Chapter 111

Melanocortins

Sylvie Jégou, Roger D. Cone, Alex N. Eberlé and Hubert Vaudry

ABSTRACT

Melanocortins are a family of related peptides comprising α-MSH, γ-MSH, and ACTH, which all derive from the precursor protein POMC. In the brain, processing of POMC gives rise essentially to α-MSH and γ-MSH. A prominent group of POMC neurons is located in the arcuate nucleus of the hypothalamus, and these neurons project toward multiple brain regions. Melanocortins exert a wide range of biological activities in the brain, including control of feeding, grooming, hyperalgesia, social and sexual behaviors, central regulation of inflammation, fever, and cardiovascular functions, as well as neurotrophic activities. Five melanocortin receptor subtypes (MC1-R to MC5-R) have been characterized. The central effects of melanocortins are mediated through two types of receptors, namely, MC3-R and MC4-R.

DISCOVERY

The term melanocortins refers to a family of structurally related peptides that includes α-melanocyte-stimulating hormone (α-MSH), β-MSH, γ-MSH, and adrenocorticotrophic hormone (ACTH). α-MSH and β-MSH were initially isolated and characterized from the porcine pituitary by virtue of their ability to induce darkening of frog skin.[15] ACTH was first characterized from the ovine pituitary on the basis of its capacity to stimulate adrenocortical activity.[22] Finally, β-lipotropin (β-LPH), whose sequence encompasses β-MSH, was isolated as a side fraction during the course of purification of ACTH from the ovine pituitary gland. The observation that the α-MSH sequence corresponds to the first third of the ACTH molecule and that the β-MSH and β-endorphin sequences are part of β-LPH suggested the existence of a precursor–product mode of biosynthesis for this family of peptides. This hypothesis was confirmed when Nakanishi et al.[26] reported the nucleotide sequence of a cDNA encoding a protein that encompasses both ACTH and β-LPH. This precursor protein, which has the potential to generate the opioid peptide β-endorphin, three MSH sequences (α-, β-, and γ-MSH), and ACTH, was termed proopiomelanocortin (POMC).

The POMC gene is primarily expressed in corticotroph cells of the pars distalis and melanotroph cells of the pars intermedia of the pituitary.[9] Besides, it has long been known that biologically active MSHs are also present in the hypothalamus[34] and that central administration of α-MSH facilitates learning and memory, elicits stretching, yawning and grooming, and induces antipyretic effects,[2,9] suggesting that melanocortins could also act as authentic neuropeptides. The occurrence of the highly potent opioid peptide β-endorphin within the precursor sequence further supported the notion that POMC could generate various neuroactive peptides. Finally, the cloning of melanocortin receptors (MC-Rs)[24] and the demonstration that some members of the MC-R family are expressed in the brain[12,29] confirmed the existence of a brain melanocortin system.

Structure of the Proopiomelanocortin mRNA/Gene

The POMC genes of all species examined so far exhibit essentially the same structural organization with 3 exons separated by 2 large introns.[9] In mammals, the second exon encodes for the signal peptide and the first 18 amino acid residues, whereas the third exon encodes for all bioactive POMC-derived peptides (Fig. 1). In mammals and amphibians, POMC encompasses four melanocortins namely α-MSH, β-MSH, γ-MSH, and ACTH (Fig. 2). In teleost fish, POMC lacks the γ-MSH region, whereas, in elasmobranch fish, POMC contains an additional MSH peptide named δ-MSH that is located between the ACTH and β-MSH sequences. The sequence of the POMC cDNA has been preserved in the regions coding for pro-γ-MSH/γ-MSH, ACTH/α-MSH, β-MSH, and β-endorphin. The POMC sequence is more variable in the regions corresponding to the joining peptide (JP) and the N-terminal portion of β/γ-LPH. Most of the dibasic motifs that are typical cleavage sites for prohormone convertases are conserved across species, except for the Arg^{63} and Lys^{190} of human POMC that are lacking in the rat and mouse POMC

sequences, indicating that, in rodents, γ3-MSH and γ-LPH cannot be further processed to generate γ-MSH and β-MSH, respectively. In contrast to other mammals that have only one POMC gene, the mouse also possesses a pseudogene. Several submammalian vertebrates, including xenopus, salmon, trout, and sturgeon, possess two functional POMC genes.

