place in the context of the autologous MHC molecules, and T cells with high-affinity TCR for complexes of foreign MHC and self-peptides are found at high frequencies in the peripheral repertoire. Further, it has recently been stated that the recognition of varying endogenous peptides selected by the foreign MHC molecules, rather than inability to interact with, or react to allogeneic MHC molecules, is the primary determinant of alloreactivity.

CHARACTERISTICS OF PEPTIDES PRESENTED BY MHC-CLASS I

Because of their important role as cytotoxic effector cells during viral infections, CD8+ MHC-class I-restricted T cells have probably received greater attention earlier. MHC restriction was discovered by Rolf M. Zinkernagel when examining virus-specific CD8+ T cells with specificity for lymphocytic choriomeningitis virus.[35] Because of its great importance to the understanding of adaptive immune responses, Zinkernagel, together with Peter C. Doherty, was awarded the Nobel Prize in 1996. As already mentioned, studies of influenza virus-specific cytotoxic T cells led to the observation that T cells recognize short overlapping stretches of viral peptides rather than whole proteins or conformational structures of infectious agents.[32] Subsequently, synthetic peptides rather than whole proteins or transfected genes were used for *in vitro* and *in vivo* immune studies to understand the nature of the peptides that are recognized by T cells in the context of MHC-class I. The observation of the periodic occurrence of amino acids with certain physicochemical characteristics initially led to the assumption that antigenic peptides assume a helical conformation, when they associate with MHC molecules.[28] However, soon thereafter, biochemical studies that sequenced peptides eluted from MHC-class I molecules, and X-ray crystallographic examination of MHC-class I molecules and bound peptide showed that antigenic peptides are embedded in an extended linear conformation in a peptide-binding groove that is formed by a beta-pleated sheet at the bottom of the groove and two flanking alpha helices of the MHC-class I heavy chain.[29,31] Many different cell biology-, molecular biology-, biochemical-, and protein chemistry-techniques have been applied to identify the characteristics of the class-I-associated peptides including direct sequencing of pools of self-peptides eluted from either class I or class II molecules, the sequencing of individual self-peptides eluted from HLA-molecules, the use of truncated or L-ala-substituted peptides that were known to bind to a given allele and also peptide libraries either generated recombinantly in phage or synthetically.[6,12] The following characteristics of peptides that are presented by MHC-class I molecules emerged from these studies. Crystal structure analysis of MHC-class I molecules showed that the class I binding groove is closed at both ends,[13,14] and the groove itself accommodates peptides that are usually octamers or nonamers, sometimes decamers, and less often longer peptides are found that do not fit completely into the groove but partly extrude outside.[25,26] Peptides, as short as pentamers, have been shown to be efficient antigens. Depending on the amino acids that line the groove in individual MHC-class I molecules, certain amino acids with charge, hydrophobicity, or size preferences are accommodated preferentially in separate binding pockets, which are numbered from the N- to C-terminus of the peptide as P1 through P9. In almost every class I molecule, one dominant anchor is located at the C-terminus (P9 in nonamer peptides).[25] The second dominant anchor residue is found at varying positions but most frequently at P2 of the peptide. Peptides that have only dominant anchor residues in common can differ in their binding affinity for the same MHC molecule by four orders of magnitude.[23] Amino acid residues present at other positions in the peptide can have significant positive or negative effects on peptide binding. Nondominant amino acids with positive effects are termed auxiliary anchor positions. Using the preceding strategies, the binding motifs and most important anchor amino acids have now been identified for many different MHC-class I alleles in mice, rats and humans. These anchor motifs and additional *in vitro* generated results have been used to devise prediction algorithms that allow scanning any protein and to predict the presence of areas that bind well to an MHC-class I allele of interest.[23] One very useful and publicly available tool is SYFPEITHI (www.syfpeithi.de)[25] or the International Epitope Database (www.iedb.org). Peptides that are presented in the context of MHC-class I to CD8+ T cells are usually generated from cytosolic proteins, proteolytically degraded by the proteasome involving a number of distinct proteases, and subsequently transported

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

into the endoplasmic reticulum, where they are loaded onto nascent class I molecules and subsequently shuttled to the cell surface. This pathway is referred to as the endogenous processing pathway, and it is most important for mounting the T cell responses against infections with intracellular pathogens such as enveloped viruses.[8]

CHARACTERISTICS OF PEPTIDES PRESENTED BY MHC-CLASS II

CD4+ T_H cells recognize peptides that are bound by MHC-class II molecules. The same investigational approaches that have been mentioned above for MHC-class I have also been used to study class II-bound peptides, and many distinct characteristics were found. Different from the MHC-class I binding groove, the one of class II molecules is open at either end and hence accommodates the peptides that are often substantially longer than those bound by class I.[31] Most peptides that have been eluted from MHC-class II molecules were 12–20 amino acids long, but even trimers were found to bind to class II and stimulate T cells. At the other extreme, it was shown that entire proteins such as myelin basic protein (MBP), a polypeptide of 170 amino acids that may be present in unfolded form in solution, can bind to surface MHC-class II. The MHC-class II binding groove is formed by the polymorphic stretches encoded by exon 2 of the class II α- and β-chain genes and typically depicted from the top with the alpha helical parts of the DR/DQ/DP α-chain on top, and the β-chain at the bottom. As for class I, the binding groove accommodates usually 9 amino acids, and the numbering of the putative pockets follows the same order from P1–P9, and different MHC-class II molecules favor distinct anchor amino acids of the peptides in the various pockets, although there is considerable sharing of the requirements at least in some of the main anchors such as P1 and P4 between different alleles. Another important feature of peptide:MHC interaction has been discovered when comparing the limited number of crystallographically analyzed structures. It seems that the overall peptide conformation is more divergent toward the N-terminus, as, for example, in the case of $MBP_{85–99}$ binding to HLA-DR2, where the N-terminal part of the peptide is elevated out of the binding groove, thereby impeding TCR engagement to this portion, and resulting in a reduced accessibility of the peptide:MHC surface that is available for recognition to the TCR. Accordingly, it has been hypothesized that this could enhance the probability of molecular mimicry to occur.[15] Certain other features lead to additional characteristics such as the amino acid in position 86 of exon 2 in the different HLA-DR alleles, which determines the size of pocket P1. All alleles have either a valine or glycine in this position, and accordingly the respective allele can either accommodate a large aromatic residues in P1, if the DR allele expresses G86 or a substantially smaller residues, if a valine flanks P1. Further unique pocket properties, like pocket P6 determining the pH dependency and certain conformational pocket–pocket interactions, emphasize the structural plasticity of peptide binding to MHC molecules. Because class II binding grooves are open at both ends, peptides are not necessarily fixed in one position but can bind in multiple different registers—that is either shifted or bound in an inverse fashion. Because the interface of the MHC–peptide complex to the TCR is affected by such a register shift, it may negatively or positively influence T cell recognition. Further, one needs to take into account not only amino acids in anchor positions that interact with the specificity pockets but also those that contribute negative influences—that is, by the size of the side chain, length of the molecule, proline or charge of amino acids in other positions.[12] Although the unique surface structure of a peptide:MHC complex is mainly determined through the vast number of amino acid combinations, two-thirds of the interaction surface between TCR and peptide:MHC is provided by the conserved α-helices of the MHC backbone structure. Taking peptide-induced conformational changes into account results in an even more diverse and highly plastic peptide:MHC surface configuration, wherein the MHC backbone plays an important role. Antigen processing of peptides that are presented by MHC-class II molecules usually follows the so-called exogenous pathway, which differs from the above class I-associated endogenous processing of antigens. Peptides that are later loaded onto MHC-class II originate from endocytosed or phagocytosed proteins—for example, from a bacterial protein—that are proteolytically degraded in the acidic environment of endolysosomes, where they are loaded onto the newly synthesized MHC-class II molecules. On entering the processing compartment as heterotrimers of class II α- and β-chain complexed with the class II-associated invariant chain (Ii),[8] the Ii-derived class II-associated invariant chain peptide is removed from the antigen presenting groove under the influence of HLA-DM and -DO, that serve as peptide editors and replaced by peptides that are derived from proteolysis of the exogenous protein. Similarly to the main class I-associated processing pathway, the majority of class II-bound peptides are generated through the above exogenous pathway, although different loading compartments and processing paths have been described, which would explain the natural abundance of MHC-class II presented self-peptides from within an APC.

BIOLOGICAL ROLES OF MHC-BOUND PEPTIDES

Defense against Foreign Agents/Vaccines

As just outlined, our T cell repertoire constantly probes the internal environment, which is formed by cells expressing

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

self-MHC molecules loaded with self-peptides. As long as this environment does not change substantially in the quality of MHC–peptide complexes or the relative amounts of antigenic peptides displayed, T cells stay alive but are not fully activated. On infection with, for example, an enveloped virus, such as influenza virus, epithelial cells are infected, and viral proteins are produced in relatively large quantities and loaded onto MHC-class I molecules of these virus-infected cells. The display of viral peptides in the context of self-MHC class I is recognized by CD8+ T cells with TCR that are specific for these MHC–peptide complexes, which become rapidly activated, then lyse the virus-infected cells and interrupt viral spread from one infected cell to the next.[32] In the context of other infectious agents, for example, those that replicate extracellulary such as many bacteria, the infectious agent itself or protein breakdown products are taken up by phagocytes and shuttled into the class II-associated presentation pathway. Eventually, peptides derived from the infectious organism are presented on the surface of APC in the context of MHC-class II molecules to CD4+ T_H cells, which, according to their functional phenotype, produce either proinflammatory cytokines such as interferon-gamma or interleukin-4, which supports B cell development. The dynamics of the infection, the site of inflammation, the tropism and other characteristics of the infectious organism, the amount of antigen that is produced, the cell types that are infected or take up antigen, and many other factors determine the relative contribution and role of CD4+ versus CD8+ T cells. In most instances, efficient immune responses will require both, potent activation of cytotoxic cells and also T helper cell functions, including the production of growth factors, such as interleukin-2, which is required for the expansion of both CD4+ and CD8+ cells and also helper function to B cells to mount efficient antibody responses. Because the presentation of peptide antigens from infectious organisms in the context of self-MHC plays such a central role for effective immune responses, many of the above strategies that have been used for deciphering MHC–peptide interactions and for understanding the specificity of T cells are also of interest for vaccine developments. Because of the complexity of some infectious organisms and the observation that numerous antigenic sites of viruses, bacteria, and parasites are rapidly mutated under the pressure of the host's cellular immune system, vaccine design aims at combining multiple immunodominant peptides and variants thereof in vaccines—for example, for human immunodeficiency virus (HIV) or malaria—although many questions as to how to render these effective vaccines remain open.

Transplantation

The existence and importance of MHC were discovered in the context of transplant rejection by George Snell, Baruj Benacerraf, and Jean Dausset, who were awarded the Nobel Prize in 1980 for their discovery. Until now, the rejection of organ and cell transplants by the host's cellular immune system or graft-versus-host responses, for example, after hematopoetic stem cell transplants, remain the major obstacles to transplantation medicine or cell reconstitutive approaches in oncology or any field, where autologous cell sources are not available. The reason for these usually very strong and often lethal allospecific immune responses has already been mentioned briefly. T cell development involves "education" of T cells on self-MHC/self-peptide complexes, and T cells expressing high-affinity TCR for these complexes are eliminated, thus creating a TCR repertoire that is broad and reactive with high affinity to complexes that are different from self-MHC/self-peptide. If an allogeneic organ transplant is introduced into the host, all nucleated cells of this transplant express nonself MHC-class I. Further, because the binding grooves of these molecules bind different self-peptides than the autologous MHC molecules, the T cell repertoire of the host is exposed to a large number of complexes of nonself MHC-class I loaded with a different set of self-peptides than the one that was "educated" on in the thymus. As a result, the frequencies of cells with alloreactivity are usually high in the peripheral blood and allospecific immune responses are fulminant and one of the strongest responses observed in the human body. Consequently, matching donor and recipient carefully for the entire HLA-class I and -class II haplotypes is necessary, although many other aspects need to be taken into account as well.

AUTOIMMUNE DISEASES

T cells not only mediate physiological immune responses against infectious organisms but they may also cause pathological immune reactions.[34] If organs or tissues of the host are affected, the resulting diseases are referred to as autoimmune diseases, and many of these result from damage by T cells themselves or by T cell-dependent immune mechanisms. Some well-known examples are rheumatoid arthritis (RA), insulin-dependent type 1 diabetes mellitus (IDDM), and multiple sclerosis (MS),[30] among numerous others. One piece of evidence that strongly suggests a role of CD4+ T cells in these diseases is the observation that HLA-DR or -DQ genes are the strongest susceptibility-conferring genetic factors in each of them.[11] To give one example, MS in Caucasians, the ethnic group with the highest prevalence of MS, is associated with the DR15 haplotype that includes the two DR-β alleles DRB1*15:01 and DRB5*01:01 and the DQ molecules DQA1*01:02 and DQB1*06:02. The relative risk to develop MS that is contributed by these class II alleles has been estimated to be between 10 and 60% of all the genetic susceptibility factors.[11] It is currently not known as to how the presence of one HLA-class II allele or several that are part of one

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

haplotype confer risk at the molecular level. The following major possibilities have been considered and are partly supported by experimental data. (1) It has been speculated that disease-associated MHC-class II molecules preferentially present certain autoantigenic peptides from a tissue, in the case of MS, for example, myelin protein-derived peptides resulting in T cell responses against these peptides. (2) As a variation of possibility 1, certain disease-associated MHC-class II molecules present an overall narrower range of peptides with the result that negative selection for autoreactive T cells in the thymus is less complete, and relatively more autoreactive T cells escape to the periphery. (3) MHC-class II gene expression could be regulated differentially in certain tissues, resulting in overexpression of certain MHC-class II molecules in the target organ. Such a mechanism would be particularly attractive in the brain, where most cells do not express any MHC-class II.[30] There is, however, currently no evidence for this possibility in MS. (4) Involvement of MHC-class II molecules in shaping the peripheral TCR repertoire through mechanisms of homeostatic proliferation, thus creating a more cross or autoreactive T cell repertoire. (5) Interaction between certain HLA alleles acting in *trans*, influencing each other on an epigenetic or functional level. Evidence for this hypothesis has been reinforced by results proving the existence of HLA alleles mediating almost complete disease protection or conferring risk in a multiplicative fashion.

Trying to understand which self-peptides are the most important targets for autoreactive T cells in an autoimmune disease and which foreign agents might trigger their initial activation is a central goal of research in this area. T cell responses against some autoantigenic peptides such as myelin basic protein MBP83-99 are probably among the best examined of all T cell responses.[20,22,24] MBP83-99 has been analyzed systematically with respect to peptide binding to the MS-associated HLA-DR alleles—that is, DRB1*15:01 and DRB5*01:01, and later also cocrystallized with them. Although the crystal structure analysis yielded important new insights, many conclusions that had previously been derived from T cell studies and binding experiments were confirmed. The two preceding MBP83-99/DR complexes have been cocrystallized with two different TCR derived from MS patients, one restricted by DRB1*15:01,[10] the other by DRB5*01:01.[19] Different from the few foreign antigen-specific class II-restricted TCR that had been cocrystallized before, these autoreactive TCRs show either an unusual binding topology on the MHC-class II/peptide complex[10] or a remarkable absence of any salt bridges or hydrogen bonds between TCR and MHC-bound peptide explaining the low affinity of this autoreactive TCR.[19] By contrast, more recent investigations show that autoreactive TCR can also bind in an optimal, "foreign-reactive like" conformation, with structural properties, which are stabilizing and even compensating weak peptide:MHC interactions. These results demonstrate that thymic evasion hypotheses not only have to consider TCR affinity, but also have to take into account that peptide binding affinity can have significant impact on thymic selection kinetics. Despite this remarkable progress, too few crystal structures have been resolved so far to distinguish certain TCR binding patterns, leaving many questions related to T cell reactivity to autoantigens open, especially because there is currently no single autoantigen, which can be assumed to be a general target in all patients suffering from one particular autoimmune disease.

Regarding the foreign agents that may trigger autoreactive T cells, a mechanism referred to, as molecular mimicry appears particularly attractive. Molecular mimicry in the context of T cell responses means that a peptide derived from a foreign agent looks similar to a self-peptide. Seminal studies by Fujinami and Oldstone,[7] who proposed this mechanism, showed that molecular mimicry requires sequence identity over a stretch of 6 or more amino acids—for example, between a hepatitis B virus-derived peptide and a peptide from MBP.[7] They showed that the injection of the viral peptide into rabbit causes an immune-mediated encephalomyelitis and crossreactivity of immune cells against the brain protein MBP. The subsequent dissection of the molecular recognition of peptide by T cells led to a better understanding of the rules of T cell crossreactivity, which has to be a necessary feature of the physiological T cell receptor repertoire. It became clear that some amino acids in an antigenic peptide are particularly relevant for binding to the MHC molecule and others for contacting the TCR. Based on this knowledge, searches for molecular mimics concentrated on the presence of these contact amino acids or structural motifs rather than complete sequence homology between an autoantigen and a peptide from a virus or bacterium.[33] Further, the additional and steadily increasing complexity of MHC alleles poses a major challenge to look for molecular mimics. Based on the diversity of binding pockets, MHC molecules present diverse sets of peptides, and moreover are characterized through differences in peptide:MHC binding flexibility, confirming that both, TCR–peptide:MHC interaction and peptide–MHC interaction are highly flexible. Based on theoretical considerations that the T cell repertoire in a mammalian host is orders of magnitude smaller than the potential spectrum of antigenic peptides that can be encountered, it has been proposed that single T cells must be able to recognize large numbers in the range of up to 10^5 different peptides, and these speculations are supported by data that were mainly generated by probing the specificity repertoire of single T cell clones with systematically arranged peptide mutations or combinatorial peptide libraries.[13] These tools are currently being used to better understand the range of molecular mimicry, the

relative affinity of single clones for peptides, and other related questions.

THERAPEUTIC USE OF PEPTIDES

Not surprisingly, many investigators quickly began to apply the knowledge about the central role of peptides for T cell recognition during infections, tumor control and autoimmune diseases also for therapeutic purposes. The potential relevance of peptides for vaccines has already been mentioned above, and the authors anticipate that this will be one interesting strategy to counter the occurrence of rapidly mutating immunodominant epitopes and immune evasion that is observed in some infectious diseases, such as HIV and malaria. Tumor immunologists have identified the specific target peptides for tumor-infiltrating lymphocyte CD4+ and CD8+ populations, and in numerous cases, these were "neoantigens," that is, peptides that emerged through mutations in the tumor. There are numerous clinical trials ongoing, in which either dendritic cells pulsed with the tumor peptide, peptide alone, or the former in combination with *in vitro* expanded tumor-infiltrating lymphocytes are used for tumor-specific immunotherapies.[27] In the case of infectious diseases and tumor immunology, the use of peptides or peptide-specific T cells aims at enhancing the respective immune responses. By contrast, under conditions in which immune responses are damaging, such as allergic responses or autoimmune diseases, investigators have tried to modulate the phenotype and reactivity of T cells by modifying autoantigenic peptides or peptides derived from an allergen or administered the peptide in a way that causes immunomodulation. Such therapeutic approaches were spurred by the discovery that systematic amino acid modifications of a peptide that serves as an agonist to a T cell clone, that is, it stimulates a full immune response including proliferation, cytokine release, and cytotoxicity, can result in partial agonists or even TCR antagonists.[9]

In summary, such peptides are described as altered peptide ligands (APL). Partial agonism results from the modifications of peptides that still stimulate some functions in the responding T cell but not others, such as proliferation in the absence of cytokine release. Thereby the antigenic peptide does not only determine if a T cell is activated, but also, regulated by the dose and structural quality of the antigenic peptide, shapes the response profile. Further, the different T cell effector functions—for example, cytokine release, surface marker expression, cytotoxicity, and proliferation—are activated in a clone-specific hierarchy, depending on the early signaling events of the trimolecular complex (TCR–peptide:MHC).[14] In this context, TCR antagonists are peptides that have been modified in a way that they inhibit a T cell response even if the agonist peptide is present at the same time by altering the TCR signaling machinery.[9] Each of these effects could be shown *in vitro* or *in vivo* in several different experimental systems, and APL peptides were also successfully used as therapeutic agents in experimental animal models of MS.[5] One particularly attractive mechanism refers to the generation of T cells on vaccination with the APL that are specific for the APL peptide and express immunomodulatory cytokines that attenuate the proinflammatory autoimmune process. The induced APL-specific T cells cross-react with the native autoantigenic peptide, and hence, whenever tissue is damaged and autoantigen is released, the APL-specific T cell population is stimulated to secrete "beneficial" immune mediators. Despite the elegant *in vitro* and *in vivo* findings, the use of APL in human autoimmune diseases remains problematic. A phase II trial of an APL derived from MBP83-99 in MS resulted in disease exacerbation of some patients on injection of high doses and a trend toward benefit at lower doses. Intriguingly, however, a peptide mixture that was designed to induce encephalomyelitis in the mouse model, evolved to be one of most widely prescribed and best-tolerated drugs in relapsing—remitting multiple sclerosis—namely, glatiramer acetate or copolymer-1. It was first synthesized 30 years ago to mimic the peptidic characteristics of myelin basic protein, one of the major candidates as primary autoantigen in multiple sclerosis. Glatiramer acetate is a random synthetic peptide mixture, consisting of only four amino acids, glutamate (E), alanine (A), lysine (K) and tyrosine (Y), differing in length between 40 and 100 aa, which are only fixed in their molar ratio (1.0:1.5:4.5:3.6). It is administered to patients by daily injections, proving to be efficacious, even though the mechanisms of actions are only poorly understood thus far. One of the proposed mechanisms of glatiramer acetate is the shift toward a more T_H2 dominated cytokine profile, probably mediated through glatiramer-acetate specific T cells. Also effects such as bystander suppression, a function as altered peptide ligand, crossreactivity of glatiramer acetate-specific T_H2 cells, influences on the phenotype of antigen presenting cells, and even neuroprotective effects have been discussed. These observations showed, however, that autoantigens that had been discovered in animal or human *in vitro* studies are indeed relevant targets in the human autoimmune diseases. Future research will have to address how such peptides should be applied, that is, by what route, at which dose, and what other factors need to be considered to further improve and use the full capacity of peptide-based therapies.

CONCLUSIONS

The investigation of T cell specificity for antigenic peptides under physiological and pathological conditions remains a focus of basic research in immunology. Beyond this, the use of antigenic peptides for therapeutic or vaccine purposes

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

rapidly gains importance in clinical medicine in infectious disease, tumor immunology, for allergic diseases, and in the field of T-cell-mediated autoimmune diseases.

Chapter 95

RGD Peptides

Ignacy Z. Siemion, Alicja Kluczyk and Marek Cebrat

ABSTRACT

Peptides containing the RGD (Arg–Gly–Asp) motif and their molecular mimetics bind integrin receptors with high affinity and inhibit cell adhesion by competing with the integrins/matrix interaction leading to anti-inflammatory, anticoagulant, antimetastatic, and antiangiogenic effects. RGD peptides are also involved in bacterial pathogen invasion, tumor and endothelial cell-targeting via the integrin receptors as well as in noninvasive tumor imaging, targeting, and radiation treatment. This review presents various functions of RGD peptides and perspectives of their application as potential drugs.

DISCOVERY OF THE ANTIADHESIVE RGD PEPTIDES

A very useful approach in the search for biologically active peptides is the analysis of appearance of particular sequences in proteins involved in the main physiological processes. The classic example of such a procedure is the use of protein fragments that form the sites of interaction of regulatory proteins as templates for design of inhibitors of cell growth and functions. From this point of view, especially interesting are the "universal signal sequences" of proteins, which could be recognized by their broad distribution among different regulatory proteins of various living species.

In the search for biologically active peptides, the sequential analogs of signal sequences present in the proteins are also of interest. This review concentrates on the Arg–Gly–Asp (RGD) signal motif, crucial for cell adhesion and several other vital phenomena.

In 1982, Pierschbacher determined the complete amino acid sequence of the cell attachment domain of human fibronectin, a 250-kDa eukaryotic extracellular matrix protein which contains an RGD motif and plays crucial roles in cell–cell communication, development, tissue homeostasis, and disease development. Fibronectin orchestrates the functions of other extracellular matrix proteins, promoting cell adhesion, migration, and intracellular signaling including activation of several tyrosine kinases. Pierschbacher and Ruoslahti reported that the tetrapeptide RGDS in module III_{10} plays a big role in the formation of the adhesive site of fibronectin. The Arg (R) and Asp (D) residues present in the tetrapeptide were shown to be of major importance for this activity. The peptides containing the RGD sequence compete with fibronectin for cellular receptors and may act as antiadhesive substances.[8]

The cellular adhesion processes can be divided into two categories: cell–cell and cell–extracellular matrix (ECM) adhesion. In both cases, a major role is played by cell adhesion receptors known as integrins. The integrin glycoproteins are evolutionary old. They appear as obligate heterodimers of noncovalently associated α- and β-subunits. Evolutionary divergence has generated 18 α- and 8 β-subunits. At least, 24 αβ dimeric integrins are known to exist in vertebrates. The two subunits consist of a short cytoplasmic tail, a single transmembrane domain, and a multidomain extracellular portion. The ligand-binding site of integrins is present in the globular head domain of the extracellular part of the molecule and is formed by both integrin subunits. The binding of integrins to their ligands is cation dependent. The history of integrin recognition, their structure, and functions were recently reviewed.[6]

Integrin receptors can interact with matrix proteins such as fibronectin, vitronectin, and laminin, with serum fibrinogen, von Willebrand factor, thrombospondin, osteopontin, different kinds of collagen, and others. The RGD sequence in the native ligands is recognized by 8 out of 24 integrins (α_v integrins and integrin $\alpha_5\beta_1$). In some ECM molecules, such as collagen and certain laminin isoforms, the RGD sequences are exposed on denaturation or proteolytic cleavage. Molecules that contain this sequence or its mimetics compete with the natural ligands for binding. Ligands of the integrin receptors were extensively reviewed by Humphries et al.[14]

The cellular adhesion is important for many fundamental biological processes, such as cell differentiation and growth, tumor metastasis, several immune functions, and tissue repair. They regulate cell movement and migrations, wound healing, and the inflammatory phenomena, as well as embryonal development. There is growing evidence that integrins function as receptors for signal transduction and

Handbook of Biologically Active Peptides. http://dx.doi.org/10.1016/B978-0-12-385095-9.00095-6

Copyright Elsevier 2024

that integrin-mediated signaling can affect cell behaviour and even cell survival. Under certain circumstances, loss of integrin-mediated signaling will induce apoptosis. The crucial role of adhesive interactions of cells with other cells and with matrix proteins within the immune system was reviewed by Mousa.[21]

In sequence databases, such as ELM (The Eukaryotic Linear Motif resource for Functional Sites in Proteins, http://elm.eu.org), the RGD sequence is given a separate chapter, due to its importance in inter- and intracellular events. In other bioactive peptide databases, the RGD fragment can be found in several peptides. The search in PepBank (http://pepbank.mgh.harvard.edu) results in 1217 hits (in August 2011 PepBank database contained 21,691 sequences), although a closer analysis reveals that the database includes in the result set all peptides related to RGD or even mentioned in relation to RGD. More reasonable numbers (22 out of 2599 and 32 out of 10,229 peptide sequences) are found in BIOPEP (http://www.uwm.edu.pl/biochemia/index.php/pl/biopep) and EROP-Moscow (http://erop.inbi.ras.ru) databases, respectively.

The importance of RGD and integrin system and the efforts directed at understanding their functions can also be ascertained from the number and character of publications presenting the results of research on integrins. The search for RGD and integrin concepts in the selected scientific databases shows the increasing number of publications, with nearly 60% of articles published in the last 10 years, and again more than half of them published since the first edition of Handbook of Biologically Active Peptides in 2006 (see Table 1 for details). The differences in the numbers result from the scope of respective databases. It is worth noting that a separate volume (vol. 426) of Methods of Enzymology, edited by David A. Cheresh, was devoted to integrins in 2007.

RGD PEPTIDES IN PLATELET AGGREGATION

Because of the role of the RGD peptides in the pathophysiology of thrombosis, the interactions of adhesive proteins with platelets have gained the attention of many research groups.

Platelet aggregation takes place during the development of such cardiovascular diseases as myocardial infarction, transient ischemic attacks, strokes, etc. A key step in platelet aggregation is the crosslinking of fibrinogen or von Willebrand factor to the GP IIb/IIIa ($\alpha_{IIb}\beta_3$) platelet integrin receptor.

Each of the Aα peptide chains of fibrinogen contains two adhesive sites (sequences RGDF and RGDS) and the HHLGGAKQAGDV fragment responsible for receptor recognition. Six binding sites of a dimeric form of fibrinogen participate in binding to the integrin receptors, thus mediating platelet aggregation. Because the fibrinogen-GP IIb/IIIa interaction is the final major step in platelet aggregation and GP IIb/IIIa is only expressed on platelets, it is clear that the development of GP IIb/IIIa antagonists is an attractive strategy for antiplatelet therapy with an expected strong and specific effect.[32]

Disintegrins, very potent inhibitors of the integrin receptors, are cysteine-rich polypeptides containing the exposed RGD motif, which were originally discovered in snake venoms, but are also produced by blood-sucking arthropods and leaches. Echistatin, ornatins, kistrin, variabilin, ixodegrin, and decorsin represent just a few members of this family. In barbourin and ussuristatin, the RGD motif is changed into the KGD sequence, whereas in disagregin, there is an RED sequence.[10]

Some disintegrins specifically bind to integrin $\alpha_v\beta_3$ and are applied as therapeutic agents for angiogenesis-dependent tumor growth and metastasis. Others, such as

contortrostatin, which is a disulfide-linked homodimer of 13.5-kDa containing two RGD sites isolated from the venom of *Agkistrodon contortrix*, can bind $\alpha_v\beta_3$, $\alpha_v\beta_5$, as well as $\alpha_5\beta_1$ and have been shown to inhibit tumor growth and angiogenesis in an orthotopic xenograft model for breast cancer.[28] Variabilin from tick *Dermacentor variabilis* is a 4-cysteine, 5-kDa RGD-containing disintegrin that blocks ADP-induced platelet aggregation and prevents integrin $\alpha_{IIb}\beta_3$ binding to immobilized fibrinogen.

The search for new antithrombotic agents was also oriented at the mimetics of RGD motif (extensively reviewed by Cox et al.[8] and Auzzas et al.[5]). The structural investigations of cyclic venom peptides clearly show that the distance between the guanidine and carboxyl groups is crucial for the activity and specificity of the antithrombotic agents. It should be similar to the respective distance in the RGDS peptide in the extended conformation. Assuming that this distance should be about 10–20 Å, a substituted tyrosine was proposed as a new lead motif in the search for antithrombotic drugs, resulting in development of Tirofiban (compound A, Fig. 1). Tirofiban is a specific nonpeptide antagonist of GP IIb/IIIa that mimics the GP IIb/IIIa recognizing peptide RGD. It is effective in unstable angina and non-Q-wave myocardial infarction and is approved in patients undergoing coronary angioplasty for acute coronary syndromes. Another drug developed from the RGD concept is Eptifibatide, cyclic heptapeptide that mimics the KGD sequence of the snake venom barbourin (compound B, Fig. 1). It effectively and safely reduces the acute adverse outcome of patients undergoing PCI and is also beneficial in unstable angina.

The guanidine group of RGD was frequently replaced by the p-amidinophenyl moiety, leading to several drug candidates, including Orbofiban (compound C, Fig. 1), although in this case the clinical trials were terminated at Phase III.

It was found that the RGD amide is sufficient for platelet aggregation inhibition at a high concentration. Replacement of L-Arg residue by D-Arg, Gly by D-Ala, or L-Asp by D-Asp, results in inactive compounds. The Ser residue in RGDS can by replaced by other amino acids, especially hydrophobic ones, whereas the substitution of the Asp β-carboxyl group by a tetrazole moiety leads to a completely inactive compound. The peptides bearing a primary amine instead of the guanidine group (i.e., with Arg/Lys substitution) exhibit enhanced platelet aggregation potency and $\alpha_{IIb}\beta_3$ selectivity. The introduction of Har (homoarginine) instead of Arg into the cyclic RGD peptides also greatly increases the platelet aggregation inhibitory potency.

BIOLOGICALLY ACTIVE CONFORMATION OF RGD PEPTIDES

Information on the integrin structure is limited to ectodomains of two integrins that lack αI domains, $\alpha_V\beta_3$ and $\alpha_{IIb}\beta_3$ and to fragments of α_I integrins.[33] RGD ligands bind at an interface between the α and β subunits, with the R residue fitting into a cleft in a β-propeller module in the α subunit, and the D residue coordinating a cation bound in a von Willebrand factor A-domain in the β subunit.[14]

The crystal structure of the extracellular part of the $\alpha_v\beta_3$ integrin receptor alone and complexed with the Cilengitide (cyclic pentapeptide: cyclo-(Arg–Gly–Asp–D-Phe–(N-Me) Val)) was resolved by Xiong et al.[34] The ligand is located at the major interface between the α_v and β_3 subunits, binding them together. The guanidine group of Arg forms a bidendate salt bridge to Asp^{218} and Asp^{150} of this receptor and the carboxyl group of Asp participates in a hydrogen bond with the amide carbonyls of Tyr^{122} and Asn^{215}. The distance between the carbon atoms of these two groups equals 13.72 Å, and the Arg and Asp side chains are extended in opposite directions. These results enable a more precise analysis of the interaction of adhesive peptides with integrins, presented in the article of Arnaout et al.[3]

The binding selectivity of RGD tripeptide to specific integrin depends much on the conformation of the RGD sequence and its flanking residues. Various conformations, proposed as the receptor-bound conformations of RGD ligands, have led to many independent approaches to the design of RGD-peptide mimetics. NMR, CD, and molecular modeling studies have been applied in the conformational investigations, with special attention given to semirigid, cyclic RGD-peptide analogs. By chemical modification and conformation restriction of the RGD sequence, many researchers have developed a variety of cyclic RGD-containing peptides not only with diverse secondary structures of the RGD fragment, but also with enhanced binding affinity and bioavailability.[5,19,25]

The IC_{50} values for $\alpha_v\beta_3$ for some of the cyclic RGD peptides clearly demonstrate the importance of proper conformation of RGD fragment

- c(RGDRGD) $\alpha_v\beta_3$ 140 nM
- c(RGDfV) $\alpha_v\beta_3$ 50 nM
- c(RGDf(NMe)V) $\alpha_v\beta_3$ 0.6 nM, $\alpha_{IIb}\beta_3$ 860 nM (Cilengitide).

The involvement of pairs of integrins in various diseases and the attempts at design and synthesis of selective antagonists were recently presented.[23]

The pseudodihedral angle between the Arg Cβ and Asp Cβ atoms can be used as the criterion for evaluation of the structure–activity relationship of RGD-containing peptides. The value of this angle in the active compounds is between +45° and −45°. Activity increases with an increase in the distance between the charged centers and diminishes with the increase in ionic interactions between Arg and Asp.

The conformation of the RGD sequence controls the selectivity between $\alpha_v\beta_3$ and the platelet integrin $\alpha_{IIb}\beta_3$.

Peptides selective for $\alpha_v\beta_3$ vs. $\alpha_{IIb}\beta_3$ have a turn in Gly region, whereas $\alpha_{IIb}\beta_3$ antagonists prefer an extended conformation of Gly.[11]

RGD PEPTIDES IN IMMUNOLOGICAL PHENOMENA

The role of cell adhesion molecules and extracellular matrix proteins in various pathological processes including angiogenesis, thrombosis, apoptosis, cell migration, and proliferation are well documented. These processes can lead to both acute and chronic disease states such as ocular diseases, metastasis, unstable angina, myocardial infarction, stroke, osteoporosis, a wide range of inflammatory diseases, vascular remodeling, and neurodegenerative disorders. The possibility of an influence of the RGD peptides on such processes is evident.

The homotypic adhesion of T-cells is mediated by intercellular adhesion molecules (ICAM-1), which interact with the leukocyte integrin receptors LFA-1 (leukocyte-function associated antigen-1), and MAC-1, expressed on macrophage cells. MAC-1 mediates the adhesion of granulocytes and monocytes to endothelial cells. LFA-1 contributes also to the binding of killer T-cells to target cells. Natural killer cells constitute a conserved lymphocyte subpopulation that regulates many types of immune response by a rapid secretion of such cytokines as IL-4 and IFN-γ.[2]

ICAM-1 belongs to the group of most intensively studied adhesion molecules of the immune system. It is also the cell surface receptor for human rhinoviruses and red blood cells infected by *Plasmodium falciparum*. Blocking of the cell adhesion signal by inhibition of the ICAM-1/LFA-1 interactions suppresses the allograft rejection and may also induce the apoptosis of antigen-specific T cells. The blockade can be achieved by means of linear and cyclic peptides derived from the ICAM-1 sequence.

The interacting site of ICAM-1 consists of the PSKVIL-PRGGSVLVTG sequence. The PRGGS sequence closely resembles the recognition sequence of fibronectin (GRGDS). Several peptides, peptidomimetics, and small molecules were developed to inhibit ICAM-1/LFA-1 interaction to control immune response in autoimmune diseases and allograft rejection. Several examples, including two potent LFA-1/ICAM-1 interaction inhibitors, cyclic peptides closed by disulfide bridges: cyclo(1,12)-Pen-Pro–Arg–Gly–Gly–Ser–Val–Leu–Val–Thr–Gly–Cys–OH and cyclo(1,12)-Pen–Pro–Ser–Lys–Val–Ile–Leu–Pro–Arg–Gly–Gly–Cys–OH (Pen - L-penicillamine (β,β-dimethyl-L-cysteine)) were reviewed by Anderson et al.[2] As frequently observed, not only in the case of RGD analogs, these cyclic peptides have higher activities than the parental peptide in inhibiting T cell adhesion and mixed leukocyte reaction (MLR). Their structures, especially the β-turn formed by the Pro-Arg-Gly-Gly fragment, are identical to that of ICAM-1. These peptides can also bind to LFA-1 and get internalized into T cells.

Another RGD motif is found in HLA-DQ, the molecule of human leukocyte antigen class II, located on the surface of antigen-presenting cells including macrophages. HLA class II molecules present the peptide fragments of foreign proteins to CD4 T cells. They are composed of two peptide chains (α and β). The thymopentin-like sequence, RGDVY, occupies the 167–171 fragment of the β2-extracellular domain of the β-chain of HLA and is located within the exposed loop of this domain. The synthetic linear peptides containing this sequence suppress cellular immune response, whereas thymopentin (RKDVY) is inactive in this test. The effect of the peptides on humoral immune response depends on the length of the peptide chain; e.g., for the elongated QRGDVY sequence, stimulation of the immune response is observed, but the further elongation of the peptide chain results in suppression of the response.

The presence of the adhesive RGD sequence within the HLA-DQ suggests that the molecule may interact with some integrin receptors, enhancing its binding to the CD4 cell receptor. The synthetic peptides related to the indicated HLA-DQ fragment inhibit the adhesion of platelets to fibrinogen, as well as the adhesion of K562 tumor cells to fibronectin. A disulfide bridged, semirigid CRGDVYC peptide showed a significant increase in inhibitory potency as compared with that of the RGDVY linear pentapeptide.[29] The RGDVF sequence, very similar to the RGDVY motif, appears in the molecule of an adhesive protein, vitronectin.

In HLA-DP and HLA-DR subclasses of HLA II, the RGDVY sequence of HLA-DQ is changed into QGDVY and SGEVY, respectively. A similar sequence, ILDVP, without the basic Arg residues, is the second adhesive site on fibronectin. Therefore, it seems that the indicated mutational changes do not destroy the adhesive properties of the respective HLA-DP and HLA-DQ fragments. The peptides corresponding to these sequences show a distinct immunosuppressory activity in both the cellular and humoral immune responses in mice.

In some proteins, retro-RGD sequences are present. Such a situation appears, for example, in the human CD23 molecule (low affinity receptor for IgE), expressed on a variety of hematopoietic cell types. The (GCY)CPDP-DGRLPTPSAPLHS peptide derived from this protein binds to MHC class II molecules, but not to CD23.[17]

A retro-RGD sequence is found in ubiquitin. Ubiquitin system is involved not only in protein metabolism, but also in the processing of MHC class I antigens. Ubiquitin also augments the production of TNFα in murine macrophages and may also be involved in the modulation of immune response. A series of linear peptides, derived of ubiquitin, were synthesized and investigated for immunomodulatory properties. The 50–59 fragment with retro-RGD motif (LEDGRTLSDY) possesses immunosuppressive activity comparable with that of ubiquitin, and shows conformational resemblance to the respective loop of ubiquitin. A model of the 48–59 loop, a

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

cyclic peptide: cyclo-(Glt-QLEDGRTLSDK)-NH_2 (Glt—glutaryl), with the bridge between Glt and the ε-amino group of Lys, was also synthesized.[22]

RGD-containing peptides inhibit cell growth by inducing detachment from extracellular matrix and adhesion-dependent apoptosis, named anoikis. Recent evidence by different investigators has identified an additional mechanism by which RGD peptides participate in cellular internalization, intracellular targeting and direct activation of caspase-3, caspase-8 or caspase-9 in lymphocytes, cardiomyocytes, endothelial cells and chondrocytes, leading to apoptosis most likely by an integrin-independent mechanism.[1]

RGD PEPTIDES AND PATHOGEN INVASIONS

The bacterial and other pathogen invasion into host cells is mediated by adhesive reactions in which the integrin receptors and matrix proteins participate. Attachment to the host tissue is one of the key early steps of the bacterial infection process. Bacterial attachment to surfaces is mediated by surface structures that are anchored in the bacterial outer membrane and covers a broad group of structures, commonly known as adhesins. Many microbial proteins contain the RGD motif that enables binding to human integrins.

Gram-positive bacterial pathogens such as *Streptococcus pneumoniae* and *Streptococcus pyogenes* use vitronectin for effective adhesion to host cells and subsequent internalization. Vitronectin has an RGD sequence for binding the host cell integrin receptors and a separate bacterial-binding domain for pathogens, and thus functions to crosslink bacteria and epithelial cells. Once bacteria are attached to the vitronectin–integrin complex, various host cell-signaling events are activated to promote internalization. RGD-containing peptides and antibodies directed against $\alpha_v\beta_3$ integrin inhibit the bacterial adhesion and internalization. *Candida albicans* yeasts also exploit vitronectin as a tool for cell adhesion. Their binding to vitronectin is strongly inhibited by RGD, but not RGE peptides.[27]

A short review of the role of cell adhesion molecules in the pathogenesis and host defense against microbial pathogens including protozoa, fungi, bacteria, and viruses was presented by Kerr.[16] The role of fibronectin binding in bacterial adherence and the subversion of fibronectin-integrin system by pathogens was presented by Schwarz et al.[24] In particular, the entry of Mycobacteria into leukocytes is mediated by formation of a complex between the bacterial antigen Ag85 and fibronectin. Mycobacteria can invade the cells only in the form of this complex interacting with the fibronectin specific integrin receptor.

It was shown by Siemion and Wieczorek that the GRGDS fibronectin peptide, as well as the RGDVY HLA-DQ peptide and their analogs inhibit the entry of *Mycobacterium kansasii* into leukocytes.[26] The effect consists of the competition of fibronectin and the investigated peptide for the same integrin receptor. Thymopentin (RKDVY) is also a potent inhibitor of Mycobacteria phagocytosis. The exchange of Asp by Glu in splenopentin (RKEVY) results in a decrease of activity. The fragments of such proteins as cecropine, systemine, and BRCT proteins, containing the modified RGD sequences, were also examined for inhibitory activity.

The ω-guanidino acids ($H_2N–C(=N)–NH–(CH_2)_n–COOH$) were used as mimetics of RGD peptides in the Mycobacteria phagocytosis inhibition. Inhibitory activity is seen for amidinohexanoic acid. The compounds with a shortened hydrocarbon chain are practically devoid of any activity, with the exception of the guanidinoacetic acid. *Staphylococcus aureus*, *S. pyrogens*, and several other bacteria also use the binding to fibronectin as a tool for host cell invasion. However, the RGDVY peptide is inactive in *S. aureus* phagocytosis inhibition.[26]

CagL, a 26-kDa protein of the gastric pathogen and type I carcinogen *Helicobacter pylori*, mimics fibronectin in various cellular functions. Like fibronectin, CagL contains an RGD motif and is located on the surface of the bacterial type IV secretion pili. CagL binds to the integrin receptor $\alpha_5\beta_1$ and mediates the injection of virulence factors into host target cells. CagL mimics fibronectin in triggering cell spreading, focal adhesion formation, and activation of several tyrosine kinases in an RGD-dependent manner.[30]

The synthetic peptidomimetics of RGD are used for the inhibition of binding of adenoviruses to integrin receptors. The human adenovirus contains the RGD sequence in the penton base protein.[12] The γ-herpes viruses also use integrin receptors for their entry into the cells via the RGD sequence.[31] Adhesins, such as the *E. coli* antigen 43 and pertactin from *B. pertussis*, bind to integrins via conserved RGD motifs.

Similar to their roles in animal tissue, integrin-like molecules of plants, are involved in connecting the plant cell wall to the plasma membrane, and this interaction can be disrupted by treatment with RGD-containing peptides. Candidate integrin-like RGD-binding receptors have been identified by immunolabeling with integrin-specific antisera, by crosslinking of iodinated RGD-heptapeptides and by affinity chromatography using immobilized RGD-containing peptides. The plant-pathogenic oomycete *Phytophthora infestans* secretes an RGD-containing protein that might bind to a specific receptor protein of *Arabidopsis thaliana*, thus enabling/promoting the infection process via a loosened cellular organization. Subsequently, an RGD-reactive receptor-like kinase with a lectin-like extracellular domain was identified, and it was speculated that

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

RGD-dependent protein–protein interactions could play a structural and signaling role at the plant cell surface. Whether bacterial plant pathogens take advantage of RGD motifs for binding to plant cells is still unknown. However, conserved RGD motifs have been found in the monomeric autotransporters XCV2103 and XCV4444 but not in the trimeric autotransporters XadA or XadB. RGD motifs are also present in the FhaB homologs. Even if RGD-mediated binding to integrin-like proteins is involved in attachment to host cells, it is not clear whether these bacterial proteins determine host specificity because of the evolution of new binding specificities. Rather, diversifying selection might lead to host adaptation via escape from detection by the plant's immune system, and these adhesins would thus constitute a further class of pathogen-associated molecular patterns.[20]

RGD PEPTIDES IN OTHER PATHOLOGICAL PHENOMENA

Certain integrins may be important targets for selective antagonists aimed at blocking the pathological processes. The commercial and therapeutic potential of cell adhesion molecules is on the rise. The possibility of use of the $\alpha_4\beta_1$ and $\alpha_4\beta_1$ integrin receptor inhibitors in the treatment of autoimmune disorders was discussed by Jackson.[15]

Changes in the number and identity of integrin receptors are common in cancer cells, resulting in the alteration of the ability of malignant cells to interact with the extracellular matrix, and promoting migration as well as facilitating survival outside the tumor environment. Preclinical studies reveal that integrin antagonists inhibit tumor growth by affecting both tumor cells and tumor-associated host cells, most notably the angiogenic endothelium. Integrin antagonists currently in clinical trials include monoclonal antibodies and RGD peptide mimetics.[8,9]

The development of small-molecule antagonists of β_3 integrins based on the RGD sequence and their potential anticancer applications was reviewed by Sheldrake et al.[25] It is worth mentioning that some integrin antagonists may display agonist-like activity at low doses, including stimulation of angiogenesis. Controlling the concentration of drug in the body is quite difficult in the case of oral administration. Cilengitide (compound D, Fig. 1) shows antiangiogenic and antitumor activity in various animal models and undergoes clinical trials for treatment of glioblastoma (phase III) and several other tumors (phase II) (reviewed by Mas-Moruno et al.[19]). See the Cancer/Anticancer section of this book for other peptides involved in treatment.

The application of turn-inducing motifs allows specific observation of structure–selectivity relationships in RGD analogs in the search for selective $\alpha_v\beta_3$ and $\alpha_v\beta_5$ antagonists, potential antitumor agents. Various analogs of proline have been used to synthesize macrocycles with finely tuned affinity to these integrins.[5]

PERSPECTIVES

The recognition of the RGD-binding motif common to the disintegrins and natural integrin ligands allowed the development of small molecule integrin antagonists, progressing from linear peptides containing the RGD sequence to cyclic peptides with well-defined conformation, and hence to small molecule peptidomimetics with improved pharmacological properties. RGD peptides, and small molecules have become a popular area for the development of new drugs and drug delivery agents.[25]

Many linear and cyclic RGD peptides have been developed as ligands that preferentially bind to integrin $\alpha_v\beta_3$, related α_v forms, or other types of integrins. Among these, cyclic peptides c(RGDfK), c(RGDyK), and RGD4C (compound E, Fig. 1) show high binding affinity and selectivity for integrin $\alpha_v\beta_3$, with Cilengitide undergoing clinical trials for brain tumors. There seems to be a positive synergy for this agent in combination with radiochemotherapy in preclinical studies,[19] which not only encourages further research but also attracts attention to cyclic RGD peptides as vectors for integrin targeted delivery of chemotherapeutics.[7]

Several RGD conjugates, containing relatively small molecules, are used as biological tools. A typical example, c(RGDyK) attached to fluorescent Cy5.5 dye, is used for *in vivo* NIR fluorescence imaging.[18] Radioactive RGD peptides represent an important new class of radiotracers for diagnosis of tumor or thrombosis, detection of inflammatory processes, and monitoring outcomes of therapeutic interventions in patients with cancer, myocardial infarction, and inflammation.[35] [^{18}F]-galacto-c(RGDfK) as well as [^{18}F]-bearing tracers with RGD4C and PEG linker, are being investigated for noninvasive imaging of integrin expression in cancer patients. ^{99m}Tc-apcitide (Fig. 2), a cyclic RGD peptide mimetic that specifically binds to the $\alpha_{IIb}\beta_3$ expressed on fresh thrombi, has been approved by the FDA for the diagnosis of deep vein thrombosis in patients.[5]

Drug delivery systems use RGD sequence to target cancer cells and administer cytotoxic drugs. Conjugating doxorubicin with RGD4C improves the inhibition of tumor growth and spreading of pulmonary metastases in mouse MDA-MB-435 breast cancer model. Moreover, the resulting compound is less toxic to the liver and heart. Because of solubility problems, prodrug development has been attempted (Fig. 2). The conjugation strategy is also applied to RGD-based platinum(IV) complexes and paclitaxel, resulting in the formation of an efficient prodrug with a cleavable linker.

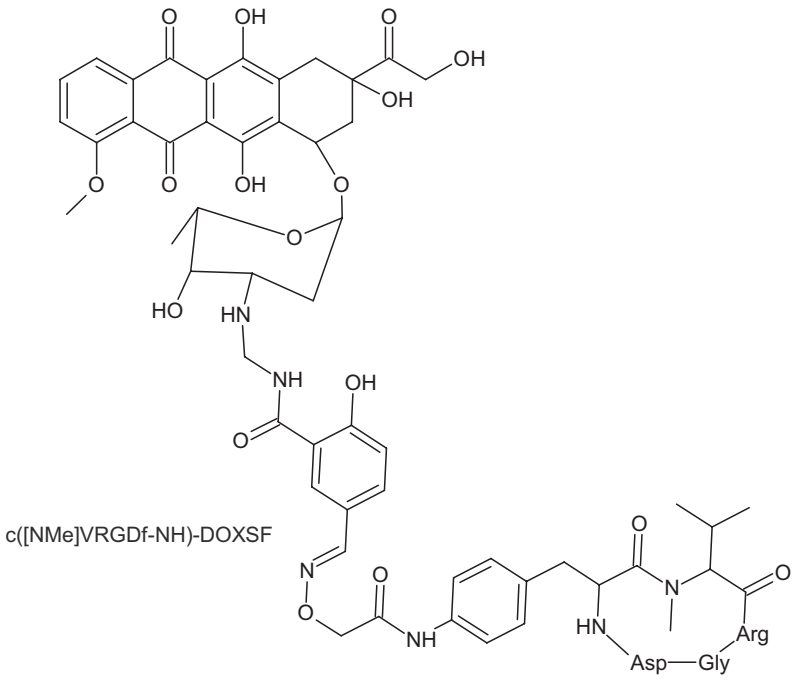

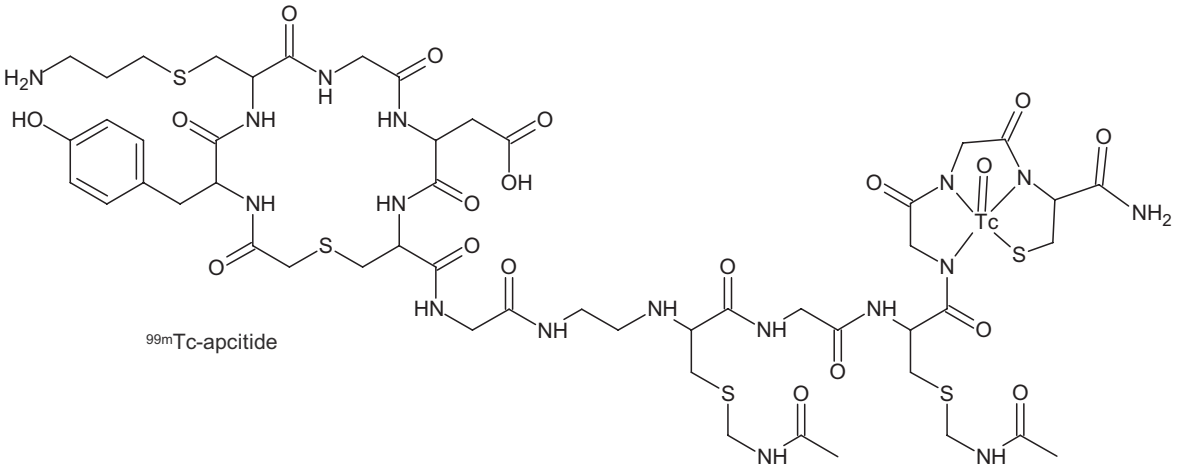

FIGURE 2 RGD conjugates of pharmaceutical interest.[5]

To improve the cellular uptake and accumulation, multimeric systems exploiting the enhanced permeability and retention (EPR) effect of RGD fragment, have been designed.[5,7,18] Dimeric and multimeric constructs, and RGD-decorated liposomes, particulates, and nanoparticles are used not only as drug vesicles but also as tissue-repairing materials, resembling and restoring extracellular matrix.[13] Gold nanoparticles are considered as polyvalent platforms for targeted drug delivery. The cRGD-conjugated gold nanoparticles display an enhanced affinity for $\alpha_V\beta_3$ integrin and *in vitro* target $\alpha_V\beta_3$ overexpressing cells, thus opening the possibility of future application in cancer therapy.[4]

The presented material indicates that besides the well-known role of the RGD peptides in cardiovascular processes, they gain the increasing importance in various areas of modern medicine.

Chapter 96

Apelin

Xavier Iturrioz and Catherine Llorens-Cortes

ABSTRACT

The APJ receptor was originally isolated as an orphan seven-transmembrane-domain G-protein-coupled receptor in humans. Its endogenous ligand, apelin, was identified in 1998 and is generated from a 77-amino-acid precursor, preproapelin. Apelin and its receptor are expressed in hypothalamic vasopressinergic and oxytocinergic neurons. Apelin acts as a potent aquaretic neuropeptide, counteracting vasopressin actions. Apelin may also act on the kidney to increase diuresis. Central injection of apelin in lactating rats inhibits hypothalamic parvocellular and magnocellular OXY neuron activity in a direct autocrine or paracrine manner, reducing the amount of milk ejected for the pups. Apelin exerts peripheral actions, decreasing mean arterial blood pressure and improving myocardium contractility and load. Altogether these results suggest that apelin may be a key peptide for the fine regulation of functions relating to the maintenance of body fluid homeostasis in certain physiological conditions and plays a crucial role in the regulation of cardiovascular functions.

DISCOVERY

The apelin story began in 1993 with the cloning of the cDNA of the orphan APJ receptor (putative receptor protein related to the type 1 angiotensin receptor) from a human genomic library, which was subsequently cloned in rodents.[6,23,24] The human receptor is 380 amino acids long and is a member of the family of orphan seven-transmembrane-domain G-protein-coupled receptors (GPCRs). Its amino acid sequence was found to be 31% identical to that of the human type 1 angiotensin (AT1) receptor, but it does not bind radiolabeled angiotensin II (Ang II), and exposure of the rat APJ receptor to Ang II does not modify cyclic adenosine monophosphate (cAMP) production, showing that this receptor is not an angiotensin receptor subtype. It therefore remained an orphan GPCR for which the endogenous ligand had to be isolated. The APJ receptor was deorphanized in 1998 when apelin, its endogenous ligand, was isolated from bovine stomach tissue extracts.[34] This ligand was named "apelin" for the endogenous ligand for the APJ receptor.

STRUCTURE OF THE mRNA/GENE

Apelin is a 36-amino-acid peptide (apelin-36) generated from a larger precursor, the 77-amino-acid proapelin (Fig. 1A). The human preproapelin gene is located on chromosome X at locus Xq25–q26.1 and contains three exons, with the coding region spanning exons 1 and 2. The 3′-untranslated region also spans two exons (2 and 3). This may account for the presence of transcripts of two different sizes (~3 and ~3.6 kb) in various tissues.[23]

PROCESSING OF THE PRECURSOR

The alignment of preproapelin amino acid sequences from cattle, human, rat, and mouse shows strict conservation of the C-terminal 17 amino acids, known as apelin-17 or K17F (Fig. 1B). *In vivo*, proapelin gives rise to various molecular forms of apelin of 36, 17, and 13 amino acids, but the mechanism implicated in this processing remains unknown. The presence of pairs of basic residues in proapelin suggests that prohormone convertases could be implicated in this processing. In the brain and plasma of rat, the predominant forms of apelin are the pyroglutamyl forms of apelin-13 (pE13F) and, to a lesser extent, K17F (Fig. 1B).[7] In rat lung, testis, and uterus and bovine colostrum, apelin-36 predominates, whereas, in the rat mammary gland, both apelin-36 and pE13F are present.[10,15] In human heart, pE13F has been identified as the predominant molecular form of apelin,[17] whereas in human plasma, K17F predominates followed by pE13F and to a lesser extent, apelin-36.[1]

DISTRIBUTION OF THE mRNA/PEPTIDE

The apelin precursor, mRNA is expressed in the brain and also in the lung, heart, kidney, adipose tissue, and vascular endothelium.[3,14,16,21,26,27] The development of a polyclonal antibody with high affinity and selectivity for K17F has made it possible to visualize, for the first time, apelin-containing neurons in the central nervous system of rats.[26] The precise neuroanatomical distribution of apelin immunoreactivity shows that apelin-immunoreactive (IR) cell bodies are

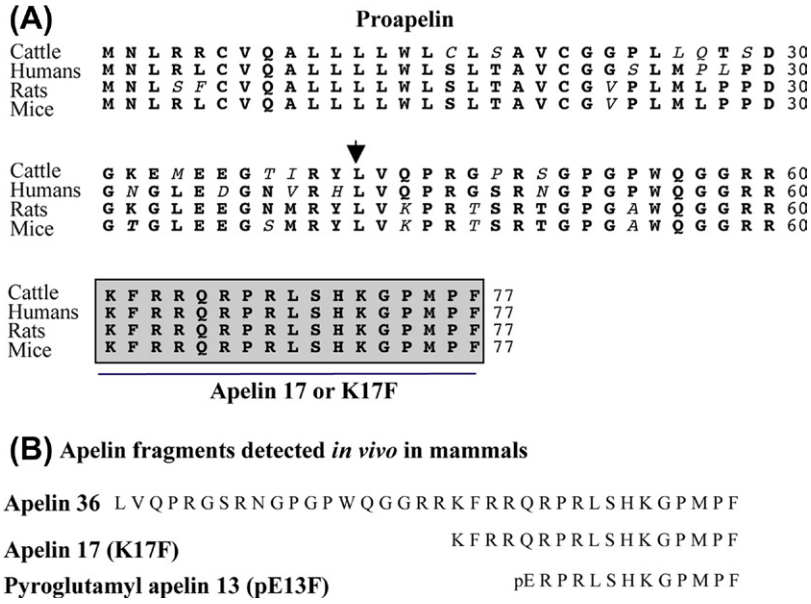

FIGURE 1 (A) Amino acid sequences of the apelin precursor, preproapelin, in cattle, human, rat, and mouse. The first amino acid of apelin-36 is indicated by an arrowhead and the apelin-17 sequence is indicated by a box.[34] (B) Apelin fragments detected *in vivo* in mammals: apelin-36, apelin-17 (K17F), and the pyroglutamyl form of apelin-13 (pE13F).

particularly abundant in the structures of the hypothalamus and medulla oblongata involved in the control of neuroendocrine activities, drinking behavior, and arterial blood pressure (BP), notably in the hypothalamic supraoptic nucleus (SON) and the magnocellular part of the paraventricular nucleus (PVN), the arcuate nucleus, the lateral reticular nucleus, and the nucleus ambiguus (Fig. 2).[26,27] Conversely, apelin-IR nerve fibers are much more widely distributed in many regions of the brain. The density of IR nerve fibers and apelinergic nerve endings is the highest in the inner layer of the median eminence and in the posterior pituitary,[4,27] suggesting that apelin neurons of the SON and PVN, like magnocellular AVP and oxytocin neurons, project into the posterior pituitary. In support of this notion, double immunofluorescence staining showed that apelin colocalizes with AVP[7,29] and oxytocin[2,4] in magnocellular hypothalamic neurons in rats.

Apelin-IR nerve fibers also innervate the median preoptic nucleus, mesencephalon, pons, medulla oblongata, and several circumventricular organs such as the vascular organ of the lamina terminalis (OVLT), the subfornical organ (SFO), the subcommissural organ, and the area postrema.[27]

RECEPTORS AND SIGNALING CASCADES

Distribution of the Apelin Receptor

Like apelin, the apelin receptor mRNA is widely distributed throughout the central nervous system[6,16,21,23] of rats and is also present in peripheral tissues such as heart, vascular endothelium, kidney, adipose tissue, spleen, muscle, and uterus.[8,10,11,14,21] *In situ* hybridization analysis of apelin receptor mRNA expression in the adult rat brain shows intense labeling in the hypothalamus, especially in the SON and PVN and to a lesser extent in the arcuate nucleus. The anterior and intermediate lobes of the pituitary are also strongly labeled, as well as the pineal gland. Labeling is also found in extrahypothalamic structures such as the piriform cortex, the nucleus of the lateral olfactory tract, the central gray matter, the structures containing monoaminergic neuronal cell bodies (pars compacta of the substantia nigra, dorsal raphe nucleus, and locus coeruleus), the entorhinal cortex, the dentate gyrus and Ammon's horn.[6] Further, double-labeling studies combining immunocytochemistry and *in situ* hybridization in rats have shown that in SON and PVN apelin receptors,[23,26] like type 1A and 1B AVP receptors (V1A and V1B), are synthesized by magnocellular AVP neurons suggesting an interaction between AVP and apelin. More recently, Bodineau et al. have shown that apelin receptor mRNA is expressed by magnocellular and parvocellular oxytocin neurons in the SON and PVN, suggesting an interaction between oxytocin and apelin.[2]

Signaling Cascades

The human and rat apelin receptors are 380 and 377 amino acids long, respectively, and belong to class A seven-transmembrane GPCRs. These receptors share high identity (90%) in amino acid sequence. Rat and human apelin receptors are negatively coupled to adenylyl cyclase.[6,21] Indeed, apelin-36, K17F, apelin-13 (Q13F), and pE13F are potent inhibitors of forskolin-induced cAMP production in CHO or HEK 293 cells stably expressing the rat or human receptor.[6,21] Masri et al. have shown that both apelin-36 and pE13F activate Gαi1 and Gαi2 isoforms but not Gαi3 in CHO cells stably

Adapted from Reaux et al.[27]

expressing the murine apelin receptor.[20] Ala-scan of pE13F[21] and N- or C-terminal deletions of K17F [9] showed that the arginine residues in positions 2 and 4 or the leucine residue in position 5 in pE13F play a critical role in binding affinity and inhibition of cAMP production. Apelin-36, K17F, and pE13F also increase intracellular calcium mobilization in several cell lines such as NTera 2 human teratocarcinoma cells or HEK 293 and RBL-2H3 cells stably expressing the human apelin receptor.[5,21] Several kinases are activated by apelin receptor stimulation in different cell types. Masri et al. have shown that pE13F activates extracellular signal-regulated kinases (ERKs) in CHO cells stably expressing the mouse apelin receptor, via a pertussis-toxin-sensitive G protein, a PKC-dependent pathway, and in a Ras-independent pathway.[18] Apelin also activates p70S6 kinase in human umbilical vein endothelial cells (HUVEC) and in CHO cells expressing the mouse apelin receptor via two independent signaling pathways, ERK-dependent and PI3-kinase-dependent pathways.[19] Apelin-36, K17F, and pE13F trigger rat and human apelin receptor internalization.[9,26] Interestingly, the presence of the C-terminal phenylalanine (Phe) of K17F is essential to induce apelin receptor internalization and *in vivo* to decrease arterial blood pressure.[9] The deletion of the C-terminal Phe of K17F (K16P) or its substitution by an alanine (K17A), strongly decreases the ability of the peptide to trigger apelin receptor internalization with no effect on its binding to apelin receptor or its ability to activate Gαi-coupling.[9,12] More recently, Iturrioz et al. by combining molecular modeling and structure–function studies by site-directed mutagenesis of the rat apelin receptor have shown that the C-terminal Phe of pE13F or K17F is embedded in a hydrophobic pocket constituted by the Phe255 and the Trp259 residues in helix VI of the apelin receptor.[12] The substitution of these residues by an alanine abolishes the capacity of the receptor to internalize upon ligand exposure confirming the critical role of the C-terminal Phe residue of pE13F and K17F in inducing apelin receptor internalization.[12]

BIOLOGICAL ACTIONS WITHIN THE BRAIN AND PITUITARY GLAND

Involvement of Apelin in the Regulation of Water Balance

Action of Central Apelin on AVP Neuronal Activity, AVP Release in the Blood Circulation, and Diuresis

Magnocellular neurosecretory neurons release AVP, an antidiuretic vasoconstrictor peptide, in the vicinity of

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

the fenestrated capillaries of the posterior pituitary in response to changes in plasma osmolality and volemia or under action of different neurohormones including Ang II or III and natriuretic peptides. The fact that AVP and apelin colocalize in hypothalamic magnocellular neurons and the presence of receptors for AVP and apelin on these neurons (Fig. 3) strongly suggest the existence of an interaction between these two peptides and a potential apelin response to these stimuli. With regard to the involvement of apelin in the regulation of water balance, it is possible that, independently of the feedback control exerted by AVP on its own release, apelin may regulate AVP release. This hypothesis has been tested in lactating rats exhibiting a reinforced phasic pattern of AVP neurons during lactation, thereby facilitating systemic AVP release to maintain body water content for optimal milk production. In this model, icv injection of K17F inhibits the phasic firing activity of AVP neurons, thereby decreasing AVP release into the bloodstream, leading to water diuresis[7] (Fig. 3). Similarly, a marked decrease in systemic AVP release is observed after icv injection of K17F or pE13F in mice deprived of water for 24 h,[26] a condition known to increase AVP neuron activity and AVP release. These results suggest that apelin is probably released from the SON and PVN AVP cell bodies and inhibits AVP release by acting directly on the apelin autoreceptors expressed by AVP/apelin-containing neurons. This mechanism probably involves apelin acting as a natural inhibitor of the antidiuretic effect of AVP. The colocalization and opposite biological actions of these two peptides raise questions concerning how these two peptides are regulated to maintain body fluid homeostasis. This question has been addressed by two different studies focusing on the effects of water deprivation on the neuronal content and release of both apelin and AVP in rodents and on of the effects of hypertonic saline infusion or water loading on plasma AVP and apelin levels in human volunteers.

Opposite Regulation of Vasopressin and Apelin after Water Deprivation

In rats deprived of water for 24 h, a large increase in the hypothalamic apelin content especially in that of the PVN and SON magnocellular neurons[7,29] is mirrored by a decrease in plasma apelin levels,[7] suggesting that, under these conditions, apelin accumulates within AVP neurons rather than being released. The apelin response to dehydration is therefore the opposite of that of AVP, which is released faster than it is synthesized.[7,29] Such a mechanism implies that apelin and AVP which are produced in the same neurons should be released differentially by these neurons. Indeed, double-labeling and confocal microscopy studies have shown that AVP and apelin are mainly present in distinct populations of vesicles which differ in size and distribution in magnocellular neurons[7,29] (Fig. 3).

These opposite regulatory patterns of apelin and AVP suggest that the two peptides act in concert to maintain body fluid homeostasis. During dehydration, an increase in the somatodendritic release of AVP optimizes the phasic activity of AVP neurons, facilitating the release of AVP into the bloodstream while apelin accumulates in these neurons rather than being released into the bloodstream and, probably into the nuclei. Thus, a decrease in the local supply of apelin to SON and PVN AVP cell bodies may facilitate the expression of AVP by AVP neurons and optimize phasic activity by decreasing the inhibitory effects of apelin on these neurons. In addition, apelin gene expression in the brain has been recently reported as a hydration-sensitive gene expression. Indeed, water deprivation in mice decreases brain apelin mRNA transcription and apelin release in the blood circulation.[33] Opposite regulation of apelin and AVP makes it possible to maintain the organism's water balance by preventing additional water loss at the kidney level.

Such a crossregulation of apelin and AVP after osmotic stimuli has also been studied in humans. The relationship between osmolality, apelin, and AVP was investigated in 10 healthy men after infusion of hypertonic saline to increase plasma osmolality or water loading to decrease plasma osmolality.[1] Increased plasma osmolality simultaneously raises plasma AVP concentration and reduces plasma apelin concentration. Conversely, decreased plasma osmolality decreases plasma AVP concentration and rapidly increases plasma apelin concentration. This observation is consistent with plasma osmolality being a major physiologic regulator of plasma apelin levels in humans. Further, the inverse relationship between the regulation of apelin and AVP is consistent with the findings in rats submitted to water deprivation. This strongly suggests that, like AVP, apelin contributes to the maintenance of body fluid homeostasis in humans and rodents.

Involvement of Vasopressin and Apelin in the Maintenance of Water Balance in the Kidney

In addition to a central action, the aquaretic effect of apelin probably involves a renal action because mRNA transcripts for apelin receptor and preproapelin, as well as apelin peptide, have been detected in rat and human kidney.[21,23] Apelin receptor mRNA is present in all renal zones, most abundantly in the inner stripe of the outer medulla.[11] A high expression level is also found in the glomeruli and a moderate expression is observed in all nephron segments, especially in collecting ducts that express vasopressin V2 receptors.[11] Apelin receptor mRNA is expressed in juxtamedullary efferent (EA) and afferent (AA) arterioles, in which K17F induces vasorelaxation by inhibiting the Ang II-induced rise in [Ca^{2+}]. This occurs *via* release of NO through receptors located on the endothelium layer.[11]

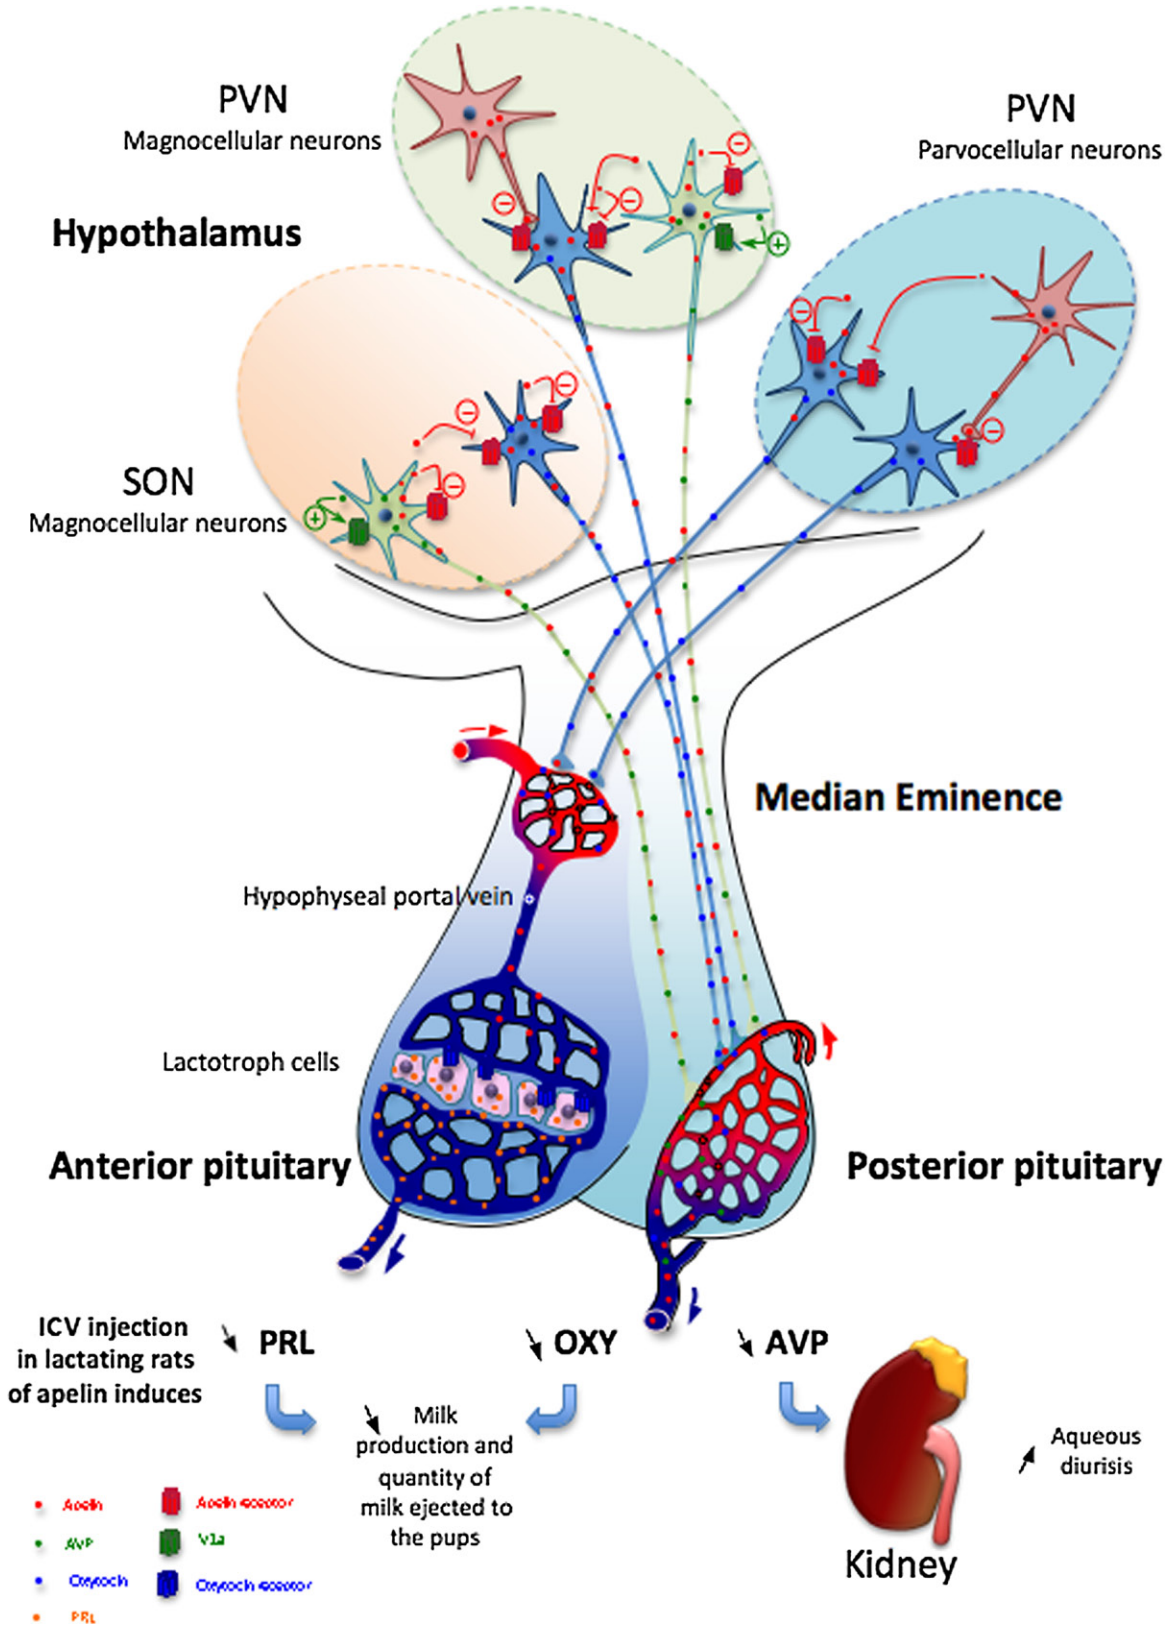

FIGURE 3 Putative schema of apelin of the interactions with AVP and oxytocin. In lactating rats, apelin and its receptor are colocalized with AVP and oxytocin in the SON and PVN magnocellular neurons. Apelin and its receptor are also colocalized with oxytocin in parvocellular neurons. ICV administration of apelin inhibits the phasic electrical activity of AVP and oxytocin neurons. The decrease of AVP neuron activity results in a decrease of AVP secretion into the bloodstream and thereby the increase of aqueous diuresis at the kidney level. In contrast, the decrease of oxytocin neuron activity in magnocellular neurons and in parvocellular neurons would certainly decrease the secretion of oxytocin and PRL in the bloodstream in the anterior pituitary respectively. Adapted from De Mota et al.[7] and Bodineau et al.[2] See color plate 25.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

The Ang II-induced vasoconstriction that is rapidly reversed by apelin in AA and EA, confirms the opposing vascular roles of the apelinergic and renin angiotensin systems.[11] The apelin-dependent vasorelaxation observed in muscular EA, which gives rise to vasa recta, therefore strongly supports a key role of apelin in the control of renal medullary circulation.[11] Further, the expression of apelin receptor mRNA along the nephron and in the collecting duct suggests that apelin acts as an aquaretic peptide through a direct action on this segment. This hypothesis is supported by the observation that intravenous injection of increasing doses of K17F in lactating rats increases diuresis in a dose-dependent manner.[11] This apelin-induced increase in medullary blood flow in addition to a potential direct tubular effect might contribute to increased diuresis, as reported in lactating rats. By contrast, AVP decreases medullary blood flow *via* its action on V_{1A} receptors by inducing vasoconstriction of the outer medullary descending vasa recta, and decreases urinary flow rate *via* its action on V_2 receptors. Apelin therefore seems to exert a complex and fine regulation on renal hemodynamic function through actions on preglomerular and postglomerular microvasculature and probably also on tubular function.

Recent studies have underlined the role of apelin in controlling fluid homeostasis. As previously reported, water deprivation significantly decreases urine volume and increases urine osmolality in wildtype female and male mice, whereas mice deficient for the apelin receptor ($APJ^{-/-}$) are unable to concentrate their urine to the same extent.[30,31] This lack of effect probably does not result from an inability of these mice to increase plasma AVP levels because comparable increases are seen in wildtype and $APJ^{-/-}$ mice after water deprivation, suggesting the presence of an intact central vasopressinergic system in $APJ^{-/-}$ mice. These observations have therefore led these authors to suggest that because the defect in water metabolism observed in $APJ^{-/-}$ mice is probably not resulting from altered AVP neurosecretory function, they have sought the possibility of a deficiency at the kidney level.

Apelin and Drinking Behavior

Consistent with a role of apelin in the regulation of water balance depending not only on the synthesis and release of AVP and on its action at the kidney level but also on the regulation of thirst, apelin-immunoreactive cell bodies and fibers have been detected in brain structures involved in the control of drinking behavior. These include the two circumventricular organs, SFO and OVLT, as well as the median preoptic nucleus.[27] According to this localization, central injection of pE13F (1 nmol) significantly reduces water intake in dehydrated rats.[26] By contrast, Taheri et al. have shown opposite results because icv administration of apelin-13 (3, 10, and 30 nmol) increases water intake in rats with free access to water.[32] Further, $APJ^{-/-}$ mice drink significantly less water than wildtype mice.[30] However, the total absence of apelin receptors during fetal and adult life, could elicit compensatory mechanisms leading to this opposite effect. At present, it is therefore difficult to attribute a clear role for apelin in drinking behavior but whatever its true function is in this process, apelin could contribute to the fine regulation of water balance, and this would vary according to the physiological state.

Apelin Regulates Hypothalamic Oxytocin Neurons in Lactating Rats

Firstly, dual-labeling studies in male and virgin female rats have shown that apelin colocalizes with neurophysin I (a marker of oxytocin-containing neurons) in SON and PVN magnocellular OXY neurons.[4] More recently, double immunofluorescence labeling revealed the colocalization of apelin with OXY in about 20% of the hypothalamic OXY-positive neurons in lactating rats.[2] Finally, a combination of *in situ* hybridization and immunohistochemistry showed the presence of apelin receptor mRNA in hypothalamic OXY neurons in lactating rats.[2] These results suggest an interaction between apelin and oxytocin. Consistent with this hypothesis, infusion of K17F into the lateral ventricle of lactating rats inhibits the neuronal activity in most hypothalamic OXY neurons (i.e., magnocellular and parvocellular neurons) as shown by the measurement of c-fos expression in OXY neurons. The infusion of K17F into the third ventricle also inhibits the electrical activity of magnocellular OXY neurons of the SON displaying a strong rhythmic pattern during lactation. K17F inhibits the basal and bursting activity of these neurons, and this is expected to decrease OXY release from neurohypophyseal axon terminals. These observations suggest that apelin released from OXY or AVP neurons during breastfeeding directly inhibits magnocellular and parvocellular OXY neurons in an autocrine or paracrine manner via the apelin receptors expressed on these neurons. Magnocellular OXY neurons are activated by the suckling pups, leading to the release of OXY into the bloodstream, where OXY acts on the myoepithelial cells of the mammary gland, causing smooth muscle contraction and milk ejection. Parvocellular OXY neurons project to the external layer of the ME and release OXY into the hypophyseal portal circulation to increase directly the release of adenohypophysis prolactin (PRL) from lactotrophs known to express OXY receptors into the bloodstream, participating in milk production (Fig. 3).

Quantification of milk delivery to the pups after icv injection of K17F in conscious lactating rats shows a marked decrease in milk ejection after K17F injection,[2] suggesting that brain apelin, by inhibiting both magnocellular

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

and parvocellular neuron activity, decreases the amount of milk delivered to the pups (Fig. 3). The inhibitory control of magnocellular OXY neurons by K17F should decrease the amount of OXY released into the bloodstream, whereas this control on parvocellular OXY neurons would decrease the release of PRL into the bloodstream, both effects decreasing the amount of milk ejected for the pups.

Consistent with the inhibitory effect of apelin on parvocellular OXY neurons, a decrease in plasma PRL levels was previously observed after icv administration of pE13F.[32] The inhibitory effect of apelin on magnocellular OXY neurons is not in agreement with the findings of another study reporting an absence of effect of administration by microdialysis of apelin-13 on the firing rate of these neurons.[35] This difference may result from the physiological status of the animals (lactating rats for Bodineau et al. vs. virgin rats for Tobin et al.), to the mode of administration of apelin (icv route vs. diffusion over the ventral surface of the SON through a dialysis probe) and to the molecular form of apelin used (K17F vs apelin-13).

In conclusion, in lactating rats, the coexistence of apelin receptor mRNA and, to a lesser extent, apelin, with OXY in magnocellular and parvocellular OXY neurons of the PVN and SON, and the inhibitory effect of apelin on OXY neuron activity, markedly decreasing the amount of milk delivered to the pups, provide evidence for the autocrine and paracrine inhibitory regulation of OXY neurons by apelin.

Involvement of Apelin in the Regulation of the Hypothalamus–Adrenal–Pituitary (HPA) Axis

The existence of an apelinergic system within the adult male rat anterior pituitary gland has been reported.[4] Apelin is highly coexpressed in corticotrophs and to a much lower extent in somatotrophs and a high expression of apelin receptor mRNA is also found in corticotrophs.[28] These morphological results suggest a local interaction between apelin and adrenocorticotropin (ACTH). This was confirmed by *ex vivo* anterior pituitary gland perfusion studies, which showed that apelin increases basal or K^+-evoked ACTH release. Together, these results indicate that apelin released from corticotrophs or somatotrophs exerts a direct stimulatory effect in the anterior pituitary gland on ACTH release in an autocrine/paracrine manner.[28] Apelin nerve fibers and apelin receptor mRNA expression were also visualized in the parvocellular part of the PVN.[22] Central administration of apelin significantly increases plasma ACTH[32] and corticosterone[13,32] release, at least in part by stimulating corticotropin-releasing hormone (CRH) release.[32] Apelin has also been shown to stimulate significantly the release of CRH and AVP from hypothalamic explants *in vitro*.[34] These results suggest that apelin stimulates ACTH release not only through a direct effect in the anterior pituitary, but also via indirect effects involving the stimulation of CRH release in the hypothalamus. Consistent with this model, apelin receptor mRNA expression is increased in the parvocellular division of the PVN in rats subjected to acute stress (restraint stress), which is known to increase the activity of the HPA axis.[22]

PERIPHERAL CARDIOVASCULAR ACTIONS

Apelin and its receptor are also present in the cardiovascular system.[25]Apelin receptor mRNA expression has been detected in the endothelial cells of large arteries, coronary vessels, and endocardium of the right atrium. Injection of apelin into the bloodstream decreases arterial BP, via a mechanism dependent on NO production. In normotensive or hypertensive rats, apelin increases the contractile force of the myocardium via a positive inotropic effect. Moreover, APJ knockout mice display an enhanced vasopressor response to systemic Ang II, suggesting a counterregulatory action of apelin on Ang II. This counterregulatory action of apelin on Ang II is also supported by the observation that apelin infusion in ApoE-knockout mice abrogates the formation of atherosclerosis and abdominal aortic aneurysm induced by Ang II. Acute administration of apelin *in vivo* results in a vasodilation-induced decrease in left ventricular preload and afterload, and a potent increase in contractility accompanied by a slight decrease in cardiac output. Conversely, chronic apelin infusion increases cardiac output without causing hypertrophy. In addition, mice deficient for apelin develop progressive impairment of cardiac contractility associated with systolic dysfunction with the age. Moreover, these knockout mice subjected to chronic pressure overload by aortic banding develop severe heart failure. It thus appears that apelin is crucial to maintain cardiac contractility in pressure overload and aging.

Overall, these results suggest that the apelin receptor could constitute a potential therapeutic target in the treatment of heart failure. Indeed, the administration of an agonist of the apelin receptor might improve the contractile performance of the myocardium while reducing peripheral resistance and increasing aqueous diuresis in patients with heart failure.

PATHOPHYSIOLOGICAL IMPLICATIONS

The identification of apelin as the endogenous ligand of the orphan APJ receptor constitutes a major advance, for both fundamental research and, potentially, clinical practice. It shows the validity of the "deorphanization" approach to orphan receptors for the identification of novel bioactive peptides and new therapeutic targets. The experimental results obtained to date show that apelin colocalizes with AVP and

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

OXY in hypothalamic vasopressinergic and oxytocinergic neurons and that apelin receptors are expressed by these neurons. Apelin increases aqueous diuresis in lactating rats via its central and renal actions: (i) by inhibiting in an autocrine manner the phasic electrical activity of vasopressinergic neurons and secretion of AVP in the blood circulation, and (ii) by a direct effect on the renal microcirculation and probably on tubule function. Apelin inhibits the activity of OXY neurons in lactating rats through a direct action on apelin receptors expressed by these neurons in an autocrine and paracrine manner. Thus, apelin, which limits the action of OXY during lactation and counteracts the antidiuretic action of AVP, may be an important peptide for the fine regulation of functions related to the maintenance of body fluid homeostasis in certain physiological conditions. Finally, when injected into the bloodstream, apelin decreases blood pressure and improves cardiac contractility, suggesting a crucial role for apelin in regulating cardiovascular functions. Clinically, the development of nonpeptidic agonists of the apelin receptor, based on the knowledge of the structures of apelin and its receptor, could provide new therapeutic tools potentially useful for the treatment of heart failure and states of water and/or electrolyte retention.

Chapter 97

BNP/CNP

Yoshio Takei

ABSTRACT

The natriuretic peptide (NP) family consists of atrial, brain, and C-type NP (ANP, BNP, and CNP) in mammals, of which BNP and CNP were isolated from the brain. However, BNP is a circulating hormone secreted from the heart, and its brain concentration is extremely low in some species. Thus, BNP is now called B-type NP. CNP is a true brain peptide, but its cerebral actions are still emerging. The most prominent phenotype of CNP knockout mice is a short statue resulting from impaired endochondral bone growth. Four CNPs (CNP1–4) are found in teleost fish, of which CNP4 is an ortholog of mammalian CNP. Comparative genomic analyses of the NP family show that CNP4 is an ancestral molecule of the family and that cardiac ANP and BNP are produced by tandem duplication from CNP3 before divergence of ray-finned fishes and lobe-finned fishes (tetrapods).

DISCOVERY

Natriuretic peptides (NPs) have a common intramolecular ring structure consisting of 17-amino-acid residues and N-terminal and C-terminal extensions of variable lengths (Figures 1 and 2). After the report of a potent diuretic/natriuretic and hypotensive factor in the rat atria in 1981, the factor (atrial natriuretic peptide; ANP) was isolated in 1983.[19,28] Subsequently, the second NP was isolated from the porcine brain in 1988 and named "brain" NP (BNP).[19] In contrast to pigs, however, BNP and its gene transcript are practically undetectable in the brain of rodents and human, while BNP is synthesized abundantly in the heart, particularly in the failing ventricle. Thus, much attention has been paid to BNP in the diagnosis and treatment of cardiac failure.[19] Therefore, only the basic structure and function of BNP are described here, and details are provided in the Cardiovascular Peptides section of this volume. BNP is also present in the heart of birds, amphibians, and fishes.[11,29] Therefore, the B of BNP is now recognized as "B-type."

In 1990, a third NP was isolated from the brain of mammals, amphibians, and fishes.[19,28] In the killifish and eel, it was initially named ANP-like or BNP-like peptide, but C-type NP (CNP) is now generally used in all species. CNP is most abundantly synthesized and stored in the brain, and thus, CNP is the true "brain" peptide of the NP family. CNP has the structural characteristic of lacking the C-terminal extension from the intramolecular ring (Figure 2). CNP has been identified in all vertebrate classes ranging from cyclostomes to mammals.[10]

Phylogenetic studies of the NP family reveal the evolutionary history of the whole family in vertebrates.[10] In ray-finned fishes, four CNPs have been isolated from the brain and named CNP1, 2, 3, and 4 (Figure 2). Synteny analyses show that CNP4 is an ortholog of mammalian CNP. CNP1 is a major brain peptide of teleost fish and thus initially isolated from fish brains. Despite the difference in their origin, mammalian CNP(4) and teleost CNP1 are most similar in sequence with each other at the mature sequence of 22-amino-acid residues (Figure 2). CNP3 is localized in tandem with ANP and BNP on the same chromosome, showing that ANP and BNP are duplicated from CNP3.[11] A novel NP was isolated from the cardiac ventricle of ray-finned fish in addition to ANP and BNP and named ventricular NP (VNP),[28] which is also produced from CNP3 by tandem duplication.[11] Only a single CNP has been isolated from the brain and heart of cartilaginous fish (sharks and rays) and cyclostomes (lamprey), while a single NP with long C-terminal sequence and amidated C-terminus has been found in the brain and heart of another cyclostome (hagfish).[28] Phylogenetic analyses show that shark CNP is a CNP3 type, and lamprey CNP and hagfish NP are CNP4 types.[10] Collectively, an ancestral molecule of the NP family is CNP4, which is duplicated to produce first CNP3 and then CNP1 and CNP2 (Figure 3). ANP, BNP, and VNP are produced by tandem duplication from CNP3. Seven NPs (ANP, BNP, VNP, and CNP1–4) exist in ray-finned fish, but some have disappeared in the tetrapod lineage; ANP, BNP, CNP3, and CNP4 exist in amphibians, BNP, VNP, CNP1, and CNP3 in birds, and ANP, BNP, and CNP4 in mammals (Figure 3). Thus, BNP, not ANP, is the common cardiac NP present throughout vertebrate species.[29]

STRUCTURE OF THE mRNA/GENE

The cDNAs encoding BNP have been cloned in several species of mammals, chicken, frog, and several species of bony fishes (Table 1).[29] The precursor sequence of BNP is most versatile among the members of the NP family in mammals, but it is conserved in teleosts and other tetrapod species. All BNP mRNA sequences thus far cloned are characterized by the presence of AUUUA repeats in the 3′-untranslated region, which is known to facilitate mRNA degradation.[19,28] The genomic DNA sequences of the BNP gene are also determined in several species of mammals and teleost fish. In the vicinity of the human BNP gene, *cis*-acting elements such as activator protein-1 site, serum responsive element, and the GATA sequence have been identified.

The cDNAs coding for different types of CNPs have been sequenced in several species of tetrapods and fishes (Table 1). The CNP gene is also expressed in the venom gland of snakes and duckbill, an egg-laying mammal.[28] The genomic DNAs of the CNP genes have been sequenced in mammals and teleost fishes (Table 1). A cAMP responsive element-like sequence and GC boxes are localized in the promoter region of the CNP gene.

PROCESSING OF THE PRECURSOR

The BNP prohormone is cleaved by a processing enzyme, furin, to produce mature BNP in the brain[25] (see the chapter on furin in the Peptide Biosynthesis/Processing section of this book). Furin acts on a consensus sequence, Arg-X-X-Arg, so that mature human and porcine BNP have 32-amino-acid residues (BNP-32) and those of rats and mice contain 45 amino acid residues (BNP-45) depending on the location of the sequence. BNP is also processed to BNP-26 in the porcine brain.[33] BNP-32 circulates in the blood of human and pig as a mature hormone. ANP also exists in the brain, and the brain forms have 3–4 amino acids

deleted from the N-terminus of the mature circulating form. Only BNP prohormone is detected in the porcine atria, but BNP-32 is a major form stored in the human atria.[19] BNP-45 is a major form circulating in the rat blood, and both prohormone and BNP-45 are stored in the rat atria.

Although BNP exists in several nonmammalian species, their mature, circulating forms have not been determined yet. There is a furin-processing signal in the prosegment of chicken BNP, but the signal is absent in most other species.[28] Instead, two consecutive basic amino acids for cleavage by typical proprotein convertases exist in the prosegment of nonmammalian BNP. BNP has been identified in all species of bony fishes, amphibians, reptiles, birds, and mammals thus far examined, whereas ANP and its cDNA are undetectable in most species of birds and reptiles and some species of bony fishes.[29] All BNP sequences are characterized by the presence of two consecutive basic amino acids at positions 4 and 5 of the intramolecular ring.

Two molecular forms of CNP have been isolated from the porcine brain, CNP-22 and CNP-53.[16] CNP-22 is processed after dibasic amino acid residues, whereas CNP-53 is cleaved by furin. Both forms have similar biological activities and have been identified in the brain of all mammalian species. Teleost CNP4 is an ortholog of mammalian CNP, and it is the only teleost CNP that has a furin processing signal.[10] Lamprey CNP(4) and hagfish NP (CNP4) also have furin processing signals to form mature peptide. CNP1 is a major teleost CNP in the brain and most similar to mammalian CNP, but it lacks a furin-processing signal. Elasmobranch CNP(3) is highly similar to mammalian CNP but lacks furin processing signal. Thus, all CNP4-type molecules thus far known have furin-processing signals. High sequence similarity of mature mammalian CNP(4), teleost CNP1 and elasmobranch CNP(3) (Figure 2) indicates convergent evolution, probably because of the binding to their specific receptor (see below).

DISTRIBUTION OF THE mRNA/PEPTIDE

Although BNP was initially isolated from the pig brain, its concentration in the brain is much lower than in the heart in pig and other species.[19] BNP is even less abundant than ANP in the brain of rodents and human. Therefore, BNP is not a brain peptide but is a cardiac hormone like ANP. In the pig brain, BNP is localized preferentially in the striatum, hypothalamus, medulla-pons region, and spinal cord when each brain region is measured by specific radioimmunoassay.[33] *In situ* hybridization histochemistry of the rat brain showed that BNP mRNA is not detectable, but ANP mRNA is expressed in the anterior olfactory nuclei, limbic cortices, dorsal endopiriform nucleus, hippocampal subfield CA1, cortical amygdaloid nuclei, medial habenula, anteroventral periventricular and arcuate nuclei, periventricular stratum, zona incerta, mammillary nuclei, inferior olive, nucleus ambiguus, and pontine paragigantocellular nuclei.[15] In rodents and human, ANP seems to play a more significant role in brain function than BNP. In bony fishes, BNP mRNA expression is also sparse in the brain and abundant in the heart.[11] BNP has not been localized by histochemical methods in the brain of nonmammals yet.

CNP peptide and its mRNA are more abundant in the brain than in the periphery in all mammalian species thus far examined.[19] Immunoreactive CNP and its gene transcripts are ubiquitously distributed in the whole brain, with the highest concentration in the olfactory bulb. In the rat and mouse, relatively high expression of the CNP gene is detected in the tegmentum, as determined by RNase protection assay.[27] More detailed mapping of CNP mRNA by *in situ* hybridization revealed that CNP gene transcripts are localized in the olfactory nuclei, limbic cortices, dorsal endopiriform nucleus, hippocampal subfields CA1–3, anteroventral periventricular and arcuate nuclei, and numerous brainstem regions including pontine, lateral reticular, solitary tract, prepositus hypoglossal, and spinal trigeminal nuclei (Figure 4).[15] Colocalization of CNP and ANP in the same brain nuclei suggests their cooperative function. In the hypothalamus, both CNP and ANP gene transcripts are abundantly expressed in the anteroventral preoptic area and arcuate nucleus, which is consistent with their role in the regulation of neuroendocrine functions and appetite regulation.[8] Only CNP mRNA is detectable in the vasopressin-producing magnocellular paraventricular nucleus and supraoptic nucleus. Interestingly, water deprivation decreases and salt loading (2% NaCl for drinking water) increases CNP gene expression in the olfactory region of the rat brain as shown by northern blot and *in situ* hybridization.[4] CNP is also detected in the pineal gland of the dog.

From a comparative viewpoint, all CNPs thus far obtained are expressed abundantly in the brain in all species examined to date including cyclostomes, cartilaginous fishes, bony fishes, amphibians, and birds, although CNP is also expressed abundantly in the heart of cyclostomes and cartilaginous fishes where CNP is the only peptide of the NP family.[28] Four CNP genes identified in bony fishes are all expressed briskly in the fish brain. CNP3, from which cardiac ANP, BNP, and VNP are derived, is also expressed in the heart of the medaka, *Oryzias latipes*.[11] However, a detailed localization of CNP or its transcripts in the brain by immunohistochemistry or *in situ* hybridization has not yet been examined in nonmammalian species.

RECEPTORS AND SIGNALING CASCADES

BNP and ANP bind with high affinity to the A-type NP receptor (NPR-A or GC-A) that possesses guanylyl cyclase and kinase-like domains intracellularly in its

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

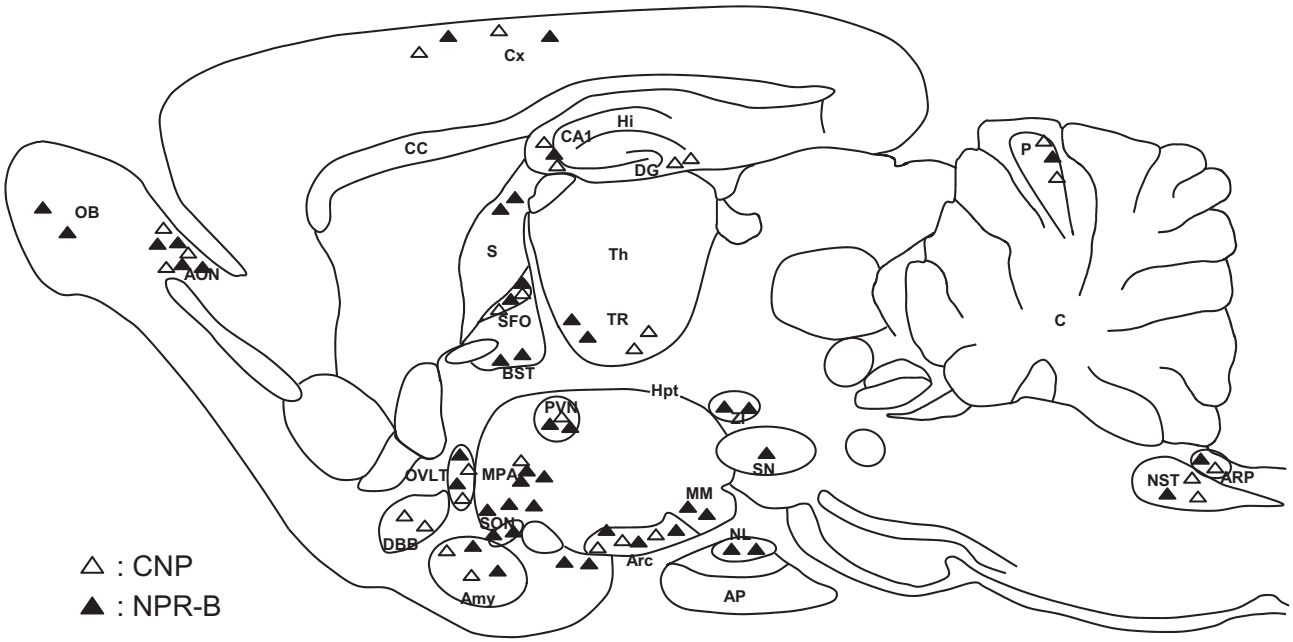

FIGURE 4 Distribution of CNP and NPR-B gene transcripts in the rat brain as revealed by *in situ* hybridization.[7,15] Amy, amygdala; AON, anterior olfactory nucleus; AP, anterior pituitary; Arc, arcuate nucleus; ARP, area postrema; BST, bed nucleus of stria terminalis; C, cerebellum; CA1, CA1 of hippocampus; CC, corpus callosum; Cx, cerebral cortex; DBB, diagonal band of Broca; DG, dentate gyrus; Hi, hippocampus; Hpt, hypothalamus; RN, lateral reticular nucleus; MM, mammilary nucleus; MPA, medial preoptic area; NL, neural lobe of pituitary; NST, nucleus of solitary tract; OB, olfactory bulb; OVLT Organum vasculosum of the lamina terminalis; P, Purkinje cell layer of the cerebellum; PVN, paraventricular nucleus; S, septum; SFO, subfornical organ; SN, substantia nigra; SON, supraoptic nucleus; Th, thalamus; TR, Nucleus reticularis thalami; ZI, Zona incerta.

molecule.[20] CNP, however, binds specifically to cognate B-type NP receptor (NPR-B or GC-B). After ligand binding to the receptors, guanylyl cyclase is activated with the help of ATP to produce cGMP. Increased cGMP acts as a second messenger to activate G-kinase, resulting in phosphorylation of various target proteins.[20] In addition, both BNP and CNP bind with high affinity to a C-type NP receptor (NPR-C) that has only a short (27 amino acids) intracellular domain and exists ubiquitously in various tissues. Judging from the rapid internalization after ligand binding and subsequent degradation of the ligand in the cell, NPR-C was initially believed to be a clearance-type receptor that regulates NP concentration in plasma and tissues. However, physiological functions have been suggested later for this receptor through an interaction with Gi proteins.[18]

In situ hybridization histochemistry shows that significant levels of NPR-A mRNA are expressed in the restricted cell populations of the rat brain that also contain high levels of ANP.[7,21] These include the olfactory bulb and circumventricular organs such as the subfornical organ and area postrema. By contrast, NPR-B mRNA is widely expressed throughout the brain, which coincides well with the wide distribution of CNP in the brain and suggests its paracrine/autocrine action (Figure 4). Autoradiography of the rat brain using ^{125}I-labeled ANP, CNP, or cANF-(4–23) that binds only to NPR-C shows that NPR-A is localized in the olfactory bulb, nucleus tractus solitarius, and circumventricular organs such as the subfornical organ and area postrema, as well as the choroid plexus.[3,19] However, this autoradiographic study could not detect CNP-specific NPR-B.

In addition to NPR-A, NPR-B, and NPR-C, another NP receptor devoid of the guanylyl cyclase domain was identified in the eel and named NPR-D.[28] The relative abundance of NPR-D in the brain suggests some biological function by an intracellular messenger other than cGMP like NPR-C. Two types of NPR-A and NPR-B have been cloned in the medaka fish. In other nonmammalian species, NPR-A has been cloned in the bullfrog and NPR-B in the dogfish where only CNP3 exists in the brain and heart.[28] It is interesting to note that medaka CNP1, 2, and 4 bind with high affinity to NPR-B, but medaka CNP3, from which ANP, BNP, and VNP are originated, binds to a medaka homolog of NPR-A.[11] Our immunohistochemical study using eel-specific NPR antisera shows that immunoreactive NPR-A is detected in the area postrema, glossopharyngeal vagal motor complex, reticular formation, and commissural nucleus of Cajal (equivalent to the nucleus tractus solitarius) in the eel brain, whereas immunoreactive NPR-B is distributed widely in the vascular smooth muscle cells of whole brain.[32]

BIOLOGICAL ACTIONS WITHIN THE BRAIN AND PITUITARY

As mentioned above, BNP is undetectable in the rodent brain by immunohistochemistry or *in situ* hybridization, and BNP concentration is much lower than ANP concentration in the human and rat brains. Thus, the biological action of ANP in the brain has been characterized in the rat, which will be reviewed here.

ANP is implicated in the central regulation of body fluid homeostasis in rat.[1] It has been shown that water deprivation reduces ANP content in several discrete regions of the brain such as the neural lobe of the pituitary, organum vasculosum lamina terminalis, supraoptic and suprachiasmatic nuclei, but not in other regions.[22] In fact, infusion of rat ANP-(4–28), a major brain form, into the third ventricle inhibits drinking induced by water deprivation or by central infusion of angiotensin II in normally hydrated rats.[9] Interestingly, intravenous infusion of ANP at similar doses equally inhibits drinking induced by these dipsogenic treatments, suggesting that ANP acts on a central site devoid of a blood–brain barrier such as the circumventricular organs. Similarly, central infusion of ANP causes a dose-dependent and long-lasting inhibition of sodium appetite in sodium-deplete rats.[9] In nonmammalian species, direct injection of eel ANP into the area postrema inhibits drinking, and lesioning of the area postrema abolishes the antidipsogenic action of peripheral ANP.[32] Thus, ANP may act on this circumventricular structure for inhibition of drinking caused by reflex swallowing in this aquatic animal.

Central ANP also influences hypothalamic and pituitary hormone secretion in mammals. The hormones that are regulated include vasopressin, GnRH, and CRH secreted from the neural tissues, and prolactin, growth hormone, ACTH, and luteinizing hormone secreted from the anterior pituitary.[22] Vasopressin, whose secretion is induced by angiotensin II or dehydration, is inhibited by ANP *in vivo*, or administered directly onto the supraoptic or paraventricular nuclei in brain slices *in vitro*. ANP also inhibits sympathetic tone through its action on the nucleus tractus solitarius and inhibits the release of catecholamines from sympathetic nerve endings. Noradrenergic projections from the nucleus tractus solitarius to the anterior hypothalamus play pivotal roles in the central cardiovascular control in mammals. ANP has been shown to act on both sites and to decrease arterial pressure via inhibition of norepinephrine release at the anterior hypothalamic area. The deletion of the BNP/ANP gene and/or the NPR-A gene does not induce changes related to their central actions but to cardiovascular actions. Knockout of the gene coding for BNP induces cardiac fibrosis, and mice with deletion of the NPR-A gene exhibit ventricular hypertrophy and fibrosis.[15] Because mice with targeted disruption of the ANP gene are free from cardiac fibrosis, BNP and ANP seem to play differential roles in the cardiovascular regulation through NPR-A.[15]

In contrast to the many studies on the central action of ANP, studies on CNP are still limited, although CNP is a true brain peptide of the NP family. CNP is generally less potent than ANP and BNP as exemplified by neuroendocrine actions such as inhibition of vasopressin[34] and luteinizing hormone (LH) secretion.[31] CNP is produced in rat pituitaries and cultured gonadotrope cells but fails to stimulate cell proliferation and LH release, although it stimulates cGMP production.[31] With respect to body fluid regulation, CNP weakly stimulates, rather than inhibits, water drinking in rat when administered into the cerebral ventricle.[28] There has been no report on the effect of CNP on sodium appetite. Similar opposing actions are suggested on prolactin secretion: stimulation by CNP and inhibition by ANP.[23] In teleost fish (tilapia), CNP stimulates growth hormone secretion from the isolated pituitary, but ANP has no effect. Both CNP and ANP have no effects on prolactin secretion.[29]

CNP affects neurons and brain development. NPR-B gene transcripts are most abundant 1 day after birth in the brain of developing mice, suggesting a role of CNP/NPR-B system in neonatal brain maturation.[17] In sensory neurons, CNP is synthesized abundantly in the dorsal root ganglion of the spinal cord and regulates axonal development via NPR-B and cGMP.[24] Thus, CNP functions as a bifurcation factor of sensory neurons responsible for axonal branching. It has also been suggested that CNP and NPR-B expressed in the rat hippocampus are involved in the regulation of long-term potentiation and depression in the area CA1.[5]

Mice lacking the CNP gene show severe dwarfism as a result of impaired endochondral ossification.[15] Further, most of them die early during postnatal development. Targeted expression of the CNP gene in growth plate chondrocytes rescues the skeletal defect of CNP-deficient mice and prolongs their survival. Thus, their short life results in part from skeletal abnormalities. Disruption of NPR-B also induces profound dwarfism and early death in mice.[15] NPR-B knockout also impairs female, but not male, reproductive organs.[30] The knockout mice exhibit self-clasping and priapism, showing severe neuronal disorder, although no histological abnormalities are detectable in the brain and spinal cord. This result coincides with the perinatal peak expression of the NPR-B gene in the developing mouse.[17] In humans, autosomal recessive skeletal dysplasia is shown to have mutations in the NPR-B gene, and obligate carriers of the mutations are shorter than matched controls.[2] A genomewide association study shows that polymorphism in CNP and its receptor genes plays an important role in determining human body height in the tall populations of northeastern Europe.[6] These results show that the major role of CNP/NPR-B is in the regulation of skeletal growth, although the peptide is most abundant in the brain.

In relation to the prominent dwarf phenotype of CNP or NPR-B knockdown mice, the role of CNP/NPR-B in skeletal growth has been investigated intensively. These studies show that liver-targeted CNP transgenic mice with high plasma CNP concentrations exhibit skeletal overgrowth in proportion to the plasma CNP concentrations and increased CNP in plasma rescues the dwarf phenotype of CNP knockout mice.[35] Thus, endochondral ossification can be stimulated by circulating CNP and locally produced CNP. CNP also stimulates growth by regulating food intake and energy expenditure as CNP knockout mice with cartilage-specific CNP overexpression still exhibit impaired skeletal growth.[19] The regulatory role of appetite is consistent with CNP gene expression in the arcuate nucleus and paraventricular nucleus, which are important appetite-regulating sites. The CNP/NPR-B system may also be involved in the regulation of adipogenesis.[13] The dwarf phenotype of NPR-B gene-mutant mice may result in part from the lack of gastrointestinal motility.[26] As a result of various central and peripheral actions, CNP seems to maintain normal growth during development.

PATHOPHYSIOLOGICAL IMPLICATIONS

BNP secretion is profoundly augmented from the heart, particularly from the ventricle, in patients with congestive heart failure and acute myocardial infarction, and the increase is correlated with the enlargement, decreased contractility, and increased stiffness of the left ventricle, suggesting its role in ventricular remodeling. Indeed, mice with targeted disruption of the BNP gene show cardiac fibrosis defined as a proliferation of interstitial fibroblasts and biosynthesis of extracellular matrices in the cardiac ventricle.[14] More information on clinical relevance of BNP and ANP is described in the Renal, Cardiovascular, and Endocrine Peptides sections of this book.

CNPs are ancient peptides of the NP family and CNP4, an ortholog of mammalian CNP, is the ancestral molecule of the NP family.[11] Consistent with the phylogenetic ancestry, the genes of CNP and its receptor, NPR-B, are expressed early during development in the brain and seem to play important roles in neurogenesis and axonal branching of neurons. Thus, it is possible that CNP seems to play important roles in neural development in patients with CNP mutations. More promising is a replacement therapy of CNP for retarded skeletal development in CNP mutation diseases such as chondrodysplasia, because direct administration of CNP to the endochondral plate restores normal bone growth.[20] Systemic administration of CNP can also have a therapeutic potential against impaired growth of chondrodysplasias.[35] It seems that CNP acts as an important regulator in the brain for food intake and energy metabolism to regulate body size in cooperation with the peripheral CNP/NPR-B system.[19,12]

Chapter 98

CART

Csaba Fekete and Ronald M. Lechan

ABSTRACT

Cocaine- and amphetamine-regulated transcript (CART) peptides are widely expressed in the central nervous system and in the pituitary. ProCART peptides are directed to secretory granules by a signal sequence and further processed by prohormone convertases into smaller biologically active peptides. These peptides have an important role in the regulation of a number of physiological processes in the central nervous system including reward, feeding, neuroendocrine function, pain, cardiovascular function, and gastrointestinal motility.

DISCOVERY

Cocaine- and amphetamine-regulated transcript (CART) was discovered in 1995 as a striatal transcript induced by psychostimulant administration.[9] As revealed by differential display PCR, the acute administration of either cocaine or amphetamine is capable of inducing an approximately 5-fold increase in CART mRNA in the striatum but not in other regions of the brain.[9] It was later recognized that a somatostatin-like peptide fragment isolated in 1981[25] is identical to the N-terminal portion of CART 55–102 peptide.

STRUCTURE OF THE CART PRECURSOR mRNA AND CART GENE

CART transcript is present in rat tissues as an RNA doublet.[7] An alternate polyA site used in the 3′ noncoding region generates two CART mRNAs approximately 700 and 900 bases long.[7] In addition, alternate splicing generates even further mRNA species resulting from the presence or absence of an in-frame 39 base insert in the coding region.[7] This results in the production of two proCART peptides with 102 or 89 amino acid residues, respectively.[7] Approximately one-third of the CART mRNA content in the rat brain contains the 39 nucleotide insert.[7] Although multiple polyA sites are also present in the human CART gene, only one site is used, resulting in an approximately 900-base-long CART mRNA.[7] In addition, human CART mRNA does not contain the 39-base-long insert observed in the rat.[7] Two different CART mRNAs are also present in the goldfish, resulting in the production of two different proCART polypeptides with 117 and 120 amino acid residues, respectively. However, in this species, the two different CART mRNA are products of two different CART genes.[7]

The chromosomal location of the CART gene has been identified in humans on chromosome 5 and in mice on chromosome 13.[7] Comparison of the cDNA sequence to that of the genomic DNA in different species reveals that in all instances, mature CART mRNA is encoded by three exons.[7]

The proximal promoter (340-nucleotides upstream of the transcription initiation site) of the mouse CART gene that has >80% identity with the human sequences contains multiple putative transcription factor binding sites.[7] The predicted transcription factor binding sites are as follows: TATA box, STAT, cAMP response element (CRE), AP1, SP1, AP2, and E-box. A Pit-1 site is found in a more distal promoter region.[7] Among these sites, the canonical CRE site has been functionally validated. This CRE site binds phosphorylated CREB *in vivo* and *in vitro*, and the absence of this site prevents forskolin responsiveness of the promoter in an *in vitro* promoter assay.[7] Pit-1 responsiveness of the CART promoter has also been shown, but the exact binding site is unknown.[7] Although CART mRNA was believed to be initiated 19 nucleotide upstream of the AUG codon, four additional CART mRNAs have been identified with different 5′-untranslated region lengths (63, 105, 132, and 151 nucleotides upstream of the translation initiation site),[7] suggesting that the mouse CART promoter may lack a functional TATA box.[7]

PROCESSING OF CART PEPTIDES

CART peptides derive from two precursor polypeptides of 129 and 116 amino acid residues that arise via alternative splicing of a single CART gene in rats and mice.[9] The longer form of the CART precursor (rlCART) contains a 13-amino acid insert compared with the short precursor (rsCART).[9] In contrast to rodents, only the shorter CART precursor exists in humans.[8] Both forms of prepro-CART begin with

Copyright Elsevier 2024

a 27-amino acid signal peptide motif, suggesting that CART peptides are targets for posttranslational processing.[9] Cleavage of the signal peptide yields proCART peptides of either 102 or 89 amino acids, which are further processed by protein convertases.[6] The long form of proCART gives rise to an intermediate fragment rlCART 33–102 that is further processed into two bioactive peptides, rlCART 55–102 and rlCART 62–102.[6] Similarly, the shorter form is processed into an intermediate residue, CART 10–89, and two bioactive forms, rlCART 55–102 and rlCART 62–102.[6] (The nomenclature of CART peptides is based on the amino acid sequence of the two forms of the CART precursor (rlCART and rsCART).)

The two main enzymes involved in processing of CART are PC1/3 and PC2 protein convertases[6] (see the chapters on proconvertases in Peptide Biosynthesis/Processing section of this book). PC1/3 is much more potent than PC2 in producing intermediate CART residues. It cleaves the long form of the CART precursor to result in CART 33–102[6] and is exclusively responsible for the production of CART 10–89 from the short CART precursor.[6] By contrast, PC2 is the primary enzyme responsible for the production of CART 55–102, and is exclusively responsible for the generation of CART 62–102.[6] Both intermediate forms and the two bioactive forms of CART peptides are present in the brain.[6] By contrast, only CART 62–102 is present in the neurointermediate lobe where both PC1/3 and PC2 are present, whereas CART 55–102 is present in the anterior lobe, which expresses only PC1/3.[6] Experiments using RNAi-mediated knock down of PC5/6 in GH3 cells have also demonstrated an important role for this enzyme in the processing of CART peptides. The PC5/6A isoform of the enzyme has similar cleaving properties as PC2, cleaving the pairs of basic residues within the proCART isoforms.[29] A fourth enzyme implicated in the processing of proCART is carboxypeptidase E (CPE) (see the chapter on this enzyme in the Peptide Biosynthesis/Processing section of this book). Mature forms of CART are undetectable in CPE KO mice, while the levels of intermediate and high molecular mass CART molecules are increased, indicative of abnormal processing.[2]

DISTRIBUTION OF CART mRNA AND PEPTIDES

CART mRNA is expressed in discrete neuronal groups in the brain, and it is also present in the anterior lobe of the pituitary gland (Fig. 1).[9] The highest concentration of the CART mRNA is found in the hypothalamus, and in particular, neurons of the arcuate, paraventricular, supraoptic and dorsomedial nuclei, periventricular region, zona inzerta, and lateral hypothalamus.[9] Lower concentrations of CART mRNA are also present in the ventral and medial premamillary nuclei and in the lateral aspect of the supramamillary nucleus.[9] The pituitary gland contains as high a concentration of CART mRNA as the hypothalamus,[3] expressed in 80% of the gonadotrophs but not in GH-, TSH-, ACTH-, or prolactin-producing cells.[19] In the telencephalon, CART mRNA is localized to the olfactory tubercle, nucleus accumbens, primary somatosensory, and piriform area of the cortex, bed nucleus of the stria terminalis, dentate gyrus, and amygdaloid complex.[9] The brainstem also contains CART-expressing

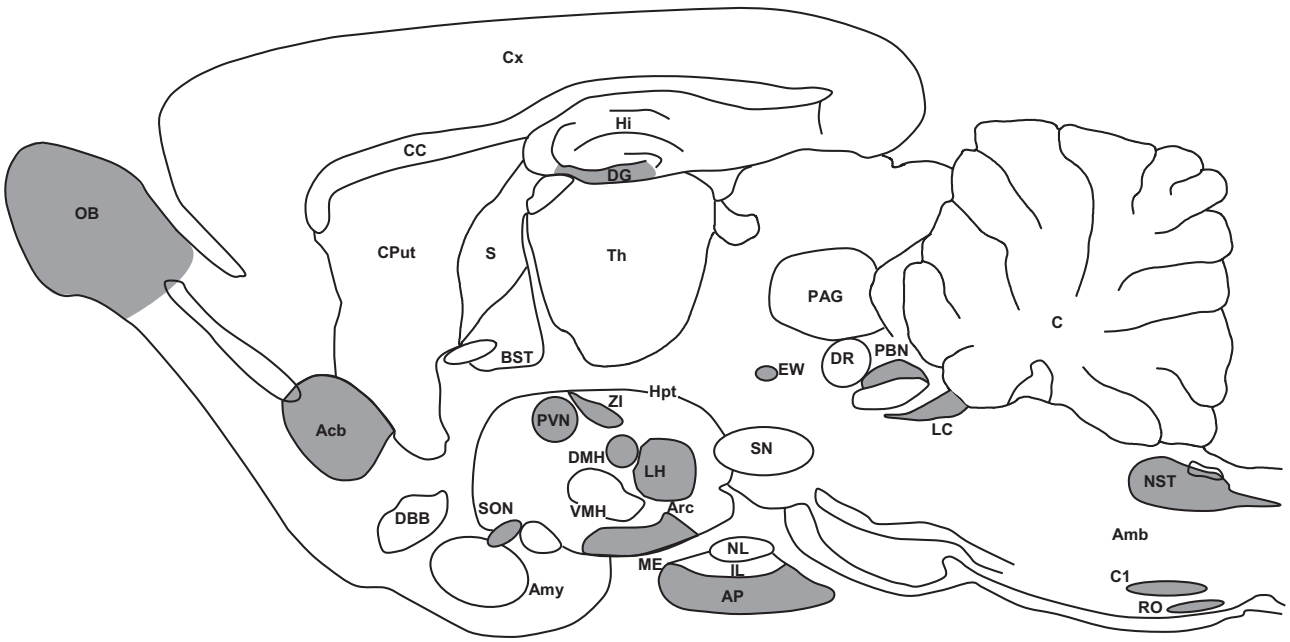

FIGURE 1 Schematic illustration showing the location of main populations of CART-synthesizing neurons.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

cell groups, including the Edinger–Westphal nucleus, locus ceruleus, parabrachial nucleus, nucleus of tractus solitarius, A1/C1 region, and raphe nuclei.[9]

The distribution of CART-immunoreactive (IR) perikarya shows a pattern similar to that observed for CART mRNA-containing cells. However, there are some discrepancies. Although in situ hybridization identifies numerous CART-expressing neurons in the hypothalamic dorsomedial (DMN) and ventral premamillary nuclei, only a few CART-IR cells can be detected in these regions.

The projection fields of CART neurons have been described in detail by Koylu et al.[16,17] Of particular importance is the observation that CART fibers densely innervate vegetative centers of the central nervous system, including the PVN, DMN, arcuate nucleus, nucleus tractus solitarius, C1-3 adrenergic cell groups, and the intermediolateral column of the spinal cord.[16,17] Furthermore, a dense CART-IR fiber network is found in the median eminence and in the posterior lobe of the pituitary arising from the CART expressing hypophysiotropic neurons and magnocellular neurosecretory neurons of the PVN and supraoptic nuclei, respectively.[17]

RECEPTORS AND SIGNALING CASCADES

Until now, little has been known about CART receptors and the intracellular signaling cascades mediating the effects of CART. Even though CART was discovered 16 years ago, CART receptors have not yet been identified and characterized. Tremendous effort was made to map CART binding sites in the brain, but without success. Saturable binding sites were detected, however, on AtT20 cells and on PC12 pheocromocytoma cells, and the membrane preparations of these cells. Furthermore, CART binding was observed in primary culture cells originating from the nucleus accumbens.

Despite the failure to identify even one receptor, it is conceivable that CART may act on more than one receptor: the two active CART peptide fragments show different relative activities in different testing paradigms, but the differences are not always in the same directions in the various tests.[31] In addition, CART signaling would seem to use multiple second messenger pathways. CART inhibits voltage-dependent intracellular $Ca(2^+)$ signaling in the hippocampus, probably through the inhibition of L-type voltage-gated $Ca(2^+)$ channel activity via a G protein-dependent pathway.[31] Sarkar et al.,[26] however, found that CART induces phosphorylation of cyclic-AMP response element binding protein (CREB) in corticotropin-releasing hormone (CRH)-synthesizing neurons of the PVN, suggesting that the cAMP–CREB signaling pathway may be involved in the mediation of CART effects. In addition, CART can rapidly induce ERK phosphorylation in AtT20 cells, mediated through pertussis toxin-sensitive G protein coupled receptors.[31]

BIOLOGICAL ACTIONS OF CART PEPTIDES WITHIN THE BRAIN AND PITUITARY

During the processing of proCART, several different CART fragments are produced. The two biologically active, naturally occurring CART peptides are rlCART 55–102 and 62–102. As the biological activity of N-terminal fragments remains controversial, we focus here only on the most studied biological effects of rlCART 55–102 and 62–102 including their role in the central regulation of reward, feeding, energy metabolism, neuroendocrine regulation, pain, cardiac function, and gut motility.[25] Each action will be briefly summarized below.