Processing of Proopiomelanocortin

After the removal of the signal peptide from the precursor protein, the first steps of POMC maturation consist of glycosylation of pro-γ-MSH and ACTH, and phosphorylation of ACTH (Fig. 1), two events that apparently do not affect processing or release of the mature peptides.[9] Then, prohormone convertases 1 and 2 (PC1 and PC2) catalyze differential cleavage of POMC at dibasic or tetrabasic sites in a tissue-dependent manner (see Convertase chapters in the Peptide Biosynthesis/Processing section of this book). Thus, in corticotroph cells of the pars distalis, which only express PC1, cleavage occurs at three Lys-Arg sites to generate the large N-terminal fragment pro-γ-MSH, JP, ACTH, and the large C-terminal peptide β-LPH. In melanotroph cells of the pars intermedia and in hypothalamic POMC neurons, which both express PC1 and PC2, processing of the precursor gives rise to the formation of shorter peptides including (Lys-)γ3-MSH, $ACTH_{1-17}$, corticotrophin-like intermediate lobe peptide (CLIP), γ-LPH, and β-endorphin. (Lys-)γ3-MSH can be further processed to yield (Lys-)γ2-MSH. Carboxyterminal basic residues are trimmed from the cleaved peptides by

carboxypeptidase E. Then, $ACTH_{1-14}$ and (Lys-)γ2-MSH are C-terminally amidated by peptidylglycine-α-amidating-monooxygenase (PAM) to form des-Nα-acetyl α-MSH and (Lys)γ1-MSH, respectively. Finally, Nα-acetylation of des-Nα-acetyl α-MSH and β-endorphin may occur, and this last event profoundly affects the biological activity of the two peptides: mono- and diacetylation of the N-terminal serine residue of des-Nα-acetyl α-MSH generally enhances the biological potency of the peptide, whereas acetylation of the N-terminal tyrosine residue of β-endorphin suppresses its analgesic activity.[2]

Distribution of POMC mRNA and Melanocortins in the Brain

The arcuate nucleus (Arc) of the hypothalamus and the nucleus of the solitary tract (NTS) in the medulla are the only two sites of POMC expression in the rodent brain (Fig. 3 left).[18,27] In primates, POMC expression has been found in the infundibular nucleus but has not yet been reported in the NTS. In rat, the predominant POMC neuronal population is located in the Arc. POMC neurons project ventrally to the median eminence, rostrally to the anterior hypothalamic and medial preoptic nuclei, the nucleus of the stria terminalis, and the lateral septum, dorsally to the thalamic periventricular nucleus and the periventricular, paraventricular, dorsomedial, and posterior hypothalamic nuclei, laterally to the amygdala, and caudally to the substantia nigra, the dorsal raphe nucleus, the periaqueductal gray, the parabrachial nucleus, the locus coeruleus, the nucleus ambiguus, the lateral reticular nucleus, and the nucleus of the solitary tract (Fig. 3, left). NTS POMC neurons project within the nucleus solitarius, as well as to the nucleus reticularis gigantocellularis, the A1 group, and all along the spinal cord (Fig. 3, left).