Reward

One of the first recognized actions of CART in the CNS is its involvement in reward processes, based on the regulation of CART gene expression in the striatum by cocaine and amphetamine and the presence of CART peptides in the mesolimbic reward circuit including the nucleus accumbens, lateral hypothalamic area, and ventral tegmental area (VTA).[25] In the striatum, CART is synthesized in neurons of the nucleus accumbens, where the majority of CART-expressing cells are GABA-ergic inhibitory neurons and synthesize substance P, the marker of striatal neurons projecting to the substancia nigra.[23] Amphetamine upregulates CART gene expression in the nucleus accumbens, and this is mediated via dopaminergic signaling. CART-containing neurons are innervated by dopaminergic terminals, and CART gene expression is upregulated by dopamine in these cells. Conversely, CART administration into the nucleus accumbens reduces the effect of amphetamines and dopamine on locomotor activity and inhibits amphetamine-induced behavioral sensitization. It is hypothesized, therefore, that CART has a homeostatic function in the nucleus accumbens by blunting the effects of the drug-induced increase in dopamine release.[25] Indeed, CART peptides reduce the rewarding effects of cocaine and inhibits the context induced reinstatement of reward seeking.[15,23]

In the VTA of rodents, CART peptides are present in axon terminals, but CART mRNA is not expressed in this brain region. CART administration into the VTA induces psychostimulant like effects including increase of locomotor activity and induction of conditional place preference.[23] CART innervation of the VTA primarily arises from lateral hypothalamic and perifornical areas, where CART-containing neurons are GABA-ergic and coexpress melanin-concentrating hormone (MCH), a peptide known to influence reward processes.[23] CART neurons in the lateral hypothalamus also project to the nucleus accumbens, but it is not known whether they contribute to reward processes. The strong anatomical interaction of lateral hypothalamic CART neurons with the nucleus

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

accumbens and VTA and the well-known role of the lateral hypothalamus in the regulation of reward, however, raise the possibility that the lateral hypothalamic CART has an important role.[23] CART peptides in the amygdala and the prefrontal cortex have also been implicated in the regulation of reward processes.

Feeding and Energy Metabolism

The synthesis of CART peptides in specific neuronal groups that have been implicated in the central control of energy homeostasis has suggested an important role for CART in the regulation of feeding and energy metabolism. These neuronal groups include alpha-melanocyte–stimulating hormone (α-MSH)-producing neurons of the hypothalamic arcuate nucleus, MCH neurons of the lateral hypothalamus, neurons of the DMN and NTS and epinephrine-synthesizing neurons of the C1-3 regions of the brainstem.[12,32] Along these lines, an acute injection of CART into the CSF induces c-fos in the above-mentioned feeding-related regions, decreases feeding, and inhibits the orexinogenic effects of NPY, whereas chronic administration induces significant weight loss.[25] Conversely, the central administration of CART antiserum increases food intake.[25]

In anorexigenic neurons of the arcuate nucleus, the synthesis of CART is highly regulated by circulating levels of leptin.[25] Exogenous administration of leptin or elevated leptin levels induced by high fat diet-induced obesity increases CART mRNA in the arcuate nucleus.[25] Conversely, CART gene expression is decreased in the arcuate nucleus of leptin resistant, fa/fa Zucker rats and leptin deficient ob/ob mice. In the latter animal model, CART mRNA level can be normalized by leptin replacement.[25]

The actions of leptin on CART gene expression is believed to be exerted directly on CART/α-MSH-producing neurons of the arcuate nucleus, as these neurons express leptin receptors and show evidence of SOCS-3 expression following leptin administration.[25] In contrast to POMC gene expression, however, CART does not seem to be regulated by insulin, suggesting that the two anorexigenic peptides of the anorexigenic arcuate nucleus neurons (α-MSH and CART) may have highly different functions in the regulation of energy metabolism.[11]

CART-synthesizing arcuate nucleus neurons project directly to the PVN[25] and the intermediolateral column of the spinal cord,[25] thereby coordinating the effects of CART to simultaneously regulate food intake and energy metabolism.[25]

Hypothalamic CART populations also have connections with the nucleus accumbens shell. Focal injection of CART into the accumbens shell decreases food intake in *ad libitum* fed animals and attenuates the orexigenic effect of GABA administration into the accumbens shell, suggesting that CART may influence the rewarding effect of food. The accumbens shell receives CART innervation from the arcuate nucleus, the perifornical area, and from the accumbens shell, itself. As fasting downregulates CART mRNA level in all three regions, it is probable that hypothalamic CART-synthesizing neurons and local interneurons act together in the accumbens shell to inhibit food intake.[35]

CART also influences food intake through effects on brainstem feeding centers, as administration of CART into the fourth ventricle inhibits food intake.[25]

Although there is general agreement that icv. administration of CART has anorexigenic effects, some discrepancies have been reported. Wang et al.[33] observed inhibition of food intake when CART is injected directly into the PVN, whereas Abbott et al.[1] observed increased food intake after focal injection of CART into either the PVN or arcuate nucleus. In addition, in contrast to the rodent findings, CART is absent from anorexigenic α-MSH neurons and present in the orexigenic AGRP/NPY neurons in the human infundibular nucleus, the analog of the rodent arcuate nucleus.[21] Nevertheless, consistent with the role of CART as an anorexic peptide, CART deficient transgenic mice develop obesity when placed on a high caloric diet,[25] and polymorphisms of the 5' flanking region of the CART promoter are associated with obesity.

Neuroendocrine Regulation of Hypothalamic Hypophysiotropic Neurons

CART has a number of important actions on hypophysiotropic neurons of the hypothalamic–pituitary axes as indicated by the synaptic association of CART-containing axon terminals with CRH-, TRH-, and GnRH-producing hypothalamic neurons. The CART-IR innervation of TRH and CRH neurons originates primarily from two sources: adrenergic C1–3 regions of the medulla and the hypothalamic arcuate nucleus. The central administration of CART activates CRH neurons, and its stimulatory effect on ACTH and corticosterone secretion can be blocked by the CRH antagonist, astressin B.[25] CART also exerts stimulatory effects on hypophysiotropic TRH neurons in the PVN, increasing TRH content and secretion from hypothalamic cells[10] and preventing the fasting-induced decline in TRH gene expression in the PVN.[10] Although these actions may be involved in the mediation of the action of leptin via projections from CART/α-MSH neurons of the arcuate nucleus,[10] dense innervation of TRH neurons by CART/IR cells of the brainstem indicates that CART may also be involved the regulation of the hypophysiotropic TRH neurons by other physiological processes.

CART also seems to play a crucial role in mediating the effects of leptin on the central regulation of gonadal function.[22] LHRH pulse amplitude is similarly increased by both leptin and CART in female rats.[22] Further, immunoneutralization of CART prevents the leptin induced increase of LHRH pulse amplitude in hypothalamic explants.[22]

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

In addition to regulation of hypophysiotropic neurons through afferent inputs, CART is also coexpressed in hypophysiotropic neurons that synthesize TRH, somatostatin, vasopressin, and oxytocin, presumably to regulate pituitary function. CART has a direct inhibitory effect on prolactin secretion *in vitro*,[19] and can completely block the stimulatory effects of TRH on prolactin secretion at even low concentrations (10^{-8} to 10^{-10} M).[24] CART has no effect, however, on either basal or stimulated TSH, LH, or FSH secretion. As noted previously, CART has been identified in gonadotrophs in the rat anterior pituitary gland,[19] suggesting the additional possibility that it may be involved in paracrine regulation of prolactin secretion.[19]

Pain

CART peptides 55–102 and 49–89, when administered icv or intrathecally, have been reported to produce significant antinociceptive effects as measured by hindpaw withdrawal latency in the hot-plate test and to enhance antinociceptive effects of morphine in the tail flick test.[25] CART has also been shown to reduce neurophatic hyperalgesia.[4] It is presumed that the major analgesic actions of CART are exerted in the spinal cord, consistent with the presence of CART in peptidergic, nociceptive, primary afferents in the superficial laminae of the dorsal horn of spinal cord.[18]

Vegetative Functions

Intracerebroventricular and intracisternal administration of CART increases mean arterial pressure and heart rate in rats and rabbits,[25] and CART is a potent vasoconstrictor in the cerebral circulation.[25] Because a relatively high dose of CART is necessary to influence cardiovascular function when administered intrathecally,[25] the brain may be the primary site of the action for these physiologic effects of CART. At least two different regions of the brainstem have been identified as mediating these responses, including the rostral ventrolateral medulla, a critical pressor area where intracisternal CART administration induces c-fos expression, and the nucleus tractus solitarius, where local administration of CART attenuates phenylephrine-induced bradycardia.[27] However, CART, alone, is relatively ineffective in influencing the cardiovascular system if administered intrathecally, but even low doses of CART are sufficient to potentiate the stimulatory effects of intrathecally administered glutamate on cardiovascular function.[28] It is presumed that this effect is exerted through the intermediolateral column of the spinal cord,[28] which is heavily innervated by CART-synthesizing vasomotor neurons of the rostral ventrolateral medulla.

CART also acts in the CNS to inhibit gastric acid secretion and gastric motility, and stimulate colonic motility.[25] It is presumed that these actions are mediated in the brain by CRH-synthesizing neurons, as the effects of CART on gastrointestinal function can be inhibited with CRH antagonists.[25]

Neuroprotection (also see Neurotrophic Peptides section of this book)

CART expression is induced in the cerebral cortex after focal cerebral ischemia in the rat *in vivo* and after oxygen-glucose deprivation (OGD) in cultured cortical neurons.[20] This increase is further enhanced by estradiol administration.[20] Because immunoneutralization of CART attenuates estradiol-induced neuroprotection, and administration of CART peptide *in vivo* reduces infarct size after middle cerebral artery occlusion,[20] it is suggested that CART plays important role in neuroprotection. The neuroprotective mechanism of action of CART may be linked to the preservation of mitochondrial function and prevention of energy failure after ischemia–reperfusion injury.[20]

PATHOPHYSIOLOGICAL IMPLICATIONS

To date, little is known about the role of CART in pathological conditions, but an association has been suggested by genetic linkage studies in the development of obesity, alteration in lipid profile, bone remodeling, and alcoholism. Polymorphism in the 5′ flanking region of the CART gene (−156) is significantly associated with an increased BMI,[34] and a missense mutation at codon 34 in the N-terminal region cosegregates with a severe obese phenotype.[5] Subjects bearing the −3608 C allele have a plasma lipid profile protective against atherogenesis[30] and increased bone mineral density in postmenopausal woman.[13] Jung et al.[14] also found that an AvaII polymorphism in intron I predisposes to alcoholism but not with depression or schizophrenia.[14]

Chapter 99

CCK

Margery C. Beinfeld

ABSTRACT

CCK is one of the most abundant and widely expressed peptides in the brain. The major form found in the brain is CCK 8 amide. It is present in both local and long projecting neurons. It is colocalized with several classical neurotransmitters. Both the CCK receptors are found in the brain but have different distributions. CCK functions as an excitatory neurotransmitter and modulates the release and function of other neurotransmitters. The precise physiological role of brain CCK has not been established, but it seems to be involved in satiety, anxiety, analgesia, learning, memory, and dopamine-mediated behaviors.

The discovery of the substance that is now called cholecystokinin (CCK) dates to the beginning of the 20th century. Bayliss and Starling showed that intestinal acidification caused gall bladder contraction. They correctly surmised that this treatment was causing something to be released into circulation from the intestine, which caused the gall bladder to contract. The release of CCK and other peptides after this treatment was shown later, and administration of CCK was found to cause gall bladder contraction. Porcine intestinal CCK 33 was isolated and sequenced by Mutt and Jorpes in the 1960s.[20] The name CCK/gastrin arose in 1975 with the detection of CCK-like immunoreactivity in the brain with a gastrin antiserum that crossreacted with CCK.[27] Based on its biological activity, chromatographic profile, and amino acid sequencing, it soon became clear that this material was not gastrin but CCK 8.[9] Small amounts of gastrin are found in the brain and pituitary of several species.

CCK and gastrin share the same five carboxyl-terminal amino acids, and gastrin is believed to have evolved from CCK by gene duplication. CCK has a long evolutionary history. Caerulein, a frog skin peptide that is related to CCK and gastrin, is described in the Amphibian/Skin Peptides section of the book.

The final processed form of both CCK and gastrin has a sulfated tyrosine residue. CCK is completely sulfated, whereas the degree of sulfation of gastrin varies in a tissue-specific manner. The functional and evolutionary relationships between CCK and gastrin are described in more detail in the Gastrointestinal Peptides section of the book.

STRUCTURE OF THE PRECURSOR mRNA/GENE

The CCK cDNA was first cloned using mRNA from a rat thyroid medullary carcinoma, which expressed very high levels of CCK. The cDNAs from many species were subsequently cloned. The transcriptional unit of CCK spans 7 kb and is interrupted by two introns. The promoter is found within 144 bp of the transcription start site.[8] The complex regulation of CCK expression has been studied in detail, reviewed in Ref. 13. The CCK promoter contains cyclic AMP and estrogen response elements. It also contains an E-box element. CCK expression is stimulated synergistically by cAMP and fibroblast growth factor.

DISTRIBUTION OF CCK

CCK is one of the most abundant and widely distributed peptides in the brain. There are numerous CCK mRNA-positive cell bodies in the olfactory bulb (OB), cerebral cortex (Cx), hypothalamus (Hpt), thalamus (Th), hippocampus (Hi), amygdala (Amy), various nuclei in the mesencephalon, ventral tegmental area (VTA), and substantia nigra (SN).[4,23] The distribution of CCK cell bodies and their projections is shown in Fig. 1. One fascinating aspect of the anatomy of CCK in the Cx and Hi is the overlap between neurons, which express CCK, GABA, and cannabinoid CB1 receptors.[11]

PROCESSING OF THE PRECURSOR (SEE PEPTIDE BIOSYNTHESIS/PROCESSING SECTION OF THIS BOOK)

The processing of proCCK occurs mainly at single Arg or Lys residues (Fig. 2). The sequence and structure of proCCK and gastrin are similar, and they both display tissue-specific processing. CCK 8 is the major form in brain, whereas the intestine has larger forms. CCK and gastrin in the gut are discussed in the Ingestive and Gastrointestinal Peptides section of this book.

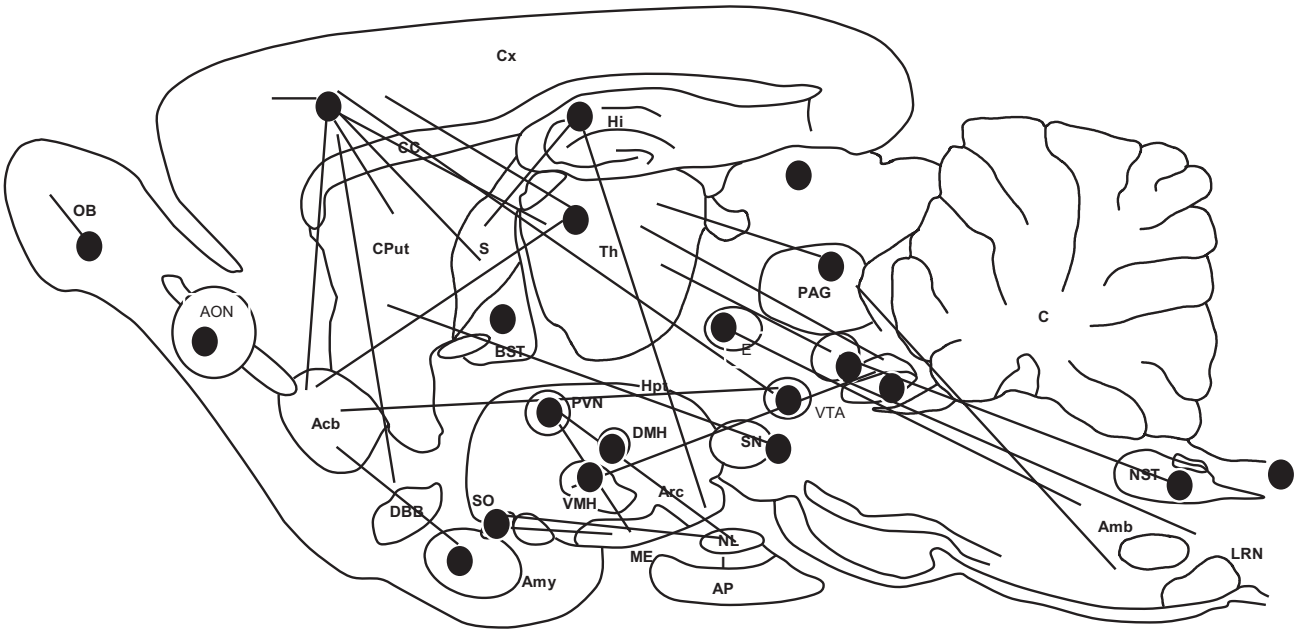

FIGURE 1 Distribution of CCK neurons and their major projections in the rat brain. CCK cell bodies are indicated by dots and their projections by solid lines.

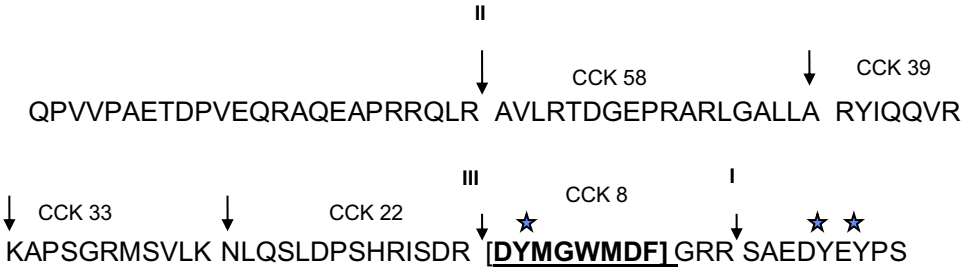

FIGURE 2 Sequence of mouse proCCK written in the single amino acid code. The endoproteolytic cleavage sites are indicated by spaces and downward arrows, the CCK 8 sequence is underlined. CCK peptides are numbered backward from the carboxyl-terminal of CCK 8. The amino terminal end of the major forms of amidated CCK peptides is indicated by the downward arrows. Stars mark the location of the sulfated tyrosine residues. The temporal order of endoproteolytic cleavages for the production of CCK 8 is indicated by the roman numerals.

A strict temporal order of cleavages has been shown for a number of prohormones, including CCK. It is believed that the first site where cleavage occurs is the most accessible. After cleavage of the first site, the remaining prohormone changes structure, making additional sites available for cleavage in a specific order.

The order of proCCK processing to CCK 22 and CCK 8 is indicated in Fig. 2. It is based on products identified in normal and *fat/fat* mouse brain and on site-directed mutagenesis studies in endocrine tumor cells.[28]

Signal Peptide Cleavage

The signal sequence of preproCCK allows it to be inserted into the lumen of the endoplasmic reticulum (ER). The signal sequence is removed by the signalase enzyme located on the luminal surface of the ER membrane.

Tyrosine Sulfation

Three out of four tyrosine residues in proCCK are sulfated by protein tyrosine sulfotransferase in the trans-Golgi network (TGN). The tyrosines that are sulfated have adjacent acidic residues that constitute the consensus sequence for sulfation.

Sorting into Secretory Granules

In the TGN, sulfated proCCK is sorted into secretory granules with the enzymes responsible for its processing.

Cleavage 1 on the Carboxyl-terminal of CCK 8 Gly Arg Arg (GRR)

Mutation of the GRR site on the carboxyl-terminal of CCK 8 to Gly Ala Ala blocks the production of amidated CCK.[28]

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Cleavage 2 at RA (Arg Ala) at CCK 58 (Removal of the Propeptide)

Mutation of the RA cleavage site to Ala Ala completely prevents subsequent production of amidated CCK 22 or CCK 8. CCK 58 GRR does not accumulate in the brain or in cell lines because it is efficiently cleaved to smaller forms.[28]

Cleavage 3 at CCK 22 Lys Asn and Arg Asp CCK 8 to Produce CCK 22 GRR and CCK 8 GRR

Removal of these cleavage sites by mutation prevents their cleavage, but it otherwise has a minor impact on any other aspect of the processing.[28]

Removal of Carboxyl-terminal Arginine Residues by Carboxypeptidase E (CPE)

Conversion of CCK 22 G and CCK 8 G to CCK 22 Amide and CCK 8 Amide by the Amidation Enzyme

The last step in CCK biosynthesis is the amidation of glycine-extended CCK peptides by peptidyl glycine-α-amidating monooxygenase.

Enzymology of ProCCK Processing (see Peptide Biosynthesis/Processing section of this book)

Tyrosyl Protein Sulfotranferase

Two Golgi enzymes (TSP1 and TSP2) have been identified that are believed to be responsible for the sulfation of the three tyrosine residues in proCCK.

Endoproteases

The most probable candidates enzyme(s) responsible for the endoproteolytic cleavages in CCK during its processing are the prohormone convertases (PCs),[25] most notably PC1, PC2, PC5, and PC7. Evidence has *also* been obtained that cathepsin L may *also* be involved in CCK processing.

They are widely colocalized with CCK in the brain[5,6] and present in cell lines that express CCK mRNA. A number of studies have shown that they have the correct catalytic activity to cleave proCCK. Antisense and RNAi studies in cell lines also support a role for these enzymes in CCK processing.

PC1,2, PC7, and cathepsin L knockout mice have decreased levels of CCK in specific brain regions, although considerable CCK is still detected. This is strong evidence that they are involved in CCK processing. In no situation was CCK completely eliminated, indicating that there are multiple enzymes that can compensate for the loss of a single enzyme and continue to provide some CCK.

Carboxypeptidases

In adult *fat/fat* mice that lack carboxypeptidase E (CPE), the levels of amidated CCK in brain are decreased by 85% showing that this enzyme is required for CCK processing. The fact that some CCK remains indicates that other carboxypeptidases are acting in the absence of CPE. There is also a large accumulation of glycine and arginine extended CCK 8, the immediate precursor of CCK 8. This also shows that CCK 33 or CCK 22 amide cannot be the immediate precursor of CCK 8 amide in brain.

Amidating Enzyme

Although C-terminal amidation is a widespread modification, glycine-extended CCK is abundant in rodent brain, intestine and CCK-expressing endocrine cells. This enzyme is dependent upon copper and ascorbate and at least in some cell lines, the quantity of glycine-extended CCK is decreased by adding ascorbate.[2] It is unclear whether this glycine-extended CCK has a function or is simply the precursor of amidated CCK.

Receptors and Signaling Cascades

Two CCK receptors have been cloned. The CCK 1 subtype is relatively specific for sulfated CCK 8, while unsulfated CCK 8, CCK 4, and gastrin are 2–3 orders of magnitude less potent. For the CCK 2 subtype (identical to the gastrin receptor), this difference in potency is about one order of magnitude. The CCK 2 receptor is more abundant and widely distributed in the brain than the CCK 1 receptor, although distinct populations of the CCK 1 receptor are present. The CCK 1 receptor is present on soma and fibers in the SN, VTA, nucleus accumbens (Acb), and dorsal striatum but not in the prefrontal Cx, Amy, or Hi. The CCK 2 receptor is present on soma and fibers in the SN, VTA, Cx, Abc, dorsal striatum, Hi, and Amy.

What happens after CCK activates its receptors has been extensively studied. The model that has been studied in the most detail is the rodent pancreatic acinar cell, which expresses mainly CCK 1 receptors. The AR42 J pancreatic cell line and adrenal chromaffin cells, which express the CCK 2 receptor have also been studied.[32]

In pancreatic acinar cells, CCK receptor activation recruits the heterotrimeric G proteins G_q and G_{11} and results in increased levels of inositol triphosphate, increased intracellular calcium and activation of protein kinase C. At higher concentrations, CCK can activate adenylyl cyclase, increasing cAMP levels. CCK also activates three mitogen-activated protein kinase cascades leading to ERK, JNK and p38 MAPK. CCK also activates the NF-κB pathway and the P13 K-PKB-m-TOR pathway, which regulates protein synthesis.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Activation of the CCK 2 receptor in gastric cancer cells activates protein kinase D2,[32] and in human adrenal chromaffin cells, it increases adenylyl cyclase and cAMP.[26]

Active and/or Solution Conformation

Biophysical measurements of sulfated and nonsulfated CCK 8 show that these peptides are found mainly in folded forms with beta and gamma turns around the sequence Gly-Trp-Met-Asp and Met-Asp-Phe-NH_2, respectively.[10] NMR spectroscopy and molecular modeling methods have shown that CCK 15 assumes a helical conformation.[1]

Biological Actions within the Brain

The actions of CCK in the brain are diverse and have been widely studied. Progress has been aided by the development of specific agonists and antagonists and the discovery or creation of rodent models that lack the receptors or the peptide.

Satiety

CCK released from the intestine by ingestion of food was shown to have a major influence on food intake even before CCK was detected in the brain.[12] Central CCK seems to have a distinct effect on food intake in the hypothalamus, which may be mediated in part by its interactions with NPY and CART (cocaine- and amphetamine-regulated transcript peptide). The role of CCK in satiety is discussed in the Ingestive and Gastrointestinal Peptides section of this book.

Analgesia

CCK acting through the CCK 2 receptor has antiopiate activity (see Opioid Peptide section of this book). Opiate analgesia is mainly mediated by neurons in the rostral ventromedial medulla (RVM). CCK exerts its inhibitory effect on morphine analgesia by inhibiting activation of pain inhibiting output neurons of the RVM.[14] Acute administration of CCK into the RVM causes acute tactile and thermal hypersensitivity that is antagonized by the CCK 2 receptor antagonist or lesion of the dorsolateral funiculus. Continuous administration of morphine produces sustained tactile and thermal hypersensitivity that is reversed by the CCK 2 antagonist. Continuous morphine treatment results in a fivefold increase in basal CCK levels in the RVM relative to controls.[34] Activation of the endogenous CCK system by repeated morphine treatment may be partially responsible for the observed hypersensitivity. The opiate antagonist effect of CCK appears to be particularly evident in neuropathic pain where increased CCK release as well as changes in expression of CCK receptors has been reported.[31]

CCK Modulation of Dopamine Neurotransmission, Dopamine-Mediated Reward and Psychostimulant Sensitization

CCK is colocalized with dopamine in the VTA,[15] and these neurons project to medial and posterior subdivisions (shell) of the Acb, the olfactory tubercle, and prefrontal Cx.[35] CCK 1 receptors in the Acb shell display DA agonist-like activities (increased dopamine release and enhancement of dopamine-mediated behaviors), whereas in the Acb (core), CCK 2 receptors display DA antagonist-like activities (decreased dopamine release and inhibition of dopamine-mediated behaviors). CCK infusion into Acb shell increases dopamine release while core infusion decreases dopamine release.

Treatment of rats with psychostimulants and stress increases CCK release and augments their locomotor behavior (sensitization). The CCK 1 antagonist blocks expression of psychostimulant sensitization while the CCK 2 antagonist blocks acquisition of this behavior. OLETF rats lacking the CCK 1 receptor display much less behavioral sensitization to repeated cocaine than wild type LETO rats.[3]

CCK 2 receptor knockout mice behave as if they have augmented dopamine neurotransmission. They display more locomotor activity than the wildtype[7] and more locomotor activity in response to a single high dose of amphetamine.[17] This implies that the CCK 1 receptor is required for full expression of cocaine sensitization while the CCK 2 receptor is tonically inhibiting dopamine release.

Anxiety, Learning, Memory, and Sexual Behavior

CCK is very abundant in the Cx, Amy, and Hi, so it is not surprising that it plays a role in these behaviors through modulation of the expression or release of other peptides and classical neurotransmitters. CCK is known to modulate the release of glutamate and GABA. CCK increases the release of glutamate in the hippocampus by increasing the release probability and the number of readily releasable vesicles.

CCK-positive basket cells in the hippocampus express the CB1 cannabinoid receptor on their axon terminals and CB1 antagonists are able to block the CCK-induced suppression of GABA release. Similar results have been seen in other brain areas, including the midbrain periaqueductal gray.

CCK acting through the CCK 2 receptor in the Hi is involved in spatial memory.[24] Other memory tasks that CCK facilitates involve a dopaminergic projection from the VTA to the Nac, central Amy, and Hi.[33] CCK improves spatial memory in elderly rats[29] and in rats whose dopamine has been depleted by 6 hydroxy-dopamine.[22] CCK acting through the CCK 1 receptor is involved in maternal

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

behavior and in infant–maternal recognition in sheep[21] and in appetitive learning in infant rats.[30] CCK released by a meal activates peripheral CCK 1 receptors to initiate these behaviors. CCK interacting with estrogen and endogenous opiates in the Hpt is involved in regulating sexual behavior in female rodents.[19]

A large amount of literature describes the ability of CCK to trigger panic attacks in human subjects and to produce anxiety-related behaviors in rodents and primates. This is mediated through the CCK 2 receptor. The CCK 2 receptor seems to act synergistically with CRF 1 receptor in producing anxiety-like behavior induced by immobilization stress.

Pathophysiological Implications

There is currently no CCK-based drug in clinical practice. CCK and its receptors are widely distributed and have many different physiological functions in the brain and the periphery. Selectively targeting CCK receptors in a single organ will not be easy.

Satiety

Although CCK does cause short-term inhibition of food intake, this activity has not been used therapeutically. Interestingly, the CB1 antagonist Rimonabant (Acomplia) was in clinical trials as a satiety agent but was withdrawn because it caused anxiety. Perhaps that is related to its effect on the CCK system.

Analgesia

CCK 2 antagonists have been tested in humans where they improve pain management when given with morphine.[18] It is possible that CCK 2 antagonist treatment might be promising particularly in neuropathic pain to increase morphine efficacy and reduce tolerance. Novel ligands incorporating an opiate peptide with a CCK 2 antagonist have been designed, which might be useful in the treatment of pain.[16]

Anxiety

CCK 2 antagonists have not been shown to be beneficial in the treatment of anxiety, but questions remain about whether these antagonists get into the brain.

Chapter 100

CGRP/Adrenomedullin

Denise Wootten, Nanda Tilakaratne, Arthur Christopoulos and Patrick M. Sexton

ABSTRACT

Calcitonin-gene-related peptide (CGRP) and adrenomedullin (AM), two structurally related peptides, are synthesized and secreted by many mammalian tissues, including the central nervous system. The two peptides, which were initially described as vasodilators, are now considered as multifunctional regulatory agents. Their cellular actions are mediated by pharmacologically distinct receptors, each comprising two subunits: a classic 7 transmembrane spanning G protein-coupled receptor (GPCR) and one of 3 single transmembrane spanning accessory receptor activity modifying proteins (RAMP). Two GPCRs—the calcitonin receptor (CTR) and calcitonin-receptor-like receptor (CLR)—contribute to CGRP/AM receptor phenotypes. In the brain, CGRP and AM are widely expressed and, in addition to their vasodilator effect, activate several autonomic centers involved in the regulation of fluid and electrolyte balance. Additionally, they have modulatory effects on the synthesis and release of several other neuropeptides and have neuroprotective roles. The potent vasodilator activity of CGRP in cerebral microvasculature is possibly relevant to the pathology of migraine.

DISCOVERY

Discovered in 1983, calcitonin-gene-related peptide (CGRP) was so named because the peptide is a product of the same gene, calcitonin-related polypeptide alpha (CALCA), that encodes calcitonin (CT)—a thyroidal hormone that regulates bone metabolism. Rosenfeld et al. found that the CT gene transcript, which yields CT in thyroidal "C" cells, is alternately spliced in brain cells to produce CGRP.[26] CGRP is a 37-amino-acid peptide that shares 55% amino acid sequence identity with CT. This peptide was later named CGRP-α (or CGRP-I), to distinguish it from another related peptide CGRP-β (or CGRP-II). CGRP-α and CGRP-β differ from each other by only a single amino acid in rats and by 3 residues in humans. CGRP-β is encoded by a gene distinct from the CALCA gene. The following discussion will be limited to CGRP-α.

In 1993, Kitamura et al. discovered a peptide that was able to stimulate cyclic AMP (cAMP) production in blood platelets.[15] The 52-amino-acid peptide was isolated from an extract of a pheochromocytoma—a tumor of the adrenal medulla. Hence, the peptide was named adrenomedullin (AM). However, AM is also produced by healthy adrenal medulla and a wide range of other tissues including vascular endothelium, vascular smooth muscle, and the central nervous system.

Although AM and CGRP share only 30% sequence identity, the two structures required for biological activity—a C-terminal aromatic amide and a ring structure made up of six amino acids linked by disulfide-bonded cysteines—are well conserved between the two peptides. These features are also present in the related peptides, CT, amylin, and intermedin (AM2), and there is a degree of crossreactivity of the peptides across their target receptors.[25]

STRUCTURE OF THE PRECURSOR mRNA/GENE

The CT/CGRP cDNAs have been cloned from several species. In humans, the genomic copy is localized to chromosome 11 (11p15.2-p15.1; Fig. 1). The gene spans a region of about 6.3 kilo bases (kb), and comprises 6 exons. As mentioned previously, the primary transcript undergoes tissue-specific alternate splicing. In the brain, the transcript is principally spliced to yield CGRP mRNA; it is formed by the splicing of exon I (5′ noncoding) with exons II, III, and V that form the coding region, and exon VI (3′ noncoding) (Fig. 1). In normal thyroid, the splicing involves exons I, II, III, and IV to form the CT mRNA. The calcitonin-related polypeptide beta gene encoding CGRP-β is also localized to chromosome 11.[33]

Human AM is encoded by a gene also localized to chromosome 11 (11p15.4). The gene spans approximately 2.1 kb DNA and consists of 4 exons and 3 introns (Fig. 1). The 5′ flanking region contains several elements such as TATA, CAAT, and GC boxes, required for its functional expression. There are also consensus transcription factor binding sites for activator protein-2 (AP-2) and a cAMP-regulated

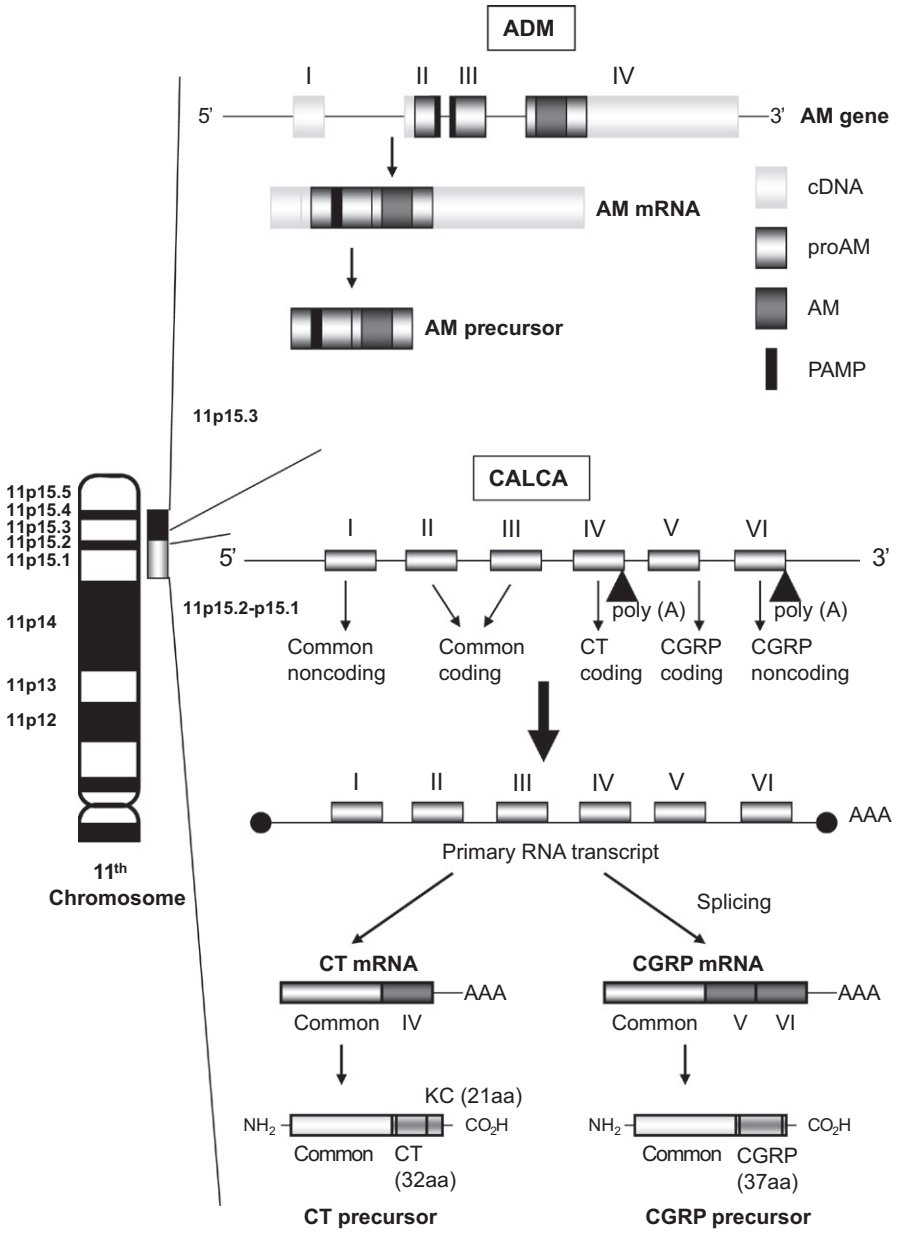

FIGURE 1 Schematic representation of the AM and CALCA genes and their processing to yield the biologically active peptides AM and CGRP. In addition to these peptides, alternative splicing of the CALCA primary transcript leads to the generation of the calcitonin (CT) precursor that yields CT and katacalcin (KC), whereas processing of the AM precursor yields an additional bioactive peptide, PAMP.

enhancer element suggesting that gene expression may be subject to regulation by protein kinase C (PKC) and cAMP.[13] The AM precursor has the potential to generate two bioactive peptides, AM and proadrenomedullin-N-terminal 20 peptide (PAMP), which are released from a common precursor protein (discussed below; Fig. 1).

DISTRIBUTION OF THE mRNA/PEPTIDE

CGRP and AM are widely expressed in many regions of the mammalian brain. This has been revealed by several studies that detected both mRNA (by in-situ hybridization) and the peptide (by immunohistochemistry).

CGRP

Neurons and fibers that contain CGRP mRNA and are immunoreactive to anti-CGRP antibodies are widely but unevenly distributed in the central nervous system (CNS). CGRP-positive cell bodies are observed in the preoptic area and hypothalamus (medial preoptic, periventricular, anterior hypothalamic nuclei, perifornical area, medial forebrain

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

bundle), premamillary nucleus, medial amygdala, hippocampus, dentate gyrus, central gray, and the ventromedial nucleus of the thalamus. In the midbrain, a large cluster of CGRP-positive cells is found in the peripeduncular area. The cholinergic motor nuclei (III, IV, V, VI, VII, XII) in the hindbrain also exhibit CGRP immunoreactivity. CGRP is also detected in cell bodies in the parabrachial nuclei, the ventral tegmental nucleus, superior olive, and nucleus ambiguus, and fibers in the central amygdala, caudal caudate putamen, sensory trigeminal area, and substantia gelatinosa (Fig. 2A). Other areas containing CGRP-immunoreactive fibers include the septal area, bed nucleus of the stria terminalis, preoptic and other hypothalamic nuclei (e.g. medial preoptic, periventricular, dorsomedial) median eminence, medial forebrain bundle, central gray, medial geniculate body, peripeduncular area, interpeduncular nucleus, cochlear nucleus, parabrachial nuclei, superior olive, nucleus of the solitary tract, and in the confines of clusters of cell bodies (Fig. 2A). The neuroanatomical localization of CGRP is reviewed more comprehensively elsewhere.[16,29,31]

There is also enrichment of CGRP in the cerebral microvasculature, in both vascular endothelial cells and nerve fibers that are closely associated with blood vessels.

Adrenomedullin

Although initial studies suggested that AM was poorly expressed in the brain, more recent work indicates that it has a widespread distribution and that it is dynamically regulated by events such as ischemia and/or glucose deprivation. Several autonomic centers including the hypothalamic paraventricular nucleus (PVN), hypothalamic supraoptic nucleus (SON), locus coeruleus, and the ventrolateral medulla express high levels of AM, with low to moderate AM immunoreactivity found in many other regions including multipolar neurons and pyramidal cells of layers IV–VI of the cerebral cortex, parts of the thalamus, and cerebellar Purkinje cells and cerebellar nuclei (Fig. 2B). Immunoblotting of brain extracts has shown that the fully processed peptide is the predominantly expressed form, with a relatively smaller amount of the propeptide. The detailed distribution of AM in brain is reviewed elsewhere.[27,31]

AM and PAMP are also expressed in the pituitary, with particularly high levels in the adenohypophysis and neural lobe, and relatively lower expression in the intermediate lobe of the pituitary. The role of AM in the pituitary is discussed elsewhere in this book.

PROCESSING OF THE PRECURSOR

As described above, the precursor for CGRP is derived from alternately spliced mRNA from the CALCA gene. The CGRP precursor in humans consists of 128 amino acids with a molecular mass of 13.87 kDa. The N-terminal region that is encoded principally by exons II and III incorporates a signal peptide from residues 1–21; it is cleaved at the dibasic motif KR (residues 81–82) to yield the biologically active 37-aa CGRP polypeptide together with a short C-terminal fragment. The glycine at residue 120 of the precursor provides the amide for amidation of the C-terminal phenylalanine (aa. 119 in the precursor) (Fig. 1).

The primary polypeptide product of the human AM mRNA is 185 amino acids in length and is called preproAM. The N-terminal signal sequence of 21 residues is cleaved to yield proAM. Further processing of proAM yields two peptides: PAMP derived from residues 22 to 41 and AM (a 52-aa peptide) composed of the amino acid residues 95–146 of preproAM. Glycine 147 provides the amide for amidation of tyrosine 52 (aa. 146 of the precursor) of the mature AM.

Some investigators have reported the presence of two forms (a and b) of the AM mRNA. Form A is devoid of introns and results in a prohormone containing both AM and PAMP. Form B retains the third intron, which introduces a premature stop codon, producing a shorter prohormone with only PAMP. Treatments that modify AM expression, such as hypoxia, have been shown to change the B/A ratio and the relative levels of AM and PAMP, indicating that the splicing mechanism is subject to modification and is physiologically relevant.[19]

RECEPTORS AND SIGNALING CASCADES

CGRP Receptors

CGRP receptors are widely distributed in the brains of many species, and there has been extensive work mapping the distribution of these receptors using ^{125}I-CGRP, particularly in rat brain.[28,31,33] High densities of CGRP-binding sites are present in regions including, accumbens nucleus, *organum vasculosum of the lamina terminalis*, ventral caudate putamen, median eminence, much of the hypothalamus, including enrichment in the arcuate nucleus and premammillary area, various amygdaloid nuclei, the superior and inferior colliculi, pontine nuclei, cerebellar cortex, nucleus of the solitary tract, inferior olivary nucleus, hypoglossal complex, and the vestibular and cochlear nuclei, along with lower levels of binding to many other brain regions. CGRP receptors are also present on most of the cerebral vasculature. The sites labeled by ^{125}I-CGRP are heterogeneous, and there are multiple subtypes of "CGRP" receptor.

AM Receptors

Although membrane-based radioligand binding studies have demonstrated the existence of significant levels of AM receptors in the brain, there is only limited information on the anatomical distribution of AM receptors in this tissue.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

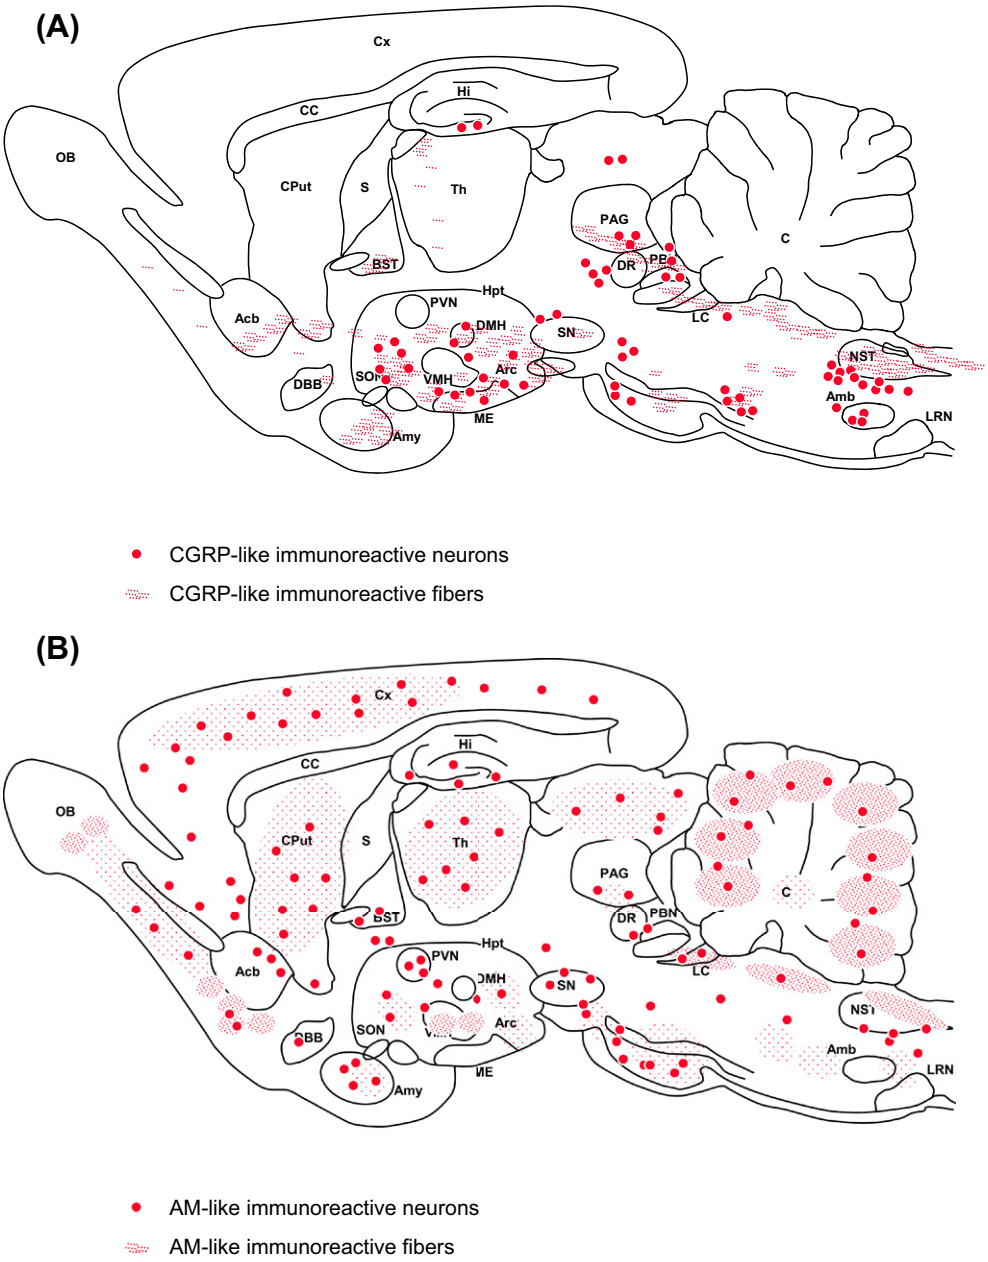

FIGURE 2 Schematic representation of (A) the distribution of CGRP-like immunoreactive fibers (dots) and cell bodies (circles) summarized from Refs. 13, 24, 26, 27 and (B) The distribution of AM-like immunoreactive fibers (dots) and cell bodies (circles) summarized from Ref. 23. Data are indicative of location of immunoreactivity and are not meant to reflect the quantitative levels of neurons or fibers.

Using ^{125}I-AM$_{13–52}$, Juaneda and colleagues observed high levels of AM binding in regions including choroid plexus, the ependymal linings of the cerebral ventricles, cerebellum, and parts of the amygdala, together with the neural lobe of the pituitary gland.[2,14] Elsewhere, only low levels of binding were observed, although this may reflect the sensitivity of the methodology and radioligand probe, as there is evidence for more widespread distribution of the constituent components of the AM receptor complexes (see below).[23] AM receptors are also heterogeneous, with two high affinity receptors characterized.

Molecular Basis of CGRP and AM Receptor Phenotype

The molecular basis of CGRP and AM receptor phenotype(s) is complex; the ligand-binding domains of the receptors comprise two subunits: a classic 7 transmembrane spanning

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

GPCR and one of 3 single transmembrane spanning accessory receptor activity modifying proteins (RAMP).[9,25] Two GPCRs, namely, the calcitonin receptor (CTR) and calcitonin-receptor-like receptor (CLR), contribute to CGRP/AM receptor phenotypes. The CLR/RAMP1 heterodimer is a classic $CGRP_1$ receptor and has high affinity for CGRPs but lower affinity for related peptides. CLR/RAMP2 is a high-affinity AM receptor (termed AM_1 receptor) and only weakly interacts with CGRP. CLR/RAMP3 is also a high affinity AM receptor (termed AM_2 receptor), but it may respond with moderate potency to CGRP in a system-dependent manner. In addition to CLR-based receptors, a high-affinity CGRP receptor is also formed by heterodimerization of CTR/RAMP1. This receptor, like other CTR/RAMP-based receptors, exhibits high affinity for the peptide amylin and is termed the AMY_1 receptor (previously also known as a "C3" receptor). Other CTR/RAMP receptors have only low affinity for CGRP, and all CTR/RAMP receptors have very low affinity for AM. Signaling via CLR-based receptors also involves an additional protein, termed receptor component protein (RCP), which is required for the efficient coupling of CLR/RAMP heterodimers to at least $G_{\alpha s}$ proteins.[6]

CLR, RAMPs, and CTR are all expressed within the brain, although with often discrete patterns of distribution. The distribution of the mRNA of the molecular components for CGRP and AM receptors generally correlates well with the distribution of radioligand binding sites in regions including the hypothalamus, caudate putamen, and cerebral vasculature, supporting the heterodimer as the basic unit for these receptors.

An additional receptor, termed the $CGRP_2$-subtype has also been proposed. $CGRP_2$-subtype receptors are defined as having low affinity for $CGRP_1$ receptor antagonists, such as $CGRP_{8-37}$ and BIBN4096BS, but can be activated with reasonable potency by linear CGRP analogs.[31] Recent results suggest that most of the pharmacology ascribed to "$CGRP_2$" receptors can be attributed to one or other of the CTR/RAMP1, CTR/RAMP3, or CLR/RAMP3 complexes.[8,17]

The possible existence of additional non-RAMP modulated CGRP receptors has been suggested. This comes principally from early expression data in the cerebellum, which showed abundant CGRP binding sites that are pharmacologically similar to $CGRP_1$ receptors. However, there is some controversy about their molecular identity because there are reports indicating no expression of CLR or RAMP1 mRNA in this tissue, whereas others suggest that low expression of these mRNA does indeed occur. A more recent study using immunohistochemistry to examine the distribution of CGRP and its receptor components in the rat cerebellum detected CGRP intracellularly in cerebellar Purkinje cell bodies and both CLR and RAMP1 at the surface of the Purkinje cell bodies and in their processes, suggesting the presence of functional CGRP receptors.[4] The cerebellum is also particularly enriched in RCP, and this may contribute to efficient and/or stable expression of the CLR and RAMP protein components in a high affinity complex.[9]

Signaling

CGRP and AM receptors are family B GPCRs; these receptors pleiotropically couple to multiple G proteins, with prominent coupling to $G_{\alpha s}$. CGRP and AM receptors strongly activate $G_{\alpha s}$, and many of their actions are downstream of cAMP generation. This has been confirmed by several studies in various tissues, primary cultures, or transfected cells. As described above, an efficient coupling of the CLR-based receptors to $G_{\alpha s}$ requires the presence of RCP. However, the receptors can also activate pertussin-toxin-sensitive G proteins and probably also $G_{\alpha q/11}$ proteins, the latter leading to Ca^{2+} mobilization. Only limited functional studies have been performed in nerve tissues, primarily in neuronal tumor cells or primary cultures of astrocytes and glial cells. Rat AM stimulates cAMP production in rat astrocytes and NG108-15 neuroblastoma/glial hybrid cells, in a dose-dependent manner. This effect is not blocked by a $CGRP_1$ receptor antagonist, indicating that activation of selective AM receptors is involved. Similarly, CGRP-induced cAMP production has been found in human glioblastoma A172 cells and SKNMC neuroblastoma cells. The effects of AM on Ca^{2+} signaling mechanisms have also been investigated in neuroblastoma and glial tumor cell lines, because endothelial nitric oxide (NO) has been implicated in AM-mediated vasodilation and there is a well-known link between intracellular Ca^{2+} and activation of NO synthase (NOS).[10,27] CGRP-stimulated Ca^{2+} signaling has also been shown, with CGRP triggering responses from intracellular stores in cultured mouse astrocytes and glial cells from isolated cerebellar slices.[21] In addition, both CGRP and AM facilitate Ca^{2+} currents from L-type voltage-dependent calcium channels in the *nucleus tractus solitarius*, with CGRP responses involving $G_{\alpha s}$ and protein kinase A, whereas AM-facilitated responses are via $G_{\alpha i}$ and mitogen-activated protein kinases.[11]

PEPTIDE CONFORMATION

Nuclear magnetic resonance and circular dichroism studies have indicated that CGRP can adopt an α-helical secondary structure in a solvent-dependent manner. Organic solvents such as tetrafluoroethylene promote the formation of the α-helix, and this is believed to more closely resemble the active conformation at the receptor. Under such conditions, *nuclear magnetic resonance (*NMR) studies indicate that an amphipathic α-helix is formed between residues 8 and 18, two β-turn structures between amino acids 17 and 21 and amino acids 29 and 34 together with random coil "structure" from amino acids 23–29. It is believed that the

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

disulfide-bonded N-terminal region (aas. 1–7) is important in the stabilization of the helix but that residues 19–37 do not contribute significantly.[31]

AM is disordered in water; however, under certain experimental conditions, residues 22–34 have a tendency to adopt an α-helical structure. The 3-dimensional structure of AM in a membrane mimicking environment has recently been solved using NMR spectroscopy.[29] Under these conditions, AM had an α-helical region spanning approximately one-third of its total length, flanked by two disordered segments at both the N- and C-termini. AM and CGRP likely adopt a similar secondary structure when bound to their receptor(s). The N-terminal 14-amino-acid extension seen in AM, but not in other related peptides, does not seem to be important for biological activity and may not directly interact with the receptor.

BIOLOGICAL ACTIONS WITHIN THE BRAIN

CGRP and AM are best known for their hypotensive effects through their vasodilatory action. However, because the peptides and their receptors are widely distributed in the brain, outside the cerebral vasculature, there is interest in their potential roles in other biological actions within the brain. There is evidence that some of the peripheral effects of both these peptides result from their actions within the brain, particularly on neurons in the autonomic centers.

CGRP

Consistent with its widespread distribution in the brain, CGRP has been implicated in a wide range of centrally mediated functions. As with peripheral vascular beds, CGRP is a potent dilator of cerebral and pial vessels, and via this action, contributes to the pain of migraine headache (see below). Central injection of CGRP elicits multiple effects including hypothermia, catalepsy and reduced motor activity, as well as actions on the hypothalamic–pituitary axis including modulation of growth hormone, luteinizing hormone, and prolactin secretion. CGRP potentiates haloperidol-induced catalepsy and decreases apomorphine-induced hypermotility. Central CGRP can also inhibit thalamic neuronal firing evoked by peripheral noxious mechanical stimuli (at least in rat) and can modulate pain responses at the level of the spinal cord. It is also reported to have a role in learning and memory processing and can increase the production of insulin-like growth factor-1. This has beneficial effects on cognitive function by increasing synaptic transmission and inducing angiogenesis and neurogenesis in the mouse hippocampus.[7] In addition, CGRP has protective effects and can reduce blood–brain barrier injury, brain infarct volume, and cerebral edema after focal cerebral ischemia.[18] CGRP can decrease feeding via receptors in the hypothalamus and also the area postrema (reviewed in more detail elsewhere in this book), but has a more prominent effect on diuresis and natriuresis. It can also decrease gastric acid secretion and gastric motility. In contrast to the hypotensive effect of peripherally administered CGRP, centrally administered CGRP increases the mean arterial pressure and heart rate through increased sympathetic outflow. The coincident distribution of CGRP fibers and receptors in functionally linked nuclei involved in auditory, gustatory, and visual processing suggests that CGRP may also play a role in these systems. The central biological actions of CGRP are reviewed in more detail elsewhere.[2,28,31,33]

Adrenomedullin

The most characterized physiological role of AM is in the regulation of circulation and control of fluid and electrolyte homeostasis (see the chapters on this peptide in Cardiovascular Peptides and Renal Peptides sections of this book). This function of AM is mediated via both peripheral and central actions. Effects of AM in the brain have been studied mostly by AM infusion into various brain regions. Action sites of AM in the rat brain have been mapped by *c-fos* immediate-early gene expression. Intracerebroventricular (icv) injection in conscious rats results in *fos* expression in supraoptic nucleus, paraventricular nucleus, locus coeruleus, and area postrema. This suggests that centrally administered AM causes activation of a neural network in the hypothalamus and brain stem. In the PVN, mostly the corticotropin-releasing hormone (CRH)- and nitric oxide (NO)-producing cells are activated. The *c-fos* induction is blocked by pretreatment with the AM receptor antagonist $hAM_{22–52}$. These observations suggest that AM stimulates the activity of the hypothalamic–pituitary axis, the sympathetic nervous system, and the hypothalamic NO system (see the chapter on this peptide in Endocrine Peptides section of this book). Icv injection of AM in rats also augments tyrosine hydroxylase gene expression in the locus coeruleus and plasma oxytocin levels. Thus, AM activates the neurosecretory cells of the PVN and SON via selective AM receptors, and stimulates oxytocin (OT) secretion by activating hypothalamic-OT producing cells in response to altered plasma sodium levels. Not only does this stimulate OT production but also OT acting within the CNS inhibits further NaCl consumption thus maintaining sodium homeostasis.[27,32] AM can also regulate arginine vasopressin release from the hypothalamus in response to hypovolemia, thereby acting as a physiological regulator of fluid homeostasis.[30]

Investigations have been extended to specific populations of CNS neurons. Patch-clamp studies on dissociated rat area postrema (AP) neurons revealed AM concentration-dependent

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

neuronal activity, effects that were mediated via specific ion channel activity. The results have implications to the cardiovascular actions of AM because the AP is a CNS site implicated in cardiovascular control. AM also has protective effects against ischemic/hypoxic injury to neurons. AM expression is upregulated in cultured neurons subjected to hypoxic conditions. AM gene transfer via a viral vector could protect experimentally induced ischemic brains of rats from developing cerebral infarcts, an effect that was abolished by previous treatment with an AM receptor antagonist.[34] In addition, brain-specific conditional AM (and PAMP) KO mice were less resistant to hypobaric hypoxia and displayed a significant increase in infarct size after 48 h of middle cerebral permanent occlusion compared with wild-type mice. Protein and mRNA levels of several markers of nitrosative stress, inflammation, and brain damage were also increased in the brain AM KO mice.[12] Thus, there is evidence to suggest that AM can act as a neurotransmitter, neuromodulator, or a neurohormone in brain autonomic pathways involved in the maintenance of homeostasis, and also a cytoprotective factor in ischemic/hypoxic conditions, in addition to its vasodilator role in the brain microvasculature.

AM has functions at each level of the hypothalamic–pituitary–adrenal axis, suggesting that the peptide plays a role in the organization of neuroendocrine responses to stress. Icv injection into the rat brain causes secretion of corticosterone and prolactin but not growth hormone.

PATHOPHYSIOLOGICAL IMPLICATIONS

Both CGRP and AM have been linked to a broad range of clinical conditions, most of them being inflammatory conditions of the cardiovascular system. In regard to those associated with the brain, the strongest link has been established for a role for CGRP with the physiopathology of headache, particularly migraine-type headache. The intracranial extracerebral blood vessels (e.g. middle meningeal artery and dural arterioles) are believed to dilate in response to CGRP and as a consequence stimulate perivascular sensory nociceptive nerve fibers, producing a pain sensation. Intravenous infusion of CGRP exacerbates headache pain, and CGRP levels are increased in external jugular venous blood, proportionally with pain intensity, during migraine attacks.[3] $CGRP_1$-receptor-specific antagonists BIBN4096BS (Olcegepant) and MK0974 (Telcagepant) demonstrate clinical efficacy in the treatment of migraine pain.[5] Studies with $CGRP^{-/-}$ mice have provided evidence that CGRP is important for the generation of opiate withdrawal symptoms[22] and may therefore contribute to this behavior in humans. An involvement of CGRP in psychiatric disorders has also been suggested by altered levels of CGRP in the cerebrospinal fluid of patients with dementia and depression. In addition, rats treated with either classical or atypical antipsychotic drugs had altered CGRP levels, suggesting that CGRP is involved in CNS functions related to psychiatric disorders.[20]

AM has also been implicated as having a role in the pathogenesis of several psychiatric disorders such as schizophrenia, bipolar disorder, and depression. It is believed that the effect of AM occurs through its NO-generating action. There are also suggestions that AM may have a role in autism.[35] However, the best evidence is for a protective role in ischemic episodes, which is also seen in peripheral tissue.[1]

Chapter 101

CRH Family

David A. Lovejoy

ABSTRACT

The corticotropin-releasing hormone (CRH) family of peptides consists of four distinct paralogs including CRH, urocortin (Ucn)/urotensin-I (UI), urocortin 2 (Ucn2), and urocortin 3 (Ucn3). The peptides range between 38 and 41 amino acids in length and exist predominantly as amphiphilic alpha helices. Each gene is located on separate chromosomes, and most possess a similar gene structure consisting of two exons and an intron of variable length. CRH is responsible for the hypothalamic activation of the hypothalamic–pituitary adrenal axis, but all paralogs seem to play roles in the regulation of stress and energy homeostasis. The CRH family of peptides has been linked pathologically to affective and neurodegenerative disorders.

DISCOVERY

The first evidence of a hypothalamic corticotropin-releasing substance was reported in 1955. However, the first family member of the CRH family was found not in the hypothalamus but rather in the skin of a frog.[12,20] This peptide, called 'sauvagine,' consists of 40 amino acids and is effective in releasing ACTH from rat pituitary cells (Fig. 1). About the same time, a 41-amino acid peptide, called urotensin-I (UI), from the caudal neurosecretory system (urophysis) of carp was identified. However, the actual structure of CRH was reported by Vale et al. in 1981.[33] Over the next 10 years, the discovery of CRH in fish and amphibians indicated that UI and sauvagine are homologs of CRH.[22] The rat and human orthologs of UI were eventually cloned by the Vale and Sawchenko laboratories and were termed urocortin (Ucn).[10,35] Ucn, like sauvagine, is 40 amino acids long, in contrast to the 41 residue sequence that characterizes CRH and UI (Fig. 1) Neuroanatomical observations[6] and phylogenetic studies[22] suggested that as many as four CRH/UI-like peptides were found in chordates. Then, in 2001, the presence of two additional CRH-related peptides was reported by the Vale and Sawchenko laboratories that called the peptides urocortin 2 (Ucn2) and urocortin 3 (Ucn3),[19,30] and independently by Hsu and Hseuh[15] who named the peptides stresscopin and stresscopin-related peptide on the basis of their anxiolytic effects (Fig. 1). The apparent sequence dissimilarity of Ucns 2 and 3 to CRH and Ucn/UI suggested, however, that the former were not Ucns, per se, but rather the product of a gene duplication early in CRH ancestry. Three sets of independent observations support the hypothesis that the Ucn2 and 3 sequences resemble the ancestral version of chordate CRH. First, the Ucn2/3 sequences possess a greater sequence similarity than the CRH/UI/Ucn lineage, to the insect orthologs of the CRH family.[25] Second, they also retain key amino acid motifs found in a newly discovered calcitonin-like peptide in insects,[25] confirming a close evolutionary relationship between the CRH and calcitonin peptide families. Finally, the characterization of the single CRH-like peptide found in the tunicate, *Ciona intestinalis*, indicates a sequence possessing both Ucn2/3 and insect diuretic peptide structural attributes.[23] Taken together, these observations imply that the CRH/UI (including Ucn and sauvagine) clade of peptides represents a more derived version of the CRH peptide family in chordates and the physiological functions of the Ucn2/3 peptides may resemble the ancestral functions of this peptide family to a greater degree. The highly conserved nature of CRH in chordates may, therefore, be the result of the use of this paralog for the primary control of the hypothalamic–pituitary adrenal/interrenal axis and the subsequent selection constraints imposed on this sequence.[20]

PRECURSOR GENE AND CDNA STRUCTURE

The gene structure of the CRHs and the Ucns support a gene duplication early in chordate ancestry. The basic structure of the CRH and Ucn genes are similar but are located on chromosomes 8q13 and 2p23-p21, respectively, in humans and chromosomes 3 and 13 in mice. There are two exons of unequal sizes where the first encodes for a portion of the 5′ untranslated region (UTR) and exon 2, the remainder of the 5′ UTR, entire preprohormone sequence and the entire 3′ UTR. The intron length varies considerably among species, although the Ucn intron is much smaller compared with that

FIGURE 1 Primary sequence of CRF superfamily orthologs and paralogs. Dark gray regions indicate amino acids that have been conserved in all orthologs and paralogs. Light gray regions indicated the residue identity relative to human CRH. The accession number is given for each sequence. The pufferfish sequence was obtained as a predicted translated protein product from the pufferfish genome database (accession number: lcl SINFRUP00000059907) and the tunicate sequence was obtained from Ref. 21.

of CRH (Fig. 2). Although the CRH cDNA structure remains fairly consistent among orthologs, there is considerable variability among the Ucns and UI. The UI mRNA is 3–5 times longer in fishes than the mammal Ucn mRNA. This length difference results from a much shorter gene-associated peptide in the Ucns and extended 3′ UTR in fish UI, particularly in rainbow trout. In this species, there are multiple polyadenylation sites that correspond to the differential mRNA processing that occurs in the urophysis and brain.[3] The CRH-like peptide gene of the tunicate is unique in that only a single exon is present.[23] It is not clear what the ancestral condition was, however because as many as five exons are found in the insect homologs of CRH, it is probable that at least two or possibly three exons were inherited by the protochordate and chordate ancestor.[25] Thus, the loss of the first exon probably occurred during the extensive genomic reorganization of the urochordate, or tunicate lineage.

The gene structure of the Ucns 2 and 3 also reflects a structural relationship to each other, although these genes have undergone considerable change. Both Ucn2 and 3 genes possess two exons similar to the arrangement for urocortin and CRH (Fig. 2). Ucn2 is found on human chromosome 3p21.3 and on mouse chromosome 9. In both cases, the start of the Ucn2 gene is only a few hundred bases from the terminal exon of type VII α1 collagen. Ucn3, on the other hand possesses an extended intron of >8000 bases. The position of the 3′ UTR of the mRNA is unclear. The gene is found on human chromosome 10p15.1 and on mouse chromosome 5.

Taxon-specific selection pressure has induced a number of alternative expression patterns of the CRH family genes. For example, in the elephant shark, the Ucn2 gene seems to be a pseudogene, although genes for CRH, UI and Ucn3 are present. Unusually, there are two CRH paralogs unique from UI in this species, an observation that is currently unique in chordates.[29] Although there are two CRH paralogs in a number of teleost fish,[22] these peptides are almost identical and reflect a phylogenetically late genome duplication, and probably possess the same function. However, in the sequence differences between the two CRH paralogs in the elephant shark are highly divergent indicating a gene duplication early in this lineage's 400 million year evolution. The retention of the same precursor structure in the second paralog suggests that this peptide is functional as a CRH but possesses a different function and expression pattern in this species. Interestingly, like the elephant shark, the chimpanzee, also possesses a Ucn2 gene that is a pseudogene as the result of a premature stop codon. Moreover, in humans, this gene lacks the amidation signal that is required for full activity, although despite this, numerous studies indicate that this peptide is functional in humans.[7,17] Thus, in light of the close sequence similarity between Ucn2 and 3, it seems that the Ucn2 gene and its peptide function is being lost in some taxa and its function is being replaced by Ucn3.[7,14] A similar situation occurs with the loss of gonadotropin-releasing hormone (GnRH)-II in mammals.[7]

DISTRIBUTION AND EXPRESSION OF mRNA

In mammals, the regulation of pituitary ACTH by CRH occurs primarily via projections from the parvocellular

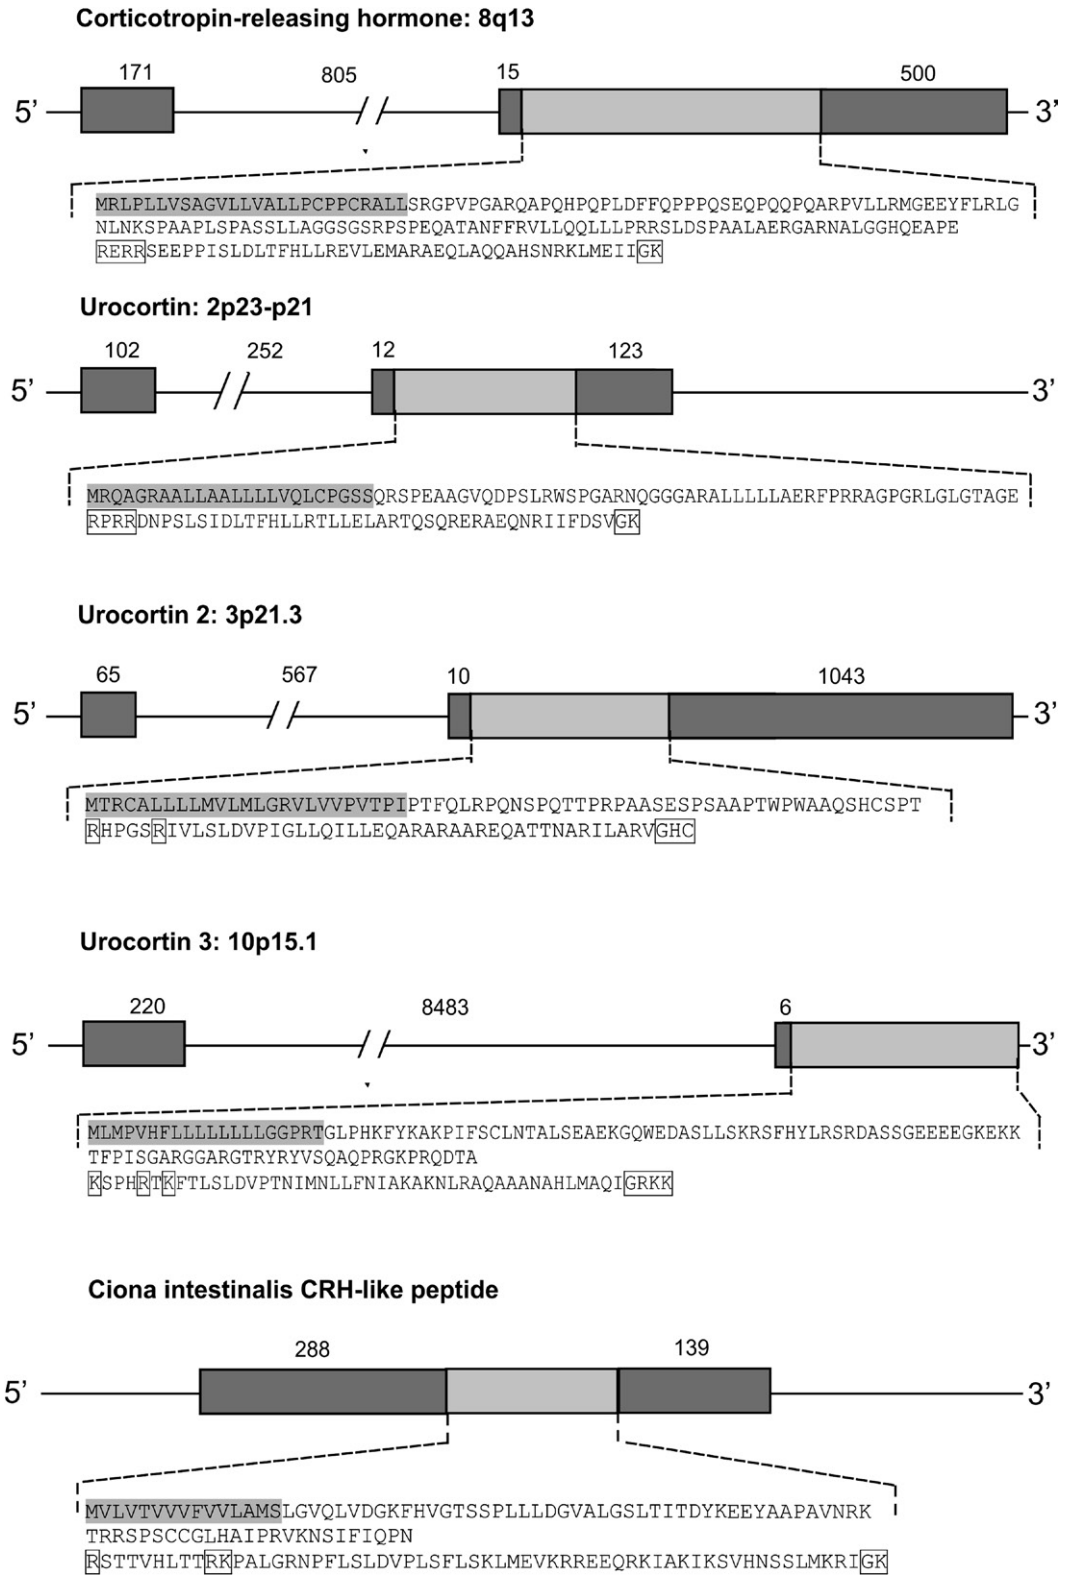

FIGURE 2 Gene and cDNA structure of CRF family members. For each paralog, a schematic of the gene structure (not to scale) is shown along with its position on the relevant human chromosome. Boxes represent exons, and lines indicate intronic regions. The number of bases of the 5′ and 3′ untranslated regions, and introns, are shown above the relevant regions. The translated region of the gene is indicated by the human preprohormone sequence corresponding to the light gray box. The mature peptide is shown bracketed by the cleavage and amidation motifs shown in clear boxes.

division of the paraventricular nucleus (PVN) in the hypothalamus to the fenestrated capillaries of the median eminence. Its role as a hypothalamic releasing factor for ACTH has been conserved in both sarcopterygian and actinopterygian lineages. Indeed, its presence in the nucleus preopticus and nucleus lateralis tuberalis of elasmobranches indicates that its role as a hypothalamic releasing factor evolved early in vertebrate ancestry.[22,31] In many teleost species, CRH is also synthesized in the nucleus preopticus and is transported along neurosecretory processes to the neurohypophysis where it is released near the pituitary corticotropes. However, CRH is expressed widely within the brain of all vertebrates, where it plays a neuromodulator role. CRH mRNA expression occurs predominantly in rostral regions of the brain. In the rat forebrain, there are clusters of expression in the bed nucleus of the stria terminalis (BNST), central nucleus of the amygdala (CeA), septal regions, olfactory lobe and olfactory tract as well in isolated expression throughout the cortex. In caudal regions, the adrenergic cell groups, A1 and A5, and the parabranchial nucleus are sites of CRH expression (Fig. 3).[6,31]

It is difficult to determine how homologous sites of CRH expression in fishes are to those in mammals, as few in situ hybridization studies in the former have been performed. Immunohistochemical studies suggest that the general pattern of CRH expression in the rostral regions is essentially retained, although the topology of the teleost forebrain differs considerably from that of mammals. For example, in the tilapia, the greatest concentration of immunoreactive (ir) CRH occurs in the lateral part of the ventral telencephalon where it may be released into the systemic circulation.[27] In the brown ghost fish, irCRH was not observed in regions caudal to the posterior diencephalon,[35] and many species show reduced irCRH in caudal regions. Amphibians have caudal CRH expression patterns similar to that found in mammals. Thus, CRH expression patterns may have evolved differently among actinopterygian and sarcopterygian lineages.[22]

In comparison with CRH, Ucn has a much more caudal distribution. The primary site for Ucn mRNA expression in mammals is the Edinger–Westphal nucleus although there are small regions of Ucn expression in the lateral hypothalamic

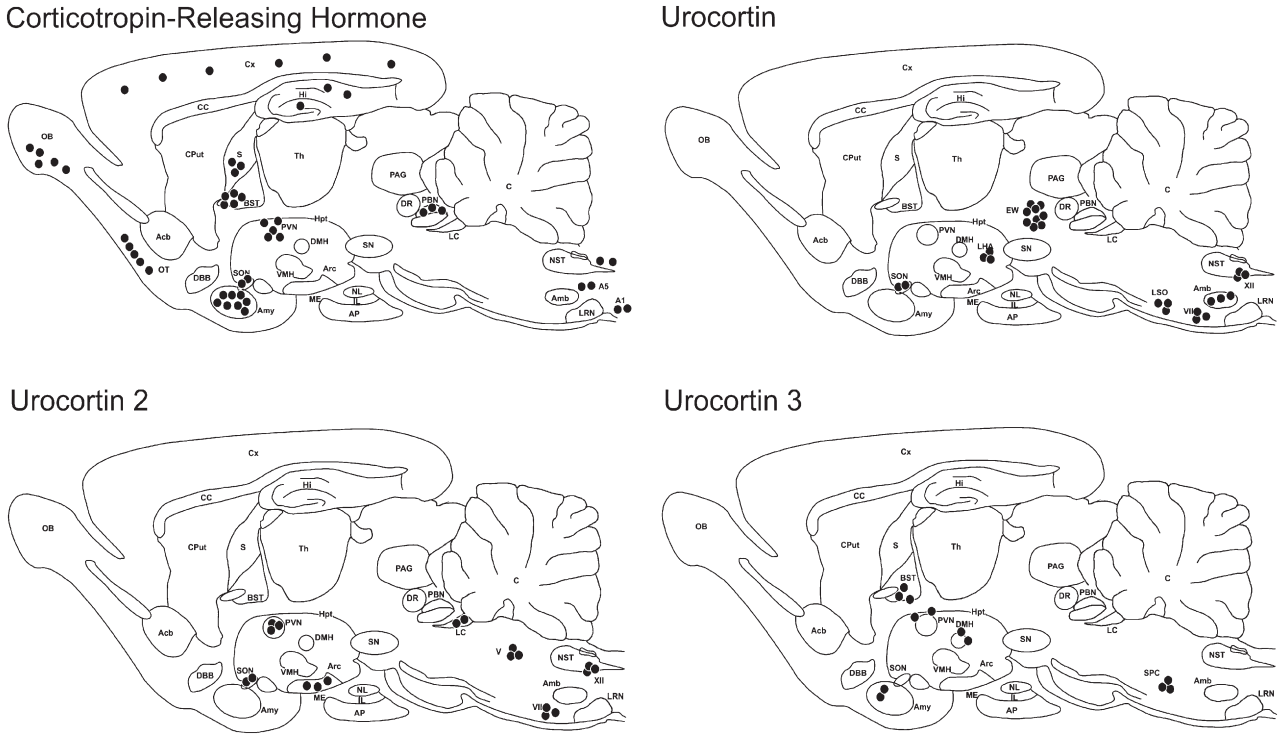

FIGURE 3 Neuroanatomical localization of CRF family member mRNA in rat brain. Regions of immunoreactivity not confirmed by in situ hybridization histochemistry are not shown. area, and the supraoptic nucleus (SON) of the hypothalamus.[34] Ucn is also expressed in a number of brainstem sites (Fig. 3). UI is expressed in the nucleus of the medial longitudinal fasiculus in fishes. However, the majority of UI expression in fishes actually occurs in the urophysis.[4] In phylogenetically older vertebrates and actinopterygians, in general, UI expression is predominant in the spinal cord and brainstem sites where CRH does not seem to be present.[22] In amniotes, however, CRH expression is associated with nuclei that contribute descending autonomic fibers.

Ucns 2 and 3 have a restricted pattern of expression in comparison with CRH and urocortin (Fig. 3). In the rat hypothalamus, Ucn2 mRNA has been detected in the PVN, SON, and arcuate nucleus (Arc). In the brainstem, Ucn2 mRNA is present in the locus coeruleus (LC) and in the trigeminal (V), facial (VII) and hypoglossal (VII) motor nuclei.[30] The main region of Ucn3 expression occurs as clusters of cells associated with the columns of the fornix and throughout the rostral hypothalamus. Regions of expression are also detected in the posterior aspects of the BNST and lateral hypothalamic regions, lateral to the PVN and in dorsal and lateral regions around the dorsomedial hypothalamic nucleus. A few Ucn3-expressing cells have also been detected in the anterodorsal part of the medial amygdaloid nucleus and near the anterior periventricular nucleus and retrochiasmatic area. In the brainstem, the superior paraolivary nucleus is one of the few sites of Ucn3 expression.[18]

PROCESSING OF PREPROHORMONE

In all CRH paralogs, the prohormone consists of a signal peptide, a gene-associated peptide, and a mature peptide (Fig. 2). The comparative simplicity of the preprohormone and conservation of the general structure among paralogs suggest that the peptide is processed in a similar manner regardless of where the gene is expressed. All CRH paralogs generally possess a well-defined signal peptide with a basic residue within a few residues from the initial methionine. Human Ucn2 lacks this basic residue, however. The signal peptides consist of <30 residues with a strong hydrophobic core. The gene-associated peptide, or cryptic peptide, spanning the region between the signal peptide and the mature peptide is highly variable where there is little consensus among paralogs. CRH and Ucn3 possess the longest gene-associated peptides, and Ucn and Ucn2, the shortest. There may be a relationship between the length of the gene-associated peptide and the physiological constraints on the peptide as CRH and Ucn3 are the most highly conserved whereas the Ucn and Ucn2 paralogs are the least conserved among the vertebrates.

The mature peptide is flanked by prohormone convertase (PC) cleavage sites (Fig. 2; see PC chapters in the Peptide Biosynthesis/Processing section of the book). The organization of the PC cleavage sites vary between the CRH/Ucn lineage, and the Ucn2/3 lineage. CRH and Ucn possess an R-X2-R motif, consistent with recognized PC cleavage motifs of R/K-Xn-R/K where X is any amino acid and typically varies between 2, 4, and 6 residues.[32] Human Ucn2 has the motif R-X4-R, but in the mouse and the rat, there are 7 residues between the two basic residues. The number of residues between the basic residues also varies among species at the Ucn3 cleavage. In most, if not all the cases, the mature peptide is amidated. Human Ucn2 has a peculiar motif of GHC instead of the usual G-R/K-R/K; thus, it is not clear whether this version of the peptide is amidated or if it exists as a larger disulfide-bridged cyclic polypeptide.[30] All peptides are amphiphilic and exist predominantly as α helices.

RECEPTORS AND BINDING PROTEINS

The first human CRH receptor (CRH_1) was isolated by expression cloning of cDNA from a human Cushing's corticotropic adenoma.[8] This discovery was followed by the characterization of receptor orthologs in numerous tetrapod and actinopterygian species. The CRH_1 receptor also exists in a series of splice variants including, a frameshift mutation in the rat, a 29 amino acid insertion in the human form, a 133-bp deletion in the sheep isoform and variant possessing a deletion in the seventh transmembrane domain expressed in human myometrium. A paralogous CRH receptor system (CRH_2) was discovered shortly after that of the CRH_1 and exists in at least three different functional splice variants in humans and two in rats although there are no major pharmacological differences among them.[8] Both CRH_1 and CRH_2 receptors belong to the family of G protein-coupled receptors and are structurally related to the calcitonin and the CRH-like insect diuretic hormone receptors.[13] In the brain, stimulatory coupling the CRH receptors to adenylate cyclase is the primary signal transduction system, although a number of other pathways have been associated with CRH signaling systems in nonneural tissues and cells.[8] The CRH_1 receptor is predominant in the brain, whereas the CRH_2 receptor is more prevalent in peripheral tissues. The mammal CRH_1 receptor binds CRH and Ucn with similar affinity but shows little affinity for Ucn2 and 3. However, there are a number of species differences in the relative affinities among the various CRH paralogs.

In addition to the receptors, a high-affinity and selective soluble CRH-binding protein is present in the brain and pituitary gland.[28] The function of the CRH-binding protein is not entirely understood. It shows the greatest affinity for Ucn, less affinity for CRH, and little affinity for Ucns 2 and 3. This protein may act as a sequestering mechanism to attenuate abrupt changes in CRH release, to reduce the CRH/Ucn response after the peptide release, or it may provide ligand specificity in loci where multiple

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

CRH family peptides are released. The basic structure of the CRH-binding protein has evolved early in metazoan history as evidenced by the presence of CRH-binding protein ortholog in insects.[16] However, the ligand specificity of the CRH-binding protein may have changed in the chordates, relative to the insects. The mammal CRH shows little binding affinity for Ucn2 and 3, yet these peptides possess a number of significant sequence similarities with the only CRH ortholog in insects. Insects do not seem to possess an analogous hypothalamic–pituitary–adrenal/interrenal (HPA/I) axis;[20,25] thus, the CRH-binding protein may have been selected for CRH/Ucn/UI specificity once these peptides became associated with the stress axis. CRH also has a second soluble binding protein that is a splice variant of the CRH_2 receptor; however, the physiological significance of this binding protein is not known, and also whether or not it plays a function distinct from the CRH-BP.[5] However, because the CRH_2 receptor binds Ucn 2 and 3, whereas the CRH-BP does not, the soluble CRH_2 receptor may act to modulate the actions of Ucn 2 and 3 in the similar manner that the CRH-BP does for CRH and Ucn.

BIOLOGICAL ACTIONS IN THE CENTRAL NERVOUS SYSTEM

The ancient evolution of CRH and its paralogs indicates that this peptide system has had a significant period of time for selective pressure to allow interaction into a number of diverse physiological systems. In vertebrates and humans, CRH and Ucn elicit behaviors resembling the response to the stress and environmental novelty such as increased arousal decreased food intake, diminished sexual and reproductive activity, and increased grooming. Thus, generally the CRH system acts to integrate the autonomic and behavioral responses to stress through interactions at the CNS level. These mechanisms are achieved by a CRH_1 receptor-mediated activation of the hypothalamic–pituitary–adrenal and sympathetic branches of the stress response. By contrast, the CRH_2 receptor has been associated with anxiolytic effects; thus, Ucns 2 and 3 have been deemed anxiolytic peptides as they bind exclusively to this receptor. CRH and Ucn are generally associated with anxiogenic actions.[7] A number of other neurological actions of CRH family peptides have been described.

Studies in nonmammalian vertebrates identified a number of additional functions of the CRH system. A CRH-mediated role on locomotor activity was established shortly after the peptides discovery and is conserved among vertebrates.[10] In the brainstem of the newt, discharges of neurons of the raphe region of the midbrain, associated with walking and swimming behaviors, could be modified by the injections of CRH into the lateral ventricle.[22] Other actions induced by CRH peptides include vocalization changes, modulation of the reproductive axis, and modulation of circadian-induced locomotor behaviors.[7,8,22] In amphibians, CRH is a potent thyrotropin-releasing factor to regulate synthesis and release of thyroid hormones. Because the thyroid axis plays a primarily role in the regulation of metamorphosis, CRH may act to directly regulate metamorphosis in this taxon.[5]

CRH family peptides have well-described effects on feeding and weight regulation in both mammals and fishes. CRH itself is intrinsically involved in energy metabolism. In vertebrates, CRH ultimately induces the release of adrenal/interrenal glucocorticoids. The metabolic actions of the glucocorticoids are to provide the organism with enough energy to survive a stressful situation. Glucocorticoids possess a number of actions associated with the use and flow of energy. This includes the de novo synthesis of glucose; gluconeogenesis, is increased in the liver after mobilization of proteins from the skeletal muscle and subsequent deamination of amino acids that are released during protein breakdown. However, glycogen can also be deposited in the liver because of a glucocorticoid-stimulated increase in the glycogen synthase reaction. In tandem with this, the breakdown of glycogen is inhibited by glucocorticoids.[24] In rats, Ucn is the most potent peptide at decreasing food intake.[8,22] In fishes, food intake is also reduced significantly after CRH administration.[9] The role for the CRH-like diuretic hormones in insect feeding suggests that this mechanism is phylogenetically ancient[2] (see Diuretic/Antidiuretic chapter in Invertebrate Peptides section of the book). The overexpression of the CRH-BP in a mouse also affects body weight[21] presumably by sequestering free CRH thereby reducing its receptor activation ability in circuits associated with food intake. The CRH family, and particularly that of Ucn2 and 3, play a critical role in energy, and especially, in glucose homeostasis. Ucn2 can increase tissue sensitivity to insulin, whereas Ucn3 may act to increase the secretion of pancreatic insulin. However, these mechanisms appear to involve the integrated actions of both CNS and peripheral targets.[17] Given that Ucn2 and 3 possess a number of ancient structural features of the CRH family, this role in energy metabolism may reflect some of their ancestral functions.

CRH can inhibit reproduction directly through direct input on GnRH secretory terminals at the level of the infundibular nucleus and also indirectly by the inhibitory actions of adrenal glucocorticoids on hypothalamic gonadotropin-releasing hormone (GnRH) and pituitary gonadotropins, luteinizing hormone (LH) and follicle stimulating hormone (FSH). Sexual dimorphism of the CRH response in humans and other vertebrates, even after the sex steroid feedback mechanisms have been taken into consideration, has been reported.[3] For example, generally the HPA and autonomic responses tend to be lower in women compared with men

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

of the same age. In aged-matched men, a greater ACTH a cortisol increase occurs with either physiological exertion such as exercise or pharmacological administration of CRH. Moreover, during aging, a significant increase in the number of CRH neurons occurs in men but not women.[3] The physiological reasons for this are not clear but may involve the different energy demands between the sexes and in particular how this energy is partitioned for use in reproductive-associated physiology. However, it is also not clear as to how this relationship translates across taxa.

The functional role of Ucn in mammals, only provides a partial understanding of its ortholog, UI, in fishes. Urophyseal UI has been implicated in ion and fluid equilibrium, cardiovascular activity and participates in interrenal tissue glucocorticoid release, all of which are necessary for the adaptability of fishes. In vertebrates, UI probably became specialized for its role in the urophysis in an analogous manner that CRH became associated with the HPA/I axis. The urophysis or caudal neurosecretory system is analogous to the neurophysis in that it is a neurohemal organ where the neurosecretory cells release their constituents into the fenestrated capillaries of the vascular system. The caudal neurosecretory system is found in all fishes but has been reduced in the sarcopterygian line and lost entirely in the tetrapods. Thus, this organ system seems to have evolved in response to the osmoregulatory stress of rapidly-changing ambient conditions that occur in aquatic environments. In addition, because water is a much denser medium than air, integration of mechanoreception with the stress response is advantageous for survival if these compression waves can alert the organism of potential prey or predators. Thus, we might speculate that, whereas the pituitary and hypothalamus has been used by chordates to link the higher integration of some sensory systems with the appropriate neural-humoral responses, the urophysis has evolved to link the peripheral osmoreceptor and mechanoreceptor inputs of fishes to the appropriate stress response. This role of UI with mechanoreceptors may also be reflected by the relationship urocortin has with the regulation of auditory sensory processing in mammals.[20,22]

PATHOPHYSIOLOGICAL IMPLICATIONS

CRH is a critical mediator of fear conditioning and other forms of emotional memory to both aversive and rewarding stimuli. In humans, the most recent investigations of the etiology of depression and mood disorders implicate a central role for CRH. Although an overactivated HPA axis has been implicated in a number of depressive disorders, it remains equivocal whether CRH overactivation, per se, has a direct effect on these pathologies. A number of these conditions may work through a common pathway associated with an overactivated HPA axis, and therefore, a direct cause and effect relationship between CRH and the pathology has been problematic to ascertain. However, the CRH-secreting brain cells receive their primary positive feedback from the amygdala and negative feedback from the hippocampus. The hippocampus and neocortex mediate the cognitive aspects of depression such as memory impairment and feelings of worthlessness, hopelessness, guilt, and suicidal feelings. A number of postmortem studies of suicidal victims have increased levels of CRH and cell numbers in the hypothalamus.[1] Increased CRH is also been implicated in addictive aspects of cocaine and other agents[18] suggesting that a CRH-mediated stress response may exacerbate the addictive potential of a number of agents. Other studies implicate a role for the CRH family peptides in neural development and plasticity and thus in the onset of some neurodegenerative disorders such as Alzheimer's Disease. However, the mechanisms and conditions by which this occurs is not understood. Other studies have indicated that CRH-related peptides can have neuroprotective effects.[8,11,26]

Chapter 102

Endozepines

Marie-Christine Tonon, Jerome Leprince, Fabrice Morin, Pierrick Gandolfo, Vincent Compere, Georges Pelletier, Maria M. Malagon and Hubert Vaudry

ABSTRACT

The existence of specific binding sites for benzodiazepines has led to the discovery of endogenous ligands for benzodiazepine receptors that are collectively designated by the term endozepines. In the brain and in peripheral nervous tissues, endozepines are exclusively expressed by glial cells. The release of endozepines from cultured astrocytes is finely regulated by neurotransmitters and neuropeptides. Endozepines exert their effects either through classical central- and peripheral-type benzodiazepine receptors or through *G* protein-coupled receptors. Intracerebroventricular injection of endozepines induces marked effects on anxiety, sleep, and food consumption. The concentration of endozepines in the brain and cerebrospinal fluid is affected in various diseases including depression, Alzheimer's disease, and hepatic encephalopathy.

DISCOVERY

Benzodiazepines (BZDs) are artificial pharmaceutical compounds that are widely used for their sedative, anxiolytic, anticonvulsivant, and myorelaxant activities. The search for endogenous ligands for BZD receptors has led to the discovery of diazepam-binding inhibitor (DBI), a 10-kDa peptide originally identified from the rat brain for its ability to displace diazepam from its binding sites. Subsequently, the purification or the molecular cloning of DBI in different species has shown that the sequence of the protein has been relatively well conserved during evolution from bacteria to mammals (Fig. 1).

STRUCTURE OF DBI mRNA/GENE

In humans, the DBI gene is located on chromosome 2 (q12-21) and is composed of four exons. In addition to the common variant encoding an 86-amino acid protein (Fig. 2), ten different transcripts of the gene have been reported in human. All of them show variable 5′-ends due to an alternative promoter or alternative first exon.[26] These variants encode N-terminal truncated or extended isoforms of DBI. The mammalian DBI promoter displays consensus recognition sites for various known transcription factors, including AP-1/2, SP-1, ETF, Y-box-binding protein, CTF/NF-1, C/EBP, HNF-3, SRE-like sequence, GREs, and PPREs (Fig. 2). Although the DBI gene exhibits several typical features of housekeeping genes (e.g. lack of TATA and CAAT boxes, high GC content, multiple transcription initiation sites, consensus sequence for binding of SP-1 and ETF), its expression is clearly regulated by insulin, glucose, NFκB, and androgens,[26,31] indicating that DBI may serve as a housekeeping protein in certain cell types and as a tissue-specific protein in others.

PROCESSING OF THE DBI PRECURSOR

Endoproteolytic cleavage of $DBI_{1–86}$ generates several biologically active peptides including, the triakontatetraneuropeptide TTN ($DBI_{17–50}$) and the octadecaneuropeptide ODN ($DBI_{33–50}$), which are present in various proportions in the different brain regions.[22] The DBI sequence is devoid of dibasic motifs that are typical cleavage sites for prohormone convertases, but it contains multiple individual lysine residues (Fig. 1), three of which, located at positions 16, 32, and 50, delimit the sequences of TTN and ODN (Fig. 3). However, to date, the enzymes responsible for the processing of DBI have not yet been characterized.

DISTRIBUTION OF DBI mRNA AND ENDOZEPINE IMMUNOREACTIVITY

In situ hybridization histochemical labeling has shown that DBI mRNA is widely distributed in the rat brain, the highest concentrations being found in the cerebellum, the ependyma, and the area prostrema.[1,4] In the cerebellum, the DBI gene is strongly expressed in Bergman (astrocyte-like) cells. High concentrations of DBI mRNA are also present in other glial cell populations, for example, ependymocytes bordering the third ventricle and tanycytes in the median eminence (Fig. 4a). In the pituitary, DBI mRNA occurs in the neural

FIGURE 1 Comparison of selected DBI sequences of representative species from bacteria to mammals. Dots denote identical amino acids to the human sequence. Basic amino acids are in bold letters. The open boxes indicate acetylation of the N-terminal S residue, and phosphorylation of the T^{41} and/or T^{64} residues.

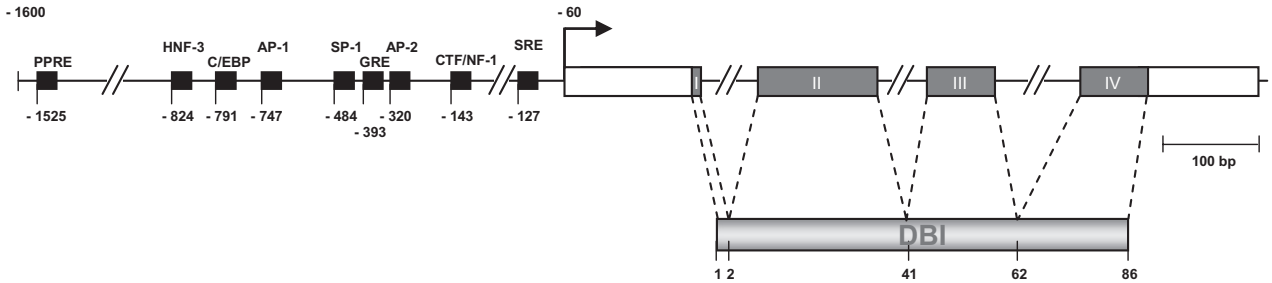

FIGURE 2 Genomic organization of the rat DBI gene. Recognition sites for transcription factors (PPRE, HNF-3, C/EBP, AP-1, SP-1, GRE, AP-2, CTF/NF-1, SRE) are indicated by black boxes. The transcribed regions are boxed and gray boxes (I, II, III, and IV) denote the coding regions. The shaded box represents the DBI sequence.

lobe in adult rat but is expressed only in the anterior and intermediate lobes during embryonic development.[4]

Immunohistochemical labeling has confirmed that in the brain and pituitary of tetrapods including frog, rat, monkey, and human, endozepine immunoreactivity is observed exclusively in glial cells,[18,32,35] that is, astrocytes, Gomori-positive astrocytes (a subset of brain astrocytes most prominent in the arcuate nucleus of the hypothalamus), Bergman cells, ependymocytes, tanycytes, and pituicytes. The density of immunoreactive glial cells is particularly high in the hypothalamus and olfactory bulb (Fig. 4b). Surprisingly, in the fish brain, endozepines are synthesized in a subpopulation of hypothalamic neurons.

DBI mRNA and DBI-like immunoreactivity are also present in numerous peripheral organs including the adrenal, testis, heart, kidney, liver, and intestine.[4] In these organs, endozepines are selectively expressed in specific cell types, notably in steroid-secreting cells and peripheral glial cells.

Scale bar = 250 μm (from Ref. 6 © Society for Endocrinology with permission). (b) Schematic parasagittal section through the rat brain depicting the distribution of endozepine-immunoreactive cells. The density of dots (•) is meant to be proportional to the density of endozepine-positive cells. Acb, nucleus accumbens; Amb, nucleus ambiguous; Amy, amygdale; AP, anterior pituitary; Arc, arcuate nucleus of the hypothalamus; BST, bed nucleus of the stria terminalis; C, cerebellum; CC, corpus callosum; Cput, caudate putamen; Cx, cerebral cortex; DBB, diagonal band of Broca; DMH, dorsomedial nucleus of the hypothalamus; DR, dorsal raphe nucleus; Hi, hippocampus; Hpt, hypothalamus; IL, intermediate lobe of the pituitary; LC, locus coeruleus; LRN, lateral reticular nucleus; ME, median eminence; NL, neural lobe of the pituitary; NST, nucleus of the solitary tract; OB, olfactory bulb; PAG, periaqueductal gray; PBN, parabrachial nucleus; PVN, paraventricular nucleus of the hypothalamus; S, septum; SN, substantia nigra; SON, supraoptic nucleus; Th, thalamus; VMH, ventromedial nucleus of the hypothalamus.

CONTROL OF BIOSYNTHESIS AND RELEASE OF ENDOZEPINES

The neuronal mechanisms regulating the secretion of endozepines have been studied in cultured astrocytes and Müller cells (retinal glial cells).[15,20,24,28,34] The release of endozepines is stimulated by pituitary adenylyl cyclase-activating polypeptide (PACAP), acting through the PACAP-specific receptor PAC1-R (see the chapter on PACAP in the Brain Peptides section) positively coupled to adenylyl cyclase and phospholipase C, by β-amyloid peptides acting through formyl peptide receptors, by urotensin II, and by steroid hormones. Endozepine release is inhibited by GABA, acting through $GABA_B$ receptors, and by somatostatin, acting through sst1, sst2, and sst4 receptors, all four receptors being negatively coupled to adenylyl cyclase (see also the chapter on Somatostatin/Cortistatin, in the Brain Peptides section). These factors also regulate DBI gene expression in a coordinated manner. In particular, PACAP and β-amyloid peptides increase, whereas somatostatin reduces DBI mRNA levels in cultured astrocytes. Altogether, these observations indicate that the biosynthesis and release of endozepines are finely regulated by various neuronal factors including classical neurotransmitters and neuropeptides.

RECEPTORS AND SIGNALING CASCADES

Endozepines have been originally characterized as inverse agonists of the central-type benzodiazepine receptor (CBR) that is an intrinsic part of the $GABA_A$ receptor–chloride channel complex. Electrophysiological studies have confirmed that DBI and ODN attenuate GABA-induced Cl^- efflux in neurons and endocrine cells,[3] indicating that endozepines act as negative allosteric modulators of the $GABA_A$ receptor. DBI and TTN can also interact with the peripheral-type benzodiazepine receptor now renamed as translocator protein (TSPO), a five-transmembrane-domain mitochondrial protein of 18kDa. In addition, endozepines can activate TSPO located at the plasma membrane, leading to an influx of Ca^{2+} through voltage-dependent calcium channels in glial cells. Finally, several studies have shown that endozepines can interact with metabotropic membrane receptors. In particular, in rat astrocytes, ODN stimulates phospholipase C through a $G\alpha_{i/0}$ protein-coupled receptor, whereas, in frog adrenocortical cells, TTN activates adenylyl cyclase, which in turn causes Ca^{2+} influx through T-type calcium channels.

INFORMATION ON SOLUTION CONFORMATION OF ENDOZEPINES

Molecular modeling of bovine DBI_{1-86} under nuclear magnetic resonance (NMR) constraints has shown that the peptide exhibits a characteristic four-helix bundle structure, stabilized by three identified hydrophobic minicores (Fig. 5). The α-helix H1 forms strong interface contacts with α-helix H4, made up of the conserved hydrophobic residues Phe^5, Ala^9, Val^{12}, and Leu^{15} in H1, and of Tyr^{73}, Val^{77}, and Leu^{80} in H4. TTN, which is a selective ligand of TSPO, contains the hydrophobic portion corresponding to H2, whereas ODN, which preferentially binds CBR, fails to adopt an α-helical conformation. A three-dimensional quantitative structure–activity relationship study performed over 130 TSPO ligands supports the hypothesis that two lipophilic regions are essential for interaction with TSPO.[5] The three-dimensional structures of DBI and TTN, derived from NMR data, reveal the existence of a triad of lipophilic amino acids located in the H2 helix (i.e. Met^{46}, Leu^{47}, and Phe^{49}) as likely residues underlying TSPO binding.[5]

Structure–activity relationship studies have shown that the C-terminal octapeptide of ODN (OP, ODN_{11-18}) is the minimum sequence retaining full activity on metabotropic PLC-coupled receptors in astrocytes. The cyclic OP analog $cyclo_{1-8}OP$ is 3 times more potent than OP, whereas the D-Leu^5-substituted analog $cyclo_{1-8}$[D-Leu^5]OP is a full antagonist of this receptor.[17] In water, $cyclo_{1-8}OP$ adopts a single conformation encompassing a γ- and a β-turn (Fig. 6).

BIOLOGICAL ACTIONS OF ENDOZEPINES WITHIN THE BRAIN

Some of the biological effects of endozepines are mediated through CBR or TSPO, whereas others can be accounted for by activation of metabotropic receptors.

Intracerebroventricular (ICV) administration of DBI, TTN, or ODN increases aggressive interactions and induces anxiety and proconflict behavior in rodents.[16] These effects are prevented either by the specific CBR antagonist flumazenil or by the TSPO antagonist PK11195. DBI and ODN, acting through CBR, also shorten pentobarbital-induced sleeping time in mice.[11] ICV injection of ODN markedly reduces drinking and increases the aversive response to 0.9% NaCl in mice, and these effects are mediated through CBR.[23] ODN, acting via CBR, also inhibits apomorphine-induced yawning in rat, suggesting that endozepines can modulate dopaminergic and cholinergic neurotransmission involved in yawning.[14] Incubation of cultured rat astrocytes with picomolar concentrations of endozepines causes a robust increase in DNA synthesis through activation of CBR and TSPO,[13] indicating that endozepines act as autocrine/paracrine factors modulating the proliferation of astroglial cells. On isolated mitochondria from a glioma cell line, endozepines activate the formation of the steroid hormone precursor pregnenolone,[27] suggesting that endozepines also act as intracrine factors stimulating the synthesis of neurosteroids in astrocytes. Because several neuroactive steroids are potent allosteric modulators of the $GABA_A$ receptor, it seems that endozepines can indirectly regulate the activity of the $GABA_A$-benzodiazepine receptor complex through their ability to control the production of neurosteroids.[9]

A single ICV injection of very low doses of ODN (30–100ng) provokes a dose-dependent reduction of food intake in rodents and fishes.[10,25] Chronic ICV infusion of ODN for 15 days inhibits food consumption and causes a significant reduction in body weight in rat and mice. Reciprocally, food

deprivation strongly decreases DBI expression in hypothalamic glial cells,[6] supporting a physiological role for endozepines in the central control of energy homeostasis. Although CBR agonists are known to stimulate food intake, the anorexigenic effect of ODN is not mediated through CBR or TSPO but via metabotropic endozepine receptors. ICV injection of ODN increases proopiomelanocortin (POMC) mRNA level and decreases neuropeptide Y (NPY) mRNA level in the arcuate nucleus of the hypothalamus,[7] suggesting that the effects of ODN on food consumption can be accounted for by stimulation of the production of the anorexigenic POMC-derived peptide α-MSH and inhibition of the production of the orexigenic peptide NPY (see the chapters on Melanocortins and NPY in the Brain Peptides and Ingestive Peptides sections). The fact that insulin stimulates DBI expression in ependymocytes bordering the lateral ventricle[6] suggests that DBI-expressing glial cells relay hormonal signals from the periphery to the central nervous system.

Endozepines also regulate the expression of the genes encoding the hypothalamic hypophysiotropic neurohormones CRH and GnRH and the pituitary adrenocorticotropic hormone precursor POMC.[7,8] Some of these effects are mediated through the activation of metabotropic endozepine receptors.[8]

PATHOPHYSIOLOGICAL IMPLICATIONS OF ENDOZEPINES

GABA is the most important inhibitory neurotransmitter in the central nervous system, and endozepines, by affecting GABA-mediated inhibition of neurotransmission, may be involved in various neurological diseases (e.g. epilepsy) and psychiatric disorders (e.g. anxiety, mood impairment, and psychotic syndromes). Indeed, patients with major depression exhibit significantly higher concentrations of DBI in their cerebrospinal fluid as compared with normal volunteers.[30] Several lines of evidence suggest that anxiety disorders have a strong genetic component. A specific allele corresponding to one single nucleotide polymorphism of the DBI gene (SNP rs8192506, Met70Val) is more frequent in healthy subjects than in patients suffering from panic attacks[33] suggesting an influence of DBI genetic variants in the susceptibility for the development of anxiety disorders. Among the eight common SNPs located in the DBI gene, two of them, SNP rs8192506 and SNP rs2084202 (5′UTR, – 132 A > G), are associated with type-2 diabetes risk,[12] supporting a role of endozepines in the control of energy homeostasis.

An increased level of endozepines in human brain is also observed in other neurological diseases such as hepatic encephalopathy[29] and Alzheimer's disease.[21] In these patients, the high concentration of endozepines is usually associated with an increase in TSPO density or neurosteroid biosynthesis, suggesting that alteration of DBI gene expression could be implicated in various neuronal diseases. In chronic morphine-treated rats, an increase in DBI mRNA level is observed in the CA1 region of the hippocampus, the ventral tegmental area, the nucleus accumbens, the prefrontal cortex, and the amygdala which play a crucial role in addiction, suggesting that endozepines may also be involved in psychological and physical dependence on opiates[19] and possibly other drugs, including nicotine and alcohol. In the rat brain, intense expression of the DBI gene and high concentrations of endozepines occur during embryonic development,[4,22] a period of active neurogenesis. Endozepines are also actively expressed in various human brain tumors and glioblastomas.[2] These latter observations support the view that endozepines could play a role in neuronal cell proliferation and tumorigenesis.

Chapter 103

Galanin and GALP

Andrew L. Gundlach and Philip J. Ryan

ABSTRACT

The galanin family of peptides consists of four members: galanin, galanin message-associated peptide (GMAP), galanin-like peptide (GALP), and alarin. Galanin/GMAP are widely distributed throughout the brain, whereas GALP and alarin have a more restricted expression. Three G protein-coupled receptors, GalR1, GalR2, GalR3 bind galanin with high affinity and are broadly expressed throughout the brain. The native receptors for GMAP, GALP, and alarin are not known. Galanin and related peptides regulate a wide range of neural and physiological functions including neuroendocrine hormone release, reproduction, feeding and metabolism, osmotic regulation, cardiovascular and respiratory control, arousal and sleep, memory, nociception, and neuronal growth and regeneration. Extensive preclinical and clinical research has implicated galanin family peptide and receptor signaling in several neuropathological and psychiatric conditions, including epilepsy, Alzheimer's disease, nerve injury, multiple sclerosis, stroke, anxiety, depression, obesity, and alcohol and drug addiction, suggesting galanin-related treatments hold significant therapeutic potential for such disorders.

DISCOVERY

The galanin family consists of four peptides: galanin, galanin message-associated peptide (GMAP), galanin-like peptide (GALP), and alarin. Galanin is a 29-amino acid neuropeptide (30 in humans), which was first isolated from porcine intestine in 1983 (see galanin chapters in the Ingestive and Gastrointestinal Peptides section of this book), and was named for its N-terminal *g*lycine and C-terminal *ala-nine*[30] (see Ref. 13). Galanin has been isolated in numerous species, and it contains a highly conserved N-terminal 1–15 amino acids. Galanin was initially considered a peptide without a family, but it was subsequently observed that the galanin precursor molecule 'preprogalanin' also, encoded GMAP, a 59- or 60-amino acid peptide, which has distinct biological actions[35] (see Ref. 13).

Galanin-like peptide (GALP) is a 60-amino acid neuropeptide that was isolated from porcine hypothalamus in 1999 and shown to be an endogenous ligand for galanin receptors.[21] GALP residues 9–21 are homologous to galanin residues 1–13. A splice variant of GALP mRNA comprises 25 amino acids and is termed alarin because of its N-terminal *ala*nine and C-terminal se*rine*[25] (see Ref. 13).

Three G protein–coupled receptors for galanin have been identified and characterized - GalR1, GalR2, and GalR3. GalR1 was initially cloned from a human Bowes melanoma cell line, and GalR2 and GalR3 were first identified in rat and subsequently in other species (see Ref. 13). Galanin (porcine [^{125}I]-galanin) has a high affinity [K_D] for each human receptor subtype, 0.15 nM for GalR1, 0.32 nM for GalR2, and 2.23 nM for GalR3, but agonists and antagonists with selectivity for these receptors have been developed that have helped to reveal their respective actions[13] (see Mitsukawa et al. in Ref. 8).

STRUCTURE OF THE mRNA/GENE

Galanin and GMAP

The structure of the 'preprogalanin' gene, which encodes galanin and GMAP, is highly conserved among vertebrates [18] (see Mensah et al. in Ref. 8). The preprogalanin gene is located on human chromosome 11q13.3, rat chromosome 1q42, and mouse chromosome 19A, spanning about 6.5 kb of genomic DNA (http://www.ncbi.nlm.nih.gov/gene/?term=galanin). It comprises 6 exons and 5 introns: exon 1 is noncoding; exon 2 starts with the translation initiation codon of the signal peptide and terminates before the proteolytic site preceding the mature galanin peptide; the mature galanin peptide is encoded on exons 3 and 4; GMAP is encoded by exons 4 to 6; exon 6 also contains the polyadenylation site.

GALP and Alarin

The preproGALP gene encoding GALP and alarin is located on human chromosome 19q13.43, rat chromosome 1q12, and mouse chromosome 7A1, spanning about 11kb of genomic DNA.[3] It comprises six exons, with a structural organization similar to that of galanin: exon 1 is noncoding; exon 2 contains the start codon; the region encoding the mature GALP is contained in exons 2–5; the portion of galanin homology

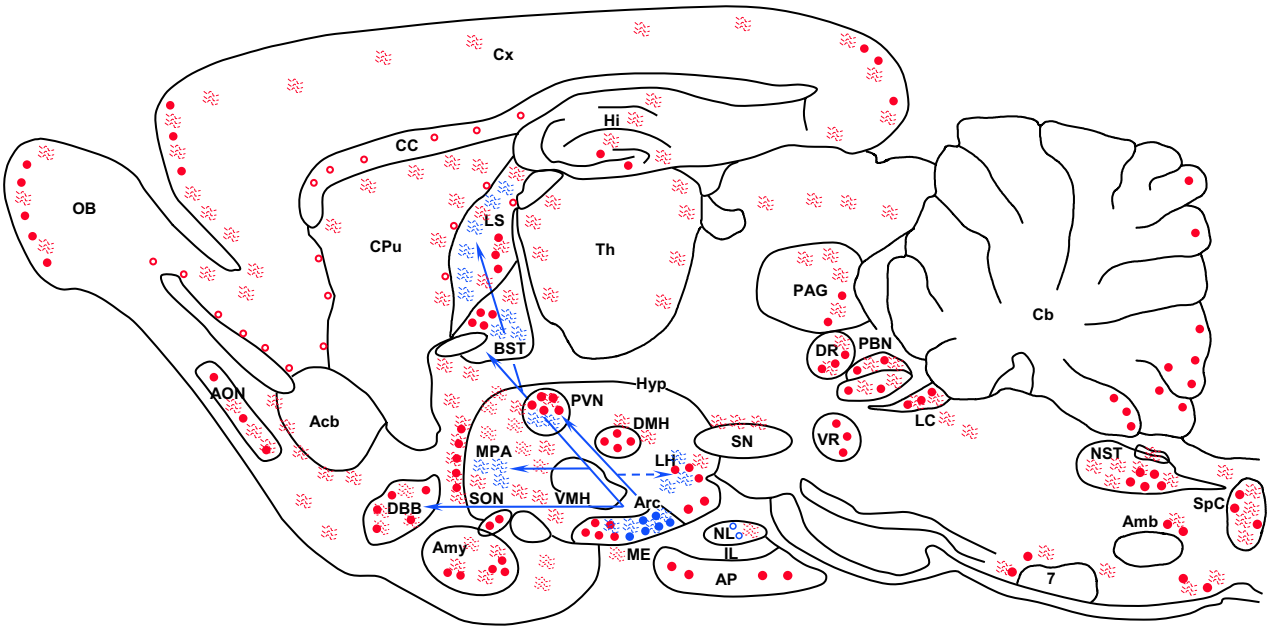

FIGURE 1 Schematic illustration of the contrasting distribution of galanin and GALP positive neurons and their innervations in rat brain. GALP (**blue** dots) are illustrated, along with the approximate localization of their immunoreactive nerve fibers/terminals (small **red** and **blue** lines). Nonneuronal GALP and galanin expression in astrocytes (pituicytes) and oligodendrocyte and other progenitors is also illustrated (**red** and **blue** circles). The two major GALP pathways proposed from the arcuate nucleus to the paraventricular nucleus and to other hypothalamic and limbic regions are indicated by **blue** arrows. The relative topography of the many, widespread galanin pathways has been omitted for clarity. See color plate 26.

[GALP(9–21)] is contained in exon 3, and the polyadenylation site is contained in exon 6.[3] Alarin is formed when post-transcriptional splicing leads to exclusion of exon 3 resulting in a frame shift and a novel precursor peptide.[25]

PROCESSING OF THE PEPTIDE PRECURSOR

Galanin and GMAP

The precursor peptide, preprogalanin, comprises 123–124 amino acids, depending on the species (123 in humans), and consists of a signal peptide, galanin and GMAP. The sequence for galanin consists of amino acids 33–62 of the precursor, and is flanked by two pairs of basic amino acids (lysine and arginine), which are cleavage sites. In most species, the C-terminal *glycine* serves as a donor for amidation; but in humans a *serine* residue replaces the *glycine*, and C-terminal amidation does not occur. Hence, human galanin contains an additional amino acid. The galanin sequence is followed by the sequence for GMAP (see Refs. 13, 18 for a review).

GALP and Alarin

The precursor peptide, preproGALP, comprises 115–120 amino acids, depending on the species (116 in humans), and consists of a signal peptide directly followed by the GALP sequence (i.e. the site of cleavage for the N terminus). The GALP sequence consists of amino acids 25–84 of the precursor peptide and the C terminus is generated by cleavage at residues Ser^{84}-Lys^{85}-Arg^{86}.[21]

The precursor peptide for alarin is 48–49 amino acids (49 in humans), which comprises the signal sequence of preproGALP and the first 5 amino acids of the mature GALP peptide, followed by 19 amino acids that do not display homology to any other protein. A further proteolytic cleavage leads to alarin (1–25).[13,25]

DISTRIBUTION OF THE mRNA/PEPTIDE

Galanin and GMAP

Galanin mRNA and peptide have been mapped in several species, including mouse, rat, primate, and human, and display widespread distribution throughout the CNS, with similar expression patterns among the species currently studied.[10,13,18] Because the rat is the species most frequently mapped its galanin expression pattern is described, and in most cases, a good correlation exists between nuclei expressing galanin precursor mRNA (assessed by in situ hybridization) and those areas containing galanin peptide (assessed by immunohistochemistry) (Fig. 1).[24]

Galanin-positive *cell bodies* are highly abundant in the dorsomedial nucleus of the hypothalamus and in the locus ceruleus, while medium to high densities are observed in the medial septal nucleus, nucleus of the diagonal band, bed nucleus of the stria terminalis, basal nucleus of Meynert (not

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

present in equivalent human area), central nucleus of the amygdala, preoptic and lateral hypothalamic areas, hypothalamic paraventricular, periventricular, supraoptic, arcuate and tuberomammillary nuclei, dorsal raphe, raphe pallidus and obscurus, the caudal spinal trigeminal nucleus, nucleus of the solitary tract, and dorsal horn of the spinal cord.[10,13,18] Galanin mRNA is also expressed by cerebellar Purkinje cells in caudal vermis, flocculus and paraflocculus.[24]

Galanin-positive fibers are generally observed in the same areas as galanin cell bodies. Very dense galanin-positive fiber bundles are present in the lateral septal nucleus, the median eminence of the hypothalamus and dorsal horn of the spinal cord. Medium to high densities of galanin fibers are present in the medial prefrontal cortex, hippocampus and dentate gyrus, nucleus of the diagonal band, bed nucleus of the stria terminalis, basal nucleus of Meynert, central nucleus of the amygdala, amygdalohippocampal area, the stria terminalis, thalamic parafascicular and periventricular nuclei, preoptic and lateral hypothalamic areas, hypothalamic paraventricular, periventricular, supraoptic, dorsomedial, arcuate and tuberomammillary nuclei, the locus ceruleus, dorsal and median raphe, raphe pallidus and obscurus, caudal spinal trigeminal nucleus, spinal tract of the trigeminal nucleus, nucleus of the solitary tract, dorsal vagal complex, the area around the central canal of the spinal cord (lamina X) and the intermediolateral column of the spinal cord.[13,18]

Galanin mRNA and immunoreactivity have also been detected in oligodendrocyte precursor cells in the corpus callosum and in immature progenitor cells in the subventricular zone and rostral migratory stream.[27]

Galanin is coexpressed with different neurotransmitters and neuropeptides, including with acetylcholine in septal and basal forebrain neurons projecting to the hippocampus; serotonin in dorsal raphe neurons; histamine in the tuberomammillary nucleus; norepinephrine (NE) in the locus ceruleus and dorsomedial hypothalamic nucleus; GABA in the arcuate nucleus and external layers of the median eminence; vasopressin in the hypothalamic paraventricular nucleus; and cholecystokinin in spinothalamic neurons, particularly in lumbar segments L1–L5[10,13] (see Hökfelt's chapter on neurotransmitters in the General Peptide Topics section of the book).

GMAP has a similar profile of expression to galanin in the rat, although in the retina, cones are reportedly GMAP positive but galanin negative, and prolactin cells in the anterior lobe of the pituitary express high GMAP levels, but low galanin levels, suggesting that differential processing of the preprogalanin precursor occurs in some tissues.

GALP and Alarin

GALP has a more restricted expression than galanin, with GALP-expressing cells found only in the hypothalamic arcuate nucleus, the median eminence and infundibular stalk, and the posterior pituitary of the rat[14,26] (see Refs. 13, 15 for a review). GALP-expressing neurons send projections to various areas of the forebrain, including the lateral septum and bed nucleus of the stria terminalis and medial preoptic area, where they target luteinizing hormone-releasing hormone (LHRH) neurons, as well as various hypothalamic regions, including the periventricular, paraventricular and arcuate nuclei and lateral hypothalamus, where they target orexin- and melanin-concentrating hormone neurons. The leptin receptor is expressed by GALP neurons in the arcuate nucleus and GALP neurons receive orexin and neuropeptide Y projections.[11,29]

Alarin-like immunoreactivity has been comprehensively mapped in the mouse brain, where it was detected in high densities in the accessory olfactory bulb, medial preoptic area, amygdala, and hypothalamic arcuate and ventromedial nuclei of the forebrain, and in the trigeminal complex, locus ceruleus, and ventral cochlear and facial nuclei of the brainstem.[5] In the rat brain, alarin-positive neurons have been described in the locus ceruleus.[32]

RECEPTORS AND SIGNALING CASCADES

The different galanin receptors are coupled to a variety of signal transduction pathways, with both GalR1 and GalR3 acting mainly on inhibitory $G_{i/o}$-proteins, while GalR2 can influence either stimulatory $G_{q/11}$- or inhibitory $G_{i/o}$-proteins, depending on a variety of factors, such as the host cell, and the G-protein repertoire of the cell. GalR1 can influence inwardly rectifying K^+ channels (GIRK) and activate MAP kinase activity; GalR2 most commonly stimulates inositol phosphate hydrolysis, mobilizing intracellular Ca^{2+} and activating Ca^{2+} dependent Cl^- channels; and GalR3 stimulates GIRKs (see Ref. 13). Ferré and colleagues[19] showed that GalR1 can form heteromers with the D1 dopamine receptor in transfected mammalian cells and *in vivo* in the hippocampus, where the D1-GalR1 heteromers integrated dopamine and galanin signaling to modulate cholinergic transmission.

The distribution of the three galanin receptors has been mapped by in situ hybridization and is described here for the rat brain (e.g. Ref. 2; see Ref. 13). GalR1 is widely distributed in the hypothalamus, amygdala, ventral hippocampus, thalamus, medulla, locus ceruleus, lateral parabrachial nucleus, and dorsal horn of spinal cord. GalR2 is moderately to highly expressed in olfactory bulb/tubercle, piriform cortex, hypothalamus (especially preoptic, arcuate, dorsal nuclei), mammillary nuclei, hippocampus, amygdala, substantia nigra pars compacta, cerebellar cortex and sensory trigeminal nucleus. GalR3 expression is highest in the hypothalamus and pituitary gland, and is also expressed in the olfactory bulb, cerebral cortex, medulla, caudate putamen, cerebellum and spinal cord. Some species-based differences in distribution have been identified.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Although galanin-like peptide (GALP) was originally shown to bind to GalR1 and GalR2 *in vitro*, and GalR3 *in vivo*, it seems that GALP does not act via galanin receptors *in vivo*. GALP retains its actions in both GalR1 and GalR2 knockout (KO) mice, and some evidence indicates that *endogenous* GALP is unlikely to activate GalR3. This suggests that GALP may have its own receptor(s), which has not yet been identified.[15] Similarly, the native receptors for GMAP and alarin have not been identified.[32,35]

BIOLOGICAL ACTIONS WITHIN THE BRAIN AND PITUITARY

Galanin and GMAP

Galanin has an established and/or putative involvement in a range of brain functions. Strong, independent, and consistent evidence supports a role for galanin signaling in the control of aspects of feeding and metabolism, reproduction, memory and cognition, nociception, and neural growth and injury response. There is also experimental evidence for modulatory functions associated with cardiovascular and respiratory control, arousal and sleep, and stress and affective behavior. Galanin is also strongly implicated in neuroplasticity associated with a range of pathological conditions, and galanin expression is highly inducible in a number of these situations.

Feeding and Metabolism

Central (icv) administration of galanin strongly activates feeding behavior in satiated rats. A similar effect has been demonstrated following targeted injections of galanin into various feeding-related hypothalamic nuclei, including the paraventricular nucleus (PVN), and lateral and ventromedial hypothalamus (see Refs. 7, 13; Barson et al. in Ref. 8 for a review). Galanin also increases food intake after injection into the amygdala, via direct interaction with the stress-related transmitter NE, which has led to the hypothesis that galanin may mediate stress-induced overconsumption. Early reports suggested that rats injected with galanin intra-PVN displayed a preference for fat intake over other macronutrients, and although other studies have not replicated this finding specifically, galanin-induced feeding is stronger and more prolonged in rats maintained on a high-fat diet, and in rat strains that naturally prefer fat.

Galanin KO and galanin overexpressing (OE) mice do not display an obese or lean phenotype, or any strong alterations in 'normal' feeding behavior, but galanin KO mice consume less fat than wildtype controls under macronutrient choice conditions and when only fat is available, and galanin OE mice consume more fat and alcohol than controls. Initial studies of GalR1 and GalR2 KO mice revealed no marked phenotype related to difference in feeding behavior or body weight, but a more recent study on GalR1 KO mice suggests that this receptor might mediate the adjustments in food intake and energy levels in response to acute changes in dietary fat.