Melanocortin Receptors and Signaling Cascades

Five subtypes of MC-Rs have been cloned in mammals and termed MC1-R to MC5-R.[32] All MC-Rs belong to the G protein-coupled receptors (GPCRs) superfamily and activate the adenylyl cyclase–protein kinase A pathway via coupling to Gs. MC3-R is also coupled to the inositol phospholipid/Ca^{2+}-mediated signaling cascade. In addition, MC3-R and MC4-R activate the mitogen-activated kinase pathway[28,31] and MC4-R inhibits c-Jun N-terminal kinase.[6] In the hypothalamic cell lines GT-7 and GT1-1, MC4-R activates pertussis toxin-sensitive $G_{i/o}$ proteins and increases intracellular Ca^{2+} through Gq/phospholipase C-dependent signaling pathways, respectively.[4] Like many other GPCRs, MC-Rs can form dimeric or oligomeric complexes that confer distinct functions both *in vitro* and *vivo*.[3] Furthermore, MC1-R, MC3-R and MC4-R have been reported to have a constitutive activity.[10,28,31] The MC-R subtypes exhibit distinct anatomical distribution and ligand selectivity (Table 1). Thus, MC1-R is expressed almost exclusively in melanocytes and mediates the effects of melanocortins on skin and coat pigmentation. MC1-R is also expressed at a much lower level in some other peripheral tissues, for example, in human adipose tissue, with elevated expression in obese subjects. MC2-R is expressed primarily in adrenocortical cells and mediates the effects of ACTH on corticosteroid secretion. MC3-R and MC4-R both occur in the brain (Fig. 3, right): MC3-R is expressed primarily within the hypothalamus, with limited expression in the thalamus and brainstem. In particular, MC3-R is abundantly expressed in POMC and agouti-related protein (AgRP)/neuropeptide-Y neurons of the Arc.[17,23] MC3-R is not expressed in the hindbrain and spinal cord. Conversely, MC4-R is widely distributed in the CNS including the autonomic centers of the hindbrain and the spinal cord. MC5-R is primarily expressed in exocrine

TABLE 1 Pharmacological Properties and Distribution of Melanocortin Receptor Subtypes

	Agonists potency/endogenous antagonists	Tissue distribution
MC1-R	α-MSH = ACTH > β-MSH >> γ-MSH/Agouti	Melanocytes, keratinocytes macrophages, leukocytes, adipose tissue
MC2-R	ACTH	Adrenal cortex
MC3-R	α-MSH = β-MSH = γ-MSH = ACTH/AgRP	CNS, gut, kidney, testis, ovary, skeletal muscle, placenta, mammary gland
MC4-R	α-MSH = ACTH > β-MSH >> γ-MSH/Agouti, AgRP	CNS
MC5-R	α-MSH > ACTH > β-MSH > γ-MSH	Exocrine glands, muscle, CNS

glands and in skeletal muscle, but low levels of MC5-R mRNA are also found in a few regions of the rat brain notably in the olfactory bulb, cerebral cortex, striatum, and medulla. Two endogenous melanocortin receptor antagonists participate in the control of melanocortin signaling, that is the agouti protein, expressed in dermal papillae, which confers the yellow color typical of agouti mice, and AgRP, mainly expressed in the hypothalamus and adrenal gland, which acts as an orexigenic peptide.[8] AgRP-containing neurons of the Arc project globally to the same hypothalamic and septal regions as POMC-containing neurons (Fig. 3, left), indicating that AgRP can actually modulate melanocortin neurotransmission.

Biological Actions within the Brain

1. Food intake and energy homeostasis

This important function of melanocortins topic is covered in the "Ingestive Peptides" section of this Handbook.

2. Stretching–yawning syndrome and grooming

One of the first reported behaviors induced by intracerebroventricular (icv) injection of melanocortins are the stretching–yawning syndrome (SYS) and excessive grooming.[11,13] The brain regions that respond to local injection of $ACTH_{1–24}$ and α-MSH with SYS and grooming behavior are the hypothalamic periventricular regions surrounding the third ventricle including the paraventricular nucleus, the dorsomedial nucleus, the anterior hypothalamic area, and the ventromedial nucleus.[1] Grooming is also elicited by local injection of $ACTH_{1–24}$ in the periaqueductal gray or the substantia nigra. Excessive grooming is observed when animals are exposed to a novel environment and various studies converge to show the implication of brain endogenous melanocortins in this process. Structure–activity relationships indicate that MC4-R is probably involved in melanocortin-induced SYS[1] and a functional knockout rat model for MC4-R shows that melanocortin-induced grooming is exclusively mediated by MC4-R.[25] Consistent with the findings that melanocortins induce stress-related behaviors in rodents, several pharmacological studies indicate a role of MC4-R in regulation of the activity of the hypothalamic–pituitary–adrenal (HPA) axis. For example, central injection of α-MSH or an MC4-R agonist increases corticotropin-releasing factor expression in the paraventricular nucleus and elevates plasma ACTH and corticosterone levels, and these responses are attenuated by a selective MC4-R antagonist. By contrast, administration of a selective MC3-R agonist has no effect on HPA axis activity.[7]