Thus, although galanin may not play an 'essential' role in food intake and body weight control, it has robust effects on the intake of dietary fat (and alcohol) and acts by modulating the activity of several other key peptides/transmitters/hormones particularly under conditions of altered diet and stress.

Release of Pituitary Hormones

Galanin seems to play a modulatory role in various neuroendocrine systems.[18] For example, in the hypothalamic–pituitary–gonadal (HPG) axis, galanin increases LH secretion and enhances LHRH binding to its receptors in the pituitary. Populations of hypothalamic galanin and LHRH neurons display reciprocal connections and galanin is coexpressed with LHRH in a sexually dimorphic manner in species such as rats, mice, and sheep (higher levels in mature females than males), but not in other species such as humans, suggesting sex- and species-based differences in the reproductive role of galanin. Other evidence that galanin plays a major role in reproduction is the ability of galanin antagonists and galanin antisera to block the preovulatory surge and ovulation in rats; although galanin KO mice are fertile. In addition, the amount of galanin in LHRH neurons is negatively regulated by estrogen in mice, but positively regulated in rats, suggesting that thorough studies of different species are required to properly determine the role and relative importance of galanin for reproduction. The estrogen-dependent presence of galanin in populations of kisspeptin neurons that innervate LHRH neurons further strengthens its role in central regulation of LHRH/LH and reproduction.[12]

Galanin and its receptors are present at each level of the hypothalamic–pituitary–adrenal (HPA) axis, including the hypothalamus (PVN/SON), anterior pituitary and adrenal gland. In the absence of stress, galanin can stimulate the HPA axis and increase corticotropin-releasing hormone (CRH) and adrenocorticotropic hormone (ACTH) release, thereby increasing glucocorticoid secretion from the adrenal cortex, but after activation of the HPA axis by stress, galanin acts to decrease responses.[22] For example, stress-induced hyperthermia, which is accompanied by elevated ACTH/corticosterone levels, is attenuated by central administration of a high dose of galanin (although a low dose enhances the hyperthermic response). Galanin lowers levels of ACTH/cortisol in humans after intravenous injection, and together these results suggest important species and 'site of action' related differences in galanin responses.

Similarly, galanin can increase circulating prolactin (PRL) levels, probably by the inhibition of dopamine release

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

from tuberoinfundibular neurons. In galanin KO mice, PRL expression is reduced in adult females, indicating that galanin acts as a growth factor for lactotrophs, particularly under conditions where estrogen levels are elevated, such as pregnancy. Galanin can also modulate other hormones, with reports of increased growth hormone (GH) levels and reduced thyroid-stimulating hormone (TSH).

Arousal and Sleep

Galanin is highly expressed in several arousal and sleep-related brain areas including histamine and serotonin neurons in the tuberomammillary and dorsal raphe nuclei that are functionally related to the control of 'arousal.' Sleep-active neurons are located in subregions of the preoptic area, with a high density in the median preoptic nucleus (MnPN) and the ventrolateral preoptic area (vlPOA) and the latter contain GABA and galanin. Anatomical studies reveal projections from vlPOA and MnPN to multiple monoaminergic arousal regulatory systems in the posterior/lateral hypothalamus and the brainstem. Cumulative evidence indicates that preoptic area neurons promote sleep onset and maintenance by inhibitory modulation of multiple arousal systems and are involved in homeostatic regulation of both rapid eye movement (REM) and non-REM sleep.[28] Notably, sleep-deprived rats express higher levels of galanin mRNA in preoptic area neurons and NE neurons in the locus ceruleus; and galanin (iv) alters sleep patterns in healthy male volunteers.[20]

Memory and Cognition

Various 'global' and site-specific effects of galanin on memory have been reported. Central (icv) and intraseptal and intrahippocampal administration of galanin impairs memory acquisition in rats, as shown in the Morris water maze and other learning and memory tasks[6] (see Crawley in Ref. 8). Galanin is postulated to alter the balance of acetylcholine release from septal afferents in the hippocampus, and galanin decreases long-term potentiation in hippocampal slices by inhibiting cholinergic Schaffer collateral fibers. Galanin receptor antagonists have been tested for their role in memory enhancement. A nonselective peptide antagonist, M40, does not alter the performance of normal rats in a working memory task (delayed nonmatching to position), but does block the effects of galanin. M40 also potentiates the memory enhancing actions of a cholinergic agonist in a working memory task in rats with a 'cholinergic' lesion. The nonselective antagonist M35 facilitates spatial learning in the Morris water maze.

Galanin OE mice have been investigated in paradigms of learning and memory. In one strain, the galanin gene is linked to a dopamine β-hydroxylase (DβH) promoter, which restricts galanin overexpression to epinephrine (E) and NE neurons; in another strain, the galanin gene is linked to the platelet-derived growth factor β (PDGF) promoter, which produces a more widespread galanin expression in the brain, including the hippocampus and cortex. Learning and memory tasks reveal learning impairments with both transgenic strains. For example, DβH-galanin OE mice display deficits in the more difficult components of several learning and memory tasks, including on the probe trial test of the Morris water maze (spatial memory), impaired learning of social transmission of food preference (olfactory memory), and reduced fear conditioned freezing on the trace-fear conditioning task (emotional memory). The PDGF-galanin OE mice display impairment in learning acquisition in the Morris water maze, but only at an older age (19 months).[23] Similarly, galanin KO mice display small learning impairments in a spatial object recognition task and in the Morris water maze at an older age, suggesting too little or too much galanin can cause learning deficits. GalR1 and GalR2 KO mice display no significant differences from wildtype in models of learning and memory, except for some impairment on trace-cued fear conditioning in GalR1 KO mice. Therefore, while galanin-related drugs may eventually be tested for the treatment of aged-related memory deficits, perhaps as an adjunct to other treatments, the ambiguous nature of the current evidence suggests further preclinical testing is warranted to elucidate the precise dose- and global/site-related effects and associated mechanisms of action of galanin receptor activation and inhibition.

Nociception

Galanin modulates pain in the spinal cord, where it is expressed along with its three receptors, particularly in dorsal root ganglion neurons and spinal cord sensory neurons (see Ref. 13; Xu et al. in Ref. 8). Endogenous galanin seems to inhibit spinal nociception to some degree under normal conditions and more strongly after peripheral nerve injury when galanin synthesis is increased in sensory neurons. Thus, independent experimental evidence suggests intrathecal administration of galanin induces a biphasic response in many pain models, with low galanin doses escalating pain via GalR2 activation, and high doses suppressing pain via GalR1 activation. Intrathecal galanin administration reduces neuropathic pain in rat models and the galanin receptor antagonist M35 produces a small enhancement of pain sensitization. Both galanin and GalR1 KO mice display moderately decreased response thresholds in tests of heat nociception, whereas mice that overexpress galanin in sensory neurons display increased pain thresholds and decreased neuropathic pain-like behaviors after nerve injury. Further testing of galanin-related drugs is warranted to determine if they have therapeutic potential as analgesics in humans.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Neuronal Growth and Regeneration

Galanin expression increases dramatically in a number of different types of neurons after injury and, on the basis of this and related findings, is proposed to play a trophic role in neuronal growth and regeneration. Galanin signaling may also play a role in neuronal development, with probably an important role for GalR2 in these processes (see Ref. 2; Hobson et al. in Ref. 8).

For example, during development, galanin is highly expressed in the dorsal root ganglion (DRG) from day 14 of gestation till shortly after birth, and seems to play a role in the survival of sensory neurons, as galanin and GalR2 KO mice have reduced numbers (>10–20%) of small diameter DRG neurons. Galanin is expressed in <5% of adult DRG neurons (predominantly in small diameter nociceptors) and GalR2-, but not GalR1-, KO mice have a reduction in adult DRG neurons. However, after nerve (sciatic) injury, galanin levels can rise by up to 120-fold, to promote nerve regeneration and outgrowth of neurites. Galanin KO mice have a 35% reduction in nerve regeneration compared to wildtype controls, associated with long-term sensorimotor deficits and decreased neurite number and length.

Galanin also seems to play a role in neuronal survival and neuroprotection after injury in the central nervous system (CNS). During development, galanin KO mice display a loss of one-third of their total number of cholinergic septohippocampal neurons, and galanin KO mice display a significantly higher degree of cell death in the hippocampus after peripheral injection of the neuroexcitatory convulsant, kainic acid, compared to that in wildtype mice, whereas galanin OE mice display less hippocampal death. GalR2 KO mice also display more injury-induced cell death than wildtype mice that cannot be rescued by exogenous galanin, implicating GalR2 in this effect. These changes have functional implications as galanin and GalR2 KO mice display markedly reduced behavioral symptoms under conditions of neuropathic and inflammatory pain; and galanin KO mice display decreased cognitive performance, possibly due to a developmentally related decrease in numbers of cholinergic septohippocampal neurons.

In contrast to galanin, far less is known about the CNS role of GMAP, but fragments of GMAP injected intrathecally facilitate the spinal nociceptive flexor reflex.[35]

GALP and Alarin

Similarly, the precise biological roles of GALP and alarin are not as well characterized as galanin, but anatomical data and independent and consistent experimental evidence support a role for GALP in the control of aspects of feeding and metabolism and reproduction, and GALP expression is regulated by other peptides/hormones associated with metabolic state including leptin, insulin, and thyroid hormone and by blood glucose levels.[15] Alarin (icv) increases feeding over a 0.5- to 4-h period.[32]

Feeding and metabolism

GALP administration modulates food intake and energy expenditure, although its actions are complex and depend on the species studied and the experimental conditions.[15] In rats, central GALP injection acutely increases food intake (over 1h), as does injection directly into the medial preoptic, paraventricular, and dorsomedial hypothalamic nuclei, but over the 24-h period after administration, food intake and body weight decrease. Icv GALP also increases core body temperature in rats for up to 8h. By contrast, in normal mice, icv GALP has no acute stimulatory effect on feeding, and it results in a decrease in food intake and body weight over 24h. Chronic injections of GALP in leptin-deficient obese (*ob/ob*) mice produced prolonged reductions in body weight, relative to lesser effects in C57BL/6 control mice. In control mice, icv GALP produces a rapid, transient drop in body temperature before a period of increased body temperature of approximately 8h, whereas in obese *ob/ob* mice, chronic GALP produces a sustained increase in body temperature. Lastly, in mice but not in rats, central GALP treatment acutely impairs locomotion; but over several days of chronic treatment, mice become hyperactive.

GALP KO mice display no marked differences in feeding, body weight or temperature compared to wildtype mice, but they consume less food after a fast and gain less weight on a high-fat diet, indicating that while GALP is not essential to 'normal' energy balance, it may play a modulatory role in maintenance of metabolic homeostasis under altered dietary conditions.[4]

Reproduction

GALP icv stimulates an increase in LHRH release, which in turn increases LH secretion in male rats. GALP icv also produces a marked stimulation of male sex behaviors in both intact and castrated male rats.[15] Alarin does not affect sexual behavior in intact male rats, but it does increase LH levels in castrated rats.[32]

PATHOPHYSIOLOGICAL IMPLICATIONS

Experimental evidence collected over two decades has highlighted the probable role of galanin in the pathophysiology of a range of neurological and neuropsychiatric conditions.

Seizures and Epilepsy

Administration of galanin receptor agonists into brain areas involved in the initiation and propagation of epileptic

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY
Copyright Elsevier 2024

activity attenuates seizures in animal models of epilepsy, and pharmacological blockade of galanin receptors is proconvulsant (see Lerner et al. in Ref. 8). For example, exogenous galanin decreases the severity of picrotoxin-kindled convulsions in rats when injected icv or into the hippocampus. Galanin seems to produce this effect by inhibiting glutamate, as galanin receptor agonists inhibit depolarization-induced glutamate release from rat hippocampal slices *in vitro*.

Transgenic mice provide further evidence for the involvement of galanin in seizures. Galanin KO mice display a higher susceptibility to seizures, a shorter latency to seizure induction and increased seizure severity. In contrast, mice that overexpress galanin in E/NE pathways (DβH-galanin OE mice), display enhanced resistance to seizure induction, while PDGF-galanin OE mice with a more widespread galanin expression pattern are resistant to kindling. Furthermore, rats injected centrally with an adeno-associated virus (AAV) carrying the galanin gene and an associated fibronectin sequence to ensure active galanin secretion into the extracellular space, display significantly decreased seizures induced by electrical stimulation of the brain.

GalR1 KO mice display spontaneous seizures, and although GalR2 KO mice do not display spontaneous seizures or altered responses to induced seizures, when GalR2 is downregulated in the hippocampus by an antisense approach, seizures produced by hippocampal stimulation are dramatically increased in severity and duration. These results suggest that GalR1 and GalR2 activation can promote the inhibition of seizures and that galanin-related peptides are attractive candidates as antiepileptic agents. Several ligands have been developed that penetrate the blood-brain barrier, including an analog of galanin with preferential affinity for GalR2 that is a potent anticonvulsant after systemic administration in mice.

Alzheimer's Disease (AD)

Galanin and galanin receptors are overexpressed in the basal forebrain of patients with AD, and increased galanin fibers and terminals innervate the surviving cholinergic neurons of the basal nucleus of Meynert (see Counts et al. in Ref. 8). Galanin can reportedly inhibit acetylcholine release in the hippocampus and decrease cognitive performance in rodents, suggesting that increased galanin may worsen the cholinergic deficit seen in AD. However, galanin protects the hippocampus from excitotoxic damage and cholinergic forebrain neurons from amyloid toxicity, suggesting the peptide might promote survival of cholinergic and other neurons in regions undergoing neurodegeneration and so improve AD symptoms. Therefore, further preclinical studies may be required to differentiate these possibilities and provide a clearer idea of the therapeutic potential of galanin receptor modulation for the treatment of AD.

Stress and Anxiety

Galanin modulates the response to stressors, as well as anxiety- and depressive-like behavior (see Ref. 9; Mitsukawa et al. in Ref. 8). Galanin is expressed in various stress-related brain regions, including the paraventricular nucleus of the hypothalamus (PVN), where it coexists with CRH and vasopressin, which are critical regulators of the HPA or 'stress' axis. Galanin is also highly expressed in the locus ceruleus, in NE neurons, which increase arousal and alertness, particularly under stressful conditions. Various stressors increase expression of galanin in the locus ceruleus, amygdala and hypothalamus, including social stress, exercise, cold, pain, and immobilization. Hypothalamic galanin injections reduce stress-induced activation of the HPA axis, suggesting a negative feedback mechanism, whereas galanin injected systemically increases activation of the HPA axis.

In the rat, galanin (icv) reduces anxiety-like behavior in the Vogel conflict test, while in contrast, galanin administered into the amygdala increases anxiety-like behavior in this test. In the elevated plus maze, injection of the galanin antagonist M40 into the central nucleus of the amygdala does not alter anxiety-like behavior in the rat suggesting no significant role for endogenous galanin under nonstressed conditions. However, with increased stress, endogenous galanin release in the amygdala is believed to decrease anxiety-like behavior (and 'balance' the anxiogenic effect of coreleased NE). Thus, galanin signaling can increase or decrease anxiety-like behavior depending on the experimental test, the baseline conditions, and whether the role of endogenous or exogenous peptide is being examined.

However, transgenic mice have helped clarify our understanding somewhat. The DβH-galanin OE strain display normal anxiety-like behaviors under baseline conditions, but notably, do not increase anxiety-like behavior after treatment with the anxiogenic agent, yohimbine, suggesting that increased galanin causes resistance to anxiety-provoking agents. PDGF-galanin OE mice, which overexpress galanin more widely (although not in NE neurons), display normal anxiety in a range of behavioral tests and conditions. These results suggest that under high stress conditions where high levels of NE are released, galanin may be specifically recruited and prevent increased anxiety-like behavior.

The varying effects of galanin observed on anxiety-like behavior may also result from actions at different galanin receptors. GalR1 is believed to mediate galanin modulation of NE activity in the locus ceruleus, as the mixed GalR1/GalR2 agonist AR-M961 is more effective at inhibiting locus ceruleus firing than the GalR2 agonist AR-M1896. GalR1 (and GalR2) KO mice display increased anxiety-like behavior in tests such as the elevated plus maze, but not in

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

others such as the light/dark box, or open field; but in GalR1 KO mice, a high dose of galanin fails to induce c-Fos in locus ceruleus and alter stress hormone levels (ACTH/corticosterone), as observed in wildtype mice. GalR3 selective antagonists have been reported to display activity in some anxiety models (stress-induced hyperthermia and punished drinking) and not others (elevated plus maze). Overall, these results reinforce the view that, rather than a unified, consistent role in modulating anxiety, effects of galanin can be facilitatory or attenuating, and are region-, context-, and response- specific.

Importantly though, a polymorphism in the galanin gene is associated with the severity of panic disorder symptoms in female patients, suggesting galanin may play a role in this clinical anxiety condition.[31]

Depression

Exogenous and endogenous galanin seems able to modulate depressive-like behavior, particularly via an interaction with the monoamines serotonin and NE (see Ref. 9; Kuteeva et al. in Ref. 8). Galanin is coexpressed with NE in the locus ceruleus and with serotonin in the dorsal raphe nucleus in the rat, although not in the mouse. Galanin inhibits serotonin neuron activity, probably via multiple receptor subtypes. For example, treatment with a GalR3 antagonist blocks the inhibitory action of galanin on serotonin cell firing. Galanin seems to modulate $5HT_{1A}$ receptor function, which is implicated in depressive-like behaviors, with icv galanin causing a reduction in affinity (K_D values) of $5HT_{1A}$, an increase in the number of $5HT_{1A}$ receptors, and a decrease in $5HT_{1A}$ mRNA levels in the dorsal raphe. Furthermore, a recent clinical genomewide association study (GWAS) suggests a possible role for galanin in relation to major depressive disorder and serotonin signaling.[34]

Galanin injected icv, or directly into the ventral tegmental area, increases depressive-like behavior, reflected by increased immobility time in the forced swim test, and this effect is blocked by coadministration of nonselective galanin receptor antagonists. By contrast, other studies have reported that increased galanin may decrease depressive-like behavior, as peripheral administration of nonpeptide galanin agonists, galmic and galnon, decreases immobility time. A preliminary study in humans reports that intravenous galanin has an antidepressant-like effect, reflected by a suppression of REM sleep in healthy male volunteers. Thus, the site of administration and any resultant differential activation of central or peripheral receptors seem to be important for the outcomes observed in these different studies.

Transgenic mice studies also indicate a role for galanin in depressive-like behavior. PDGF-galanin OE mice display increased 'depressive-like' behavior, with increased immobility in the forced swim test; in contrast, DβH-galanin OE mice, display 'normal' responses in the tail suspension test, another test of depressive-like behavior. Importantly, PDGF-galanin OE mice, but not DβH-galanin OE mice, exhibit elevated NE and serotonin release in the hippocampus after swim stress, suggesting that PDGF-galanin OE mice have a maladaptive response to uncontrollable stress, linked to monoamine release.

GalR1 and GalR2 KO mice display no significant changes in either the forced swim test or tail suspension test, although a meta-analysis combining results of GalR2 KO mice from several studies, suggests increased depressive-like behavior; and GalR2 KO mice display increased depressive-like responses in the learned helplessness paradigm. GalR2 OE mice display a response in the forced swim test that suggests a role for GalR2 in controlling depressive-like behavior.[16]

Furthermore, studies with peptides selective for individual galanin receptors suggest GalR1 and GalR3 signaling may increase, while GalR2 signaling decreases depressive-like behavior. For example, the GalR1 agonist M617 increases immobility in the forced swim test, and the GalR3 antagonist decreases depressive-like behaviors in several tests; while the GalR2 agonist AR-M1896 decreases, and the GalR2 antagonist M871 increases, depressive-like behavior (immobility) in the forced swim test.

Addiction

Galanin seems to act via GalR1 as a negative regulator of opiate (and possibly cocaine) reward (see Picciotto in Ref. 8). Central galanin administration attenuates place preference for morphine in mice, whereas galanin KO mice display enhanced place preference and increased locomotor responses to morphine. Galanin also seems to decrease signs of opiate withdrawal, with the nonspecific galanin receptor agonist, galnon, attenuating opiate withdrawal, while galanin KO mice show increased signs of withdrawal.

Galanin seems to increase intake of alcohol when injected icv into the hypothalamic PVN, which is proposed to be due to the increased caloric content of alcohol. Single-nucleotide polymorphisms (SNPs) in the galanin and the GalR3 genes have also been associated with alcoholism, suggesting endogenous galanin may play a role in this condition.[1] Variations in the GalR1 gene is associated with tobacco craving in smokers attempting to quit, suggesting a role for galanin in nicotine dependence.[17]

Multiple Sclerosis

There is increasing evidence that galanin expression is increased in glial cells and neurons after injury or insult[33] (see Butzkueven and Gundlach in Ref. 8). Notably, galanin is upregulated in oligodendrocytes in experimental autoimmune encephalomyelitis (EAE), a mouse model of multiple sclerosis

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

(MS). Galanin KO mice display significantly more severe EAE-related symptoms with an earlier peak of severity. In addition, GalR2 KO mice show a marked increase in severity of EAE symptoms, suggesting an important role of GalR2 in the response. In line with a neuroprotective role of the peptide, galanin OE mice display a marked improvement in EAE symptoms compared with wildtype mice. In addition, a study of postmortem brain tissue from five MS patients reveals a marked upregulation of galanin in ~30% of cells in chronic active MS lesions and in remyelinated shadow plaques.

Stroke

Galanin and galanin receptor upregulation occurs after ischemic brain damage (see Shen and Gundlach in Ref. 8). Focal ischemia induced by middle cerebral artery occlusion in rats increases galanin and GalR1 mRNA in the penumbral and undamaged adjacent areas on days 1 and 2 postinfarct, and increases GalR2 mRNA on day 2; consistent with the proposed neuroprotective role of galanin signaling in other injury models.

Therapeutic Potential

It is now established that most transmitter systems in the brain can release a cocktail of signaling molecules including classical transmitters and peptides and that neuropeptides are mainly recruited after severe stress or aversive/pathological events to modulate transmission and promote plasticity and repair. Human studies have also shown that dysregulation of neuropeptides is probably important for neurodegenerative and neuropsychiatric disorders. Overall, available evidence provides substantial support for the further exploration of galanin-related ligands with differing receptor selectivity as treatments for the pathology or associated physiological/behavioral symptoms of epilepsy, nerve injury and chronic pain, AD, MS and stroke; and stress-related anxiety and depression, alcohol and other addictions, and cognitive impairments associated with many of these disorders.

[This review is respectfully dedicated to the late Kazuhiko Tatemoto, who died in late 2011].

Chapter 104

Ghrelin

Masayasu Kojima, Yuki Nakamura, Takahiro Sato and Kenji Kangawa

ABSTRACT

Small synthetic molecules called growth hormone secretagogs (GHSs) stimulate the release of growth hormone (GH) from the pituitary via the GHS-R. Using a reverse pharmacology method in a stable cell line expressing GHS-R, an endogenous ligand for GHS-R was purified from rat stomach; this molecule was named "ghrelin." The characteristic structure of ghrelin contains an acyl modification at the third amino acid, a conserved serine (threonine in frogs). All ghrelin peptides isolated so far have been modified at this position with a medium-chain fatty acid, typically *n*-octanoic acid. This modification is essential for the biological activity of ghrelin. The primary production site of ghrelin is the stomach, but the peptide's major active sites are in the brain and the pituitary. Currently, ghrelin is the only known circulating orexigenic hormone that is secreted from the stomach under fasting conditions, it transmits a hunger signal from the periphery to the central nervous system, and it acts on the hypothalamic arcuate nucleus, a region involved in the regulation of appetite.

DISCOVERY

Ghrelin was identified in stomach tissues and shown to act as an endogenous ligand for the growth hormone secretagog receptor (GHS-R).[21,23] The name "ghrelin" is based on "ghre," a word root in Proto-Indo-European languages meaning "grow," and refers to the ability of this peptide to stimulate growth hormone (GH) release.

In 1976, C.Y. Bowers found that some opioid peptide derivatives had weak GH-releasing activity. After this observation, many peptide derivatives and nonpeptide compounds with potent GH-releasing activity were synthesized. These compounds are termed growth hormone secretagogs (GHS).[3] In 1996, GHS-R was identified by expression cloning.[17] After the identification of the GHS-R, a search for its endogenous ligand was actively undertaken, using the orphan receptor strategy. Finally, in 1999, the ligand was discovered in an unexpected tissue: the stomach.[21]

The structure of ghrelin is unprecedented. Ghrelin is the first known bioactive peptide modified by a fatty acid: ghrelin is modified at its Ser3 by *n*-octanoic acid, and this modification is essential for ghrelin's activity.[21]

In rat stomach, a second type of ghrelin peptide has been purified and identified as des-Gln^{14}-ghrelin.[15] Except for the deletion of Gln^{14}, des-Gln^{14}-ghrelin is identical to ghrelin, even retaining the *n*-octanoic acid modification. Des-Gln^{14}-ghrelin has the same biological activities and potency as canonical ghrelin. The deletion of Gln^{14} in des-Gln^{14}-ghrelin arises from the use of a CAG codon to encode Gln; this trinucleotide is sometimes recognized as a splicing signal. However, des-Gln^{14}-ghrelin is only present at low levels in the stomach, indicating that ghrelin is the major active form.

In the course of purifying human ghrelin from the stomach, several minor forms of ghrelin peptide were also isolated.[16] These could be classified into four groups by the type of acylation observed at Ser^{3}: nonacylated, octanoylated (C8:0), decanoylated (C10:0), and decenoylated (C10:1). All peptides found were either 27 or 28 amino acids in length, with the shorter peptides lacking the C-terminal Arg^{28} and are derived from the same ghrelin precursor via two alternative pathways. As was the case in the rat, the major active form of human ghrelin is a 28-amino acid peptide with octanoylated Ser^{3}. Synthetic octanoylated and decanoylated ghrelins stimulate the increase of intracellular Ca^{2+} in GHS-Rexpressing cells, and stimulate GH release in rats, to a similar degree (Fig. 1).

Figs. 2 and 3 show sequence comparisons of the identified vertebrate ghrelins.[22]

STRUCTURE OF THE GHRELIN GENE, mRNA, AND PRECURSOR PROTEIN

The human ghrelin gene is located on chromosome 3p25–26. The human ghrelin receptor gene is also on chromosome 3, at position q26–27.

The human ghrelin gene, like the mouse gene, contains four exons (Fig. 4). Another short exon that contains only 20 bp, encoding part of the 5′-untranslated region, is transcribed as a minor species of ghrelin mRNA.[20]

The 28 amino acids of the functional ghrelin peptide are encoded in exons 1 and 2. In the rat and mouse ghrelin genes, the codon for Gln^{14} (CAG) serves as an alternative

BY149645). There are two types of porcine ghrelin cDNA, which encode ghrelin and des-Gln[14]-ghrelin, and are present at an approximate ratio of 1:1 (GenBank Accession number: AB035703 and AB035704). In the cow, only one ghrelin mRNA exists, and it encodes a 27-amino-acid ghrelin.

DISTRIBUTION OF GHRELIN IN THE CENTRAL NERVOUS SYSTEM

Ghrelin mRNA is mainly expressed in the stomach; lower levels of ghrelin expression are also observed in the small and large intestines.[9] In contrast to the high concentration of ghrelin in the gastrointestinal tissues, the ghrelin content of the central nervous system is low. By means of immunohistochemical analysis, ghrelin-responsive neuronal cells can be identified in the hypothalamus.[6,21,29] Peptide extracts from hypothalamus were analyzed and characterized by RP-HPLC and ghrelin-specific RIAs. Two ghrelin forms (*n*-octanoyl ghrelin and des-acyl ghrelin) were identified in the hypothalamus, as seen in gastric tissue.[29] These results indicate that acyl modification is not specific to stomach tissue and that it occurs in the hypothalamus.

Ghrelin-immunoreactive neurons are also found in the internuclear space between the lateral hypothalamus, the arcuate nucleus (ARH), the ventromedial nucleus

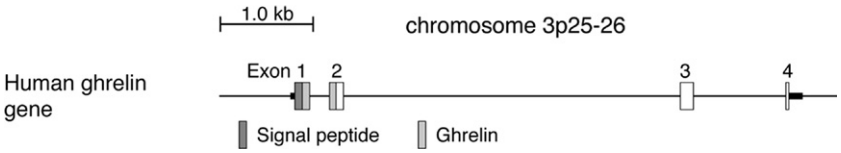

FIGURE 4 Genome structure of human ghrelin. The human ghrelin gene comprises four exons. The first exon encodes the signal peptide and the N-terminal half of ghrelin peptide. The second exon encodes the C-terminal half of ghrelin peptide.

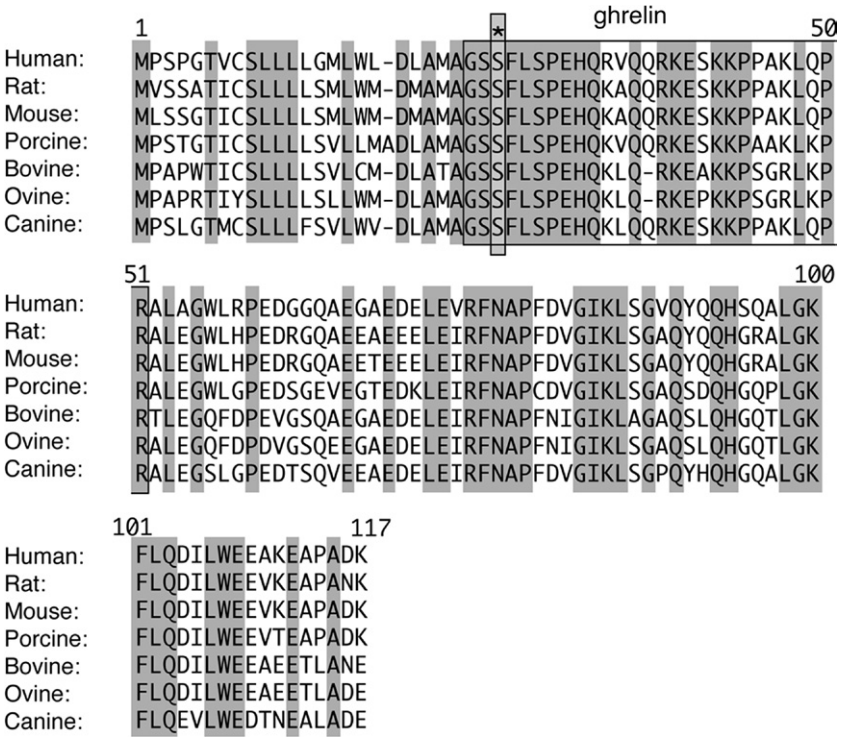

FIGURE 5 Amino-acid sequences of mammalian ghrelin precursors. A sequence comparison between mammalian ghrelin precursors is shown. Identical amino acids are shaded. The asterisk shows the position of the acyl-modified Ser^3. Note that the amino acid sequences of mammalian ghrelin precursors are well conserved; in particular, the N-terminal 10 amino acids of all of these active ghrelin peptides, each of which contains an acyl-modified serine in its active core, are identical.

(VMN), the dorsomedial nucleus (DMN), the paraventricular nucleus (PVN) and the ependymal layer of the third ventricle.[6]

Intravenous injection of ghrelin stimulates NPY/AgRP neurons in the hypothalamus.[27] Immunohistochemical analysis shows that ghrelin neuron fibers directly contact NPY/AgRP neurons.[6] These results indicate that ghrelin exerts its orexigenic activity by stimulating NPY/AgRP neurons in the hypothalamus, to promote the production and secretion of NPY and AgRP peptides.

PROCESSING OF THE GHRELIN PRECURSOR

The amino acid sequences of mammalian ghrelin precursors are highly conserved (Fig. 5).[22] The rat and human ghrelin precursors both consist of 117 amino acids.[21] In these precursors, the 28-amino-acid active ghrelin sequence immediately follows the signal peptide. The cleavage site for the signal peptide is the same in all mammalian ghrelins. Although propeptides are usually processed at dibasic amino acid sites by prohormone convertases, the C-terminus of the ghrelin peptide sequence is processed at an uncommon ProArg recognition site. In knockout mice lacking the prohormone convertases PC1/3, PC2, and PC5/6A, Zhu et al. showed that proghrelin was processed in all but the PC1/3 knockout mouse.[35] Moreover, via immunohistochemical studies, PC1/3 and ghrelin were shown to colocalize in the same cells of the stomach. Thus, PC1/3 is probably a processing protease responsible for proghrelin processing in the stomach. Because PC1/3 is expressed in the brain, it may also be the processing enzyme for ghrelin in the brain, just as in gastric tissue (see the PC1/3 chapter in the Peptide Biosynthesis/Processing section of this book).

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Acyl modification is an important processing step for ghrelin, because ghrelin requires this modification (in particular, *n*-octanoyl modification) to exhibit full activity.[21] The enzyme that catalyzes this acyl transfer to ghrelin was identified in February 2008, when two independent groups reported the identification of ghrelin *O*-acyltransferase (GOAT).[34]

One group, led by Brown and Goldstein at the University of Texas Southwestern Medical Center, searched through the genome database and identified several orphan acyltransferases, that is, enzymes whose functions had not been determined. The authors expressed both ghrelin and candidate enzyme cDNAs in a cell culture system and examined the production of acyl-modified ghrelin. Ultimately, they identified MBOAT4 (Membrane-Bound *O*-Acyltransferase) as the enzyme that acyl modifies the ghrelin peptide.[34]

Another group, at Eli Lilly, identified several candidate acyltransferases in the genome database and suppressed their expression by siRNA in TT cells, a thyroid medulla carcinoma cell line in which acyl-modified ghrelin is endogenously expressed. They also identified MBOAT4 as the enzyme responsible for ghrelin acyl modification.[14] The authors then created MBOAT4 knockout mice and confirmed that ghrelin is not acyl modified in the absence of this gene.

Thus, MBOAT4 is the acyltransferase that catalyzes the transfer of *O*-acyl groups to the hydroxyl moiety of the Ser3 in ghrelin and hereafter called ghrelin *O*-acyltransferases (GOAT). GOAT, a membrane-bound enzyme with multiple transmembrane domains, is a member of an acyltransferase family that includes at least 16 acyltransferase enzymes. Among these, only GOAT shows the ability to acyl-modify ghrelin. Like the existence of ghrelin in all vertebrate species, GOAT is also found in mammals, birds, and fish. The distribution of GOAT is similar to that of ghrelin: GOAT is predominantly found in gastrointestinal organs, particularly the stomach; it is expressed at lower levels in the brain (see the GOAT chapter in the Peptide Biosynthesis/Processing section of this book).

Interestingly, ingestion of either medium-chain fatty acids (MCFAs) or medium-chain triacylglycerols (MCTs) specifically increases the production of acyl-modified ghrelin without changing the total ghrelin level (acyl- and des-acyl-).[28] When mice ingest either MCFAs or MCTs, the acyl group attached to nascent ghrelin molecules corresponds to that of the ingested MCFAs or MCTs. Moreover, *n*-heptanoyl (C7:0) ghrelin, an unnatural form of ghrelin, is produced in the stomach of mice after the ingestion of *n*-heptanoic acid or glyceryl triheptanoate. These findings indicate that ingested fatty acids are directly used for acyl modification of ghrelin.

GHRELIN RECEPTOR IN THE BRAIN

Ghrelin receptor, or GHS-R, is a typical G-protein-coupled receptor with seven-transmembrane domains (7-TM). Two distinct ghrelin receptor cDNAs have been isolated.[17] The first, GHS-R type 1a, encodes a 7-TM GPCR with binding and functional properties consistent with its role as ghrelin's receptor. Another GHS-R cDNA, type 1b, is produced by an alternative splicing mechanism. The GHS-R gene consists of two exons; the first exon encodes TM-1 to TM-5, and the second exon encodes TM-6 and TM-7. Type 1b is derived from only the first exon and encodes only five of the seven predicted TM domains. The type 1b receptor is thus a C-terminal truncated form of the type 1a receptor, and is pharmacologically inactive.

Ghrelin receptor mRNA is prominently expressed in the arcuate (ARC) and ventromedial nuclei (VMN) and in the hippocampus.[13] Ghrelin receptor (GHS-R) mRNA is also detected in multiple hypothalamic nuclei, in the pituitary, as well as in the dentate gyrus, CA2, and CA3 regions of the hippocampus, the substantia nigra, the ventral tegmental area, and the dorsal and median raphe nuclei.

BIOLOGICAL ACTIONS OF GHRELIN WITHIN THE BRAIN

Stimulation of GH Release

Intravenous injection of ghrelin induces potent GH release, in both rat and humans.[21,30] When anaesthetized rats were injected intravenously with ghrelin, an increase in plasma GH concentration was observed. The release of GH peaks approximately 5–15 min after ghrelin injection and returns to basal levels 1 h later. Intracerebroventricular administration of ghrelin also increased rat plasma GH concentrations in a dose-dependent manner.[10] Ghrelin specifically stimulates GH release from cultured pituitary cells in a dose-dependent manner, indicating that ghrelin acts directly on the pituitary.[21] Together, these *in vivo* and *in vitro* assays have confirmed that ghrelin is a specific GH-releasing peptide.

Appetite Stimulation

Immunohistochemical analyses indicate that ghrelin-containing neural cells are localized to the arcuate nucleus of the hypothalamus, a region involved in the regulation of appetite. In fact, when ghrelin is injected into the cerebral ventricles of rats, their food intake is potently stimulated.[27] At least part of this orexigenic effect of ghrelin is exerted by ghrelin's activation of genes encoding two potent appetite stimulators, agouti-related peptide and neuropeptide Y (NPY), whose expression is located primarily in the arcuate nucleus.

Injection of ghrelin icv induces Fos expression in NPY-expressing neurons and increases the amount of NPY mRNA in the arcuate nucleus.[27] Moreover, icv ghrelin injection increases the AgRP mRNA level in the hypothalamus.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

An antagonist of NPY receptor 1 blocks the appetite-stimulating effects of ghrelin. Injections of an AgRP inhibitor icv, anti-NPY IgG, and anti-AgRP IgG inhibit the appetite-stimulating effects of ghrelin. Intravenous injection of ghrelin also stimulates NPY/AgRP neurons in the hypothalamus. Immunohistochemical analysis demonstrated that ghrelin-receptor-expression neuron fibers directly contact NPY/AgRP-expression neurons.[6] These results indicate that ghrelin exerts its feeding activity by stimulating NPY/AgRP neurons in the hypothalamus to promote the production and secretion of NPY and AgRP peptides. Studies with knockout mice lacking NPY, AgRP, or both genes have confirmed these results: although deletion of either NPY or AgRP causes a modest effect (or no effect) on the orexigenic activity of ghrelin, the double knockout mice completley lacked such activity.[4]

Molecular Mechanism of Appetite Stimulation by Ghrelin

AMP-activated protein kinase (AMP-K) has been shown to be involved in hypothalamic appetite regulation.[32] Injection of 5-amino-4-imidazole carboxamide riboside (AICAR), an activator of AMP-K, significantly increases food intake. Administration of ghrelin *in vivo* increases AMP-K activity in the hypothalamus.[1] In contrast, injection of leptin decreases hypothalamic AMP-K activity.

Lipid metabolism in the hypothalamus is believed to be important for appetite regulation.[26] After binding of ghrelin, the ghrelin receptor activates hypothalamic AMP-K (AMP-activated protein kinase), and activated AMP-K then suppresses lipid synthesis. In such experiments, malonyl-CoA level in the hypothalamus decreases while the activity of carnitine palmitoyltransferase 1 (CPT1) is increased. Activated CPT1 then accelerates lipid transport into mitochondria, where lipids are catabolized.

UCP2 in the hypothalamus may be the key target for appetite stimulation by ghrelin, because ghrelin regulates mitochondrial oxidation in hypothalamic cells via UCP2.[2] Ninety percent of UCP2-expressing cells in the hypothalamus also express the ghrelin receptor. In isolated hypothalamic synaptosomes, ghrelin increases oxygen consumption and total respiration. Ghrelin administration also increases the number of mitochondria and UCP2 expression in NPY/AgRP-expressing cells of the hypothalamic arcuate nucleus (Fig. 6).

The orexigenic effect of ghrelin is exerted via the upregulation of NPY mRNA levels in the arcuate nucleus. However, in UCP2-deficient mice, ghrelin administration does not increase NPY level, and the number of c-Fos protein positive cells in the arcuate nucleus NPY/AgRP-expression neurons is decreased. Moreover, in the UCP2-deficient mice, AMP-K activity is not changed by ghrelin administration. AICAR stimulates mitochondrial respiration in the hypothalamus and increases appetite, whereas UCP2-deficient mice show no effects in response to AICAR. By contrast, the AMP-K inhibitor compound C suppresses appetite stimulation by ghrelin; however, in UCP2-deficient mice, appetite suppression by compound C is not observed. These results suggest that AMP-K activation by ghrelin is

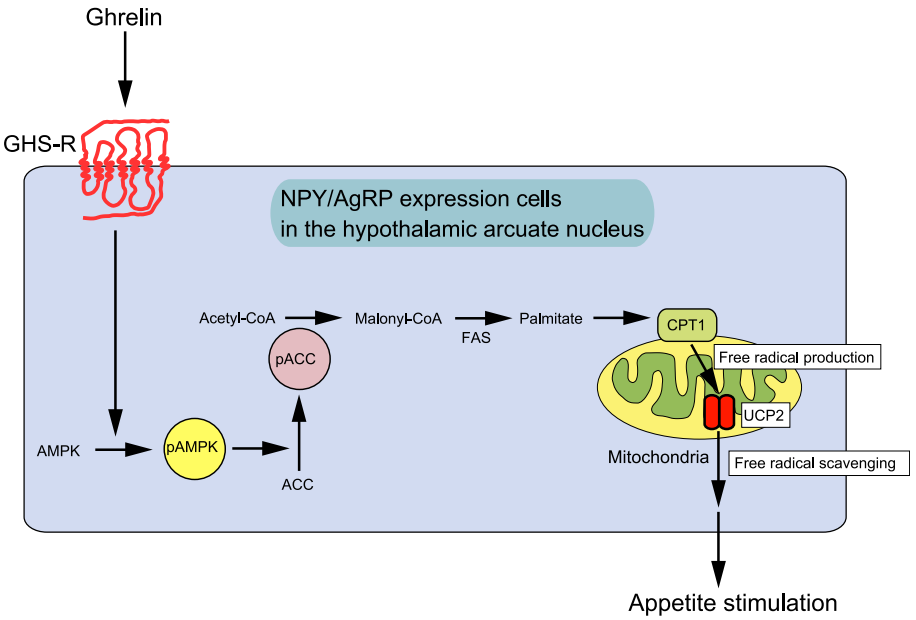

FIGURE 6 Intracellular action of ghrelin in NPY/AgRP-expression cells in the hypothalamic arcuate nucleus. In NPY/AgRP-expression cells in the hypothalamic arcuate nucleus, ghrelin stimulates AMP-K and regulates fatty acid metabolism, leading to CPT1 activation. Ghrelin's effects on mitochondrial respiration are dependent on the function of UCP2 and hence result in an increase of food intake. See color plate 27.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

upstream of UCP2. In other words, ghrelin stimulates UCP2 through AMP-K.

By lipid consumption in the hypothalamic mitochondria, free-radical production was increased. The free radicals thereby produced are scavenged by UCP2. In UCP2-deficient mice, ghrelin increases free-radical production relative to wild type.

Taken together, these results suggest that lipid metabolism and mitochondrial free-radical production in the hypothalamic neurons may be key factors involved in the regulation of appetite by ghrelin.

Pathway of the Ghrelin Signal: From Peripheral Tissues to the Central Nervous System

Circulating ghrelin stimulates hypothalamic neurons and stimulates food intake. In general, circulating peptides do not pass the bloodbrain barrier. In fact, the rate at which circulating ghrelin passes the barrier is very low. Thus, peripheral ghrelin must activate the appropriate hypothalamic regions via an indirect pathway.

The detection of ghrelin receptors on vagal afferent neurons in the rat nodose ganglion suggests that ghrelin signals from the stomach are transmitted to the brain via the vagus nerve.[11] Moreover, the observation that ICV administration of ghrelin induces c-Fos in the dorsomotor nucleus of the vagus, and stimulates gastric-acid secretion, indicates that ghrelin activates the vagus system.

Vagotomy inhibits the ability of ghrelin to stimulate food intake and GH release.[11] A similar effect was also observed when capsaicin, a specific afferent neurotoxin, was applied to vagus nerve terminals to induce sensory denervation. However, the basal level of ghrelin concentration is not affected after vagotomy. In contrast, fasting-induced elevation of plasma ghrelin is completely abolished by subdiaphragmatic vagotomy or atropine treatment.[31]

Moreover, peripheral ghrelin signaling, which travels to the nucleus tractus solitarius (NTS) via the vagus nerve, increases noradrenaline (NA) in the arcuate nucleus of the hypothalamus. Bilateral midbrain transections rostral to the NTS, or toxin-induced loss of neurons in hindbrain neurons expressing dopamine beta-hydroxylase (an NA-synthetic enzyme), abolished ghrelin-induced feeding. Thus, the noradrenergic system is necessary in the central control of feeding behavior by peripherally administered ghrelin. These results indicate that the response of ghrelin to fasting is transmitted through vagal afferent transmission.

Ghrelin Enhances Learning and Memory Processes Through Serotonin System

The ghrelin receptor is expressed in the hippocampus, implicating ghrelin in learning and memory.[13] Several reports indicate that ghrelin enhances learning and memory processes. Neuronal innervation by serotonergic neurons from the dorsal raphe nucleus (DRN) is necessary for the enhancement of learning processes in the hippocampus. These results are confirmed by the observations that direct ghrelin injection into DRN enhances memory retention, and pretreatment of a selective serotonin uptake inhibitor (fluoxetine) decreases it. Moreover, ghrelin promotes dendritic spine synapse formation, whereas ablation of ghrelin decreases the number of spine synapses in the hippocampal CA1 region.[12]

Ghrelin Regulates Emotional Behavior Through Activating Dopaminergic Neurons

Dopaminergic neurons from the ventral tegmental area (VTA) are involved in reward and motivated behaviors. Ghrelin is believed to activate this dopaminergic neural pathway and regulate reward and motivated behaviors.

The ghrelin receptor, GHS-R, is localized in the dopaminergic neurons of the VTA. Direct injection of ghrelin into the VTA region increases food and alcohol intakes dose dependently.[18] In contrast, ghrelin-KO mice, ghrelin receptor knockout or injection of GHS-R antagonists both decrease alcohol intake and suppresses alcohol-induced locomotor activity and accumbal dopamine release. Ghrelin also suppresses hyperactivity resulting from cocaine or amphetamine intake.

In humans, an SNP in the GHS-R gene is associated with heavy alcohol consumption.[24] Moreover, another SNP in GHS-R, as well as haplotypes of both the ghrelin and GHS-R genes, are associated with body mass in heavy consumers of alcohol. Thus, the ghrelin signal in the VTA may be a candidate target for the treatment of alcohol and drug abuse.

Neuroprotective Effects of Ghrelin

Using animal models of neuronal diseases, it has been shown that ghrelin has neuroprotective activity. Ghrelin administration improved symptoms in animal models, including MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine)-induced Parkinson's disease models,[19] neural ischemia models or recirculation models for cerebellar ischemia.[5] Moreover, ghrelin inhibits progress of autoimmune encephalomyelitis in an animal model of multiple sclerosis.

In addition, the ghrelin receptor is expressed in spinal cord, and ghrelin stimulates functional recovery after spinal injuries.[25] The mechanism of ghrelin's neuroprotective effects is not yet fully understood. However, it has been postulated that inhibition of apoptosis, suppression of reactive oxygen species production, and/or mitochondrial neogenesis may be involved in the neuroprotective role of ghrelin.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Thus, ghrelin may be applicable to clinical use in treatment of neuronal diseases.

Ghrelin and Sleep Regulation

The sleepwake cycle is closely associated with GH release and food intake rhythms, which are regulated partly by ghrelin. The basic sleepwake mechanism is not impaired in ghrelin-KO mice; however, ghrelin increases non-REM sleep and decreases REM sleep. During sleep, ghrelin concentrations increase in the early part of the night and decrease in the morning. Sleep deprivation blunts the increase of ghrelin during night. Thus, the nocturnal increase of ghrelin levels is probably induced by sleep-associated processes. Interestingly, the activity of orexin neurons is stimulated by ghrelin, indicating that fasting-induced ghrelin activates orexin neurons to arouse animals for foraging.[33]

Pathophysiological Implications

Plasma ghrelin concentrations are low in obese people and high in lean people. Anorexia nervosa (AN) is a syndrome often seen in young women; it is characterized by a combination of weight loss, amenorrhea, and behavioral changes. Some of these changes are reversible after weight gain. Plasma ghrelin concentrations in patients with AN are high and return to control levels after weight gain after renutrition. Patients with AN often show markedly elevated GH concentrations, which may result from high circulating levels of ghrelin. Moreover, high ghrelin increases ACTH, prolactin, and cortisol concentrations in humans, which may explain the amenorrhea and behavioral changes observed in patients with AN.

Patients who undergo gastric bypass lose weight, and their ghrelin levels decrease.[8] Changes in ghrelin concentration associated with food intake are diminished in these patients. Plasma ghrelin concentrations are also decreased in patients with short bowel syndrome, probably due to the loss of ghrelin-producing tissues.

High plasma ghrelin concentrations are observed in Prader Willi syndrome (PWS) patients.[7] PWS is a complex genetic disorder characterized by mild mental retardation, hyperphagia, short stature, muscular hypotonia, and distinctive behavioral features. Excessive appetite in PWS causes progressive severe obesity, which in turn leads to an increase in cardiovascular morbidity and mortality. The PWS genotype is characterized by a loss of one or more paternal genes in region q11–13 on chromosome 15. It has been suggested that this genetic alteration leads to dysfunction of several hypothalamic areas, including those involved in the regulation of appetite. The mean plasma concentration of ghrelin was 3- to 4-fold higher in PWS patients than in a reference population. Thus, ghrelin may be responsible, at least in part, for the hyperphagia seen in PWS. It is unclear, however, what underlies the increased ghrelin concentrations in these patients.

Chapter 105

GHRH

Maria M. Malagon, Rafael Vazquez-Martinez, Antonio J. Martinez-Fuentes, Francisco Gracia-Navarro and Justo P. Castaño

ABSTRACT

Growth hormone-releasing hormone (GHRH), a 44 amino acid peptide primarily secreted by hypothalamic neurons of the arcuate nucleus, is the main regulator of pituitary somatotrophs. GHRH binds to its G protein-coupled receptor (GHRH-R) to activate diverse signaling pathways predominantly involving cAMP and Ca^{2+}, and thereby stimulates GH secretion, GH gene transcription, and somatotroph proliferation. These actions, coupled to hypothalamic GHRH interactions with somatostatin- and ghrelin-producing neurons underlie pulsatile GH secretion. GHRH production is markedly dependent upon age, sex, and metabolic status, and is also involved in sleep and feeding regulation. Defects in GHRH/GHRH-R severely alter somatotroph function and GH production, thereby causing abnormal growth.

DISCOVERY

The original evidence for the existence of a hypothalamic factor that stimulated secretion of growth hormone (GH) from pituitary somatotrophs was followed by a long, unfruitful search through classic purification and bioassay methods using large amounts of hypothalamic extracts, which ended unexpectedly in 1982, when two independent teams isolated and characterized human GH-releasing hormone (GHRH) from two pancreatic tumors that caused acromegaly.[24] Two of the three GHRH forms of 44 and 40 amino acids found in these tumors are identical to the human hypothalamic GHRH forms.[24] Subsequently, GHRH was isolated and identified in a number of vertebrates, from rodents to fish, including a protochordate.[14,32] GHRH is a member of a growing superfamily of brain-gut peptides, which also includes, among others, pituitary adenylate cyclase-activating polypeptide (PACAP), glucagon, secretin, and vasoactive intestinal polypeptide (VIP),[32] as discussed in this and other Sections.

STRUCTURE OF THE GHRH mRNA/GENE

The human pancreatic tumor samples that enabled isolation of GHRH also provided the first cDNA sequences, whose cloning and characterization revealed that GHRH mRNA codes for a pre-pro-GHRH of 108 amino acids composed of a typical signal peptide, the 44 amino acid GHRH, and a 31 amino acid C-terminal peptide with no known function [GHRH-related peptide (GHRH-RP)] (Fig. 1).[22] A second isoform coding for a 107 amino acid precursor lacking the Ser-103 in the C-peptide was also found. Subsequently, the cDNAs and/or genes were isolated and characterized in rat, mouse, and other mammals as well as in birds, amphibians, and fish.[32] In non-mammalian species, GHRH was believed to be encoded together with PACAP by a common precursor gene.[32] However, it has been recently proposed that, at least in fish and amphibians, the previously identified GHRH-like peptides are homologs of mammalian PACAP-related peptides.[14] Indeed, data mining of the genomic sequences from several vertebrates has enabled the identification of genomic sequences encoding for putative GHRHs from amphibians and fish, which share a higher degree of sequence identity with mammalian GHRH than the previously identified GHRH-like peptides.[14]

The primary structure of GHRH is highly variable among species, especially at the C-terminus. In fact, rat GHRH, which is 43 amino acids, shares 68% homology with the human peptide, yet the N-terminal two thirds of the molecule, corresponding to the bioactive core of the peptide ($GHRH_{1-29}$), are more conserved. Likewise, human GHRH shares 81.5% and 74.1% sequence identity with goldfish/zebrafish and *X. laevis* peptides, respectively.[14] However, GHRH sequences are almost identical in the eight fish species wherein this peptide has been identified by in silico analysis.[14] In most species, but not in rodents, GHRH is amidated at its C-terminus because of the presence of a Gly residue.[24,32]

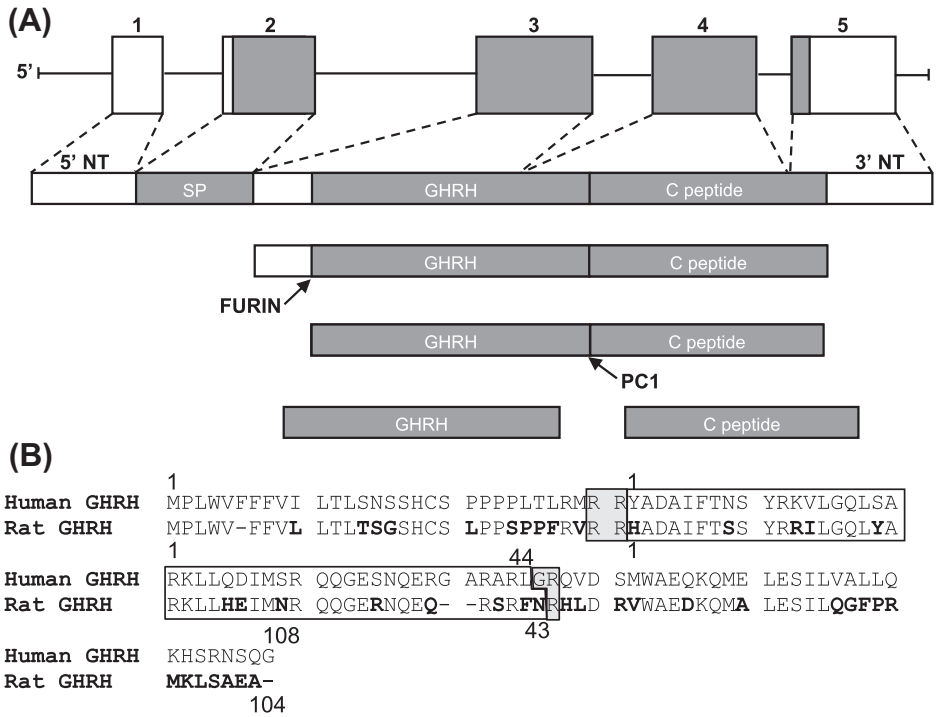

FIGURE 1 (A) Organization of the *GHRH* gene and posttranslational processing of its protein product by the sequential participation of the proprotein convertases furin and PC1. The 5′ nontranslated region (5′-NT), the signal peptide (SP), GHRH, the C-terminal peptide, and the 3′ nontranslated region (3′-NT) are indicated. (B) Alignment of human and rat GHRH precursor sequences. Bold letters illustrate mismatched amino acids in the rat GHRH sequence when compared with the human sequence. Open boxes encompass the amino acid sequence of GHRH. Gray boxes encompass amino acid residues involved in the processing of the precursor protein.

The human and rat genomes contain a single GHRH gene that maps to chromosomes 20 and 3, respectively. In both species, GHRH gene spans about 10 kb and includes five exons: exon 1 contains the 5′-untranslated region and exons 2–4 encode the pre-pro-GHRH together with exon 5, which also contains the 3′-untranslated region (Fig. 1). In fish and amphibians, GHRH genes have four exons and the mature peptides are located in exon 3.[14] The 5′-splice donor sites of intron 4 in human and rat genes differ, which explains differences between the C-terminal portion of human and rat GHRH precursors. In the human gene, differential use of two consensus splice-acceptor sites at the 5′-end of exon 5, which are also present in the rat gene sequence, gives rise to the two distinct types of mRNAs coding for the 108 and 107 amino acid precursor forms.[22] The 5′-flanking region of human and rat GHRH genes includes consensus TATA and CAT box sequences. Analysis of the 5′-promoter region of the rat gene has revealed consensus sites for the transcription factor Gsh-1, which seems to be required for both development of GHRH neurons and tissue-specific regulation of GHRH gene,[25] as well as for the nuclear factor of activated T cells (NFAT), which appears to be involved in the acute regulation of GHRH gene transcription.[3]

PROCESSING OF THE GHRH PRECURSOR

In vitro analysis of GHRH precursor processing in rat hypothalamic neurons initially demonstrated that, after removal of the signal peptide, pro-GHRH (10.5 kDa, 104 amino acids) is first processed to an 8.8-kDa intermediate form that is cleaved to yield GHRH (5.2 kDa) and the 3.6-kDa C-peptide.[29] Later, transfection studies of several neuroendocrine cell types with different members of the subtilisin-like group of proprotein convertases revealed that this process primarily involves the sequential participation of two of these enzymes, furin and PC1 (see Peptide Biosynthesis/Processing Section of this book), which cleave pro-GHRH at two typical recognition sites for these enzymes located at the N- and C-terminus of GHRH, respectively (Fig. 1).[29] Specifically, processing of pro-GHRH is initiated by furin to give rise to the 8.8-kDa intermediate form, which is subsequently cleaved by PC1 to yield mature GHRH and GHRH-RP.

DISTRIBUTION OF THE GHRH mRNA/PEPTIDE

Shortly after isolation of GHRH, the distribution of the peptide was reported in human brain, wherein

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

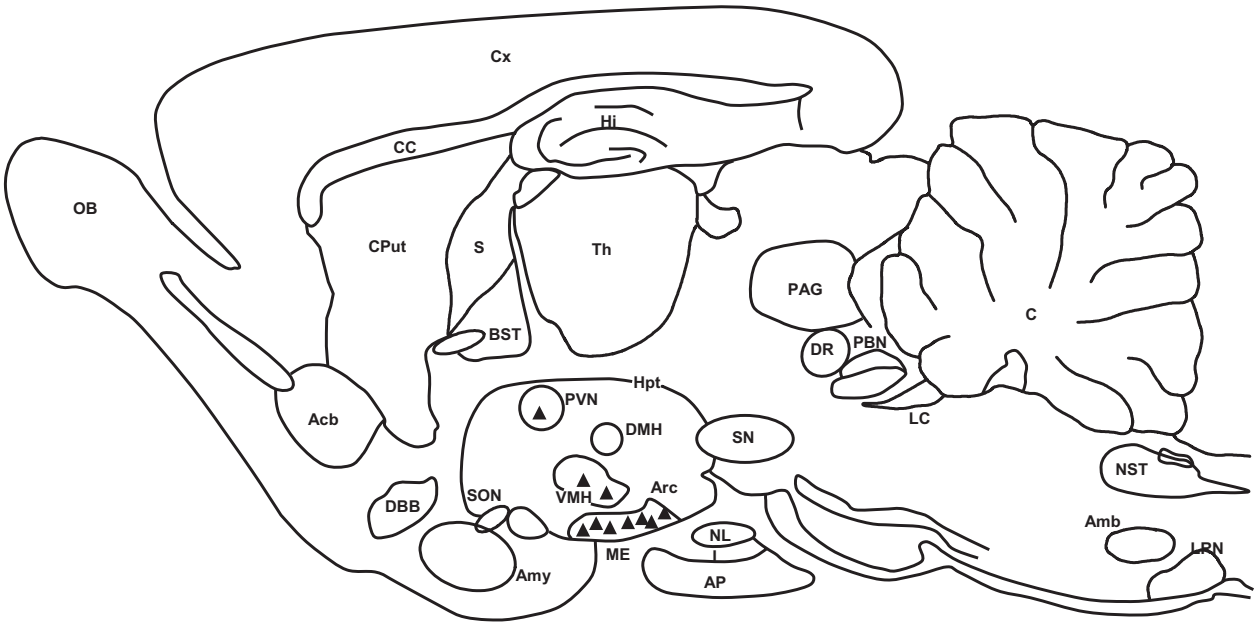

FIGURE 2 Schematic parasagittal section of the rat brain illustrating the distribution of GHRH expression. Black triangles represent GHRH mRNA-containing cell bodies. In rat, the highest GHRH mRNA levels in the brain are found in the ventrolateral part of the arcuate nucleus (Arc).