3. Sexual and social behaviors

Local injection of α-MSH or $ACTH_{1–24}$ in the hypothalamic periventricular region induces penile erection in rats,[1] and MC3-R/MC4-R have been implicated in the modulation of erectile and sexual function.[1,33] Melanocortins also seem to exert their effects in spinal cord as intrathecal administration of the synthetic MC-R agonist MTII induces penile erection in rats. By contrast, icv injection of $ACTH_{1–24}$ or $ACTH_{4–10}$ delays the copulatory behavior in inexperienced male rats, and $ACTH_{1–24}$ reduces sexual performance. In female rats that exhibit a low level of receptivity, α-MSH stimulates lordosis, whereas in receptive females, α-MSH has the opposite effect. Neuroanatomical results provide evidence for a role of hypothalamic MC4-R in the efferent control of rodent clitoris and vagina. Clinical studies show that MC-R agonists can induce transient erections in men with erectile dysfunction and increase sexual desire and arousal in female subjects with sexual disorder.[30,35] The Administration of melanocortins icv generally reduces social interactions and increases aggressive behavior. The same effects are observed when α-MSH or $ACTH_{4–10}$ is injected into the ventromedial hypothalamic nucleus or the septum, respectively. The MC4-R is involved in social interactions and mediates the anxiogenic effect of brain melanocortins. α-MSH in paraventricular and dorsomedial hypothalamic

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

nuclei and in the central nucleus of the amygdala might play a role in these processes.[19] In rodents, peripheral and central melanocortins seem to influence sexual activity and social interactions in a coordinate manner, because circulating α-MSH stimulates the release of pheromone from sebaceous and preputial glands, which in turn influence sexual behavior, while ACTH stimulates the secretion of glucocorticoids, which promote aggressive behavior.

4. Antipyretic and anti-inflammatory activities

Central administration of α-MSH provokes marked antipyretic effects in different species.[9,21] In rabbits, α-MSH inhibits cytokine-induced fever and, reciprocally, fever causes an increase in α-MSH concentrations in the septum. In rats, α-MSH reduces lipopolysaccharide-evoked fever, and this effect is antagonized by an MC4-R antagonist. Enhanced febrile responses to interleukin-1 (IL-1) and to endotoxin have been reported in the rabbit and rat after icv injection of either an α-MSH antiserum or an MC3-R/MC4-R antagonist, indicating that endogenous α-MSH actually exerts antipyretic activity. Melanocortins inhibit the hypothalamic production of proinflammatory molecules such as nitric oxide and prostaglandins induced by IL-1β. MC4-R agonists also attenuate brain inflammation and promote neuronal survival.[21]

Melanocortins inhibit different types of inflammatory responses including acute and chronic inflammation and contact hypersensitivity. Injection of α-MSH icv inhibits the response to tumor necrosis factor-α in endotoxin-induced brain inflammation and cutaneous inflammation provoked by the application of cytokines. α-MSH can only reduce inflammation induced in the mouse hind paw when the spinal cord is intact, indicating that α-MSH probably acts through descending neurogenic pathways capable of modulating inflammation in peripheral tissues. A variety of effects of central IL-1β administration are blocked by α-MSH such as activation of the HPA axis and the anxiogenic behavior and memory impairment induced by this cytokine. The protective effect of α-MSH on impairment memory consolidation induced by IL-1β is mediated by MC4-R.