GHRH-immunoreactivity is mainly associated with neuronal cell bodies in the medial hypothalamus (Hpt), especially in the arcuate nucleus (Arc).[24] In addition, some GHRH-immunopositive cells can be found in the lateral hypothalamus (i.e. nucleus lateralis tuber) and the ventromedial nucleus. GHRH-containing fibers are present in the median eminence and in various hypothalamic nuclei including the arcuate and ventromedial nuclei.[24] In rat, most GHRH-immunoreactive cell bodies are found in the ventrolateral part of the Arc, which also exhibits the highest GHRH mRNA levels in the brain (Fig. 2).[22,24] As in the human brain, these cells project their fibers toward the external layer of the ME, wherein GHRH-immunoreactive terminals are found around the capillaries of the portal vessels. In addition to the Arc GHRH-containing neurons, GHRH mRNA can be detected in some scattered perikarya in the dorsolateral region of the ventromedial nucleus, basolateral Hpt and, to a lesser extent, in the paraventricular nucleus. This distribution correlates well with that of GHRH immunoreactivity, which has been also localized to a few cells in the dorsal part of the dorsomedial nucleus, ventral premammillary nucleus, as well as in the medial perifornical region, zona incerta and the hypothalamic portion of the stria terminalis. GHRH-immunoreactive fibers from these cells extend through the periventricular region of the Hpt and adjoining parts of the basal telencephalon. Nevertheless, the presence of the peptide in extrahypothalamic regions is quite limited as only the cortex and brain stem have been reported to contain detectable amounts of GHRH mRNA.[21]

In rat, GHRH mRNA-containing neurons in the Arc appear at E16 and acquire the adult-like distribution pattern at E20.[24] Transcript levels increase gradually over the course of maturation both in males and females, although GHRH expression is higher in the male than the female from P10 onward.[24] In human fetuses, GHRH-immunoreactive neurons are detected between the 18th and 29th week, while immunoreactive fibers are detectable in the median eminence after the 31st week.[24] Finally, both GHRH mRNA levels and the number of immunoreactive Arc neurons and median eminence fibers decrease in aged rats.[24]

GHRH RECEPTOR AND SIGNALING CASCADES

Earlier studies reported specific GHRH binding sites with high-affinity and low-capacity in membrane extracts or intact cells from pituitary.[11,23,24] However, detailed knowledge of GHRH-R was only achieved after its cloning, first in rat, then in mouse, human, and pig, and more recently in other vertebrate species, including birds and fish.[11,14,23,28] GHRH-R belongs to the G protein-coupled receptor (GPCR) B-II subfamily, which also includes receptors for PACAP/VIP/secretin/glucagon family of peptides (Fig. 3).[23,24] Contrary to other receptors of this family, GHRH-R is highly selective for its cognate ligand, showing subnanomolar affinity.[11] Specificity is conferred by the N-terminal extracellular region, transmembrane domains and associated extracellular loops and also C-terminal intracellular tail.[11]

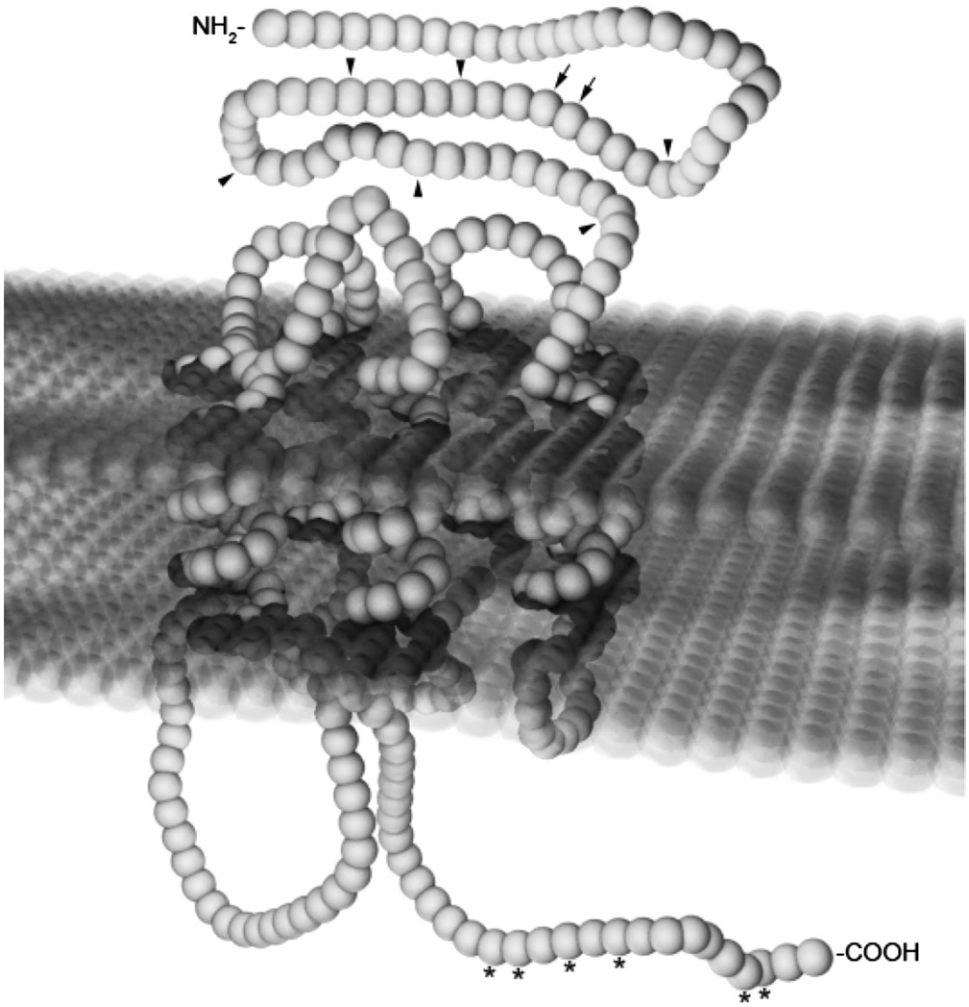

FIGURE 3 Amino acid sequence and membrane topology of the rat GHRH-R. Arrow heads indicate the six Cys residues in the NH_2-terminal domain. Asterisks represent several potential phosphorylation sites and arrows illustrate two N-glycosylation sites.

The GHRH-R gene is localized to human chromosome 7p14-15 and rat chromosome 4q24. The human GHRH gene spans over 15 kb comprising 13 exons separated by introns of variable size, which thereby enable alternative mRNA splice generating receptor isoforms.[11,23] The main form of GHRH-R in most mammals is a 423 amino acid protein,[23] whereas the chicken receptor contains 419 amino acids.[28] Additional, less abundant isoforms bearing C-terminus with distinct length and structure have been reported in the pituitary of several species including human (normal and tumoral), rat, and pig.[23] Although the precise functional significance of these GHRH-R variants is as yet unclear, they show distinct binding and/or cAMP signaling properties and may modulate signaling by the predominant receptor.[23] The N-terminal extracellular domain of GHRH-R contains a site for N-glycosylation as well as six cysteine residues and an aspartate residue that are conserved in this receptor family, while the third intracellular loop and C-intracellular domain contain several potential phosphorylation sites, which may regulate signaling and receptor internalization.[11,23]

Human and rat GHRH-R gene promoters lack a canonical TATA box motif, but contain putative binding sites for a number of transcription factors including Pit-1, Oct-1, enhancer activator protein-1 (AP-1) and AP-4, as well as consensus sequences for nuclear factor 1 (NF-1), upstream regulatory factor (USF), NF-κB, cAMP response element binding protein (CREB), glucocorticoid receptor element (GRE), and estrogen-responsive element (ERE).[20] Studies in dwarf mice and humans indicate that GHRH-R expression is strictly and reciprocally dependent upon Pit-1 gene expression.[11,23] Accordingly, GHRH-R is predominantly expressed in the pituitary in a temporal and spatial pattern corresponding to GH gene expression and therefore essentially restricted to somatotrophs.[24] In addition, GHRH-R mRNA is present in periventricular, Arc, and ventromedial nuclei, and the anterior hypothalamic area as well as in some

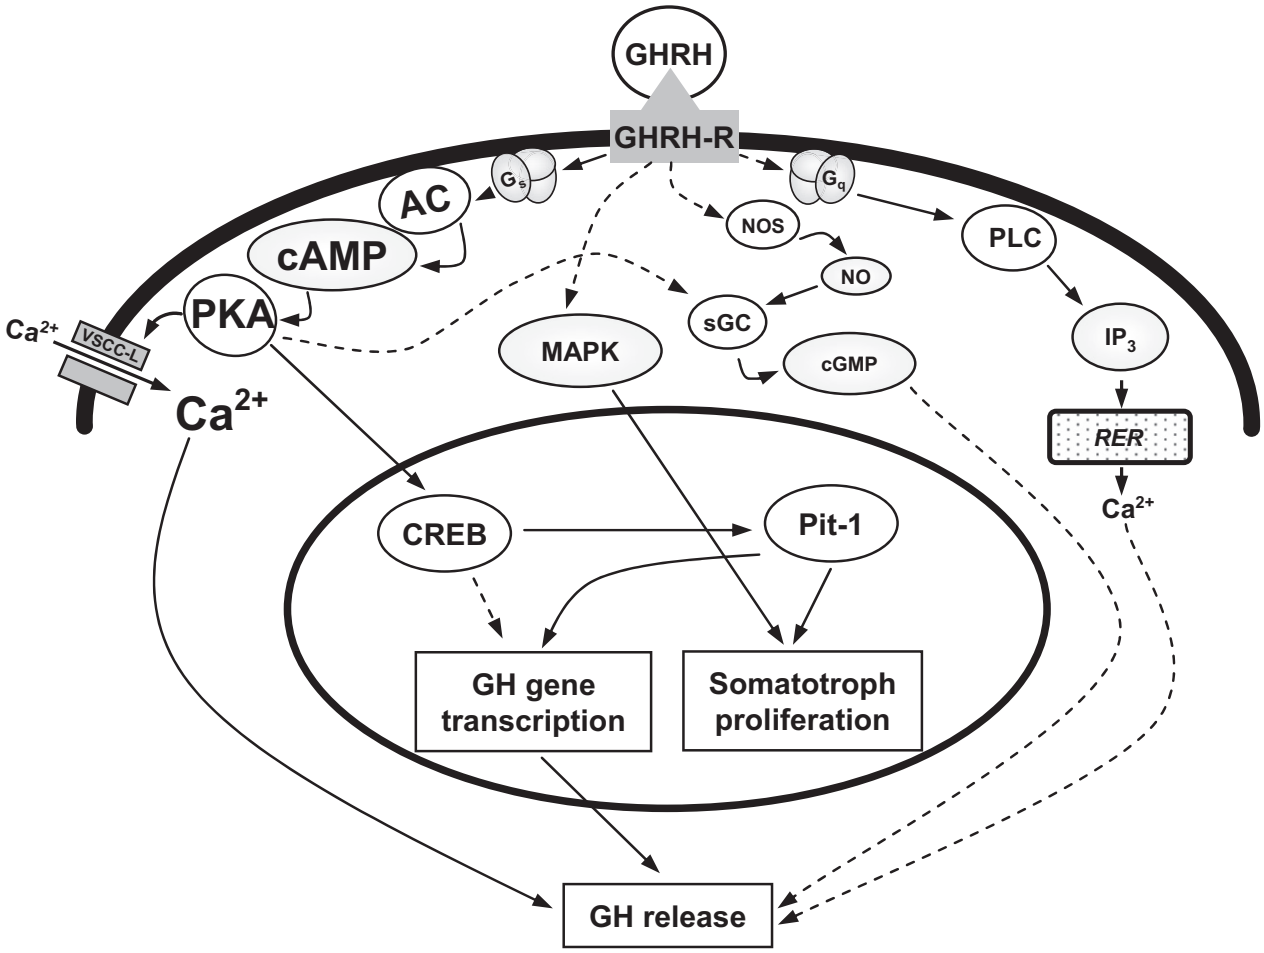

FIGURE 4 Schematic diagram summarizing the main signaling pathways involved in the response of somatotrophs to GHRH. Abbreviations: AC, adenylyl cyclase; CREB, cAMP response element (CRE)-binding protein; IP_3, inositol 1,4,5-trisphosphate; MAPK, mitogen-activated protein kinase; NO, nitric oxide; NOS, nitric oxide synthase; PKA, protein kinase A; PLC, phospholipase C; RER, rough endoplasmic reticulum; sGC: soluble guanylyl cyclase; VSCC-L, L-type voltage-sensitive Ca^{2+} channels.

peripheral tissues (e.g., placenta, kidney, testis and gastrointestinal tract).[23,24] Regulation of GHRH-R is exerted at different levels. Rapid desensitization occurs upon ligand binding, through internalization of the GHRH-R.[11,23] More lasting regulatory effects are exerted on GHRH-R expression by a number of signals including GHRH, which evokes a dual, time-dependent effect: an acute decrease in GHRH-R expression probably mediated via cAMP[11,18,23] and a long-term up-regulation of mRNA levels.[11,23] Acute inhibition of expression is also caused by ghrelin and somatostatin.[18,28] Consistent with the presence of corresponding binding sites in the GHRH-R promoter, and with its sexually dimorphic expression in pituitary, estrogen inhibits GHRH-R transcription.[23,24] By contrast, GHRH-R expression is positively regulated by glucocorticoids and thyroid hormone.[11,23,24]

Upon GHRH binding, GHRH-R activates diverse signaling cascades, which primarily involve two second messengers, cAMP and Ca^{2+} (Fig. 4).[23,24] GHRH increases cAMP levels by stimulating adenylyl cyclase (AC) through a Gs protein. Subsequently, increased cAMP levels induce activation of protein kinase A (PKA) which, in turn, activates several proteins by phosphorylation, including ion channels.[23,24] Likewise, GHRH increases cytosolic free Ca^{2+} concentration levels in somatotrophs through a mechanism essentially dependent on extracellular Ca^{2+} influx through voltage-sensitive Ca^{2+} channels, a process that involves K^+ and Na^+ channels and PKA-dependent phosphorylation.[5] There is also evidence that GHRH activates and requires additional signaling components in somatotrophs.[24] Thus, GHRH-induced GH release is also partially dependent on the phospholipase C (PLC)/inositol phosphate (IP) pathway and/or mobilization of Ca^{2+} from intracellular stores in somatotrophs.[30] In addition, the signaling cascade involving nitric oxide and cGMP also participates in mediating GHRH-induced GH release, and may represent a subsequent, interlinked step in the AC/cAMP/PKA signaling cascade, via PKA-mediated phosphorylation of soluble guanylyl cyclase.[19,24] GHRH-R signaling also activates the

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

MAP kinase pathway, which may mediate the effects of the peptide on GH synthesis and somatotroph proliferation.[11,23] Finally, the signaling properties conveyed by GHRH-R may be modulated by other G protein-coupled receptors such as that for ghrelin/GH secretagogs.[6]

BIOLOGICAL ACTIONS OF GHRH WITHIN THE PITUITARY AND THE BRAIN

It is now well established that GHRH is the primary hypothalamic stimulus for GH secretion from pituitary somatotrophs. Indeed, the remarkable ability of GHRH to induce GH release specifically, both *in vivo* and *in vitro*, in mammals, birds and amphibians (and, to a lesser extent, in fish) with a marginal effect on the release of other pituitary hormones, constitutes the major role for this peptide.[23,24] Moreover, GHRH acts as a true somatotrophic factor in that it also increases intracellular GH content by activating GH gene transcription and GH mRNA levels, and stimulates somatotroph proliferation, this latter function being fundamental for somatotroph development during pituitary organogenesis.[20,24]

Consistent with the well-known pulsatile pattern of GH release in plasma, GHRH has been shown to be released in an episodic manner into portal blood at the median eminence in various species.[24] Initial studies in male rats based on measurements of GHRH and somatostatin in portal plasma and of GH in peripheral plasma led to a valuable model wherein GH pulses were the result of alternating episodes of GHRH and somatostatin release from Hpt, which would stimulate and suppress, respectively, GH release.[24] Yet, subsequent studies revealed that this model did not satisfactorily explain GH secretory patterns in human and other species in diverse pathophysiological conditions (e.g., GH pulsatility is maintained in the absence of GHRH input resulting from a mutation in GHRH-R[31]). The available evidence led Veldhuis and coworkers to postulate, in the context of highly complex and elaborated mathematical models, that the generation of a given physiological pattern of pulsatile GH release is the combined result of intricate time-delimited interactions among GHRH, somatostatin, and GH autofeedback, as well as a new major player, ghrelin, which are exerted at both hypothalamic and pituitary levels.[9] In this scenario, GHRH acts on the pituitary to stimulate GH release and synthesis, but would also act by stimulating Arc somatostatin neurons, as suggested by the tight neuroanatomical interplay between these factors. In turn, GHRH expression and secretion from Arc neurons is negatively regulated by hypothalamic somatostatin neurons as well as by GH feedback, whereas ghrelin would act upon GHRH neurons stimulating its release. The components of this cycle are discussed elsewhere in this book.

There is ample evidence that GH levels and secretory patterns are markedly affected by development, sex, aging, and diverse pathological conditions both in human and other species, and that, accordingly, hypothalamic GHRH production is strictly and distinctly regulated by these factors.[24] Indeed, the sexually dimorphic pattern of pulsatile GH secretory profiles in both human and rat, which underlies the distinct (higher in males) gender-dependent growth pattern, probably results from the higher number and mRNA content of hypothalamic GHRH neurons, and presumably, their distinct neuroanatomical connectivity with other neurons (e.g., somatostatin) in the male compared with the female. In this regard, it has been recently shown that the percentage of ventromedial hypothalamic-arcuate GHRH neurons bearing the somatostatin receptor sst2A is higher in female than in male mice and that testosterone reduces the distribution of sst2A on these neurons.[4] Finally, basal and pulsatile GH release is markedly influenced by age, with a decline in GH during the life span in human and animal models, which seems to be paralleled by, and significantly dependent upon, a decreased production of hypothalamic GHRH and reduced somatotroph secretory responsiveness to this peptide, together with an increased somatostatinergic tone.[24]

In addition to controlling somatotroph function, GHRH also possesses extrapituitary central effects. Thus, it has been shown that GHRH promotes sleep (see last Section of this book) and, accordingly, it has been proposed to provide the subcortical mechanism synchronizing sleep and GH secretion.[26] Specifically, non-REM sleep increases in human, rat and rabbit after GHRH administration, whereas sleep is reduced in rats when GHRH action is inhibited by a specific antagonist or by GHRH antibodies. This sleep-promoting effect of GHRH has been documented to occur through a direct action of the peptide on GABAergic neurons in the ventrolateral and median preoptic nuclei.[27] Additionally, GHRH also stimulates REM sleep, although this action seems to depend on GH.

GHRH has been also proposed to be involved in the central regulation of feeding and probably contributes to the circadian pattern of food intake.[24] In support of this, central administration of GHRH stimulates food intake in rat and sheep by a mechanism that was initially proposed to involve GHRH-mediated effects on the suprachiasmatic nucleus/medial preoptic area.[24] A role for orexin A as integrator of the somatotropic axis with the nutritional status, through its inhibitory actions on GHRH neurons in the paraventricular nucleus in relation to the sleep–wake cycle, has been recently proposed.[17]

PATHOPHYSIOLOGICAL IMPLICATIONS

Because of the direct involvement of GHRH in somatotroph proliferation, defects in tandem GHRH/ GHRH-R profoundly alter the morphological and functional

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

characteristics of the pituitary, provoking generalized GH secretion disorders. Thus, excessive GHRH release into the median eminence induces somatotroph hyperplasia and an abnormal enlargement of the pituitary.[10] In rodents, symptomatology of GHRH excess has been extensively studied since Mayo and coworkers established a strain of transgenic mice expressing a mouse metallothionein I/human GHRH fusion gene, an animal model of acromegaly.[24] In these mice, chronic GHRH production leads to development of enormous pituitary glands as result of uncontrolled proliferation of somatotrophs that secrete large amounts of GH, an effect that is GHRH-specific and not mediated by GH or IGF-I.[13] In humans, GHRH-dependent somatotroph hyperplasia is very rare; it is limited to certain cases of extrapituitary GHRH overproduction and sporadic examples of gigantism.[12] Moreover, mutations in the GHRH gene have never been described, contrary to that observed in the GHRH-R gene, where a variety of spontaneous punctal mutations affecting GHRH-R activity have been reported.[20] One of these mutations (or gene polymorphism) is produced by a single base change in the GHRH-R gene in human somatotropinomas that confers hypersensitivity to GHRH binding.[20]

On the other hand, deficient GHRH secretion and/or activity is generally associated with somatotroph hypoplasia, subsequent low GH release and, consequently, development of dwarfism. These observations have been obtained from rodent (i.e., *little* mouse) or humans with inactivating mutations in the GHRH-R[20] since, as mentioned earlier, mutations in the GHRH gene have not been reported to date, neither in humans nor in rodents. Despite this, rodent models with GHRH deficiency secondary to deletion of other genes (Gsh-1[16]; PC1[35]) or caused by targeted expression of the human GH transgene in the Hpt[24] have been already reported. Certainly, the recent development of GHRH knockout mice[2,15] has provided valuable information on the precise role of GHRH in the regulation of normal and pathophysiological somatotroph function. GHRH-KO mice have also served to characterize a potent GHRH analog (i.e., CJC-1295) that exhibits a longer half-life and duration of action than the natural peptide because of its selective and covalent binding to endogenous albumin.[1] This analog has been successfully used in clinical trials, which highlights its potential utility as a therapeutic agent.[33] Indeed, since the discovery of the sequences crucial for GHRH somatotrophic activity, much effort has been invested in generating synthetic analogs with extended half-life and duration of action. Thus, besides CJC-1295, PEGylated or cyclic GHRH analogs as well as fatty body-GHRH analogs with improved biological activity have been designed.[7,34] Recently, GHRH analogs have been assayed with the aim of augmenting GH secretion in individuals with low endogenous GH levels and excess visceral obesity, including patients with HIV receiving highly active antiretroviral therapy.[8] Certainly, the growing development of potent and long-acting GHRH analogs will pave the way to prevent or ameliorate the pathological states associated to GHRH deficiency.

Chapter 106

GnRH (LHRH)

R.P. Millar

ABSTRACT

Gonadotropin-releasing hormone (GnRH) is a decapeptide produced in the hypothalamus and secreted into portal vessels to engage the GnRH receptor (a G protein-coupled receptor) in pituitary gonadotrophs, where it recruits a diversity of signaling pathways to culminate in the biosynthesis and secretion of the gonadotropins, luteinizing hormone (LH), and follicle-stimulating hormone (FSH), which stimulate gamete production and sex steroid hormone production. The predominant signaling pathway is mediated Gq/11 and mobilization of intracellular Ca^{2+} and activation of protein kinase Cs (PKCs). A wide range of GnRH analogs have been developed and extensively used for the treatment of hormone-dependent diseases, as well as for controlling the ovulatory LH surge in the induction of ovulation in *in vitro* fertilization. High continuous doses of GnRH agonists inhibit gonadotropin secretion through the desensitization of the gonadotroph, whereas GnRH antagonists do so by directly competing with endogenous GnRH. In addition to the GnRH and its receptor regulating the pituitary, there are isoforms with diverse other functions.

DISCOVERY AND BACKGROUND

Gonadotropin-releasing hormone (GnRH) is the central initiator of the reproductive hormonal cascade and was first isolated from mammalian hypothalami as the decapeptide (pGlu-His-Trp-Ser-Tyr-Gly-Leu-Arg-Pro-Gly·NH_2).[1] GnRH is processed in specialized neurons of the hypothalamus from a precursor polypeptide by enzymatic processing and packaged in storage granules that are transported down axons to the external zone of the median eminence. GnRH is released as synchronized pulses from the nerve endings of about 1000 neurons into the hypophyseal portal system every 30–120 min to stimulate the biosynthesis and secretion of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from pituitary gonadotrophs.[4] Each GnRH pulse stimulates a pulse of LH, but FSH pulses are less clear. The frequency of pulses is the highest at the ovulatory LH surge and lowest during the luteal phase of the ovarian cycle. Differential LH and FSH release, necessary for the ovarian cycle, results from changes in GnRH pulse frequency, modulating effects of gonadal steroid and peptide hormones on FSH and LH responses to GnRH, and differences in the half lives of the two hormones. Moreover, although LH is stored and largely dependent on GnRH for secretion, FSH tends to be constitutively secreted and more dependent on biosynthesis for secretion.

STRUCTURE OF GnRHs AND THEIR PRECURSORS

Primary Structures

Mammalian hypothalamic GnRH was believed to be a unique structure that was conserved among vertebrates. However, it became apparent that diverse forms exist in vertebrates.[12] This led to the structural identification of 13 different forms in vertebrates and another 9 in protochordates (Fig. 1).[3] It also became apparent that GnRHs are distributed in a wide range of tissues in vertebrates, where they apparently have diverse functions in addition to their primary role in gonadotropin secretion. These include other neuroendocrine functions, paracrine and autocrine functions in GnRH neurons, gonads, immune cells, breast, and prostatic cancer cells, and neurotransmitter/neuromodulatory roles in the central and peripheral nervous system. Although a single GnRH is theoretically capable of serving these different roles, it is evident that at least two, and usually three, forms of GnRH are differentially expressed in various tissues as regulators. The most ubiquitous GnRH in vertebrates is chicken GnRH II (first isolated from chicken brain), which is totally conserved from bony fish to human[6] and is probably the earliest evolved form. This form has been designated GnRH II, whereas the hypophysiotropic form is designated GnRH I. In many vertebrate species, a third form of GnRH occurs (localized to the forebrain in fish) and is designated GnRH III. Analysis of the genes encoding the GnRHs supports this general classification.[16]

Three Dimensional Structures

The amino acid sequences of the structural variants of GnRHs from vertebrate and protochordate species (Fig. 1) reveal that there has been conservation in the NH_2 terminus

FIGURE 1 Primary amino acid sequences of naturally occurring decapeptide GnRH structural variants spanning approximately 600 million years of evolution. The boxed regions show the conserved amino- and carboxyl-terminal residues that are involved in receptor binding and activation. The GnRHs are named according to the species in which they were first discovered, and they may be represented in more than one species. For example, mammalian GnRH is widely conserved in amphibians and primitive bony fish, and chicken GnRH II is present in most vertebrate species, including humans. An octopus GnRH and an additional Ciona GnRH comprising 12 and 16 amino acids, respectively, but retaining the conserved amino and carboxy terminal domains are not shown. From Ref. 6 with permission.

(pGlu-His-Trp) and the COOH terminus (Pro-Gly·NH_2), over 600 million years of evolution, indicating that these features are critically important for receptor binding and activation (Fig. 2). This is borne out by structure–activity data from thousands of analogs that were developed largely on an empirical basis.[5–20] Position 8 is the most variable amino acid (Arg, Gln, Ser, Asn, Leu, Try, Lys, Ala, Trp, Thr, Met), suggesting that virtually any residue is tolerated in this position. However, this is not the case for the mammalian pituitary type I receptor, which requires Arg in position 8,[20] and work on cloned nonmammalian receptors also indicates certain specificities for the amino acid in this position. Thus, this residue seems to play an important role in ligand selectivity of the different GnRH receptors and in modulating intracellular signaling at the same receptor.[12]

The conserved NH_2- and COOH-terminal domains of GnRH are closely apposed when mammalian GnRH binds its receptor, resulting from a β-II-type turn involving residues 5–8 (Fig. 2).[5,12,20] This partly results from intramolecular interactions with the side chain of Arg^8. Trp fluorescence studies, computer simulations using the technique of conformational memories, and nuclear magnetic resonance (NMR) studies have shown that substitution of Arg^8 results in a less compact structure, with a loss of predominance of the folded conformers and a low biological activity.[3,12,20] Yet these extended forms (e.g. Gln^8 in chicken GnRH I) exhibit high activity in many nonmammalian GnRH receptors, despite their low activity at the mammalian receptor. The β-II-type turn conformation of GnRH also seems to be induced in part by the interaction of Arg^8 with an acidic residue (D302) in extracellular loop 3 (EC3) of the mammalian receptor (Fig. 5). Substitution of a D-amino acid for Gly^6 enhances the β-II-type conformation and increases the activity of GnRH about tenfold, and this feature is used in enhancing receptor-binding

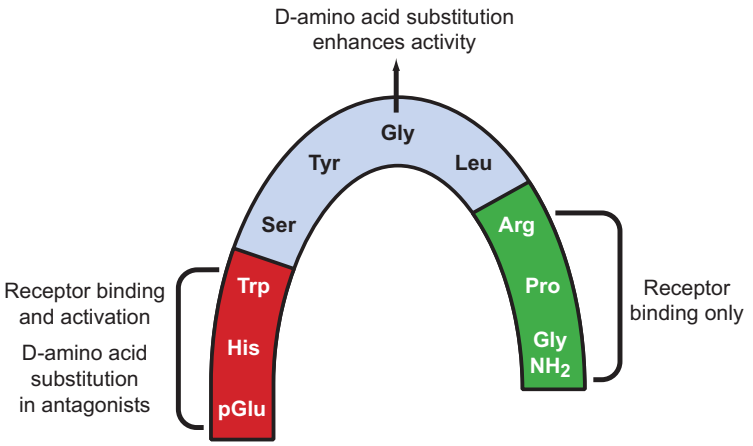

FIGURE 2 Schematic representation of mammalian GnRH in the folded conformation in which it is bound to the GnRH pituitary receptor. The molecule is bent around the achiral glycine in position six. Substitution with D-amino acids in this position stabilizes the folded conformation, and increases binding affinity and decreases metabolic clearance. This feature is incorporated in all agonist and antagonist analogs. The NH_2 (dark grey) and COOH (mid grey) termini are involved in receptor binding. The NH_2 terminus alone is involved in receptor activation, and substitutions in this region produce antagonists. From Ref. 12 with permission.

affinity in agonists and antagonists.[5,12,20] The amino-terminal residues of GnRH are involved in receptor activation, and modification of these residues in GnRH produces analogs with antagonistic properties (Fig. 2).

GnRH DISTRIBUTION

The diversity in molecular structure, function, and anatomical distribution of GnRHs raises the question as to whether GnRH neurons expressing the different GnRHs are embryonically derived from a single precursor population, or have multiple origins. The neuroanatomical organization of GnRH neurons in different vertebrates has been reviewed.[6,17] As discussed earlier, two or three different forms of GnRH are expressed in most vertebrate species. The GnRH I cell bodies regulating the brain–pituitary–gonad axis are located principally in the medial septum and anterior preoptic area in mammals, and give rise to the major GnRH axonal projections through the ventral hypothalamus to the median eminence. GnRH III cell bodies are also present in the terminal nerve, associated with the olfactory system and GnRH II is present in the ventral forebrain, and in several regions of the posterior diencephalon and midbrain. GnRH fibers project to almost all areas of the central nervous system, the vasculature, and the ventricles.

A model for the development of GnRH neuronal systems has been proposed by Muske:[5,17] (a) GnRH neurons have at least two embryonic origins: the olfactory placode, which gives rise to the terminal nerve-septo-preoptic system, and a second, nonplacodal structure, which gives rise to the posterior diencephalon/anterior midbrain system. (b) The two embryonically distinct populations express different molecular forms of GnRH. The posterior neurons express GnRH II, whereas the terminal nerve-septo-preoptic neurons express a different form(s) of GnRH, which varies in different species. Immunocytochemical studies of brain regions reveal many similarities among vertebrate species in their cytoarchitectonic organization, suggesting that, like the peptides, the neuronal systems are phylogenetically ancient. The GnRH neuronal system in amphibians is typical of that described in species from other vertebrate classes (Fig. 3). The terminal nerve–septo–preoptic system is the prime regulator of gonadotropin release in most vertebrates and the neurons originate in the embryonic olfactory placode and migrate centrally during development. The ontogeny of the terminal nerve–septo–preoptic system is thought to reflect its evolutionary origin as a peripheral endocrine organ associated with the olfactory system. The second GnRH system, which arises from nonplacodal precursors, comprises cell bodies in periventricular regions of the posterior diencephalon and midbrain. Evidence suggests that these cells served as the ancestral brain GnRH system, and are the cellular locus of the early-evolved GnRH II peptide. Although GnRH I and GnRH II are both present and have distinct neural distribution patterns in primates, GnRH II has been deleted from the laboratory mouse and rat genome.[14,16] It seems that GnRH I has taken over the role of GnRH II in neurons in which this peptide was previously expressed. In vertebrate species, it is widely established that the different roles of GnRHs are as a releaser of pituitary gonadotropins, and as a neurotransmitter or neuromodulator in extrahypothalamic areas of the brain.

PROCESSING OF THE GnRH PRECURSOR

Initial studies claimed a nonribosomal biosynthesis of GnRH as had been established for the antibiotic small peptides,

but other studies provided evidence for biosynthesis from a precursor of a molecular weight of about 5000 through tryptic and carboxypeptidase B cleavage of a dibasic site.[13] These researchers proposed that the product was further processed by the cyclization of Gln to the N-terminal pyro Glu and amidation of the C-terminal glycine using the adjacent glycine as NH_2 donor (Fig. 4). These proposals were supported by the subsequent revelation of the GnRH cDNA sequence.[21] The 56 amino acid sequence following that of GnRH was claimed to affect prolactin and gonadotropin secretion, but this has never been substantiated.

GnRH RECEPTORS AND SIGNALING CASCADES

The amino acid sequence of the GnRH receptor was first deduced for the mouse receptor in the αT3 gonadotroph cell line,[23] and this provided the basis for the cloning of GnRH pituitary receptors from the rat, human, sheep, cow, and pig, which share >80% amino acid identity. Subsequently, GnRH receptors have been cloned from marsupials, birds, and several fish and amphibian species.[12,16]

A second form of GnRH receptor (type II) was identified in humans[10] and subsequently cloned from primates.[11,19] However, the human homolog seems to be a nonfunctional pseudogene whose function has been taken over by the type I receptor.[14,16] In some amphibian and fish species, a third GnRH receptor exists.[12,16] The findings suggest an early evolution of the three GnRH receptor subtypes in vertebrates that parallels that of the GnRH ligands.[12] The conservation of amino acids during evolution from bony fish to mammals probably indicates those residues crucial to GnRH receptor function (Fig. 5).

The GnRH receptor has the characteristic features of G protein-coupled receptors (GPCRs) with an N-terminal domain, followed by seven putative α-helical transmembrane (TM) domains that are connected by three extracellular (EC) loop domains and three intracellular (IC) loop domains (Fig. 5). The EC domains and superficial regions of the TMs are usually involved in the binding of peptide hormones such as GnRH. The highly conserved TMs are believed to be involved in conforming the receptor, and conformational change is associated with signal propagation (receptor activation). The intracellular domains are involved in interacting with G proteins for signal transduction. A unique feature of the mammalian GnRH receptor is the absence of a C-terminal tail, which is present in all other GPCRs and in all the nonmammalian GnRH receptors, and is responsible for rapid desensitization. The structures of the genes encoding the mouse and human GnRH receptors have been elucidated. In both genes, the three exons are separated by introns in the coding regions of TM4 and IC3, and there are numerous splice variants whose function may be regulatory, as some truncated receptor variants affect the expression of the functional receptor. The promoters of the rat and human receptors have been analyzed, and the genes are highly regulated by GnRH, and by gonadal, steroid, and peptide hormones.

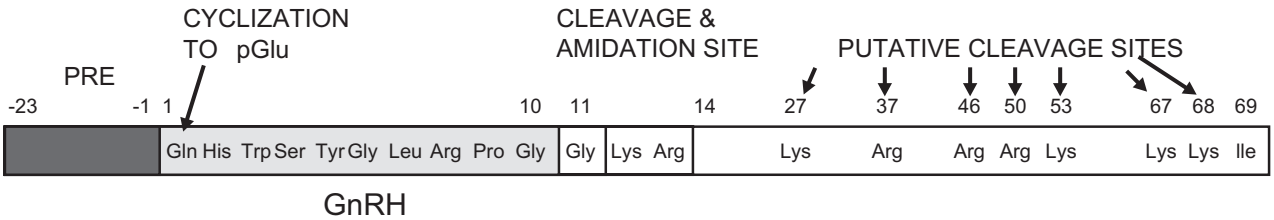

FIGURE 4 Schematic diagram of the structure of the human GnRH precursor. The precursor consists of a signal sequence (PRE) of 23 amino acids followed immediately by the GnRH decapeptide sequence. Cleavage of the signal peptide reveals an NH_2-terminus Gln that cyclizes (enzymatically or spontaneously) to pyro-Glu. The GnRH sequence is followed by a Gly, which is the donor for the COOH-terminal amide of GnRH, and Lys-Arg, which is a conventional dibasic amino acid cleavage site. This is followed by a 56 amino acid peptide sequence. The positions of pairs and single basic amino acid residues present in the 14–69 sequence are shown as potential sites of further processing.

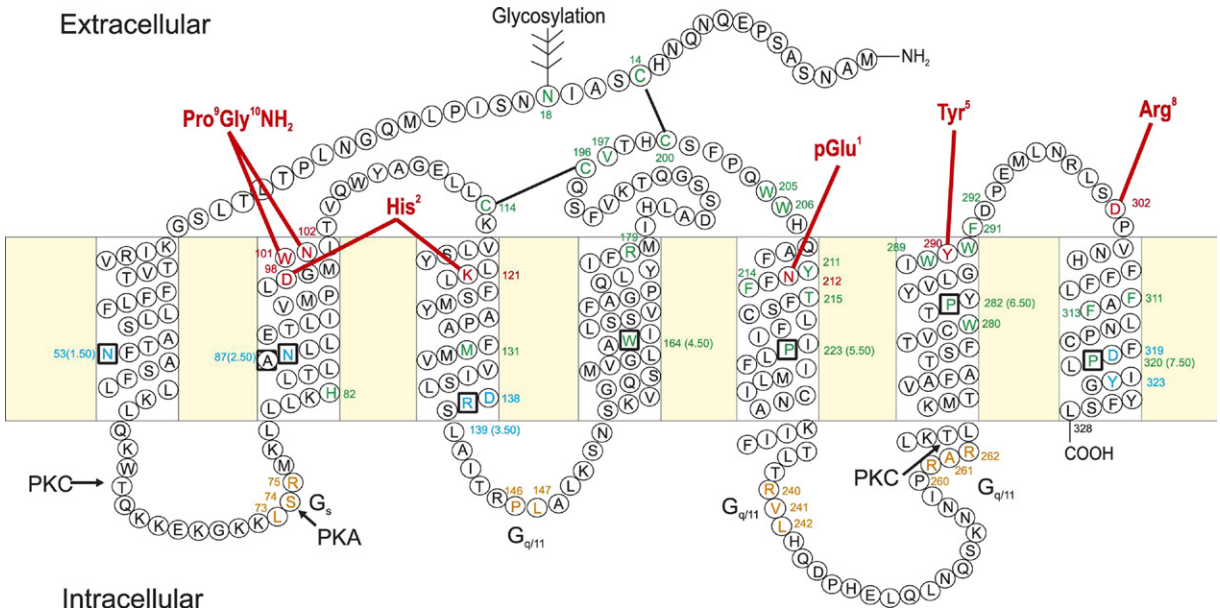

FIGURE 5 Two-dimensional representation of the human GnRH receptor: the 7-(TM) α-helical domains (boxed) are connected by three extracellular loops (ECLs) and three intracellular loops (ICLs). Residues in squares are ones that are highly conserved throughout the rhodopsin family of GPCRs. Ligand-binding residues (red) and residues believed to be important in receptor structure or binding pocket configuration (green) are shown. These include residues involved in disulfide bond formation (black lines) and a glycosylation site. Residues involved in receptor activation are shown in blue. Residues involved in coupling to G proteins are shown in orange. Putative PKC and protein kinase A (PKA) phosphorylation sites are indicated. The intermolecular interactions between GnRH I residues and the receptor are indicated with red lines. Residues shown to alter selectivity for relative binding affinities of GnRH I and GnRH II are shown in bold circles. Figure modified from Ref. 12 with permission. See color plate 29.

Insights Into the Tertiary Structure of the GnRH Receptor

A knowledge of the three-dimensional structure of the GnRH receptor is essential for a complete understanding of its molecular functioning. Recently, crystal structures have been solved for rhodopsin, the B_2-adrenergic, B_1-adrenergic, and adenosine A_{2A}. Molecular models of the GnRH receptor have been generated based on the alignment with these structures. This structure forms the basis for mutagenesis experimental studies designed to test hypotheses and refine the model. The positioning and orientation of the TM helices are therefore crucial. In this regard, an unusual feature of the GnRH receptor has allowed the identification of interhelical interactions. Two residues that are highly conserved in GPCRs, aspartate in TM2 and asparagine in TM7, seem to have undergone reciprocal mutation to Asn^{87} and Asp^{319} (Fig. 5). This suggests that the two residues interact with each other. Mutation of Asn^{87} in TM2 to aspartate abolished receptor function, but a second mutation of Asp^{319} to asparagine in TM7, recreating the arrangement found in other GPCRs, regenerated ligand binding.[7] This restoration of binding by reciprocal mutation suggests that the side chains of two residues in helixes TM2 and TM7 have complementary roles in maintaining the structure of the receptor and occupy the same microenvironment within the receptor.

The 7 TM helical domains are known from the crystal structures of GPCRs to be arranged in a tight bundle enclosing a hydrophilic pocket and surrounded by the hydrophobic membrane environment. The evolutionary conservation of residues along a distinct face of the TM domains in the various GnRH receptors is clearly evident in Fig. 5. This suggests that the conserved, more hydrophilic faces are orientated toward the hydrophilic pocket formed by the helical bundle.

GnRH Agonist Binding to Its Receptor

In the course of the systematic and targeted mutation of more than one-third of all the amino acid residues of the GnRH receptor, considerable advances in identifying ligand contact sites in the mammalian GnRH receptor have been made (Fig. 5). Four putative ligand interaction sites have been identified in the mammalian GnRH receptor. These are $pGlu^1$ with N^{212}, His^2 with K^{120} and D^{98}, Trp^3 with F^{178}, Tyr^5 with Y^{290}, Arg^8 with D^{302}, and $Gly.NH_2^{10}$ with N^{102} [12] (Fig. 5). All these sites have been conserved in vertebrate pituitary GnRH receptors cloned from bony fish, amphibian, and bird species. For details on GnRH binding,

activation, and desensitization of its receptors, the reader is referred to Ref. 12.

Intracellular Signaling Pathways

The coupling of the GnRH receptor to intracellular signaling pathways has been intensely investigated and comprehensively reviewed.[7,9,18] Although a wide range of intracellular signaling pathways have been implicated in GnRH action, there is a general consensus that the primary pathway is the activation of phospholipase Cβ (PLCβ) through the Gq/11 small guanine nucleotide-binding protein (Fig. 6). PLCβ hydrolyzes phosphatidylinositol-4-5 bisphosphate (PIP_2) to inositol-1-4-5-trisphosphate (IP_3) and diacylglycerol (DAG). IP_3 binds to receptors in the endoplasmic reticulum (ER) to release Ca^{2+} transiently from these intracellular stores, and this elicits a rapid spike of LH release. DAG activates protein kinase Cs (PKCs). These phosphorylate proteins such as the mitogen-activated protein kinases (MAPKs) that include ERK, JNK, and P38, which are involved in the more sustained release of LH and in gonadotropin biosynthesis. A second major effect of GnRH binding to its receptor is the activation of L-type voltage-operated Ca^{2+} channels (VOCCs), which results in the influx of extracellular Ca^{2+} required for recharging intracellular stores and the prolonged (second phase) of LH release (Fig. 6).

GnRH stimulates DAG production biphasically in pituitary cells, and at a high molar ratio relative to IP_3. This suggests that GnRH stimulates DAG production from a second source independent of PLCβ action on PIP_2. Phospholipase D (PLD) is activated in a gonadotroph cell line a few minutes after PLC activation. Because its substrate phosphatidylcholine is present at almost 100 times higher concentrations in the plasma membrane than that of PIP_2, GnRH stimulation of PLD may be the main source of sustained DAG production.

Another potential signaling pathway of GnRH action is through phospholipase A_2 (PLA_2), which produces arachidonic acid (AA) and its 5-lipoxygenase products, the leukotrienes (LTs), in pituitary cells some minutes after the increase in IP_3. Although PLA_2 may be activated directly by the GnRH receptor, activation is probably by MAPKs, which are known to phosphorylate and activate

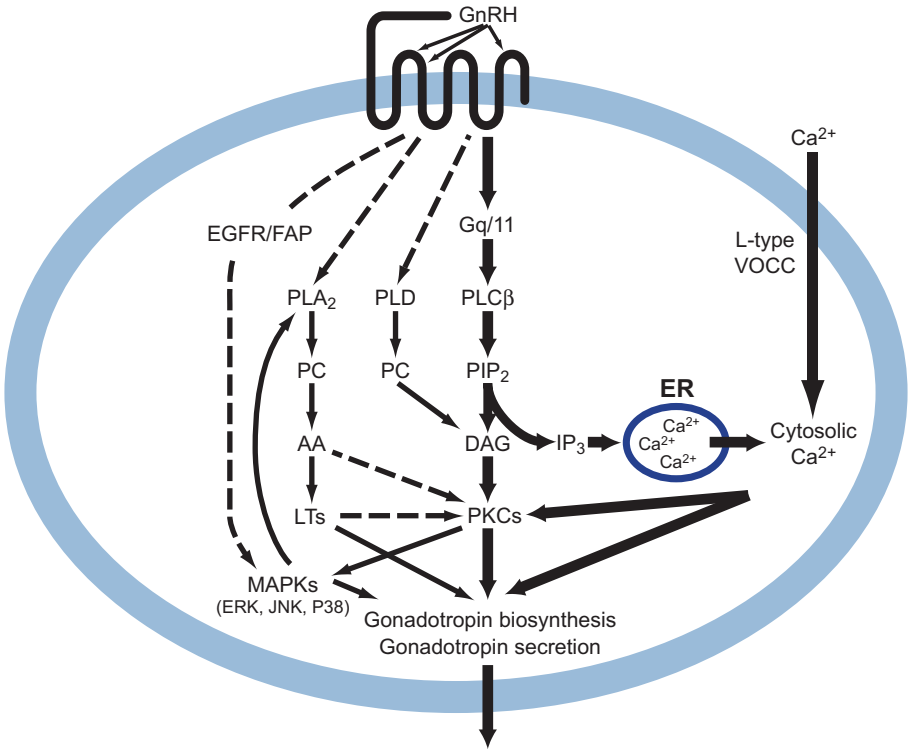

FIGURE 6 Signaling pathways of mammalian, GnRH type I receptor. The primary pathway shown by heavy arrows involves the activation of PLCβ via the Gq/11 G protein and the hydrolysis of phosphatidylinositol-1-4 bisphosphate (PIP_2) to DAG, which activates PKC, and to IP_3, which stimulates Ca^{2+} release from the ER. A second major effect is the entry of extracellular Ca^{2+} through VOCCs. The GnRH receptor also activates PLD, which hydrolyzes phosphatidylcholine (PC) to DAG, and PLA_2, which generates AA and LTs from PC. PLA_2 activation may be mediated via a primary stimulation of MAPK. DAG activates PKC which in turn can activate MAPKs. MAPK isoforms may also be stimulated via FAPs and EGFR and monomeric G proteins such as ras. The products of the diverse pathways affect gonadotropin biosynthesis and secretion. Note that many of the signaling events occur in the plasma membrane, where enzymes (e.g. PLCβ, PLD, PLA_2) and substrates (e.g. PIP_2) are anchored. For simplicity, this is not shown.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

PLA_2. Several studies have shown that GnRH indirectly activates MAPKs in pituitary cells and gonadotroph cell lines via PKCs phosphorylation of Raf-1. MAPKs may also be activated by focal adhesion protein (FAP) complexes involving integrins and by transactivation of the epidermal growth factor receptor (EGFR).

All the signaling pathways outlined above can result in the activation of PKC isoforms (Fig. 6). However, there are distinct differences in the timing and the PKC isoform activated, such that a sequential, coordinated and sustained activation of PKCs occurs. The early DAG and Ca^{2+} generated by PLCβ action might activate Ca^{2+}-dependent PKCs, while late DAG generated by PLD might activate Ca^{2+} independent PKCs. Similarly, the more slowly generated products of PLA_2 such as AA and LTs are known to activate specific PKC isoforms.[7,9,18]

GnRH Regulation of Gonadotropin Gene Expression

The distal targets of the signaling pathways, PKC isoforms, Ca^{2+} calmodulin, MAPKs, and LTs are all variously involved in gonadotropin gene expression, biosynthesis, and exocytosis.[7,18] The mobilization of Ca^{2+} and activation of PKCs resulting from the primary GnRH signaling pathway have both been reported to increase α-, LHβ- and FSHβ-subunit mRNA levels and PKC response elements have been identified in the promoters of these subunits. The more protracted activation of PKCs resulting from the products of the PLD and PLA_2 pathways presumably contributes to the increased gonadotropin subunit mRNA levels. GnRH activation of MAPKs also stimulates the expression of subunit mRNA, and since PKCs can activate MAPKs part, or all, of the PKCs effects may be via MAPKs. These effects may be mediated via distinct GnRH-response elements in the gene promoters.

The relative stimulation of gonadotropin subunits in the rat pituitary is influenced by GnRH pulse frequency. High pulse frequencies stimulate LHβ mRNA levels more that FSβ, whereas the converse is true at low pulse frequencies. Thus, the combination of alterations in pulse frequency together with different phasing and duration of the various signaling pathways provides the potential for fine regulation of gonadotropin secretion. Feedback by gonadal steroid and peptide hormones at the gonadotroph provides additional modulation and the means for asynchronous LH and FSH secretion in response to GnRH, which is crucial for normal ovarian function.

Desensitization

Exposure of the gonadotroph to continuous high doses of GnRH agonists results in the phenomenon of desensitization.[9,12] Gonadotroph desensitization comprises many contributing phenomena, including GnRH receptor down-regulation, receptor uncoupling from cognate G proteins, additional downstream uncoupling (e.g. PKC, Ca^{2+} stores, inositol trisphosphate receptor), inhibition of gonadotropin synthesis, and alterations in the glycosylation of gonadotropins rendering them biologically inactive or even antagonistic. At the level of the GnRH receptor, agonist activation leads to two potential mechanisms of desensitization. For many GPCRs, agonist stimulation results in the activation of protein kinases, which phosphorylate IC domains, resulting in uncoupling from G proteins and internalization of the receptor. GnRH receptors have several putative phosphorylation sites in the IC domains that may serve this function (Fig. 5). However, the mammalian GnRH receptors lack the carboxy-terminal IC domain, which is the prime target for phosphorylation by G protein-coupled receptor kinases and protein kinases. Phosphorylation in this region facilitates the docking of arrestins, thus inducing G protein uncoupling and receptor internalization. Hence, the absence of the carboxy-terminal tail in the mammalian GnRH receptors is associated with a lack of rapid desensitization in inositol phosphate production and an arrestin-independent slow rate of receptor internalization, 7-fold less than that of the chicken GnRH receptors, which have carboxy-terminal tails. Removal of the carboxy-terminal tail from the chicken receptor greatly reduces the rate of internalization to one similar to that of the human receptor. Addition of the carboxy-terminal tail of a nonmammalian GnRH receptor to a mammalian GnRH receptor conveys both rapid desensitization of inositol phosphate production and a more rapid internalization.

It seems that physiological requirements have selected for removal of the carboxy-terminal tail during the evolution of the mammalian GnRH receptor, to prevent rapid desensitization and internalization. A possible driving force is the physiological need of a prolonged LH surge for ovulation in mammals. Thus, although pharmacological doses of GnRH can produce desensitization of the gonadotroph, the GnRH receptor is less susceptible to ligand-mediated desensitization than other GPCRs and may not undergo desensitization under physiological conditions. Nevertheless, pharmacological desensitization occurs with high doses of superactive GnRH agonists, and this has important therapeutic applications (see below).

GnRH Receptor Genes

The structures of the genes encoding GnRH receptors from many mammalian, amphibian, bird, and fish species have been elucidated.[16] In all genes, introns exist in the coding regions of TM4 and IC3. There are numerous splice variants

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

whose function may be regulatory, as some truncated receptor variants affect the expression of the functional receptor. The promoters of the rat and human receptors have been analyzed, and the genes are highly regulated by GnRH and downstream signaling molecules resulting from GnRH receptor activation, and also by gonadal, steroid, and peptide hormones.

PHYSICAL STRUCTURE OF GnRH

GnRH is highly flexible in solution, and a crystal structure has yet to be accomplished. However, structure–activity relations and molecular modeling had suggested that GnRH interacts with its receptor in a folded conformation incorporating a βII' bend around Gly^6 [5,12,20] and Section 22. This conformation is supported by NMR studies and approaches combining molecular modeling and ion mobility mass spectrometry.[3]

BIOLOGICAL ACTIONS

GnRH was believed to function exclusively as a stimulator of gonadotropin release from the vertebrate pituitary, but it soon emerged that the peptide has been recruited for diverse functions in vertebrates and protochordates during evolution. This conclusion arose from revelations that

(1) Multiple forms of GnRH are present in tissues of single species;
(2) GnRH is expressed in extrahypothalamic regions of the nervous system (e.g. midbrain, spinal cord, sympathetic ganglia) and in nonneural tissue (e.g. gonads, placenta, breast);
(3) GnRH receptors are present in extrapituitary tissues and GnRH affects cell activity in these tissues;
(4) GnRH stimulates the release of other pituitary hormones (e.g. growth hormone in fish);
(5) GnRH is present in organisms that do not have a pituitary but is still able to stimulate reproduction.

The isolation of several forms of GnRH in neural tissue of tunicates, which represent chordate progenitors, and their activation of the gonads suggest that direct regulation of the gonads was an early-evolved function, and that the neuroendocrine role in regulating the pituitary was a later evolutionary development. The presence of GnRH and GnRH receptors in the gonads of various vertebrate species may reflect this early function. The stimulation of sexual reproduction in yeast by the α-mating factor, which seems to be structurally related to GnRH, may point to an even more ancient example of the direct effects of GnRH on reproduction. It is plausible, therefore, that GnRH peptides were originally involved in cellular communication and in sexual reproduction of simple unicellular and multicellular organisms. Later, they were recruited for expression in nerve cells, to translate external and internal signals into activation of reproduction, initially by acting directly on germ cells, and subsequently via pituitary gonadotroph activation. Although the peptide has been coopted as a regulator at a number of levels in the reproductive system (hypothalamus, gonad, breast, and placenta), there is apparently considerable plasticity in also recruiting it as a regulator in non-reproductive tissues (e.g. adrenal, extrahypothalamic brain, the immune system, retina, and pancreas).

The second form of GnRH originally identified from chicken brain (chicken GnRH II (Fig. 1)) is ubiquitous in vertebrates from primitive bony fish to humans. This complete conservation of structure over 500 million years suggests that the GnRH II has an important function that is mediated through a discriminating receptor that has selected against any structural change in the ligand. The wide distribution of GnRH II in the central and peripheral nervous systems suggests a neurotransmitter/neuromodulatory role. This has been thoroughly demonstrated by the inhibition of M-currents in the bullfrog sympathetic ganglion, which sensitizes neurons to depolarization. GnRH II is present in amphibian sympathetic ganglia, and the receptors are highly selective for the peptide.[6,12]

GnRH has direct effects on sexual arousal in vertebrates, and GnRH II is localized in brain areas associated with reproductive behavior, suggesting that this may be a role for the peptide. GnRH II and an analog are potent stimulators of reproductive behavior in ring doves and song sparrows.[6,12,20] The cognate receptor for GnRH II was cloned from the marmoset[11] and found to be distributed in those areas of primate brain associated with reproductive behaviors. In both the female marmoset[2] and musk shrew,[22] central administration of GnRH II is much more effective than GnRH I in stimulating reproductive behavior. However, the type II GnRH receptor is nonfunctional in humans,[14,16] but cellular context can alter the pharmacology of the GnRH I receptor so that GnRH II can induce different signaling from that of GnRH I.[8]

THERAPEUTIC APPLICATION OF GnRH ANALOGS

Clinical applications of GnRH and its agonist and antagonist analogs are summarized in Fig. 7.[23] Low doses of GnRH (pg/ml) delivered in a pulsatile fashion equivalent to that found in the hypothalamic portal vessels restore fertility in hypogonadal men and women, and are also effective in the treatment of delayed puberty. However, high doses of GnRH or agonist analogs desensitize the gonadotroph, with a resultant decrease in LH and FSH and a decline in ovarian and testicular function (see the earlier section). This

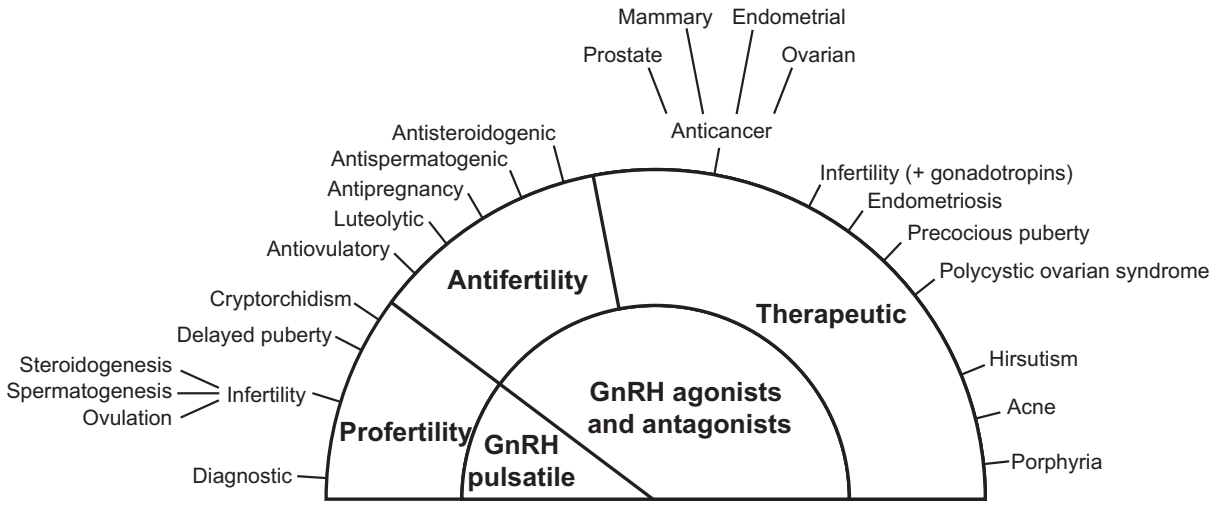

FIGURE 7 Clinical applications of GnRH and GnRH agonists and antagonists. Modified from Ref. 15.

desensitization phenomenon is extensively applied in clinical medicine for the treatment of a wide range of diseases (Fig. 7). GnRH peptide antagonists also inhibit the reproductive system but through competition with endogenous GnRH. The doses required are much higher than the desensitizing agonist doses (mg/day compared with μg/day), and antagonists are currently less extensively used. However, they have the advantage of inducing an immediate inhibition in contrast to agonists which initially (7–14 days) stimulate gonadotropin before the desensitization phenomenon sets in. The development of nonpeptide, orally active GnRH antagonists[12] will probably lead to the replacement of agonists, as they avoid the undesirable stimulation that precedes desensitization, dosage can be more easily modified than for injectable peptides, and treatment may be rapidly withdrawn when required.

FUTURE PERSPECTIVES

GnRH neurons are regulated by novel neuropeptides, kisspeptin, neurokinin B, and dynorphin; all colocalizing in neurons in the arcuate nucleus that has long been recognized as the site of the GnRH pulse generator. The discovery of kisspeptin and neurokinin B as major regulators of the GnRH neuron arose from the observation that inactivating mutations in these genes or their receptors result in a failure to advance through puberty in humans. Intriguingly, these neurons express sex steroid receptors and receptors for metabolic and inflammatory mediators. They thus represent "whole body sensors" for relaying diverse inputs into the regulation of GnRH and provide novel opportunities for the developments of more subtle therapeutic regulation of reproductive hormone secretion.

Chapter 107

Gonadotropin-Inhibitory Hormone

Kazuyoshi Tsutsui and Takayoshi Ubuka

ABSTRACT

Gonadotropin-inhibitory hormone (GnIH) is a hypothalamic neuropeptide that was discovered in quail as an inhibiting factor for gonadotropin release. GnIH inhibits gonadotropin synthesis and release in birds through actions on gonadotropin-releasing hormone (GnRH) neurons and gonadotrophs, mediated via GPR147. Subsequently, GnIH orthologs were identified in other vertebrate species from fish to humans. As in birds, mammalian and fish GnIH orthologs inhibit gonadotropin release, indicating a conserved role for this neuropeptide in the control of the hypothalamic–pituitary–gonadal (HPG) axis across species. Discovery of GnIH, a novel endogenous inhibitor of reproduction, has opened up new vistas for understanding the regulation of reproduction.

DISCOVERY

Gonadotropin-inhibitory hormone (GnIH) was first discovered in the brain of the Japanese quail *Coturnix japonica* in search of a novel RFamide peptide that has an Arg-Phe-NH_2 motif at its C-terminus. RFamide peptides were first isolated in invertebrate species in the late 1970s. The initial RFamide peptide, Phe-Met-Arg-Phe-NH_2 (FMRFamide), is a cardioexcitatory molecule isolated from the ganglia of the venus clam *Macrocallista nimbosa*.[20] After this discovery, numerous RFamide peptides that act as neurotransmitters, neuromodulators, and peripheral hormones have been identified in various invertebrate phyla, including cnidarians, nematodes, annelids, molluscs, and arthropods. Immunohistochemical studies in vertebrates suggested the presence of RFamide peptides in the nervous system. Some of the FMRFamide-immunoreactive (-ir) neurons projected close to the pituitary gland suggest a role in the regulation of pituitary function. Tsutsui et al.[26] thus hypothesized that avian hypothalamus may also possess a novel RFamide peptide that regulates anterior pituitary function.

In 2000, Tsutsui et al.[26] successfully isolated a novel RFamide peptide from 500 Japanese quail brains by high-performance liquid chromatography (HPLC) and a competitive enzyme-linked immunosorbent assay using an antibody developed against the dipeptide Arg-Phe-NH_2. The isolated peptide has a previously unreported dodecapeptide structure, SIKPSAYLPLRFamide (Table 1). Its C-terminus is identical to chicken LPLRFamide that was reported to be the first RFamide peptide isolated in vertebrates,[8] which may be a degraded fragment of the dodecapeptide. The isolated peptide was localized in the quail hypothalamo–hypophysial system by immunohistochemistry and shown to decrease gonadotropin release from cultured quail anterior pituitaries.[26] This RFamide peptide was thus named gonadotropin-inhibitory hormone (GnIH).[26]

After the isolation of GnIH in the quail brain, the precursor polypeptide for GnIH was examined.[22] A cDNA that encodes GnIH precursor polypeptide was identified by a combination of 3' and 5' rapid amplification of cDNA ends (3'/5' RACE).[22] The GnIH precursor consists of 173 amino acid residues that encode one GnIH and two GnIH-related peptides (GnIH-RP-1 and GnIH-RP-2) possessing an LPXRFamide (X = L or Q) sequence at their C-termini. These peptide sequences are flanked by a glycine C-terminal amidation signal and a single basic amino acid on each end as an endoproteolytic site. GnIH-RP-2 was also identified as a mature peptide by mass spectrometry[22] (Table 1). GnIH was further isolated as mature peptides in European starlings[29] and zebra finch within the class of birds (Table 1).

In mammals, cDNAs that encode LPXRFamide peptides similar to GnIH have been investigated by a gene database search.[10] The cDNAs identified from human and bovine brains encode three RFamide-related peptides (RFRP-1, -2, and -3).[10] RFRP-1 and -3 are both LPXRFamide peptides, but RFRP-2 is not an LPXRFamide peptide. RFRP-1 and -3

having LPXRFamide sequences were purified from bovine hypothalami (Table 1). Rat RFRP-3, Siberian hamster RFRP-1 and -3,[28] macaque RFRP-3,[30] and human RFRP-1 and -3[31] were also identified as mature peptides in mammals (Table 1). Subsequently, it was shown that human RFRP-3, rat RFRP-3, and Siberian hamster RFRP-3 also inhibit gonadotropin synthesis and/or release in mammals.[7,11,17,21,28] Accordingly, a mammalian LPXRFamide peptide (RFRP-3) acts as a functional ortholog of GnIH in terms of reducing gonadotropin secretion.

In amphibians, a GnIH ortholog that consists of 12 amino acids (SLKPAANLPLRFamide) with a C-terminal LPLRFamide motif was identified in the bullfrog hypothalamus[14] (Table 1). This neuropeptide in frog, named fGRP, has a high sequence homology with GnIH.[22,26] The fGRP precursor also encodes one fGRP and three fGRP-related peptides (fGRP-RP-1, -2, and -3), later identified as mature LPXRFamide peptides.[33] At the same time, fGRP and fGRP-RP-1 were independently purified from the European green frog (R-RFa; 4) and bullfrog (fNRP), respectively. Subsequently, from the goldfish brain, a cDNA that encodes three fish GnIH orthologs (gfLPXRFa-1, -2, and -3) was characterized and gfLPXRFa-3 was identified as a mature peptide (for reviews, see Refs 24, 25; Table 1). Recently, the evolutionary origin of LPXRFamide peptides was discovered in the brain of lamprey, one of the most ancient vertebrate species (for reviews, see Refs 24, 25; also Osugi et al. (2012) as recently reported in *Endocrinology*).

As summarized in Table 1, GnIH and its orthologs have now been documented in a variety of vertebrates from fish to mammals, including humans: RFRPs in mammals, GnIH and GnIH-RPs in birds, fGRP, fGRP-RPs, nLPXRFamides in amphibians, and gfLPXRFamides in teleosts. All the identified GnIH and its orthologs possess a common C-terminal LPXRFamide motif. Tsutsui et al. therefore designated these peptides as LPXRFamide peptides, which form a new group in the RFamide peptide family (for reviews, see Refs 24, 25) (Fig. 1). Extensive studies over the past decade have shown that vertebrate brains produce a variety of RFamide peptides. To date, five groups in the RFamide peptide family have been documented, that is, PQRFamide (NPFF) group, LPXRFamide peptide (GnIH) group, PRL-releasing peptide (PrRP) group, kisspeptin group, and pyroglutamylated RFamide peptide (QRFP)/26RFamide group (Fig. 1).

STRUCTURE OF THE mRNA/GENE

The mRNA encoding for GnIH precursor polypeptide was identified in the quail brain.[22] The GnIH precursor consisted of 173 amino acid residues that encoded one GnIH and two GnIH-RPs that have a C-terminal LPXRFamide motif. These peptide sequences are flanked by a glycine C-terminal amidation signal and a single basic amino acid on each end as an endoproteolytic site. GnIH precursor cDNAs were also cloned in white-crowned sparrow,[18] European starling,[29] zebra finch, and chicken in birds, and they all had similar structures (for reviews, see Refs 24, 25).

Fig. 2A shows the organization of the human RFRP gene, mRNA and posttranslational processing of RFRP precursor polypeptide. The mRNAs encoding for precursor polypeptides of RFRPs, mammalian GnIH orthologs have been reported by a gene database search.[10] Although human and bovine mRNAs encode three RFRPs (RFRP-1, -2, and -3), only RFRP-1 and RFRP-3 possess a C-terminal LPXRFamide structure, and human and bovine RFRP-2 have C-terminal RSamide and RLamide sequences, respectively (Fig. 2B). On the other hand, rodents (rat and hamster) completely lost the RFRP-2 sequence in their precursors (Fig. 2B). The regions that encode RFRP-1/GnIH-RP-1 or RFRP-2/GnIH in the precursor polypeptides are conserved between mammals (only RFRP-1 in rodents) and birds (Fig. 2B). However, the positions of RFRP-3 and GnIH-RP-2 in the precursor polypeptides are different between mammals and birds (Fig. 2B).

Tsutsui et al. also cloned cDNAs that encode GnIH orthologs from bullfrog and newt brains.[14,33] The frog and newt GnIH ortholog precursors consist of 221 and 233 amino acid residues, respectively, both encoding four LPXRFamide peptides (in frog: fGRP, fGRP-1, -2, and -3; in newt: nLPXRFa-1, -2, -3, and -4) (Table 1). The goldfish precursor of GnIH orthologs consists of 197 amino acid residues that encode three LPXRFamide peptides (gfLPXRFa-1, -2, and -3) (for reviews, see Refs 24, 25) (Table 1).

PROCESSING OF THE PRECURSOR

Three and two mature LPXRFamide peptides are possibly cleaved from their precursor polypeptides in birds and mammals, respectively. Fig. 2A shows the posttranslational processing of human RFRP precursor polypeptide. Fig. 2B shows the alignment of precursors of GnIH and GnIH orthologs in human, bovine, rat, Siberian hamster, Japanese quail, white-crowned sparrow, European starling, and zebra finch as representative precursors encoding RFRP-1 and RFRP-3 in mammals, GnIH-RP-1, GnIH, and GnIH-RP-2 in birds. The LPXRFamide motif at their C-termini is followed by glycine as an amidation signal and arginine or lysine as endoproteolytic basic amino acids. Endogenous LPXRFamide peptides can be cleaved at basic amino acids at their N-termini. However, there are some exceptions in the cleavage site at the N-terminal, such as that of Siberian hamster RFRP-1 (Fig. 2B). There is an LPLRSamide peptide sequence encoded in the RFRP-2 position of the human precursor polypeptide (Fig. 2B), although this mature peptide has not yet been isolated.[31] The bovine RFRP-2 with LPLRLamide sequence may not

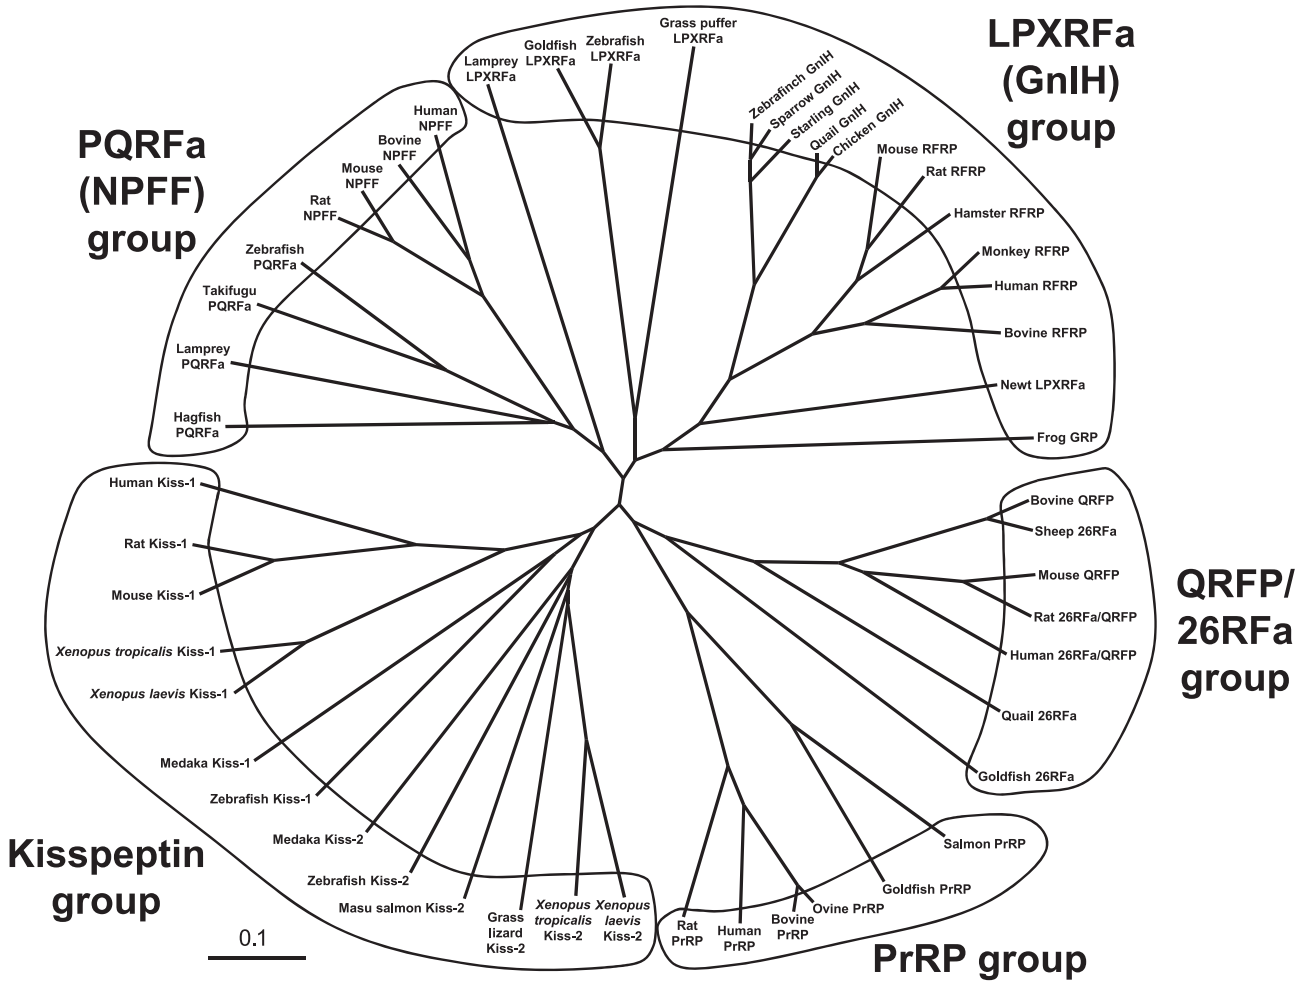

FIGURE 1 Phylogenetic tree of the RFamide peptide family. Vertebrate brains produce a variety of RFamide peptides. To date, five groups in the RFamide peptide family have been documented as follows: PQRFamide peptide (NPFF) group, LPXRFamide peptide (GnIH) group, PRL-releasing peptide (PrRP) group, kisspeptin group, and pyroglutamylated RFamide peptide (QRFP)/26RFamide group. Scale bar refers to a phylogenetic distance of 0.1 amino acid substitutions per site among the precursors.

be processed because this sequence is included within the mature bovine RFRP-3 peptide sequence (Fig. 2B).

DISTRIBUTION OF THE mRNA/PEPTIDE

After cloning GnIH precursor mRNA in the quail brain, its location was first investigated by Southern blot analysis of the RT-PCR products of GnIH precursor cDNA. Within the samples from telencephalon, diencephalon, mesencephalon, and cerebellum, GnIH precursor mRNA is only expressed in the quail diencephalon.[22] In situ hybridization for GnIH precursor mRNA further showed that the cells expressing GnIH mRNA are clustered in the paraventricular nucleus (PVN) in the hypothalamus.[34] Immunohistochemistry with a GnIH antibody has revealed that clusters of GnIH-ir neurons are expressed in the PVN in the quail.[26,34] GnIH expressing cell bodies are also clustered in the PVN in other birds.[2,18,29] In contrast to the highly clustered cell bodies in the PVN, GnIH-ir neuronal fibers are widely distributed in diencephalic and mesencephalic regions in birds.[2,29,34]

In mammals, expression of precursor mRNA of RFRPs, mammalian GnIH orthologs, is only detected in the dorsomedial hypothalamic area (DMH) in the mouse and hamster, investigated by in situ hybridization.[15,24,25,28] In the rat brain, RFRP precursor mRNA is expressed in the periventricular nucleus (PerVN), and the portion between the dorsomedial nucleus (DMN) and the ventromedial nucleus (VMN) of the hypothalamus[10,24,25] (Fig. 3). The majority of RFRP mRNA expression is localized in the intermediate periventricular nucleus (IPe) of the hypothalamus in the macaque,[30] and in the DMN and PVN in the sheep.[7] RFRP-ir neuronal fiber processes and terminals occur widely in the central nervous system. Abundant RFRP-ir fibers are in the median eminence (ME) of sheep,[7] macaque,[30] and

The alignment of RFRP or GnIH precursor polypeptides in human (NM_022150), bovine (NM_174168), rat (NM_023952), Siberian hamster (JF727837), Japanese quail (AB039815), white-crowned sparrow (AB128164), European starling (EF486798), and zebra finch (AB522971). Identified mature peptides are underlined. Endoproteolytic basic amino acid (**R** or **K**) at the N-termini are shown in bold. A broken line indicates the putative human RFRP-2 sequence.

human,[31] consistent with a role for GnIH orthologs in pituitary gonadotropin regulation. On the other hand, relatively few or no immunoreactive fibers are found in the ME in rodents[15,28] (for reviews, see Refs 24, 25).

In lower vertebrates, amphibian GnIH orthologs, such as fGRP, fGRP-RPs, and nLPXRFamides, are expressed in the cell bodies in the suprachiasmatic nucleus (SCN) of the hypothalamus in the frog[14] and the newt. Abundant immunoreactive fibers are also present in the diencephalon, mesencephalon, and rhombencephalon in these species.[14] In the goldfish, expression of precursor mRNA of gfLPXRFamides, fish GnIH orthologs, is localized in the nucleus posterioris periventricularis (NPPv) of the hypothalamus (for reviews, see Refs 24, 25).

RECEPTORS AND SIGNALING CASCADES

The receptor for GnIH (GnIH-R) is considered to be GPR147. Bonini et al.[3] have identified two G protein-coupled receptors (GPCRs) for NPFF, and designated them as NPFF1 (identical to GPR147) and NPFF2 (identical to GPR74). Hinuma et al.[10] have also reported a specific receptor for RFRPs, mammalian GnIH orthologs, named OT7T022, which is also identical to GPR147. Other groups have shown that HLWAR77, which corresponds to GPR74, is a receptor for NPFF. The binding affinities for GPR147 and GPR74 and the efficacies on signal transduction pathway were examined with various analogs of RFRPs and NPFF. RFRPs have a higher affinity for GPR147, whereas NPFF had potent agonistic activity for GPR74.[3,16] Taken together, GPR147 (NPFF1, OT7T022) was suggested to be the receptor for RFRPs, mammalian GnIH orthologs (for reviews, see Refs 24, 25). In situ hybridization, autoradiography, and immunohistochemistry in the rat brain have shown that GPR147 is expressed in various brain regions including the limbic system of telencephalon, diencephalon, mesencephalon and the pituitary,[3,16] (See Son et al. (2012) recently reported in *Endocrinology*) (Fig. 3).

To elucidate the mode of action of GnIH in birds, Tsutsui et al. identified GnIH-R in the quail diencephalon and characterized its expression and binding activity.[35] First, a cDNA encoding a putative GnIH-R was cloned by a combination of 3′/5′ RACE using PCR primers designed from the sequence of the receptor for RFRPs (GPR147). The crude membrane fraction of COS-7 cells transfected with the putative GnIH-R cDNA specifically bound GnIH and GnIH-RPs in a concentration-dependent manner, indicating that GPR147 is GnIH-R.[35] GnIH-R is also widely expressed in the brain and the pituitary in birds (for reviews, see Refs 24, 25).

Since GPR147 couples with $G\alpha_i$ to inhibit adenylyl cyclase (AC),[10] GPR147 (GnIH-R) activation may reduce intracellular cAMP levels, and reduce the activities of cAMP-dependent protein kinase (PKA) and mitogen-activated protein kinase (MAPK) signaling cascade. On the other hand, GnRH receptor (GnRH-R) couples with $G\alpha_{q/11}$ to activate phospholipase C (PLC), which results in the production of inositol triphosphate (IP3) and diacylglycerol (DAG). In turn, IP3 and DAG increase intracellular Ca^{2+} and activate the protein kinase C (PKC) pathway and MAPK signaling. GnRH-R also couples with $G\alpha_s$ to stimulate AC/cAMP/PKA pathway (for reviews, see Refs 24, 25). The inhibitory action of GnIH and RFRPs on gonadotropin gene expression was suggested to be mediated by an inhibition of AC/cAMP/PKA-dependent extracellular signal-regulated kinase (ERK) pathway (see Son et al. (2012) as reported in *Endocrinology*). In the sheep, RFRP-3, a GnIH ortholog, can inhibit both GnRH-induced intracellular Ca^{2+} increase and ERK phosphorylation, impacting GnRH-induced gonadotropin release and synthesis.[21] In the chicken, activation of GnRH-R can activate AC and stimulate cAMP responsive element (CRE) binding protein.[23] GnIH may partly inhibit this GnRH-induced CRE activation, thus impacting gene transcription[23] (for reviews, see Refs 24, 25).

BIOLOGICAL ACTIONS ON THE PITUITARY AND WITHIN THE BRAIN

Dense population of GnIH-ir fibers at the ME in quail[26,34] and in other birds[2,18,29] suggested a role for GnIH in the regulation of pituitary function in birds. That GnIH inhibits synthesis and/or release of gonadotropins from cultured quail and chicken anterior pituitary provides strong support for this function[6,26] (Table 2). Peripheral administration of GnIH also inhibits gonadotropin synthesis and/or release in birds[18,32] (Table 2). In mammals, abundant RFRP-ir fibers were observed in the ME of sheep,[7] macaque,[30] and humans.[31] As in birds, RFRP-3, a mammalian GnIH ortholog, inhibits gonadotropin synthesis and/or release

TABLE 2 Physiological Functions of GnIH and its Orthologs (LPXRFamide Peptides) in Vertebrates

Animal	Name	Physiological Function	Reference
Mammal			
Human	RFRP-1	Stimulation of prolactin release (i.c.v.)	Hinuma et al., 2000[10]
Bovine	RFRP-3*	Inhibition of GnRH-elicited gonadotropin release (*in vitro*) Inhibition of gonadotropin release (i.v.)	Kadokawa et al., 2009[12]; Kadokawa et al., 2009[12]
Ovine	RFRP-3*	Inhibition of GnRH-elicited gonadotropin release (*in vitro*) Inhibition of gonadotropin release (i.v.) Inhibition of GnRH-elicited gonadotropin synthesis and release (*in vitro*)	Clerke et al., 2008[7]; Clerke et al., 2008[7]; Sari et al., 2009[21]
Rat	RFRP-1* RFRP-3	Stimulation of adrenocorticotropic hormone, oxytocin release (i.c.v.) Stimulation of adrenocorticotropic hormone, oxytocin release (i.c.v.) Inhibition of gonadotropin release (i.c.v.) Inhibition of gonadotropin release (i.v.) Inhibition of GnRH-elicited gonadotropin release (*in vitro*) Inhibition of reproductive behavior (i.c.v.) from cultured pituitaries in sheep[21] and cattle.[12] Peripheral administration of RFRP-3 also inhibits gonadotropin release in sheep[7] and cattle.[12] It was further shown that GnIH-R mRNA is expressed in gonadotrophs in the human pituitary.[31] Taken together, it is likely that GnIH and RFRP-3 directly act on the pituitary to inhibit gonadotropin secretion from the pituitary at least in these avian and mammalian species (Table 2). It is believed that RFRP-3 does not act directly on the pituitary in rodents, because there are relatively few or no RFRP-IR fibers in the ME.[15,28] However, there are also several studies indicating that RFRP-3 can directly inhibit gonadotropin release from the pituitary[17] (for reviews, see Refs 24, 25). More detailed studies, analyzing peptide release into the hypophysial portal blood, fiber projections by retrograde labeling and other techniques are needed to elucidate the hypophysiotropic action of GnIH and its mammalian ortholog, RFRP-3 (for reviews, see Refs 24, 25).

Immunohistochemical studies using light and confocal microscopy indicate that neuronal axon terminals containing GnIH and RFRP-3 are in probable contact with GnRH neurons in birds[2,29] and mammals.[15,28,30,31] GnIH-R also is expressed in GnRH neurons in starlings[29] and hamsters.[28] Together with the observation that central administration of GnIH or RFRP-3 inhibits the release of gonadotropin in white-crowned sparrows,[1] hamsters,[15,28] and rats,[11] GnIH and RFRP-3 may inhibit the secretion of gonadotropins by decreasing GnRH neuronal activity in addition to regulating the gonadotroph directly (Table 2, Fig. 4) (for reviews, see Refs 24, 25). Direct application of RFRP-3, a mammalian GnIH ortholog, to GnRH cells in cultured mouse brain slices decreases firing rate in a subpopulation of cells, further indicating a direct action of RFRP-3 on GnRH neurons. In addition, RFRP-3 inhibits firing of kisspeptin-activated vGluT2 (vesicular glutamate transporter 2)-GnRH neurons and of kisspeptin-insensitive GnRH neurons (for reviews, see Refs 24, 25). Later results confirmed a role for RFRP-3 by use of an antagonist, RF9, against GnIH-R. Central administration of RF9 to rats and mice led to marked increases in gonadotropin concentrations, providing a pronounced role of RFRP-3 as a key regulator of the reproductive axis in mammals.[19]

More recently, an inhibitory action of zebrafish GnIH ortholog (zfLPXRFa-3) was also reported in goldfish (for reviews, see Refs 24, 25) (Table 2). In general, GnIH and its orthologs seem to act similarly across vertebrate species to regulate reproduction (for reviews, see Refs 24, 25) (Table 2). However, another study found that goldfish GnIH orthologs (gfLPXRFa-1, -2, and -3) stimulate the release of gonadotropins and growth hormone (GH) but not prolactin (PRL) *in vitro* (Table 2). In a marked departure from the actions of GnIH and its mammalian ortholog, RFRP-3, frog GnIH orthologs (fGRP and fGRP-RP-2) stimulate the release of GH and/or PRL in amphibians both *in vitro* and *in vivo*[14,33] (Table 2). Therefore, further studies are necessary to clarify the generality of GnIH function on gonadotropin release in lower vertebrates.

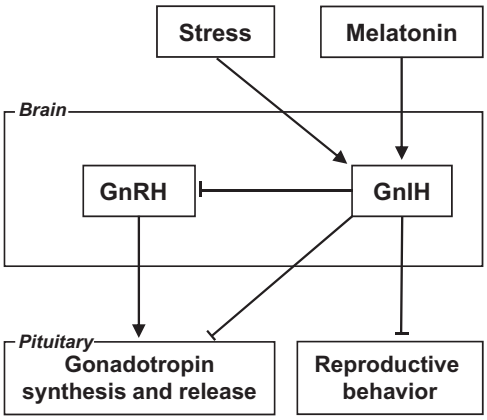

FIGURE 4 GnIH actions within the brain and pituitary

Furthermore, central administrations of GnIH and RFRP-3 inhibit reproductive behavior of female white-crowned sparrows[1] and male rats,[11] respectively. GnIH neurons are also in contact with the second form of GnRH (GnRH-II) neurons in birds,[29] and GnIH-R is also expressed in GnRH-II neurons.[29] Because GnRH-II can stimulate copulation solicitation in female birds, it is possible that GnIH inhibits reproductive behavior of female birds by inhibiting GnRH-II neurons.[1,2,29] On the other hand, central administrations of GnIH and RFRP-3 stimulate feeding behavior in chicken and rats,[11,17] respectively. There is also a recent report that central administration of RFRP-3 can stimulate adrenocorticotropic hormone and oxytocin release in rats (Table 2). It was shown that RFRP-ir fibers project to various neurons in the brain, such as dopamine and/or proopiomelanocortin neurons in the rat, sheep, and macaque,[30] indicating multiple functions of GnIH and its orthologs in the brain of birds and mammals (Fig. 4).

PATHOPHYSIOLOGICAL IMPLICATIONS

Identification of the regulatory mechanisms governing expression of GnIH and its orthologs is important in understanding the physiological role of the GnIH system. A nocturnal hormone, melatonin, seems to act directly on GnIH neurons through its receptor to induce expression and release of GnIH in quail.[5,27] Recently, a similar, but opposite, action of melatonin on the inhibition of expression of mammalian GnIH orthologs, RFRPs, was shown in hamsters, a photoperiodic mammal.[28] These results in quail and hamsters show that expression of GnIH and its orthologs are photoperiodically modulated via a melatonin-dependent process. Stress can also inhibit reproduction in birds and

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

mammals. It was shown that immobilization stress induces expressions of GnIH and its orthologs in birds and rats.[13] GnIH and its orthologs may therefore be a mediator of stress-induced reproductive disruption in birds and mammals (for reviews, see Refs 24, 25) (Fig. 4).

The role of RFRP-3, a mammalian GnIH ortholog, in regulating ovulatory function was investigated in female hamsters.[9] The cellular activity of RFRP neurons was suppressed at the time of the luteinizing hormone (LH) surge, suggesting removal of negative feedback by RFRP-3 at this time.[9] The SCN, the master circadian clock triggering ovulation in rodents, projects to a large proportion of RFRP neurons, providing a mechanism for timing removal of negative drive on the GnRH system.[9] Activities of the SCN, GnRH, and GnIH system are coordinated with ovulation.[9]

The identification of human GnIH orthologs, RFRP-1 and -3, in the hypothalamic-hypophysial system[31] and the demonstration that human RFRP-3 has potent inhibitory actions on gonadotropin secretion in sheep[7,21] have opened up new vistas for understanding the regulation of reproduction. Many factors, such as stress, anorexia, diabetes, obesity, and photoperiod, inhibit gonadotropin secretion. The possible role of GnIH in mediating these effects has been implicated in animal models.[5,9,13,27] In view of its potent inhibition of gonadotropin secretion, GnIH has the potential of an alternative or adjunct therapeutic agent to inhibit endogenous levels of gonadotropins and steroid hormones. Thus, GnIH has therapeutic potential in the treatment of hormone-dependent diseases, such as precocious puberty, endometriosis, uterine fibroids, benign prostatic hyperplasia, and prostatic and breast cancers.

Chapter 108

Hypocretins (Orexins)

Luis de Lecea and J. Gregor Sutcliffe

ABSTRACT

The hypocretins (Hcrts, also called the orexins) are two C-terminally amidated neuropeptides of related sequence. They are produced from a common precursor whose expression is restricted to a few thousand neurons of the rat dorsolateral hypothalamus. Two G-protein-coupled receptors for the hypocretins have been identified, and these have different distributions within the CNS and differential affinities for the two hypocretins. Hypocretin-containing neurons project to areas within the posterior hypothalamus that are implicated in feeding behaviors and hormone secretion. Hypocretin fibers also project to diverse targets in other brain regions and the spinal cord, including several areas implicated in cardiovascular function and sleep–wake regulation. The peptides are generally neuroexcitatory. Administration of the hypocretins stimulates food intake, affects blood pressure, hormone secretion, and locomotor activity, and increases wakefulness while suppressing rapid eye movement (REM) sleep. Inactivating mutations in the hypocretin receptor 2 gene in dogs result in narcolepsy. Mice whose hypocretin gene has been inactivated exhibit a narcolepsy-like phenotype. Most human patients with narcolepsy have greatly reduced levels of hypocretin peptides in their cerebral spinal fluid and no or barely detectable hypocretin neurons in their hypothalami, suggestive of autoimmune attack.

DISCOVERY

An open-system search for undiscovered hypothalamic regulatory peptides provided the first glimpse of the hypocretins. Gautvik and colleagues[9] used subtractive hybridization to identify messenger RNA species restricted to discrete nuclei within the rat hypothalamus. Among these was a species whose expression, as detected by *in situ* hybridization, was restricted to a few thousand neurons that were bilaterally distributed within the dorsolateral hypothalamus.[8]

A large collaborative study to identify endogenous ligands for orphan G-protein-coupled receptors discovered the peptides independently.[23] This group referred to the peptides as orexins because they stimulated acute food intake when administered to rats during the daytime. In this chapter, we will refer to the peptides by their first-used name, the hypocretins, but both names have been used extensively in the vast literature that has developed around the peptides.

STRUCTURE OF THE PRECURSOR mRNA/GENE

The mouse hypocretin gene, *HCRT*, is located on chromosome 11, and the human *HCRT* gene maps to Chromosome 17q21-q24. Genes that encode conserved preprohypocretins have been detected in pufferfish, zebrafish, frog, and chicken species, suggesting that the gene arose early in the chordate lineage. Sequence similarities with various members of the incretin family, especially secretin, suggest that the preprohypocretin gene was formed from the secretin gene by three genetic rearrangement;[2] first, a duplication of the secretin gene; second, deletions of the N-terminal portion of the 5′ duplicate and the C-terminal portion of the 3′ duplicate to yield a secretin with its N- and C- termini leap frogged (circularly permuted); and third, a further duplication of the permuted gene, followed by modifications, to form a secretin derivative that encoded two related hypocretin peptides.

The human preprohypocretin gene consists of two exons and one intron distributed over 1432 bp. The 143-bp first exon includes the 5′-untranslated region and a small part of the coding region that encodes the first seven residues of the secretory signal sequence. The second exon contains the remaining portion of the open reading frame and 3′-untranslated region. The 3.2 kilobase pairs of the 5′-upstream region from a cloned human preprohypocretin gene promoter is sufficient to direct the expression of the *E. coli* β-galactosidase (lacZ) gene in transgenic mice to neurons in the lateral hypothalamic area and adjacent regions.[24]

DISTRIBUTION OF THE mRNA

The rat preprohypocretin mRNA migrates in northern blots at approximately 700 nt in samples obtained from brain.[8] A few thousand neurons highly positive for Hcrt mRNA and immunoreactivity are located between the rat fornix and the mammillothalamic tracts.[8,21] These are first detected at embryonic day E18. Beginning at E20, hypocretin antisera detect a prominent network of axons that project from these cells to other neurons in the perifornical and posterior hypothalamus. Both mRNA and peptide expression dimin-

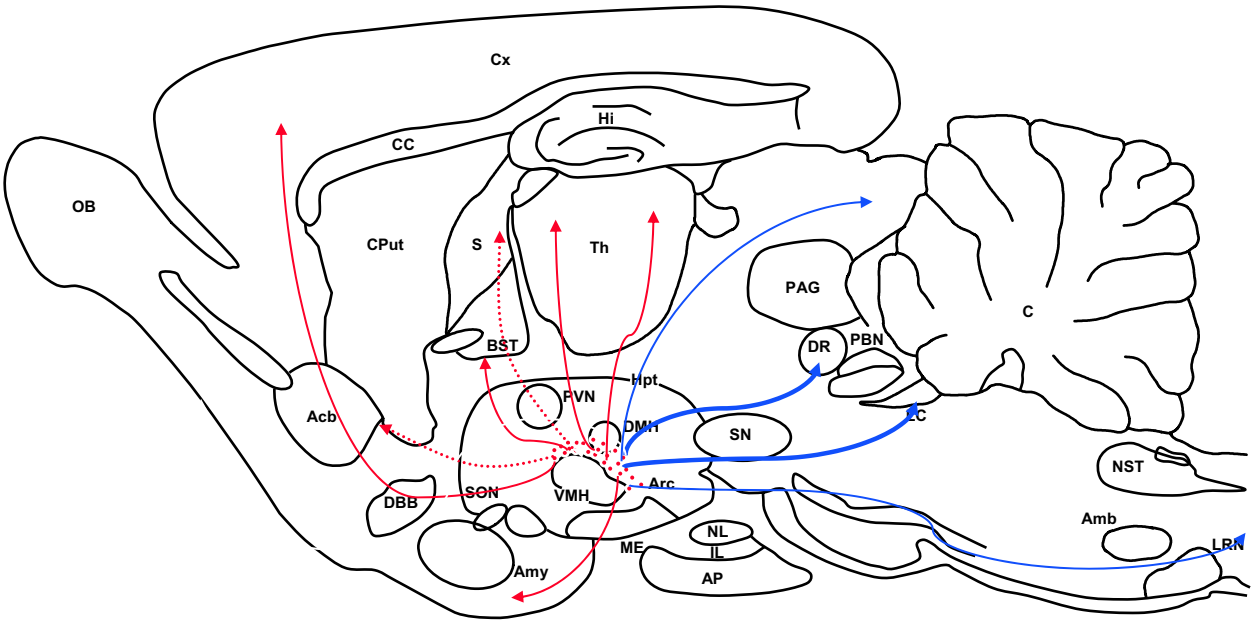

FIGURE 1 Schematic of the distribution of Hcrt projections originating in the lateral hypothalamus. A very dense intrahypothalamic network of Hcrt fibers can be detected by immunohistochemistry in the DMH, VMH, Arc, and PVN. Another set of fibers can be followed along the medial thalamus (Th). An ascending projection connects Hcrt with the ventral forebrain and amygdalar structures (Amy) and diffuse sparse innervation of neocortical areas (Cx). Descending efferent areas include the main monoaminergic nuclei such as the noradrenergic locus coeruleus (LC), serotonergic median and dorsal raphe (DR), and dopaminergic fibers passing through the ventral tegmental area. A direct monosynaptic connection to the spinal cord has also been described.DMH–dorsomedial hypothalamus; VMH–ventromedial hypothalamus; Arc–Arcuate nucleus; PVN–Paraventricular hypothalamic nucleus. See color plate 30.

ish after 1 year of age. The human lateral hypothalamus contains 50,000–80,000 hypocretin neurons. Hcrt neurons are 20–30 μm in diameter and are multipolar or fusiform in shape, with 2–4 primary dendrites bearing few spines. In addition to rats, mice, and humans, Hcrt neurons with a similar restricted hypothalamic distribution have been detected in monkey, hamster, cat, sheep, pig, chicken, various amphibians, and zebrafish. Glutamate, the excitatory amino acid transporter EAAT3, and the vesicular glutamate transporters VGLUT1 and VGLUT2 are expressed by hypocretin neurons; thus, hypocretin-containing neurons are likely to be glutamatergic. Other proteins detected in hypocretin neurons include dynorphin, $GABA_A$ receptor epsilon subunit, 5-HT_{1A} receptor, mu opioid receptor, pancreatic polypeptide Y4 receptor, adenosine A1 receptor, leptin receptor, transcription factor Stat-3, and the neuronal pentraxin Narp, implicated in clustering of ionotropic glutamate receptors.

There are several reports of Hcrt mRNA and Hcrt receptor mRNA expression in the periphery, including the enteric nervous system pancreas, kidney, stomach, and ileum. There are also several reports of Hcrt expression in the human anterior pituitary and adrenal gland. One study showed Hcrt-immunoreactivity in amacrine cells in the human retina.

PROCESSING OF THE PRECURSOR

Preprohypocretin encodes a 130-residue putative secretory protein with an apparent signal sequence and two additional phylogenically conserved sites for potential proteolytic maturation followed by modification of the carboxy-terminal glycines by peptidylglycine α-amidating monooxygenase.[8] These features suggested that the product of this hypothalamic mRNA served as a preprohormone for two C-terminally amidated, secreted peptides. One of these, hypocretin 2 (Hcrt2 or OxB), was, on the basis of the putative preprohormone amino-acid sequence, predicted to contain precisely 28 residues. The other, hypocretin 1 (Hcrt1 or OxA), had a defined predicted amidated C terminus but, because of uncertainties as to how the amino terminus might be proteolytically processed, an undefined N-terminal extent.[8] The C-terminal 19 residues of these two putative peptides shared 13 amino-acid identities, suggesting that the peptides had related structures and functions. This region of Hcrt2 contained a seven-amino-acid match with secretin. Antisera generated against synthetic peptides corresponding to regions of the deduced prohypocretin sequence and to bacterially expressed preprohypocretin have been generated.[8,21] The antisera are specific for the hypocretin-related peptides and have been used extensively to characterize the protein in both anatomical and ELISA-type studies.

The detection of the two hypocretin peptides within the brain allowed the exact structures of these endogenous peptides to be determined by mass spectroscopy.[23] The sequence of endogenous Hcrt2, RPGPPGLQGRLQRLLQAN GNHAAGILTM-amide, was the same as that predicted from the cDNA sequence. The N-terminus of Hcrt1 was found to correspond to a genetically encoded glutamine

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

that was derivatized as pyroglutamate. Hcrt1 (33 residues: *EPLPDCCRQKTCSCRLYELLHGAGNHAAGILTL-amide) contains two intrachain disulfide bonds. Human Hcrt1 is identical to the rodent peptide, whereas human Hcrt2 differs from rodent Hcrt2 at two residues.[23]

The enzyme that cleaves preprohypocretin and yields the mature peptides has not been determined. Anatomical evidence suggests that prohormone convertase 1 colocalizes with in the lateral hypothalamus and may be involved in the processing of the precursor.

RECEPTORS AND SIGNALING CASCADES

Sakurai and collaborators[23] prepared transfected cell lines stably expressing each of 50 orphan G-protein-coupled receptors (GPCRs) and then measured calcium fluxes in these cell lines in response to fractions from tissue extracts. One of these transfected cell lines responded to a substance in a brain extract. Mass spectroscopy showed that this substance was a peptide whose sequence was later identified as that of endogenous Hcrt1. The initial orphan GPCR, Hcrtr1 (also referred to as OX1R), bound Hcrt1 with high affinity, but Hcrt2 with 100- to 1000-fold lower affinity. A related GPCR, Hcrtr2 (OX2R), sharing 64% identity with Hcrtr1, was identified by searching database entries with the Hcrtr1 sequence and had a high affinity for both Hcrt2 and Hcrt1.[23] These two receptors are highly conserved (95%) across species. Radioligand-binding studies and calcium flux measurements have shown Hcrt1 to have equal affinity for Hcrtr1 and Hcrtr2, whereas Hcrt2 has an approximately 10-fold greater affinity for Hcrtr2 than Hcrtr1 has.

The mRNAs that encode the two hypocretin receptors and the receptor proteins themselves, detected by immunohistochemistry, are both enriched in the brain and moderately abundant in the hypothalamus but have different distributions within the brain.[18] Hcrtr1 mRNA is prominent in the prefrontal cortex, hippocampus, paraventricular thalamic nucleus, ventromedial hypothalamus, dorsal raphe, locus coeruleus, laterodorsal tegmentum (at a higher density than that of Hcrtr2), pontine raphe, dorsal motor vagal complex, and spinal cord. Additional forebrain regions expressing moderate-to-high levels of Hcrtr1 mRNA are the tenia tecta, bed nucleus of the stria terminalis, diagonal band, and medial amygdala. Immunoreactive terminals have been detected in the LH. This receptor has also been detected in the retina.

Hcrtr2 mRNA (there are 2 alternative splice forms, each encoding proteins with slightly different structure and anatomical distribution, but no demonstrated functional differences) is detected in the neocortex, septum, hippocampus, thalamus, dorsal raphe, and various nuclei of the hypothalamus, including the tuberomammillary nucleus, paraventricular hypothalamic nucleus, and dorsomedial hypothalamus. Periaqueductal gray and midbrain reticular formation are also positive. Hcrtr2 mRNA is prominent in the septum, diagonal band, and central amygdala.

Both receptors are detected in the dorsal raphe, ventral tegmental area, and midline thalamic nuclei. In the cortex, Hcrtr1 mRNA is expressed primarily in layers II, III, and V, whereas Hcrtr2 mRNA is found at higher density in layers II and VI and more diffusely in other layers. In the hippocampus, Hcrtr1 is expressed mainly in the CA2 region and medial dentate gyrus, whereas Hcrtr2 was most abundant in CA3.

The distribution of Hcrt receptors is largely consistent with Hcrt axon innervation patterns (Fig. 1). The composite distribution of the two Hcrt receptors strongly resembles the distribution of the MCH receptor.[13] In the LC, amygdala, and other brainstem noradrenergic groups, MCH receptor mRNA distribution is similar to that of the Hcrtr1. In regions such as the septum, hypothalamus, and much of the brainstem, the distribution of MCH receptor mRNA resembles that of the Hcrtr2.[13]

The Hcrt receptors are not restricted to the central nervous system: in the periphery, they are widely expressed, especially in endocrine tissues. Hcrtr1 or Hcrtr2 have been detected in the pituitary, adrenal gland, testis, gastrointestinal tract, pancreas, and pineal gland.

Both Hcrt1 and Hcrt2 evoke increases in Ca^{2+}, as measured by fura-2 imaging, in about one-third of hypothalamic neurons, probably by opening a TRPC-type calcium channel.[16] Responses to Hcrt peptides are completely blocked by the protein kinase C-specific inhibitors and by phospholipase C (PLC) inhibitors,[28] suggesting that the hypocretins work through a family of GTP-binding proteins (G_q) that activate protein kinase C (PKC) and mobilization of intracellular calcium. G_q activated signaling cascades result in phosphorylation of Ca^{2+} channels, which can increase Ca^{2+} conductance and neuronal excitability. The nonamidated forms of the peptides are not electrophysiologically active. In the SN, hypocretin stimulation was sensitive to an inhibitor of protein kinase A, which mediates effects of cAMP, but insensitive to blockers of PKC, implicating a role of the G_s system.

INFORMATION ON ACTIVE AND/OR SOLUTION CONFORMATION

The structures of both Hcrt1 and Hcrt2 in solution have been determined by nuclear magnetic resonance.[14] Consistent with the hypothesis that the hypocretins and secretin are phylogenically related, portions of their three-dimensional solution structures are similar despite their leap-frogged primary sequence, consisting of two adjacent α-helices (6–7 and 9–14 amino acids long) separated by a short 2-3-amino-acid turn.[14] The longer helix corresponds to the region of identity between the two peptides.

BIOLOGICAL ACTIONS WITHIN THE BRAIN

Administration of the hypocretin peptides to experimental animals stimulates food intake, affects autonomic and endocrine parameters, and increases arousal. These are discussed below in that order, but because the disease of the hypocretin system is the sleep disorder narcolepsy, the arousal aspects are the most important and will be discussed in a later section of the chapter and in the Sleep Peptides chapter in the last Section of this book.

Feeding and Metabolism

Sakurai and colleagues[23] found that intracerebroventricular (ICV) administration of either Hcrt1 or Hcrt2 increased short-term food consumption in rats. Further, rats that had been deprived of food for 48 h showed increased concentrations of preprohypocretin mRNA and peptides in the hypothalamus.[23] Feeding responses can be elicited by local administration of Hcrt1 to the paraventricular nucleus, the dorsomedial nucleus, the lateral hypothalamus, or the perifornical area. ICV administration of Hcrt2 also increases food intake in sheep and goldfish Many observations leave little doubt that the hypocretin system influences and is influenced by primary nutritional homeostasis circuits. For instance, Hcrt neurons are sensitive to glucose, leptin, and triglyceride concentration. Hcrt neurons are contacted by NPY-containing neurons in the arcuate nucleus,[12] and much of the food intake increase elicited by Hcrt1 seems to be mediated by NPY.

Other findings suggest that the hypocretins are not critical players in feeding activities, but rather play roles in increasing arousal and motivation levels so that feeding can take place. Continuous administration of Hcrt1 for seven days in rats does not significantly alter daily food intake, body weight, blood glucose, total cholesterol, or free fatty acid levels, suggesting that many of the effects of hypocretin may be limited to short-term, immediate stimulation of feeding behavior due to increased wakefulness. If hypocretin has a direct role in food intake, one would expect a lean phenotype in Hcrt-deficient mice, as has been described for melanin concentrating hormone. Hcrt knockout mice show very modest,[30] if significant, differences in food intake. Hypocretin-ataxin 3 mice, which are genetically depleted of Hcrt neurons and would be expected to be lean, show obesity and hypolocomotion,[11] and this effect seems to be dependent on diet and genetic background. During fasting, Hcrt1 accumulation in the cerebrospinal fluid (CSF) does not exceed concentrations normal for the waking period. Also, Hcrt ataxin-3 mice, unlike wild-type animals, do not show increase in locomotor activity after fasting.[31] All these data suggest that some of the food-uptake effect may result from arousal rather than direct feeding pressure.

Autonomic and Endocrine Effects

Hypocretin neurons receive input from brainstem areas that are associated with cardiovascular function, and project to the ventrolateral medulla, the locus coeruleus, the lateral paragigantocellular nucleus, the nucleus of the solitary tract, the pre-Botzinger region of the ventrolateral medulla, phrenic motoneurons, and other areas that have been implicated in the regulation of blood pressure, heart rate, and breathing. Projections to the arcuate nucleus also suggest a role in the regulation of hormone release. In the ovine hypothalamus, there are hypocretin terminals on the neurons that produce gonadotropin-releasing hormone, suggesting that hypocretin might particularly modulate reproductive endocrinology. In addition, projections to the raphe magnus and subcoeruleus suggested a role for hypocretins in the regulation of body temperature. The dense hypocretinergic projections to the ventrolateral preoptic area, tuberomammillary nucleus, pontine reticular formation, pedunculo pontine area, and locus coeruleus suggested involvement in states of arousal.[21] Very strong hypocretin-immunoreactive projections have been described in regions of the spinal cord that are related to modulation of pain,[27] and hypocretin-like immunoreactivity has also been detected in the intestinal epithelium.

In accordance with the wide distribution of hypocretin terminals, ICV administration of the hypocretins affects not only feeding but also several other functions. Both Hcrt1 and Hcrt2 elevate mean arterial blood pressure, heart rate (both suppressed by the hypocretin receptor 1 antagonist SB334867), and oxygen consumption.[25] Hcrt1 increases body temperature independent of peripheral thermogenesis, at least in part via clozapine-sensitive pathways in the cerebral cortex. Hcrt1 also increases water consumption and stimulates gastric acid secretion in the gut and increases locomotor activity and wakefulness, while decreasing slow wave and depressing REM sleep.[3]

The peptides also stimulate the secretion of luteinizing hormone in ovarectomized and proestrus female rats (suppressed by central administration of SB334867) and hypothalamic explants of male pituitaries. Consistent with these findings, in humans, LH concentration in serum and pulsatile LH secretion are lower in male narcolepsy patients (who lack hypocretin function; see below) than in unaffected controls. Hcrt concentrations are elevated during proestrus in cycling female rats but not in noncycling middle-aged rats and in pregnant rats, and c-*fos* is increased in Hcrt neurons in lactating mice. In male rats, Hcrt1 increased basal testosterone secretion. Hcrt1 decreases the concentrations of circulating growth hormone and prolactin, while increasing corticosterone, ACTH, and insulin levels. Hypoglycemia-induced elevation of pancreatic nerve firing is antagonized by SB334867 microinjection in the dorsal motor nucleus of

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

the vagus, indicative of a central circuit in this pathway. Hcrt2, but not Hcrt1, increases circulating thyroid-stimulating hormone and has direct effects on the pituitary, adrenal, and pineal glands.

Both peptides depolarize neurons containing corticotropin releasing-hormone in the paraventricular hypothalamic nucleus and increase c-*fos,* and arginine vasopressin mRNA concentrations in the paraventricular, thus exerting clear effects on the hypothalamo–pituitary–adrenal axis and stress-related physiology; various stress paradigms increase c-*fos* expression by Hcrt neurons. Hcrt2 is directly excitatory on superficial dorsal horn neurons of the spinal cord[27] and exhibits an analgesic effect in models of pain.

Motivation and Addiction

The Hcrt system has recently been shown to be a key component in the brain reward circuitry.[4] Rats can be trained to turn a wheel to deliver electrical current to the lateral hypothalamus (LH): LH self-stimulation (LHSS). LHSS thresholds measure brain reward systems; lower thresholds represent increased reward. Most drugs of abuse lower LHSS thresholds. LHSS is believed to be rewarding in part because it activates cholinergic neurons in the laterodorsal tegmentum that consequently activate dopaminergic neurons in the ventral tegmental area. Hypocretins excite brainstem cholinergic neurons both directly and indirectly acting synergistically with glutamatergic afferents[5] to drive dopamine release in the nucleus accumbens by exciting dopaminergic neurons in the ventral tegmental area. Thus, the Hcrt system acts as a modulator of brain reward function. Interestingly in this regard, naltrexone injected into the accumbens suppresses the Hcrt1-induced acute feeding response, suggesting that the response is mediated by opioidergic pathways involved in motivation.

Pain and Anesthesia

In models of pain elicited by noxious stimuli or chronic constriction, Hcrts administered intrathecally or microinjected into the posterior hypothalamus decreased pain parameters. Hypocretin knockout mice (see below) exhibited greater hyperalgesia and less stress-induced analgesia than did wild-type mice. Hcrt1 decreases barbiturate anesthesia time in rats by 15–40%, an action reversed by SB-334867. *In vitro*, barbiturates inhibit Hcrt-induced norepinephrine release, although they do not interact directly with Hcrt receptors. In isoflorane-anesthetized animals, Hcrt1 elicits arousal without cardiovascular activation, in contrast to its effect on awake animals. Pain and stress activate Hcrt neurons, which respond by inhibiting pain pathways. Some of these effects may be due to the interaction with the nociceptin system.

PATHOPHYSIOLOGICAL IMPLICATIONS

Narcolepsy affects around 1 in 2000 adults, appears between the ages of 15–30 years, and exhibits four characteristic symptoms: (i) excessive daytime sleepiness with irresistible sleep attacks during the day; (ii) cataplexy (brief episodes of muscle weakness or paralysis precipitated by strong emotions such as laughter or surprise); (iii) sleep paralysis, a symptom considered to be an abnormal episode of REM sleep atonia, in which the patient suddenly finds himself unable to move for a few minutes, most often on falling asleep or waking up; and (iv) hypnagogic hallucinations, or dream-like images that occur at sleep onset. These latter symptoms have been proposed as pathological equivalents of REM sleep. The disorder is considered to represent a disturbed distribution of sleep states rather than an excessive amount of sleep.

Hypocretin neurons seem to control the boundaries between vigilance states through direct and indirect mechanisms. Hcrt neuronal activity at frequencies >5 Hz is sufficient to elicit sleep-to-wake transitions,[1] and acute optogenetic inhibition of Hcrt correlates with behavioral arrests. However, stimulation of Hcrt neurons does not seem to affect sleep or wake maintenance directly. The neuronal targets of this state boundary control are still unknown, but they are probably related to brain structures that express Hcrt 2 receptors. Because optogenetic high frequency stimulation of locus coeruleus neurons leads to behavioral arrests that resemble narcolepsy attacks,[6] it is tempting to speculate that Hcrt r2-expressing cells that modulate the excitability of noradrenergic neurons in the LC are critical for the onset of cataplexy.

Canine Narcolepsy

Both sporadic and heritable narcolepsies are observed in dogs, and the symptoms resemble those exhibited by human narcoleptics. The first link between the hypocretins and narcolepsy came from genetic linkage studies in a colony of Doberman Pinschers in which narcolepsy was inherited as an autosomal recessive, fully penetrant phenotype. Fine mapping and cloning of the defective canine narcolepsy gene, showed it to be the gene that encodes the hypocretin receptor, Hcrtr2.[17] The mutation in the Doberman lineage is an insertion of a short interspersed repeat (SINE element) into the third intron of *HCRTR2* that causes aberrant splicing of the Hcrtr2 mRNA (exon 4 is skipped) and results in a truncated receptor protein. In cells that have been transfected with the mutant gene, the truncated Hcrtr2 protein does not properly localize to the membrane and, therefore, does not bind its ligands. Analysis of a colony of narcoleptic Labradors revealed that their *HCRTR2* gene contained a distinct mutation that resulted in the skipping of exon 6, also leading to a truncated receptor protein. A third family of narcoleptic Dachshunds carries a

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

point mutation in *HCRTR2* that results in a receptor protein that reaches the membrane but cannot bind the hypocretins.

Mouse Knockout Mutants

Continuous recording of the behavior of knockout mice in which the hypocretin gene was inactivated by homologous recombination in embryonic stem cells revealed periods of ataxia, which were especially frequent during the dark period.[7] EEG recordings showed that these episodes were not related to epilepsy, and that the mice suffered from cataplectic attacks, a hallmark of narcolepsy. In addition, the mutant mice spent almost twice as much time in REM sleep during the dark period as did their wild-type littermates, and their EEGs showed episodes of direct transition from wakefulness to REM sleep, another event that is unique to narcolepsy. Mice with an inactivated *HCRTR2* gene have a milder narcoleptic phenotype than did the *HCRT* knockouts; *HCRTR1* knockouts exhibit only a sleep fragmentation phenotype, whereas double *HCRTR1* and *HCRTR2* mutants recapitulate the full *HCRT* knockout phenotype,[29] suggesting that signaling through both receptors contributes to normal arousal, although the role of *HCRTR2* is greater than that of *HCRTR1*.[22]

Human Narcolepsy

Nishino and colleagues[19] studied hypocretin concentrations in the CSF of normal controls and patients with narcolepsy by radioimmunoassay. In control CSF, hypocretin concentrations were highly clustered, suggesting that tight regulation of the substance is important. However, of nine patients with narcolepsy, only one had a hypocretin concentration within the normal range. One patient had a greatly elevated concentration, whereas seven patients had no detectable circulating hypocretin. In an expanded study, hypocretin was undetectable in 37 of 42 narcoleptics and in a few cases of Guillain-Barré syndrome. CSF hypocretin was in the normal range for most neurological diseases, but was low, although detectable, in some cases of CNS infections, brain trauma, and brain tumors.

Peyron,[20] Thannikal,[26] and their groups of collaborators found that, in the brains of narcolepsy patients, they could detect few or no hypocretin-producing neurons. Whether the hypocretin neurons are selectively depleted, as is most likely, or only no longer expressing hypocretin is not yet known, although one report showed some indications of gliosis.[26] The codistributed neurons expressing melanin-concentrating hormone (MCH) were unaffected. Further, a single patient with a non-HLA-linked narcolepsy carries a mutation within the hypocretin gene itself. The mutation results in a dominant negative amino-acid substitution in the secretion signal sequence that sequesters both the mutant and heterozygous wild-type hypocretin nonproductively to the smooth endoplasmic reticulum.[20]

These findings leave no doubt as to the central role of the hypocretin system in this sleep disorder. Because most cases are sporadic, mutations in the hypocretin gene or those for its receptors can account for no more than a small subset of the human narcolepsies. The HLA association, loss of neurons with signs of gliosis, and age of disease onset are consistent with autoimmune destruction of the hypocretin neurons accounting for the majority of narcolepsy,[17] although a non-immune-mediated degenerative process has not been ruled out. The precipitating factor for the development of the autoimmunity is also unknown, but recent studies have suggested a link between certain cases of narcolepsy with lower expression of purinergic receptors in CD8+ cells and with the T cell receptor alpha locus.[10,15] The narcolepsies as a group are probably a collection of disorders that are caused by defects in the production or secretion of the hypocretins or in their signaling, and these could have numerous genetic, traumatic, viral, and/or autoimmune causes.

Chapter 109

Kisspeptins

Manuel Tena-Sempere

ABSTRACT

KISS1 was originally identified as a metastasis suppressor gene that encodes a number of related peptides including kisspeptin-54 (formerly, metastin) and shorter active fragments which, acting through the G protein-coupled receptor GPR54, seem capable of inhibiting tumor spread. The neuroendocrine dimension of the Kiss1/GPR54 system was disclosed by the observation, reported in late 2003, that loss-of-function mutations of the GPR54 gene are associated with the absence of puberty and hypogonadotropic hypogonadism. This seminal finding underscored a pivotal role of the Kiss1 system in the control of reproduction and boosted intense research efforts in an attempt to characterize the neuroendocrine physiology of kisspeptins. Indeed, in the past years, kisspeptins have emerged as major physiological regulators of GnRH neurons and, hence, of the reproductive axis. The major features of the Kiss1 system are comprehensively described in this chapter.

DISCOVERY OF THE KISS1 SYSTEM

Identification of *KISS1*, the gene encoding kisspeptins, occurred in late 1996 in the context of tumor biology. By the use of subtractive hybridization in melanoma cell lines with different metastatic capacity, the *KISS1* gene was originally reported to be selectively overexpressed in metastasis-suppressed tumor cells.[22,25] This original finding was expanded in the following years by assessing *KISS1* gene expression and/or the biological actions of kisspeptins in additional tumor specimens and cell lines. Those results led to the conclusion that *KISS1* has potent antimetastasis activity in several tumors, such as papillary thyroid carcinoma, breast carcinoma, melanoma, and pancreatic cancer cells, whereas the loss of *KISS1* gene expression was cataloged as a bad-prognosis factor for tumor progression and metastasis in esophageal squamous cell carcinoma, gastric carcinoma, and bladder cancer, among others.[25]

Besides its role in tumor progression, fragmentary information already showed several years ago additional roles for *Kiss1*-derived peptides in the endocrine/paracrine control of specific biological functions. Notably, the expression of the *KISS1* gene in normal human tissues is maximum in placenta, which probably accounts for the dramatic increase in serum kisspeptin levels during pregnancy, a phenomenon of as yet unknown endocrine relevance.[25,31] In terms of paracrine regulation, placental *Kiss1*-derived peptides have been suggested to play a role in the physiological regulation of trophoblast invasion.[25] In addition, some preliminary evidence pointed out already in 2001 that Kiss1 peptides might participate in the regulation of specific neuroendocrine systems, such as oxytocin release.[13] Indeed, at that time, expression of *Kiss1* and/or the putative kisspeptin receptor (see below) was found in a variety of normal tissues, including not only placenta but also different brain areas, spinal cord, pituitary, pancreas, testis, small intestine, and human plasma,[13,15,23] which strongly suggested additional, as yet unknown, physiological roles of the Kiss1 system.

However, it was not until late 2003 when the neuroendocrine facet of such system was fully recognized by the striking observation that some forms of isolated hypogonadotropic hypogonadism (iHH) are associated with inactivating mutations of the gene encoding the putative receptor for kisspeptins (GPR54).[7,26] Such a hypogonadal phenotype was reproduced in mouse models where the *Gpr54* or *Kiss1* genes were knocked out.[22,25] These clinical and experimental findings boosted an extraordinary interest among reproductive physiologists, who endeavor to characterize the physiological roles of the Kiss1 system in the neuroendocrine control of the gonadotropic axis.

As an introductory note, in this chapter, we will focus on the mammalian Kiss1 system, where the terms *KISS1* and *Kiss1* will be used to name the primate and nonprimate genes, respectively, whereas their peptide products will be termed kisspeptins, with a numeric extension (if needed) indicating the number of amino acid residues, following previous literature.[10] In addition, the kisspeptin receptor will be named here GPR54 (or Gpr54, if specific mention to studies in nonprimate species is made), to keep the homogeneity with previous and current literature. Yet, we acknowledge that the use of the term Kiss1R is fully valid as well.[10] Finally, because most of the experimental results reviewed herein have been obtained in nonprimate mammalian species, the

Copyright Elsevier 2024

term Kiss1 will be used for global reference to the ligand–receptor system.

Structure of the *Kiss1* Gene

In the human genome, the *KISS1* gene has been mapped to chromosome 1q32.[34] The original report suggested that this gene comprises four exons and three introns, with the first and second exons being nontranslated and the last two exons encoding the 145 amino acid precursor peptide. This genomic organization was later challenged by an alternative proposal, in which the human *KISS1* gene contains 3 exons: the first exon consists of 111 bases and it is not translated, whereas exon 2 contains 141 nucleotides, with the start codon at position 39, and exon 3 consists of 322 translated nucleotides, followed by the translational stop codon and the polyadenylation sequence. The deduced sequence of the precursor KISS1 protein in humans consists of 145 amino acids.

The mouse *Kiss1* gene has been mapped to chromosome 1, whereas in rat, the gene is located in chromosome 13q13. The cDNA sequences and the genomic organization of the rat and mouse *Kiss1* genes seem to be highly homologous. Thus, the mouse *Kiss1* gene has been proposed to contain only two translated exons, which correspond to the last two exons of the human gene.[33] These two exons are highly homologous to the corresponding exons 2 and 3 of the human sequence, with analogous splicing sites and a similar spacing intron of approximately 2 kb. In addition, mouse and rat cDNA sequences share 90% identity. Of note, comparison of human and mouse genomic sequences at www.ensembl.org suggest a structure of the mouse gene that is strikingly similar to that proposed for the human, with three exons: a noncoding exon 1 of 102 bases, an exon 2 with a start codon at base 41 and a final exon 3 harboring the stop codon and polyadenylation site. Likewise, although in the rat gene only two exons, corresponding to human exons 2 and 3, have been annotated, a blast search with the human exon 1 sequence and its corresponding region in the mouse detects a highly similar sequence in the rat genome, located at approximately 7500 bp upstream from the corresponding *Kiss1* gene, which conserves all putative splicing signals. Assuming that such a sequence actually corresponds to the first, noncoding exon of rat *Kiss1*, the structure of human, mouse, and rat genes would be essentially identical. Moreover, in human and rodent species, there is a TATA-box-like sequence located 15–18 bp upstream from the predicted 5′-end of the putatively common exon 1.

Despite the fact that this chapter will mostly focus on the mammalian Kiss1 system, it is stressed here that the analysis of the genomic organization of *Kiss1* in different phyla has revealed the presence of a second form of *Kiss* gene, termed *Kiss2*, which exists in the genome of fish and amphibians, as well as in nonplacental mammals.[1,8,33] In fact, several fish species do have two different *Kiss* genes in their genomes, whereas in some of them, only the *Kiss2* gene has been retained. Moreover, Kiss2-derived peptides have been suggested to play a more prominent role than Kiss1 peptides in the control of the reproductive axis in some fish species.[8] These observations illustrate the complexity and functional diversity of the molecular evolution of kisspeptins in different animal groups.