5. Nerve generation and neuroprotection

Perinatal treatment with melanocortins enhances the maturation of the CNS and accelerates maturation of the neuromuscular system. In various peripheral nerve injury models, melanocortins are effective growth factors improving axonal regeneration, muscle reinnervation, and recovery of sensory and motor function.[2,9] In addition, melanocortins stimulate neurite outgrowth in neuroblastoma cells and primary cultures of dorsal root ganglia and spinal cord neurons. The stimulatory effect of α-MSH on Neuro 2A cells is blocked by a specific MC4-R antagonist. Because MC4-R is the only receptor subtype found in the spinal cord and in sympathetic ganglia, MC4-R probably mediates the neurotrophic effects of melanocortins. However, the $ACTH_{4–9}$ analog ORG2766, which fails to activate MC-Rs, also enhances recovery of neuromuscular functions, suggesting that a distinct receptor, which does not belong to the MCR family may be involved. Nerve injury provokes an increase in POMC expression and ACTH/MSH immunoreactivity in mouse spinal cord motoneurons. ACTH/MSH levels are also higher in Wobler mice, which exhibit motoneuron disease, and in diabetic neuropathy. An increase in ACTH binding sites also occurs on diabetic, developing, and dystrophic muscle, suggesting that melanocortins may act as paracrine factors involved in the innervation of muscle, probably through MC5-R which is uniquely expressed in muscle. Melanocortins also exert strong protective effects against damage consequent to global or focal cerebral ischemia in gerbils and rats.[5] Melanocortins act by blocking several ischemia-relayed mechanisms of damage, through the activation of MC4-R, in a broad time therapeutic window and exhibit long lasting effects.

6. Cognitive functions

Melanocortins restore the deficient acquisition of shuttle box avoidance behavior in hypophysectomized rats. ACTH and α-MSH facilitate acquisition and delay extinction of active and passive avoidance responses and of rewarded behavior in intact rats, suggesting that these peptides influence motivation, attention, learning, and memory.[2,9] Although α-MSH and β-MSH have similar positive effects on active and passive avoidance, γ-MSH facilitates extinction of active avoidance and attenuates passive avoidance behavior. The short-chain analog $MSH/ACTH_{4–7}$ is the smallest fragment that exhibits full activity on learning and memory, whereas the minimum sequence required to stimulate MC-Rs is $MSH/ACTH_{6–9}$. Indeed, structure-activity relationship studies strongly suggest that the effects of melanocortins on avoidance behavior are not mediated by a receptor of the MC-Rs family.

7. Cardiovascular effects

Melanocortins exert a variety of effects on the cardiovascular system.[16] Injection of γ2-MSH or $MSH/ACTH_{4–10}$ icv induces a slight pressor effect that is not mediated through any of the identified MC-Rs but may involve FMRFamide-stimulated sodium-gated channel (see the chapter on RFamide peptides in this section of the book), which has affinity for peptides that possess a C-terminal Arg-Phe-NH_2 sequence like γ1-MSH. Microinjection of γ2-MSH into the caudal part of the NTS causes bradycardia and reduces blood pressure through reduction in sympathetic nervous system activity. A depressor effect is also observed when α-MSH is injected in the dorsal motor nucleus of the vagus nerve or the NTS where MC4-R is abundantly expressed, and the

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

response is blocked by an MC4-R antagonist indicating that the depressor activity of melanocortins is probably mediated by MC4-R. Stimulation of POMC neurons in the Arc has a depressor effect that is mediated through the dorsal vagal complex, suggesting that endogenous melanocortins may play a role in the control of cardiovascular functions. However, other mechanisms for central cardiovascular regulations by melanocortins are probably involved because icv administration of α-MSH leads to increased mean arterial pressure and heart rate, concomitant with the increase in the lumbar sympathetic nerve activity. Mice lacking MC4-R do not exhibit a cardiovascular response to icv injection of α-MSH, providing evidence for MC4-R implication in these effects. Clinical studies indicate that the prevalence of hypertension is lower in MC4-R-deficient patients than in control subjects with a similar obesity. Administration of a highly selective MC4-R to overweight or obese volunteers leads to an increase in systolic and diastolic blood pressure.[14]

8. Interactions with opiates

The melanocortin and opiate systems have opposite activities in many tests and may be considered as functional antagonists.[2] Central administration of α-MSH and ACTH causes hyperalgesia in various pain models and reverses the analgesic effect of morphine and β-endorphin. The antinociceptive response of morphine is antagonized by an MC-R agonist and potentiated by an MC4-R antagonist. Administration of melanocortins icv in morphine-dependent rats precipitates a typical opiate-withdrawal syndrome, whereas central injection of an MC4-R antagonist prevents morphine tolerance and withdrawal hyperalgesia.[20] Reciprocally, chronic administration of morphine downregulates the expression of POMC in the hypothalamus and MC4-R in the striatum and periaqueductal gray, two regions implicated in drug reward and withdrawal. Melanocortinergic and opioidergic systems also interact in the regulation of food intake. Opioid antagonists can block feeding induced by AgRP, whereas icv β-endorphin-induced feeding is reduced by pretreatment with a melanocortin agonist.