Processing of the Kiss1 Precursor: Kisspeptins

In the human, the *KISS1* gene encodes a 145 amino acid precursor, which contains a putative 19 amino acid signal sequence, two potential dibasic cleavage sites (at amino acids 57 and 67), and one putative site for terminal cleavage and amidation (at amino acids 121–124).[13,22,25] These structural features predicted the generation of secretory product(s). Indeed, through several proteolytic steps, the full-length KISS1 precursor has been shown to give rise to a number of structurally related, secreted peptides, globally termed kisspeptins.[13,22,25] Among these, the major product of the human *KISS1* gene appears to be a 54-amino acid peptide, largely secreted by the placenta, initially termed metastin or kisspeptin-54.[13,22,23,25] In addition, other derivatives of the KISS1 precursor, such as kisspeptin-14, kisspeptin-13, and kisspeptin-10, have been also identified.[13] Yet, there is an ongoing debate on whether these smaller peptide products are endogenously generated by differential proteolytic processing of the kisspeptin precursor or arise from unspecific degradation of the major product, kisspeptin-54. Notwithstanding, it has been conclusively shown that the shorter 10-amino acid fragment at the C-terminus (kisspeptin-10) retains maximal activity at the receptor level. All kisspeptins share the C-terminal region of the kisspeptin-54 molecule, and harbor an Arg-Phe-NH_2 motif distinctive of the RF-amide peptide family.[13,22,25] Other prominent members of this family have been recently involved in relevant neuroendocrine functions, as reviewed elsewhere in this book (e.g. chapters on ***GnIH/RFRPs*** and ***PrRP***). In rodent species, the overall structure of the Kiss1 precursor and derived kisspeptins is roughly similar. Nonetheless, rat and mouse kisspeptin contains 52 amino acids, where the terminal RF-amide signature is substituted by an Arg-Tyr-NH_2 motif.[22,25]

Distribution of *Kiss1* mRNA/Protein within the Brain

Upon identification of kisspeptins as endogenous ligands for the previously orphan GPR54, expression analyses were conducted to characterize the pattern of *Kiss1* (and *GPR54*) gene expression in normal tissues. Although not totally overlapping, these screening analyses show prominent expression of the *KISS1* gene in human placenta and,

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

at lower levels, in the testis and small intestine. Expression of *KISS1* mRNA is also detected in the human brain, with a scattered distribution throughout the central nervous system, including the basal ganglia and the hypothalamus.[15,23] Similar initial screening was conducted in rodent tissues. Thus, in the rat, the highest levels of *Kiss1* mRNA are in the colon and cecum, with moderate to low expression levels in different peripheral tissues including placenta.[32] In addition, *Kiss1* gene expression occurs is in rat brain and specifically in the hypothalamic area.[16,32] These expression data in the CNS were further extended by in situ hybridization assays that revealed *Kiss1*-expressing neurons at different levels along the rostral–caudal extent of the hypothalamus in the mouse, including the arcuate nucleus (Arc) and the anteroventral periventricular nucleus (AVPV).[29] In addition, *Kiss1* mRNA expressing cells are also detected in the anterodorsal preoptic nucleus, the medial amygdala and the bed nucleus of the stria terminalis, among other areas of the rodent CNS (Fig. 1)[22,25] yet, the physiological relevance of such extrahypothalamic expression remains largely unknown.[25] The expression of *Kiss1* mRNA has been also detected in the Arc/infundibular region of the hypothalamus of primates and humans, and in the Arc in the sheep, just to mention several relevant species.[25,27] Studies in a transgenic mouse line genetically engineered to express the markers green fluorescent protein (GFP) or β-galactosidase selectively in Kiss1 neurons have replicated previous results of *Kiss1* mRNA distribution in the mouse brain, with prominent expression in the Arc and preoptic area, and in different extrahypothalamic sites.[6]

Initial immunohistochemical analyses revealed a wide pattern of distribution of kisspeptin immunoreactivity (Kp-IR) within the CNS, with detectable Kp-IR cell bodies and fibers in different brain areas.[2] Yet, those studies were biased by the use of a polyclonal antiserum against kisspeptin-10, which was later found to crossreact with other peptides of the RF-amide superfamily.[14] However, subsequent studies, conducted mainly in rodent and human species, using more specific antisera have allowed confirmation of the presence of a prominent population of Kp-IR neurons in the Arc/infundibular region (Fig. 1).[14] In addition, in rodents (mainly in female mice), the existence of a subset

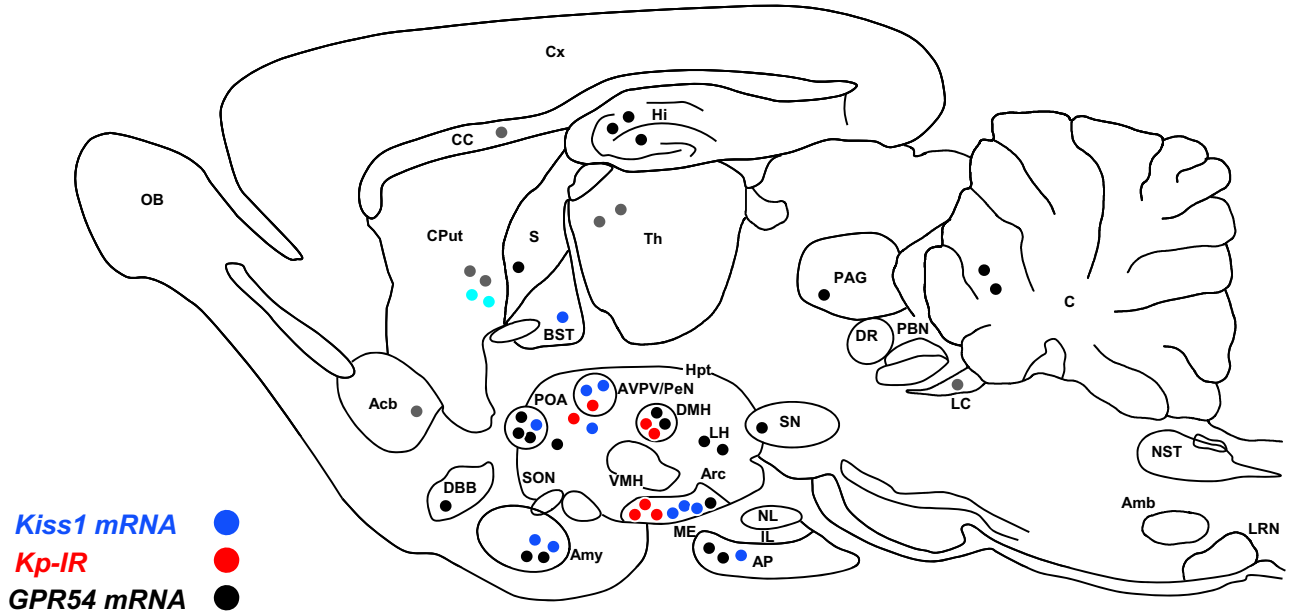

FIGURE 1 Anatomical distribution of *Kiss1* mRNA (*blue dots*), kisspeptin immunoreactivity –Kp-IR- (*red dots*) and *GPR54* mRNA (*black dots*) in the different brain areas of rodent brain. In the mouse and rat, *Kiss1* mRNA expression has been detected in the hypothalamus, mostly in the arcuate nucleus (Arc) as well as in the anteroventral periventricular area (AVPV) and the adjacent periventricular nucleus (PeN). In addition, the presence of *Kiss1* mRNA has been reported in the preoptic area (POA), amygdala (Amy) and bed nucleus of stria terminalis (BST). In addition, the expression of *KISS1* gene has been detected in the basal ganglia in humans (as detected by RT-PCR; denoted by light blue dots). In the rat brain, Kp-IR has been identified mainly in neurons in the Arc and the AVPV/PeN (the latter, especially in the female), with additional signals being detected in the dorsomedial hypothalamic nucleus (DMH), among other CNS areas. In addition, multiple Kp-IR fibers, originating from the Arc and AVPV/PeN populations and projecting to various hypothalamic and extrahypothalamic areas, have been mapped; yet, for the sake of simplicity, these are not specifically depicted in the scheme. Finally, in the rat, *Gpr54* mRNA has been detected in different forebrain areas, including the diagonal band of Broca (DBB), septum, POA, anterior and lateral hypothalamus (LH), and DMH. Likewise, prominent expression of GPR54 has been observed in the hippocampus (Hpt), locus coeruleus (LC), Amy and periaqueductal gray (PAG), among others. The functional relevance of such expression sites remains to be elucidated, except for the POA, where the expression of GPR54 in GnRH neurons has been thoroughly documented. In addition, in the human brain, scattered expression of *GPR54* mRNA has been reported, including basal ganglia –CPut-, Hpt, substantia nigra (SN-) and, at low levels, thalamus (Th-), cerebellum (C-) and corpus callosum. These are denoted by light gray dots. See color plate 31.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

of kisspeptin-positive neurons in the AVPV has been thoroughly documented.[5] Whether this more rostral population exists in other species, including humans, remains contentious. Yet, there is evidence for the presence of a population of Kp-IR neurons in the periventricular area of human hypothalamus.[12] In addition, the patterns of projections of Kp-IR neurons have been characterized in the mouse.[35] Thus, although Arc Kp-IR neurons seem to innervate a wide number of hypothalamic and limbic nuclei, Kiss1 neurons from the AVPV display a narrower pattern of projection that targets a smaller number of medially located hypothalamic nuclei. Among those, AVPV Kiss1 neurons seem to heavily project to the Arc. Although most of the Kp-IR fibers innervating GnRH neurons seem to originate from the AVPV (at least in female rodents), at least 20% of Arc Kiss1 neurons project to the POA,[35] where most GnRH neurons are located, thus providing the neuroanatomical basis for direct communication between these two neuronal populations as well. However, the wide patterns of fiber projection of Kp-IR neurons strongly suggest that Kiss1 neuronal populations are probably involved in the control of various biological functions, including reproductive and nonreproductive systems.[35]

GPR54 as receptor for Kisspeptins: Structure and Signaling Cascades

Using a degenerate PCR strategy and a rat brain cDNA library, Lee and coworkers published in 1999 the identification of an orphan G protein-coupled receptor, with a typical heptahelical conformation and significant identity (>40%) with the transmembrane regions of galanin receptors, which was termed GPR54.[25] The human ortholog of GPR54 was subsequently cloned and named AXOR12 or hOT7T175.[15] In 2001, this receptor was 'deorphanized' as three groups independently reported that kisspeptins are the natural ligands of GPR54.[13,15,23] As was the case for the ligand, expression analyses were conducted to screen the tissue distribution of *GPR54* gene. These showed a rather scattered pattern of expression, with maximal mRNA levels in placenta, pancreas, pituitary, spinal cord, and different brain areas, including hypothalamus, basal ganglia, amygdala, substantia nigra and hippocampus, among others.[25] These observations further suggested the potential involvement of the Kiss1/GPR54 system in the control of diverse biological systems, including different CNS functions. Within the hypothalamus, *GPR54* mRNA was initially reported to be highly expressed in the Arc, the dorsomedial nucleus, and the lateral hypothalamic area (Fig. 1). Interestingly, already in 2004, the expression of *GPR54* mRNA was shown in GnRH neurons in the rat and fish species.[25] In good agreement, a study, in a mouse model that expresses the reporter LacZ gene under the *GPR54* promoter, has confirmed the expression of this receptor in GnRH neurons at the rostral preoptic area.[11] These observations are in keeping with the proposed role of the Kiss1 system as a major gatekeeper of the reproductive axis. Notably, this study also showed that the highest receptor density is located at the dentate gyrus of the hippocampus, with abundant expression, in addition to the preoptic area, at the septum, anteroventral nucleus of the thalamus, posterior hypothalamus, periaqueductal gray, supramammillary and pontine nuclei, and dorsal cochlear nucleus;[11] these are areas where the function of GPR54 signaling remains largely unknown.

Initial analyses of the intracellular signaling systems recruited by GPR54 to convey the biological actions of kisspeptins revealed that, upon ligand–receptor interaction, activation of phospholipase C (PLC) and an increase in PIP_2 hydrolysis take place, which is followed by accumulation of inositol-(1,4,5)-triphosphate, Ca^{2+} mobilization, arachidonic acid release, and phosphorylation of ERK1/2 and p38 MAP kinases.[13] However, those initial signaling studies were conducted in a heterologous system (i.e. Chinese Hamster Ovary K1 cells stably expressing GPR54). Later studies with hypothalamic explants and isolated GnRH neurons confirmed the importance of the above PLC-Ca^{2+} pathway in mediating the biological effects of kisspeptins in a more relevant cellular context in terms of control of reproductive function.[4,25]

Biological Actions of Kisspeptins: Central Control of the Gonadotropic Axis

As indicated in previous sections, the *Kiss1* gene was initially labeled as metastasis suppressor and its major product was originally named metastin because of its proven ability to inhibit tumor metastasis and progression.[23] However, the possibility of additional physiological functions of the Kiss1 system was strongly suggested by the initial reports of the widespread pattern of the expression of *Kiss1* and *GPR54* genes in different peripheral and central tissues. Indeed, based on its biological properties on cell migration and prominent expression in human placenta, locally produced kisspeptins have been proposed to play a role in the physiological regulation of trophoblast invasion.[25] At the CNS, the scattered distribution of *Kiss1* and *GPR54* mRNAs, and of Kp-IR, allowed the speculation of potential roles of kisspeptins in different brain functions, including neuroendocrine regulation.[25] However, up to late 2003, such biological functions remained largely unexplored.

In 2003, two groups independently reported that a number of point mutations and deletions of the *GPR54* gene are found in patients suffering familial (or even sporadic) forms of idiopathic hypogonadotropic hypogonadism,[7,26] a clinical syndrome that was reproduced in mouse models carrying null mutations of the *GPR54* or the *Kiss1* gene.[25] These findings provided conclusive evidence for a major, previously unsuspected, role of the Kiss1 system in the

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

regulation of the development and/or function of the hypothalamic–pituitary–gonadal (HPG) axis.[22,25] Moreover, the above observations underpinned the need for a complete characterization of essential aspects of Kiss1 physiology in the neuroendocrine control of reproduction, including its key biological effects, primary site(s) of action, major signaling pathways, and main regulatory mechanisms. Elucidation of such facets of kisspeptin physiology has attracted considerable attention and research efforts during the last years.

Studies conducted in laboratory animals, initially in rodents and primates and later in other mammalian and non-mammalian species,[22,25] have conclusively shown that kisspeptins are extraordinarily potent elicitors of gonadotropin secretion. The secretory effects of kisspeptins on gonadotropins have been particularly well characterized in rodents; studies that have shown that the gonadotropin-releasing action of kisspeptins are observed both after central (intracerebroventricular) and systemic (intravenous, intraperitoneal, subcutaneous) administration of the peptides.[17,18,22,25] The sensitivity of the gonadotropic system to the stimulatory effect of kisspeptins is documented by the finding that doses as low as 1 pmol of kisspeptin-10 injected centrally, or 75 pmol injected systemically, are able to robustly increase serum LH levels.[18] Notably, FSH secretory responses to kisspeptin appear to be approximately 100- to 200-fold less sensitive than those of LH [17] (Fig. 2). Comparison of the releasing effects of kisspeptins with those of other neuropeptides and neurotransmitters indicates that kisspeptins are probably the most potent stimulator of the gonadotropic axis known so far.

Numerous studies have now addressed the mechanisms and site(s) of action whereby kisspeptins conduct the above stimulatory effects. Based on the proven expression of *Kiss1*/Kisspeptin and GPR54 in the hypothalamus, a primary site of action at this level was already suggested in the original reports underscoring the essential role of the Kiss1 system in the control of the reproduction. Indeed, direct stimulatory actions of kisspeptins upon hypothalamic GnRH neurons, as the pivotal element driving the gonadotropic axis, has been well documented in rodents.[22,25] The observation that hypothalamic GnRH content is preserved in GPR54-null mice strongly suggests that kisspeptin signaling is not critically involved in the process of GnRH neuron migration from the olfactory placode that occurs during development, but rather it plays a role in the control of GnRH secretion.[22,25] Such a contention is indirectly supported by the initial observation that the potent LH releasing effect of kisspeptin is blunted by pretreatment with a GnRH antagonist.[22,25] Similarly, the demonstration of GPR54 expression in GnRH neurons and the stimulatory effects of kisspeptin-10 on GnRH release, both *in vivo* and ex vivo, provides further support to the hypothesis that GnRH neurons are direct targets of kisspeptins.[22,25] This contention is in keeping with neuroanatomical results showing close appositions between Kiss1 and GnRH neurons, as documented in rodent and primate species.

In addition to the hormonal tests described above, a wealth of expression and functional analyses has now documented a prominent role of the Kiss1 system in key aspects of the maturation and function of the reproductive axis. Although thorough revision of such aspects of kisspeptin physiology clearly exceeds the scope of this chapter, Kiss1 neurons have been proposed to be involved in virtually all crucial facets of reproductive maturation and function, from brain sexual differentiation to puberty onset and feedback regulation of gonadotropin secretion.[22,25] A few paradigmatic examples are described in detail below.

Hypothalamic expression of Kiss1 gene seems to be developmentally regulated with increased expression at the

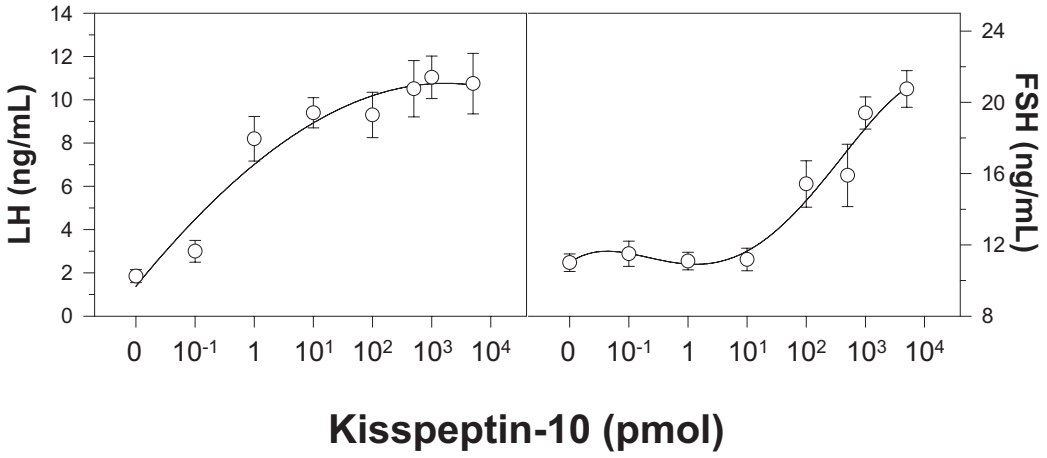

FIGURE 2 Analysis of the effects of central administration of KiSS-1 peptide upon serum LH and FSH levels. A range of doses of KiSS-1 (100-fmol, 1-, 10-, 100- and 500-pmol, 1- and 5-nmol) were tested (icv injection). Calculation of the mean effective dose (ED_{50}), as determined by nonlinear regression, indicates that LH secretion is approximately 100- to 200-fold more sensitive to the stimulatory effect of kisspeptin than FSH.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

time of puberty, in both rats and primates.[16,27] This observation suggests a role of the Kiss1 system in the timing of puberty onset in mammals, in keeping with the original observations of impuberism in humans and mouse models with inactivating mutations of GPR54 (or Kiss1). Indeed, this contention has been corroborated by functional studies that have demonstrated that the administration of kisspeptin-10 is able to induce precocious activation of the reproductive axis in immature female rats,[19] whereas blockade of kisspeptin signaling by the use of a specific antagonist delays it.[24] All in all, these observations highlight the prominent role of the Kiss1 system in the control of the timing of puberty.

Similarly, the expression analyses strongly suggest that the Kiss1 system plays a key role in mediating the classical negative feedback effect of sex steroids on gonadotropin secretion, as hypothalamic expression of the *Kiss1* gene significantly increases in various mammalian species after gonadectomy, whereas testosterone and estradiol replacement fully prevents such a response (as documented in rodents, among other species).[22,25] Interestingly, in situ hybridization assays already showed in 2004 that such a negative regulation of hypothalamic *Kiss1* gene expression takes place in the Arc, an area classically recognized as pivotal for the negative feedback actions of sex steroids.[22] In contrast, in rodents, it is well characterized that at the AVPV, *Kiss1* mRNA decreases after gonadectomy and increases after sex steroid replacement.[29] Considering that the AVPV, which is a sexually dimorphic nucleus with far more *Kiss1*-expressing neurons in the female, has been involved in mediating the positive feedback effect of estrogen upon GnRH and LH surges, it has been proposed that Kiss1 neurons at this nucleus are involved in the generation of the preovulatory gonadotropin surges via positive regulation of GnRH secretion.[22,25] This contention is supported by the observation that antagonism of kisspeptin signaling perturbs the occurrence of the preovulatory surges of LH and FSH.[24] In the same context, the hypothalamic expression of the *Kiss1* gene is also sensitive to the organizing effects of estrogens during critical periods of brain sex differentiation.[16,25] This phenomenon might contribute to the sexually dimorphic content of Kiss1 neurons within the hypothalamus (females >>> males), and opens up the possibility that decreased expression of *Kiss1* at the hypothalamus, as observed after neonatal estrogenization, may be a causative factor for the plethora of developmental and functional defects of the gonadotropic axis that take place after early exposure to pharmacological doses of estrogenic compounds.[16,25]

Although the role of the Kiss1 system as an essential gatekeeper of reproductive function is now undisputed, the eventual interplay of kisspeptins with other central transmitters with proven regulatory effects on the GnRH/gonadotropic axis remains incompletely characterized and is likely to draw considerable attention in the coming years. It is particularly exciting that Kiss1 neurons in the Arc coexpress the neuropeptide neurokinin-B (NKB), and that mutations of the genes encoding either NKB (*TAC3* in humans) or its receptor (*TACR3*) induce a state of HH similar to that of GPR54 inactivation.[21] These observations have prompted the conduction of a number of experimental studies that have documented the ability of the NKB agonist, senktide, to stimulate gonadotropin release (as surrogate marker of GnRH secretion) and that have led to the proposal that NKB participates in the autoregulation of kisspeptin output from Kiss1/NKB neurons onto GnRH neurons, thereby playing a role in the dynamic control of GnRH pulsatility.[20,21]

Peripheral Biological Actions of Kisspeptins: Reproductive and Nonreproductive Roles

The expression of *Kiss1* and *GPR54* at additional levels of the hypothalamic–pituitary–gonadal axis makes it possible that kisspeptins could operate at other (extrahypothalamic) sites to regulate reproductive function.[25] This is the case of the pituitary, where expression of Kiss1/kisspeptins and GPR54 has been documented in various species. However, the assessment of the direct biological effects of kisspeptins at the pituitary level in the control of gonadotropin secretion has received limited attention to date. Nonetheless, studies in rodent, primate, ovine, bovine, and fish species have now documented the ability of kisspeptins to modulate LH secretion directly at the pituitary level,[25] where kisspeptin-10 has been shown to induce calcium responses in gonadotrops both in rat and nonhuman primates. Admittedly, however, other studies in adult rodents have failed to find direct gonadotropin responses to kisspeptins and the physiological relevance of such direct pituitary actions in the generation of the preovulatory surge of LH has been questioned in sheep.[25] Although the causes for the above discrepancies remain unclear, kisspeptins can induce GH secretion directly at the pituitary level in rats and nonhuman primates, thereby suggesting a potential role of kisspeptins in the control of the somatotropic axis, whose physiological relevance is yet to be defined.

In addition to their potential roles at the pituitary, expression of the elements of the Kiss1 system has been also described in the gonads, where kisspeptin may also participate in the direct regulation of specific gonadal functions. This phenomenon has been well documented in the ovary, where the expression of *Kiss1*/*KISS1* and Kp-IR has been shown in rat, monkey, and human.[3,9] Interestingly, *Kiss1* mRNA levels in the rat ovary fluctuate according to the stage of the cycle, with prominent expression during the preovulatory phase that is apparently driven by the ovulatory surge of gonadotropins.[3] In addition, recent analyses in a rat model of ovulatory dysfunction induced by inhibition of prostaglandin synthesis show a marked suppression of ovarian *Kiss1* mRNA levels during the ovulatory period coincident with

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

altered ovulatory dynamics.[9] Furthermore, Kp-IR has been documented in various ovarian compartments, including theca cells, corpora lutea and the interstitial gland in rat and primate species. Although all the above evidence strongly suggests a putative role of locally produced kisspeptins in the control of ovarian physiology, the actual relevance, if any, of such local functions remains to be defined.

Finally, besides human and rodent placenta, the expression of Kiss1/kisspeptins and GPR54 has been documented in a number of peripheral tissues including, among others, blood vessels, adrenals, adipose tissue, kidney and pancreas. Although functional studies have suggested potential roles of kisspeptin signaling in these peripheral tissues, such as the control of vasomotor tone and blood pressure, glucose homeostasis and even renal development, the physiological relevance of such peripheral, nonreproductive functions of kisspeptins remains obscure. Similarly, although kisspeptins were initially cataloged as antimetastasis factors, and the loss of *KISS1* expression has been regarded as bad-prognosis factor in several tumors, the actual role of kisspeptins in the prevention of cancer spread needs to be further clarified.

PATHOPHYSIOLOGICAL IMPLICATIONS

As indicated in previous sections, identification and characterization of the Kiss1/GPR54 system as pivotal element in the neuroendocrine network controlling the reproductive axis is an illuminating example of the power of bedside-to-bench research, where the finding of disease-causing mutations in the *GPR54* gene has led to the systematic analysis of different aspects of kisspeptin physiology.[22,25] Because of these features, it is obvious that perturbation of the Kiss1 system poses pathophysiological implications in terms of reproductive health. Thus, initial reports identified several inactivating mutations of the *GPR54* gene associated with the lack of puberty onset and hypogonadism of central (hypothalamic) origin. These included the homozygous deletion of 155 nucleotides around intron IV-exon V junction, the homozygous L148S mutation, and different compound heterozygous (R331X and X399R; C223R, and R297L) mutations.[25] Additional inactivating mutations in the *GPR54* gene reported to date include an insertion at 1001_1002C, with subsequent change in open-reading frame, a L102P mutation, and a combined insertion/deletion mutation at the 3′ splicing acceptor site of exon 2. Likewise, a new homozygous mutation involving a pF272S substitution in the *GPR54* sequence has been recently described in cases of hypogonadotropic hypogonadism. A summary of the inactivating mutations of *GPR54* gene reported to date is provided in Fig. 3. Notably, the first *KISS1* gene mutation causing central hypogonadism has been published very recently, Moreover, more recent studies have described for the first time suspected activating mutations of *KISS1* and *GPR54* genes in humans. Thus, two different

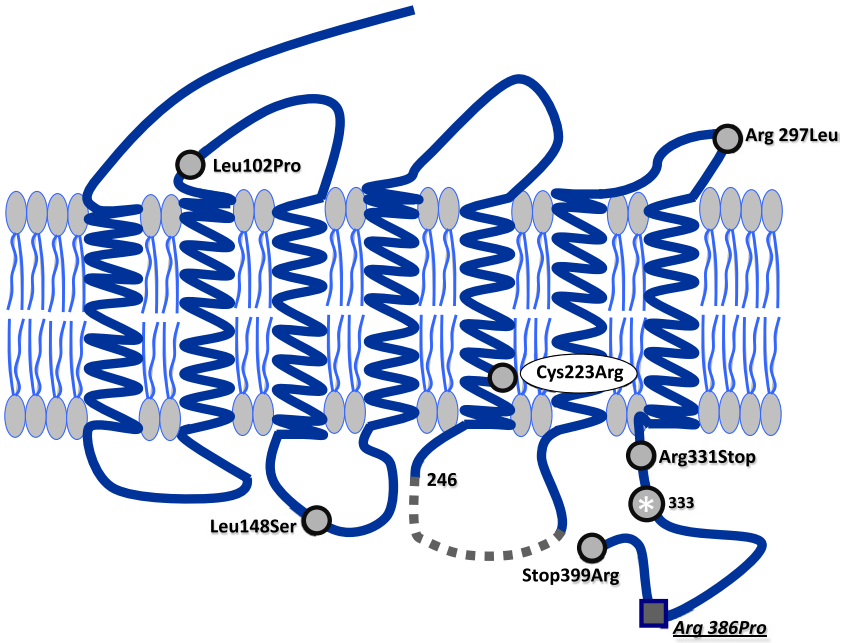

FIGURE 3 Schematic representation of deletions and disease-causing mutations of *GPR54* gene reported so far in humans. Inactivating mutations are indicated as *black dots*, with reference to the reported amino acid substitution. In addition, the location of the predicted deletion reported by de Roux et al. is marked as *gray dots*, while the position of the predicted insertion (1001_1002insC), which results in a shift of the open-reading frame is denoted by an *asterisk*. Finally, the only activating mutation of GPR54 described so far in humans, as potential cause for precocious puberty, is denoted as an open square. See color plate 32.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

missense mutations, causing P74S and H90D substitutions, have been reported in the *KISS1* gene in a cohort of children with central precocious puberty.[28] Yet, whether these mutations are the sole cause for the striking clinical phenotype of the affected individuals is yet to be clarified. On the other hand, the first case of an activating mutation of *GPR54* has been also reported[30] (Fig. 3). This consists of a R386P substitution that does not cause constitutive activity of the receptor but rather prolongs its pattern of intracellular IP response upon stimulation. Again, further studies are needed to conclusively show that such a receptor mutation is fully responsible for the state of precocious puberty of the affected child.

From an epidemiological standpoint, initial analyses already suggested that the frequency of *GPR54* null mutations as a cause for hypogonadotropic hypogonadism is rather low; a contention confirmed now by different genetic studies in various human populations. Nonetheless, besides obvious physiological implications (see previous Sections), identification of inactivating mutations of GPR54 as a causative factor for reproductive failure has helped to expand our knowledge on the molecular basis of some forms of infertility. In this sense, *GPR54* and *KISS1* enlarge the set of genes (such as KAL1, steroidogenic factor 1, DAX-1, GnRH receptor, GnRH and leptin, just to mention but few) whose inactivation had been previously linked to hypogonadotropic hypogonadism. In addition, taking into account the apparent widespread pattern of the expression of GPR54 and kisspeptins in central and peripheral tissues and their proposed biological roles (e.g. control of tumor progression and metastasis), further analyses are needed in affected humans and corresponding null mouse models to evaluate in detail whether mutations of this system can cause additional nonreproductive phenotypes. Overall, complete characterization of the panel of *GPR54*, and eventual *KISS1*, gene mutations inducing clinical alterations of sexual development and function will help to elucidate not only the molecular basis of some forms of reproductive pathology, but also the whole array of physiological roles and pathophysiological implications of this recently discovered, and critically important ligand–receptor system.

Chapter 110

MCH

Françoise Presse and Jean-Louis Nahon

ABSTRACT

Melanin-concentrating hormone (MCH) is a cyclic peptide highly conserved in vertebrates, which was originally characterized as a neurohypophyseal skin-paling factor in teleosts. In fishes, MCH participates also in the regulation of the stress response and feeding behavior. Mammalian MCH is a hypothalamic neuropeptide that displays multiple functions, mostly controlling feeding behavior and energy homeostasis and regulating sleep, the stress axis, emotion, and reward processes. The MCH precursor may generate additional putative peptides in the brain and peripheral organs but their roles remain elusive. In mammals, alternative splicing and antisense transcription at the *MCH* gene locus lead to the production of novel proteins, whereas variant *MCH* genes are found only in primates. Two G protein-coupled MCH receptors are found in fish and primates, whereas a single one appears functional in rodents. Transgenic mouse models and pharmacological studies show the importance of the MCH signaling pathway as a potential target to treat appetite disorders and obesity and also anxiety and psychiatric diseases.

DISCOVERY

The existence of a paling factor present in the pars tuberalis of amphibia that would regulate skin pigmentation in response to environmental changes in lower vertebrates was first proposed by Hogben and Slome in 1931.[18] Although this concept never received any experimental support in amphibians, melanin-concentrating activity was firmly established in teleosts with the demonstration of pituitary control of teleost melanophores by a paling neurohypophysial hormone. The development of *in vitro* teleost scale bioassays allowed functional characterization and purification of the hormone. Indeed, based on a Tilapia scale bioassay, Kawachi et al.[19] purified melanin-concentrating hormone (MCH) from pituitary glands of chum salmon (*Oncorhynchus keta*) and characterized its structure. Sequence analysis revealed that MCH is a 17 amino-acid peptide with one disulfide bond (Fig. 1). This seminal work paved the road for immunocytochemical localization, structure–activity studies, and investigation of MCH function and regulation, apart from its pigmentary action, in fish models.[4,5,10,16,32]

Thereafter, the availability of salmon MCH (sMCH) antisera facilitated the characterization of the MCH counterpart in higher vertebrates. Thanks to the strong expression of MCH-like peptide in the rat hypothalamus and using the sMCH RIA, Vaughan et al.[33] isolated the rat MCH and established its sequence. Rat MCH is a cyclic nonadecapeptide that displays strong structural similarity with the fish peptide but an N-terminal extension and four additional substitutions (Fig. 1).

The role of MCH in mammalian systems remained elusive until 1996 when MCH mRNA expression studies revealed striking overexpression in obese leptin-deficient (*Ob/Ob*) mice and after fasting.[29] Intracerebral injections of MCH further revealed an acute orexigenic effect in the rat that was confirmed in several laboratories.[27] The importance of the MCH neuronal system in the regulation of feeding behavior, body weight, and energy homeostasis is by far the most documented. However, MCH is also involved in the control of a broad spectrum of cerebral and peripheral functions.[1,2,5,16,17,20,21,24,27]

Cloning of the cDNAs encoding the MCH precursor in teleost fishes, then in rats and humans, opened the era of molecular characterization of *MCH* gene structure and expression. Most of this research concentrated on mammalian genes and led to the discovery of additional putative peptides generated from the MCH precursor, a spliced variant of the MCH primary transcript, a natural antisense *MCH* gene and a family of "variant" *MCH* genes that arose lately in the Hominidae lineage.[13,17,24] All these *MCH* gene-derived products may have functions, distinct from MCH effects, which are still to be defined.

A long-awaited achievement was the cloning and functional characterization in cellular and animal models of two MCH receptors, both members of the G protein-coupled receptor (GPCR) family.[9,15,17] The first MCH receptor, MCH-R1, was isolated by a reverse-pharmacological strategy and was found in all mammalian species, whereas the second, designated here MCH-R2, was identified by computer data mining and seemed to be absent in rats and mice

but present in other mammalian species, including primates. Because MCH-R1 *per se* seems to mediate MCH actions in the regulation of food intake and energy expenditure, several pharmaceutical companies have developed a diverse array of MCH-R1 antagonists. Preclinical studies with MCH-R1 antagonists are still limited but provide some evidence that non-peptidic MCH-R1 antagonists represent attractive molecules for the treatment of obesity, metabolic syndrome, drug addiction, sleep disorder, and anxiety in humans.[11,22,23]

STRUCTURE OF THE PRECURSOR mRNA/GENE

Two *MCH* genes and/or corresponding mRNAs have been originally cloned and sequenced from salmonids, tilapia, bonito, eel, and flounder.[16,24] Both were intronless and displayed the highest level of substitutions when compared within the same species rather than among other species, in agreement with early tetraploidization during teleost fish evolution (Fig. 2A). The salmonid and tilapia/flounder pre-proMCHs are 132- and 135 amino acids long, respectively, with the MCH peptide located at the C-terminus. In contrast with the strong conservation in the MCH region between teleost fish species, the remaining part of the precursor displays marked sequence divergences.[6,10] However, additional putative peptides could be generated from the teleost fish proMCH and named MCH-gene-related peptide (Mgrp) in tilapia, Neuropeptide-E (glutamic acid)-V (valine) (NEV) in chum salmon, or Neuropeptide-A(alanine)-L (leucine) in barfin flounder but their functional importance, if any, remains elusive.[16,24] Recently, a second MCH gene was identified in the zebrafish, fugu, three-spined sticleback, and medaka.[6] This gene, named *Pmch2*, shares striking resemblance with the mammalian *MCH* gene in terms of structure, synteny, and peptide sequence. Two different MCH peptides can be expressed in distinct regions of the zebrafish hypothalamus. Although both MCH peptides could play a role in pigmentation,[35] preliminary functional studies in zebrafish indicate that *Pmch2* could be selectively involved in food intake regulation,[6] as in mammals (discussed later).

The sequence of the single gene encoding the full MCH precursor comprises three exons and two introns and exhibits high conservation in mammalian species (Fig. 2B). In humans, this gene is located on chromosome 12q24 covering about 1.4 kb of genomic DNA. The first exon encodes the 5′-untranslated region of the mRNA and the N-terminal part of proMCH including the signal peptide that allows targeting to the secretory pathway. The second exon consists of the sequence corresponding to putative neuropeptide(N)-glycine(G)-glutamic acid(E) (NGE), neuropeptide(N)-glutamic acid(E)-isoleucine(I) (NEI), and the first three amino acids of MCH. The last 15 amino acids of MCH and the 3′-untranslated amino acids are localized in exon III. Intron B splits the methionine codon with the nucleotides A on exon II and the TG on exon III. This intronic organization is identical in the rat, mouse, and primate *MCH* genes. This unusual intron position for a neuropeptide encoding gene is of primary importance to generate by alternative splicing a short mRNA encoding a protein named MCH-gene-overprinted-polypeptide (MGOP)[3] (Fig. 2C). Rat/mouse MGOP contains 125 amino acid residues and shares an identical N-terminal part with the MCH precursor (encoded by exon I of the *MCH* gene) but lacks NGE and NEI (encoded by exon II of the MCH gene) as well as MCH that is replaced by a new C-terminal part (resulting from a shift in the reading frame within exon III of the MCH gene). Structural analysis of MGOP-IR and distribution in the rat and mouse brain revealed a strict colocalization with MCH in neurons of the zona incerta/lateral hypothalamus and a unique expression of an MGOP-like antigen that was characterized as the prosomatostatin$_{1\text{-}64}$, in neurons of the hypothalamic periventricular nucleus and other brain areas.[3] The role of MGOP in the brain remains elusive.

In addition to the *MCH/MGOP* gene, two other *MCH*-gene-related transcription units were found in mammalian genomes. First, the characterization of high molecular weight transcripts recognized by MCH cDNA/oligoprobes in the pheochromocytoma PC12 cell line and rat tissues revealed the existence of "natural" antisense RNAs transcribed from the genomic region complementary to the *MCH* gene. This new gene was named AROM for Antisense-RNA-Overlapping-MCH.[8] Two major classes of RNAs seem to be produced from the AROM gene: (1) noncoding unspliced RNAs overlapping exon II/exon III and flanking intronic/regulatory sequences of the MCH gene; (2) alternatively spliced mRNAs complementary to the 3′-flanking region of the MCH gene and coding for a new family of RNA/DNA binding proteins. Because of the reciprocal regulation of MCH and AROM gene expression in PC12 cells, it is

Black box indicates the MGOP-specific C-terminus due to exon II skipping and ORF frameshift in exon III.

tempting to speculate that AROM mRNA and/or proteins may control MCH gene expression, but this remains to be directly tested.

A decade ago, we provided evidence for the emergence in higher primates of two chimeric genes.[13] These genes were named *PMCHL1* and *PMCHL2*, genes based on partial homology with the authentic *MCH* gene, and were found respectively on human chromosome 5p14 and 5q13, that is, located on chromosomal regions clearly distinct from those of the genuine *MCH* gene. Detailed structural expression and phylogenetic analyses showed that the *PMCHL1* gene was created about 25 million years ago (mya) by a complex mechanism of exon-shuffling through retroposition of an antisense *MCH* messenger RNA coupled to *de novo* creation of splice sites. *PMCHL2* arose 5–10 mya by an event of duplication involving a large chromosomal region encompassing the *PMCHL1* locus. Interestingly, both sense and antisense transcripts from the *PMCHL1* gene are expressed in different areas of the developing human brain, whereas the *PMCHL2* gene is totally silent in the central nervous system. Further, one of the PMCHL1 mRNAs, encodes a 72 amino-acid protein carrying a putative nuclear localization signal, suggesting an intranuclear function for this *PMCHL1*-gene-derived protein in primates. However, most of the

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

PMCHL1/PMCHL2 mRNAs expressed in primate testis[31] or brain (unpublished data) appear as non-protein-coding RNAs. The *PMCHL1* gene represents a prototype of the so-called "primate specific" genes that are presently under intensive investigation because of their major interest in understanding the basis of human evolution and emergence of novel functions.

PROCESSING OF THE MCH PRECURSOR

Very few studies have attempted to investigate the biosynthesis of the proMCH-derived peptides in teleost precursors.[16] Large molecular weight MCH precursors are produced in the hypothalamus of salmon or trout and are further cleaved to generate intermediate products and mature MCH in the trout pituitary glands. Interestingly, the main intermediate corresponds to the $proMCH_{101–132}$, that is, the NEV-MCH peptide generated after cleavage at a pair of arginine residues at positions 99–100 of the trout MCH precursor.

In the mammalian brain, most of the proMCH-derived peptides are mature MCH and amidated NEI peptides (Fig. 4A). Conversely, fully processed MCH and NEI peptides are lacking or weakly produced in rodent and human peripheral organs (spleen, gut, thymus, and testis) while a large MCH-IR product is found. This large polypeptide was identified as a proMCH intermediate, bearing at least NEI and MCH (Fig. 4B). In this context, the rat $proMCH_{131–165}$ (NEI-MCH peptide) was synthesized and injected icv to investigate the effect on appetite, behavior, and energy metabolism. The NEI-MCH polypeptide exerts long-term inductions in feeding and body weight gain, being much more potent than MCH itself, probably because of better resistance to peptidase degradation.[17] It is attractive to suggest that a similar kind of proMCH intermediate may be either transiently expressed in the brain or produced peripherally under particular physiopathological conditions and may cross the blood–brain barrier to exert sustained MCH-like activity.

The processing of the mammalian MCH precursor by prohormone-convertases (PCs) was examined by recombinant vaccinia virus-infected cellular systems, PC-transfected PC12 cells, and an *in vivo* PC2 KO-mouse model (Fig. 4 B[34]). The main finding was that active PC2 is necessary and sufficient to generate NEI in the mouse brain and in PC12 cells. By contrast, several PCs, including PC1/3, PC2, and PC5/6A, may cleave at the appropriate site to produce MCH either in vaccinia expression systems or in the mouse brain (see the convertase chapters in Peptide Biosynthesis/Processing section of this book). Incidentally, colocalization studies show simultaneous expression of MCH mRNA and PC2 in all MCH-expressing cell bodies of the lateral hypothalamus, whereas only 15–20% of these perikarya contain PC1. Therefore, PC2 is probably the key enzyme that cleaves MCH-precursor to generate MCH and NEI in the brain. The counterpart in peripheral organs remains unknown.

DISTRIBUTION OF THE mRNA/PEPTIDES

The distribution of MCH-immunoreactive (IR) perikarya and projection fields has been established in most vertebrate taxa.[4,16,17,24,32] In fish, MCH neurons are located in three distinct areas, the lateral and posterior parts of the nucleus lateralis tuberis (NLTl and NLTp) and in more dorsal nuclei above the lateral ventricular recess (LVR). The magnocellular MCH expressing neurons of the NLTp predominate in lately evolved actinopterigians, including teleosts, and project massively to the posterior neurohypophysis where MCH is released into the bloodstream to act peripherally as a skin paling hormone. By contrast, the parvocellular MCH neurons of NLTl and LVR are prominent in early evolved vertebrates, including lampreys, and project widely to different brain areas with the exception of the pituitary, suggesting that NLTl/LVR-originating MCH probably acts as a neurotransmitter/neuromodulator. Both MCH neuronal cell groups function differently under white or black environmental challenge in tilapia, rainbow trout, barfin flounder,[4] or medaka.[6,35]

The mapping of MCH-IR neurons in the rat brain revealed two striking features highly conserved in mammals: (1) quite exclusive clustering of MCH neuronal perikarya in the subzona incerta, lateral hypothalamic area (LHA), and posterior hypothalamic area (PHA); (2) extensive distribution of the projections throughout the brain with the notable exception of the cerebellum, external median eminence, and pituitary gland (Fig. 3[7]). Fellmann and Risold's team performed a series of immunocytochemical investigations looking for the differential expression of neurokinin 3 (NK3) receptor and cocaine- and amphetamine-regulated transcript (CART) in MCH neurons and projections.[30] In particular, two MCH cell groups were clearly identified, based on the coexpression of MCH/CART/NK3 (type B neurons) or only MCH (type A neurons). Further, they display very different projection patterns; type A neurons have quite exclusively descending inputs to reach the spinal cord, whereas type B neurons project massively to all known telencephalic areas receiving ascending MCH inputs. Intriguingly, at least four MCH neuronal subpopulations can be distinguished according to their times of genesis during rat diencephalon development, two of them overlapping with type A and type B MCH neurons.

Minor MCH-expressing neuronal groups are also present in extrahypothalamic areas such as the olfactory tubercle and pontine tegmentum in the adult rat (Fig. 3).[7] Transient expression of MCH-containing neurons was identified throughout the embryo development in rats in the lateral

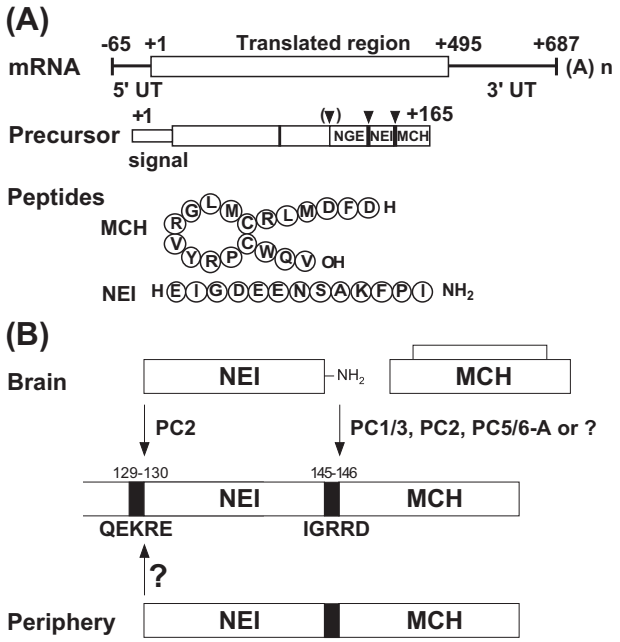

FIGURE 4 Rat MCH precursor processing and peptide production. (A) Rat MCH mRNA structure (as in Fig. 2B) and peptide sequences. (B) ProMCH processing by prohormone-convertases (PCs) in the brain and in peripheral organs. Sequences at the cleavage sites are noted as well as PCs with demonstrated effects on proMCH to generate MCH and NEI. The question mark indicates that the PC involved in MCH precursor processing at the periphery is not yet known.

geniculate nucleus, lateral ZI, PVN, and lateral septum and also in the medial preoptic area and PVN of lactating female rats.[17] The significance of this transient appearance of MCH neurons remains elusive but could be related to similar expression patterns reported for other neuropeptide systems.

RECEPTORS AND SIGNALING CASCADES

The pioneer attempts to characterize MCH receptors were largely based on binding assays with MCH analogs such as (Phe13, Tyr 19)-MCH and allowed the identification of MCH binding sites in different mammalian cell types, including melanoma and neuroblastoma cells.[14] The lack of ligand selectivity in competition experiments, ligand-induced signal transduction pathways associated with these MCH binding sites, and rapid internalization of the radioligand probably through scavenger receptor binding have cast some doubt on the reliability of these putative MCH receptors. However, a functional MCH receptor distinct from the two presently identified MCH receptors (and named MCH-Rpc) can be found in mouse and human melanoma, but its sequence is still unknown.[14]

MCH-R1 STRUCTURE AND SIGNALING

A milestone discovery in the MCH receptor field was the quite simultaneous identification by several laboratories in 1999 of an orphan GPCR called SLC-1 (GPR24) as being a *bona fide* MCH receptor, named here MCH-R1.[9,11,15] This receptor belongs to the class 1 subfamily of GPCRs and displays strong sequence conservation among mammals (91% protein sequence identity between rats and humans). The MCH-R1 gene consists of two exons that encode for a 353 aminoacid protein with seven putative transmembrane

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

domains, three N-glycosylation sites in the N-terminal part, that seem to be necessary for cell surface targeting, and multiple phosphorylation sites in the intracellular loops; some of them, located in its C-terminal tail, are involved in the MCH-dependent internalization of MCH-R1. MCH-R1 is widely and strongly expressed in rat, mouse, and primate brains with a distribution that matches with the MCH projection fields, suggesting that this receptor may mediate most MCH actions in mammals.[11,17]

MCH-R1 signaling has been mostly investigated in stably transfected cells and these studies reveal that this MCH receptor couples to a variety of G proteins, resulting in the activation of multiple signaling pathways. Indeed, in MCH-R1 overexpressing CHO or HEK293 cells, MCH inhibits forskolin-induced cAMP synthesis through a PTX-sensitive mechanism, indicating the coupling to Gαi/Gαo. In the same cellular models, MCH also stimulates IP3 production and transiently increases intracellular Ca^{2+} via Gαq interaction with MCH-R1. Finally, MCH-stimulated MAP kinase activity in transfected CHO cells seems to be mediated through both Gαi and Gαq coupled signaling pathways. Intriguingly, a combination of MCH with forskolin potentiates MAP kinase phosphorylation in HEK293 cells stably expressing MCH-R1 and in the various regions of the rat brain suggesting that a complex interaction between MCH-R1 and receptors coupled to Gαs could be the rule rather than the exception in the mammalian brain. In contrast to these results, the signaling pathways that mediate MCH action in mammalian cells endogenously expressing MCH-R1 remain poorly explored except in neuroblastoma or melanoma cell models.[12,14] Interestingly, both p53 and MAP kinase pathways contribute to mediate MCH effect through genuine MCH-R1 on neurite outgrowth in human neuroblastoma cells,[12] suggesting that MCH may play a role in neuronal cell differentiation and plasticity.

MCH-R2 STRUCTURE AND SIGNALING

The second MCH receptor, named here MCH-R2, was identified in the human genome by using in silico data mining (see the chapter on this in Peptide Biosynthesis/Processing section), and its cDNA was subsequently isolated from human brain cDNA libraries.[17] In contrast to the *MCH-R1* gene, which is intronless in its coding region, *MCH-R2* gene encompasses five coding exons and one noncoding exon and may produce receptor variants by alternative splicing that would lead to a truncated version of MCH-R2. It is noteworthy that human MCH-R1 and MCH-R2 display low sequence identity (only 36%), which is rather unusual for a family of GPCRs that bind an identical ligand, suggesting weak evolutionary constraints. In this context, the *MCH-R2* gene is found in teleots (pufferfish, zebrafish), dog, ferret, and primates (including human), but a functional *MCH-R2* gene is selectively lost in the rodent/lagomorph lineage. This proved to be useful for elucidating the physiological importance of the single MCH-R1 in rats and mice and also hampered the functional characterization of MCH-R2 in available animal models.

In mammals, the overall brain expression pattern of MCH-R2 seems quite similar to that of MCH-R1 but with a more restricted expression to the limbic regions, including medial and central amygdala, enthorhinal and temporal cortex, CA1 of the hippocampus, and to a lesser extent in the ventral hypothalamus and claustrum. In monkeys, MCH-R2 is strongly expressed in the arcuate and ventromedial nuclei. The differential distribution of the two MCH receptors, particularly in the human brain, may indicate distinct biological roles in mediating the large spectrum of MCH effects. In the periphery, weak MCH-R2 expression is detected in pituitary, adipose tissue, and pancreas, which also express MCH-R1, but the precise cellular distribution and functional relevance of MCH-R2 in these organs are presently unknown.

The signaling pathways associated with MCH-R2 activation have been studied only in transfected mammalian cells and proved to be much more restricted than those reported for MCH-R1. Indeed, MCH causes an increase in intracellular free Ca^{2+} levels and IP3 production, but has no effect on basal or forskolin-induced cAMP synthesis. This action is not blocked by PTX treatment indicating that MCH-R2 couples mainly to Gαq. The difference in G protein coupling between MCH-R1 and MCH-R2 could be ascribed to the marked sequence difference in the second and third intracellular loops that are essential for specific G-protein interaction in the GPCR family.

ACTIVE STRUCTURE OF THE MCH PEPTIDE AND RECEPTOR CONFORMATION

There have been numerous studies characterizing MCH analogs for their functional activity initially using fish skin bioassays and more recently cellular models expressing cloned mammalian MCH receptors.[9,10,23] All information converges toward the following model for MCH ligand–receptor interactions: (1) The cyclic peptide fragment ring (MCH 5–14 in fishes and MCH 7–16 in mammals; see Fig. 1) is necessary but not sufficient to get maximal activity; indeed the C-terminal part (mainly the Tyr 15 residue) of the fish peptide and additional amino acids flanking the ring structure (Arg6 and Trp17) in the rat/human MCH are required for agonist potency; (2) only Met 8, Arg 11, and Tyr 13 of the mammalian MCH are essential to elicit full and potent responses with both MCH receptors in binding and functional tests; (3) changes in Arg6, Leu 9-Gly 10, or Gln18 of the rat/human MCH generate peptides that are less efficient in binding or activating MCH-R2 than MCH-R1. In

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

addition, studies using NMR spectrometry, circular dichroism, and molecular dynamics indicate conformational flexibility of the salmon MCH 5–14 core backbone, whereas mammalian MCH exhibits a rather limited variability in the 4–17 region.

Site-directed mutagenesis of the MCH-R1 and comparative molecular dynamics simulations of both MCH receptors in their free and ligand-bound conformation have highlighted the importance of ionic interactions between Arg 11 and Tyr 13 of rat/human MCH and portions of the receptors close to the E/DRY and NPxxY motifs under the active state.

BIOLOGICAL ACTIONS WITHIN THE BRAIN (AND PITUITARY)

Feeding Behavior and Energy Homeostasis

The dominant expression of MCH in the lateral hypothalamus of mammalian brains, the so-called feeding-drinking center, has early suggested that this peptide may regulate appetite and/or energy homeostasis. The role of MCH and MCH-R1 signaling in the control of feeding behavior and energy balance is now firmly established in rodents.[11,15,17,22,25,27–29]

In this chapter, we focus on the most important results regarding the regulation of feeding behavior and energy expenditure by MCH. First, acute icv injections of MCH (>5 μg per animal) transiently stimulate food intake in rats, an orexigenic effect which is not mediated by NPY, galanin, or orexins (also known as hypocretins), but could be blocked by αMSH (see corresponding peptide chapters in the book). Intrahypothalamic injection studies and electrophysiological characterization further identified the PVN, VMH, and Arc as major targets of MCH action, with differential effects in small-litter and overnourished rats. Interestingly, MCH also stimulates water consumption independently from its feeding and water osmolality actions, consistent with the strong adipsia observed in LHA-lesioned rats. Second, chronic icv infusion of MCH in rats or mice induces hyperphagia and body weight gain, especially on a moderate high-fat diet. The development of obesity is accompanied by an increase in liver and fat weights resulting in the lipogenic activity stimulation of white adipose tissue (WAT) and concomitant reduction of brown adipose tissue (BAT) functions. Further, plasma glucose, insulin and leptin levels are also raised in these animals, all these parameters being associated with obesity in men. Third, although acute or chronic icv injections in rodents of MCH-R1 agonists fully recapitulate the feeding and/or obese phenotype observed with MCH itself, central administration of MCH-R1 antagonists leads to a sustained reduction of appetite, body weight, and fat storage without overt alteration of lean mass. Peripheral MCH-R1 signaling may also be involved in this process through regulation of leptin or insulin secretion. Finally, in agreement with the pharmacological data, genetically modified mouse models also showed an important role of *MCH* and *MCH-R1* genes in appetite and, mainly, energy metabolism. Indeed, transgenic mice overexpressing the *MCH* gene develop hyperphagia, mild obesity, and insulin resistance, when maintained on a high-fat diet. Conversely, MCH gene ablation in mice leads to a leanness phenotype associated with hypophagia and an increase in oxygen consumption, both effects being highly dependent on the genetic background and food diet. In this regard, the reduction in body fat observed in mice combining MCH and leptin deficiencies, by crossing MCH null mice and *ob/ob* mice, does not result from feeding behavior changes (the mice remaining hyperphagic) but improvements in energy expenditure regulation (increased locomotor activity and resting metabolic rate). It is worth noting that targeted disruption of the MCH-R1 gene in mice maintained on regular chow also leads to a lean phenotype associated with both hyperphagia on the one hand and increased energy metabolism on the other hand. In agreement with the hyperactive phenotype, MCH-R1 null mice are resistant to high-fat-diet-induced obesity.

Overall, pharmacological studies and animal models have shown that MCH and MCH-R1 neuronal networks play a major role in the control of energy homeostasis by increasing food intake and mostly regulating energy expenditure and thermogenesis in mammals. Interestingly, MCH1 exerts an anorexigenic action in goldfish, whereas fasting selectively induces an increase in MCH2 mRNA expression in zebrafish,[6] suggesting major differences of action between the two MCH systems in teleosts.[5,6] The relative importance of central, neuroendocrine, and local influences versus sympathetic-innervated peripheral regulatory pathways involved in mediating the MCH effects on energy balance under normal and pathological conditions remain to be determined.

Stress Response and Anxiety

In fish, MCH depresses the stress-induced activity of the hypothalamic–pituitary–adrenal (HPA) axis and repeated moderate stress enhances MCH release in the neurohypophysis and *MCH* gene expression in the NLT or LVR groups of MCH neurons, depending on the stress paradigm. Early modulation of LVR-MCH neurons may be related to a central inhibitory action on the HPA axis, whereas the late response of NLT-MCH neurons may be secondary to their regulation on pigmentation. Interestingly, MCH synthesis and release seem to be enhanced under mild stress, whereas intense stress tends to supress MCH production, a regulatory balance that is under plasma glucocorticoid control.[4,5]

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

In mammals, there are conflicting reports regarding the action and regulation of MCH on the HPA axis.[11,17] Indeed, icv injections of MCH in rats either increase or do not modify the basal secretion of ACTH in two separate studies. Results of the intravenous administration of MCH are consistent with a stimulatory effect on the HPA axis. On the contrary, icv-injected MCH inhibits ACTH release after mild stress such as ether or handling; this action can be reversed by the coadministration of NEI or αMSH. In addition, some chronic stressors, such as footshock stress or dehydration, induce a reduction in MCH mRNA expression and/or peptide release, whereas others, such as immobilization or cold stress, do not modify or even stimulate (after fasting for instance) *MCH* gene activity. Similarly, central injections of MCH agonists are either anxiogenic or anxiolytic and MCH-R1 antagonists have antidepressant-like or no anxiolytic effects. Differences in experimental parameters may explain this apparent confusing situation, but we could also consider the diurnal pattern of *MCH* gene expression (and probably peptide secretion) that seems to be higher at night and closely follows plasma glucocorticoid levels and the heterogeneity of the MCH neuronal population (see above). Both parameters could explain differential responses to distinct stimuli or even opposite regulation in MCH subpopulations under a single stress (for instance, a hypertonic saline regimen increases MCH mRNA levels in the ZI and decreases them in the LHA). Finally, MCH may have overt opposite actions in the neuroendocrine systems and in stress-mediated behaviors, a hypothesis that deserves to be carefully explored if MCH antagonists have to be used to treat depression and anxiety disorders.

Reward and Mesolimbic System

MCH neurons are projected massively to the cortex, nucleus accumbens shell (AcSh), and to a lesser extent to the ventral tegmental area (VTA), all major components of the reward control circuit.[7] MCH-R1 was found to be also strongly expressed in neurons containing D1 and D2 dopamine receptors, suggesting that MCH may regulate the mesolimbic system and modulate reward. Accordingly, *MCH-/-* or *MCH-R1-/-* mice carry marked modifications in dopamine release and reuptake and differential sensitization to psychostimulants such as amphetamine or cocaine. An important functional consequence of the alteration of the mesolimbic system in MCH -/- mice is the lack of hyperphagia induced by palatable diet. Administration of MCH-R1 antagonists to the AcSh blocks feeding and induces an antidepressant-like effect while MCH injection leads to opposite actions. Further, MCH signaling blockade with an MCH-R1 antagonist reduces cocaine self-administration and cocaine-induced reinstatement. Collectively, these results strongly suggest that the MCH system is a powerful potentiator of the dopaminergic response in the AsSh neurons and exhibits an important role in the reinforcement and reward processes linked to normal behavior (feeding behavior and stress response) or pathological situations (addiction to drugs).[2,11]

Other Functions

The actions of MCH and/or NEI on a large spectrum of behaviors have been studied in rats or wildtype and transgenic mice. These include sexual behavior, grooming, rearing, aggressive behavior, locomotion, exploratory behavior, learning, and memory formation. It is beyond the scope of this chapter to enumerate these behavioral studies discussed in exhaustive reviews.[1,16,17,24,27] Besides these multiple behavioral effects, evidence suggests that MCH neurons play an important role in sleep–wake regulation.[26] Early studies indicated that icv injection of low doses of MCH (<5 μg per rat) induces paradoxical sleep (PS also termed REM sleep) and slow wave sleep in rats. Reciprocally, MCH neuronal activity (monitored by cFos induction) increases selectively in PS recovery rats. Recently, reciprocal profiles of discharge were found for MCH and orexin neurons across the sleep–wake cycle. Overall, these results suggest a critical role for MCH in the entrance from slow-wave-sleep to paradoxal sleep.

Recent reviews[20,21] consider the local expression and role of MCH and its receptor outside the brain. Indeed, the importance of MCH/MCH-R1 in the digestive tract, adipose and bone tissues, cardiovascular or immune systems, for instance, should be considered in analyzing phenotype alterations in MCH null or overexpressing transgenic mice.

PATHOPHYSIOLOGICAL IMPLICATIONS

Feeding studies and characterization of MCH/MCH-R1 transgenic mice models have boosted interest in MCH as a suitable target for pharmaceutical intervention in the treatment of the obesity syndrome. Most of the efforts focus on the development of small-molecule antagonists for MCH-R1, because of the promising pharmacology of this receptor and the lack of suitable *in vivo* models for testing MCH-R2 -selective antagonists. Initially, a series of peptidic analogs with antagonist activity was generated and proved to counteract the orexigenic effect of MCH agonists but was ineffective alone on feeding behavior. This limited effect and the complications inherent in the use of peptidic analogs as therapeutic tools (blood–brain barrier crossing, sensitivity to peptidase degradation) prompted most of the pharmaceutical and biotech companies working in the obesity field to invest in high throughput and targeting screening for discovering new nonpeptide MCH-R1 antagonists.

The first orally active MCH antagonist in rats was originally isolated by the Takeda group in 2002 and named T-226,296. This compound binds with high affinity to MCH-R1, suppresses the stimulatory effects of MCH on food intake, and significantly decreases feeding and body weight in rats under high-fat diet by reducing meal size but not meal frequency. The T-226296 molecule does not alter locomotor activity or induce malaise in a one-hour test period. These results provide encouraging clues that T-226296 molecule (and derivatives) may be effective in the treatment of overeating disorders.

The second nonpeptide MCH-R1 antagonist, named SNAP-7941, was characterized in 2002 by the Synaptic group. This molecule is a competitive antagonist of MCH with high affinity for MCH-R1 and displays potent anorectic effects when injected intraperitoneally (ip) alone or in preventing the orexigenic effect of MCH. Chronic ip administration of SNAP-7941 in diet-induced obese (DIO) rats suppresses feeding and provokes a sustained weight loss that is reversible after the termination of drug treatment. This compound does not have apparent toxic or aversive actions. Strikingly, oral administration of SNAP-7941 molecule leads to unexpected anxiolytic and antidepressant effects as shown in the rat forced-swim test, rat social interactions, and guinea pig maternal-separation vocalization tests. The potential antidepressant property of SNAP-7941 was independently replicated at the Institut de Recherche Servier and another MCH-R1 antagonist, SNAP-94847, displayed also anxyolytic properties under acute or chronic administration. Interestingly, different MCH-R1 antagonists developed either at Taisho Pharmaceutical Company (named ATC0065 and ATC0175) or in Lilly Research Laboratories (named GW803430) exhibit also antidepressant and anxiolytic effects in rodents after oral administration, without sedation or motor coordination impairment. These results provide further support for an anxiogenic effect of MCH, as found after MCH injection in the medial preoptic area or AcSh in rats, and offer novel approaches to treat depression and/or anxiety. However, conflicting results were reported regarding the role of MCH in the regulation of mood as found for the regulation of the HPA axis. Furthermore, the specificity of the MCH antagonists needs to be systematically evaluated in MCH-R1 null mouse models to preclude the possibility that the *in vivo* activities of these compounds may be mediated by another receptor. Efforts are also needed to identify MCH-R1 antagonists with low affinity for the hERG channel, precluding major side effects associated with cardiac dysregulations.

Because of these pioneering studies, several companies have synthesized, tested, and patented a variety of nonpeptide MCH antagonists acting at MCH-R1 (close to 60 patent applications are presently registered at http://www.xennexinc.com:8080/GeneIP/). As such, the compounds are claimed to be useful in suppressing appetite and in treating or preventing a wide range of diseases, including diabetes, hyperlipidemia, depression, anxiety, and associated somatic symptoms, neurodegenerative and psychiatric disorders, as well as even more distantly related pathologies such as bacterial, fungal, and viral infections. There is no doubt that, among this huge number of compounds, suitable candidates will be identified and subsequently enter clinical trials. However, major questions remain about the role of MCH and MCH-R1 in the control of energy balance (e.g. phenotype discrepancy between MCH and MCH-R1 null mice) and other behaviors (stress response, sexual activity, sleep, and learning). Further, the MCH physiological functions mediated by MCH-R2 in the human brain deserve thorough investigations and the development of suitable animal models.