Physiological and Pathophysiological Implications

Cloning of MC-Rs, studies with genetic models, and development of selective MC-R ligands have opened new perspectives for the comprehension of the physiological roles of melanocortins. In particular, the role of α-MSH, MC3-R, and MC4-R in feeding and energy homeostasis as well as sexual activity has received a great deal of attention and has provided a framework to explore the melanocortin system for the treatment of obesity or other metabolic disorders, and sexual dysfunctions. Indeed, an MC-R agonist has proven to be effective in treating erectile dysfunction and increasing sexual desire and arousal in women in clinical trials.[30,35] The recent development of a selective, nonpeptide MC4-R antagonist has revealed that MC4-R plays an important role in stress responses and in the regulation of emotional states, suggesting that blockade of MC4-R may be of therapeutic value for the treatment of stress-related disorders such as anxiety and depression.[7] Moreover, antagonists of MC4-R may be regarded as possible therapeutic modulators of nociception and morphine tolerance.[20] α-MSH acts centrally to inhibit fever and inflammation, and a number of potential therapeutic targets for melanocortins have been proposed based on preclinical investigations in inflammatory disorders, such as acute and chronic inflammation diseases, brain inflammation, neurodegenerative diseases, and systemic host reactions.[5]

Chapter 112

MIF-1/Tyr-MIF-1

Abba J. Kastin and Weihong Pan

ABSTRACT

The MIF-1/Tyr-MIF-1 family of peptides has served to introduce several novel concepts into the field of biologically active peptides. The best known of these showed that most peptides can cross the blood–brain barrier in intact form by quantifiable transport systems. Some, like MIF-1 but not Tyr-MIF-1, enter the brain by a saturable process and a few, like Tyr-MIF-1 but not MIF-1, leave the brain by a saturable process. MIF-1 established the existence of antiopioid peptide actions, leading to the substantiated prediction that other peptides would be found with similar antiopioid actions. MIF-1 was also the first hypothalamic peptide shown to act on higher centers of the brain, including clinical effects in Parkinson's disease and mental depression. Thus, this family of small peptides has served a prototypic function.

Discovery of MIF-1: The search for the mammalian hypothalamic factor controlling the release of melanocyte-stimulating hormone (MSH; melanocortin) did not begin until one of us decided to look for the hypothalamic regulation of what was then the only mammalian pituitary hormone whose release was not being actively investigated.[14] After determining that unlike most pituitary hormones, the primary release of MSH was inhibited by the hypothalamus rather than being stimulated, the tripeptide Pro-Leu-Gly-NH_2 was isolated from bovine hypothalamic tissue and named MSH-release inhibiting factor (MIF).[26] Others also found MIF to inhibit MSH release in mammals,[29,31] but since it did not seem to do this robustly in all situations the numeral "1" was added to the abbreviation, resulting in its designation as MIF-1. Essentially no further work was done on this subject until 2009 when more sophisticated mass spectrometric quantification of this tripeptide using triple quadrupole multiple reaction monitoring established the natural occurrence of MIF-1 in the hypothalamus as well as elsewhere in the brain.[25]

Discovery of Tyr-MIF-1 and related peptides: Most radioimmunoassays involve the labeling of a peptide with radioactive iodine, but MIF-1 does not contain easily iodinated amino acids. To facilitate early research with MIF-1, Tyr was added to the N-terminal of MIF-1, resulting in Tyr-MIF-1 (Tyr-Pro-Leu-Gly-NH_2). Surprisingly, use of the resulting assay revealed that Tyr-MIF-1-like immunoreactivity was widely present in the rodent brain. The assay then was used in the isolation of Tyr-MIF-1 from bovine hypothalamus[12] as well as human brain tissue obtained many hours after autopsy.[13] Use of a sample of fresh human brain showed a 500-fold increase in the amount of Tyr-MIF-1 isolated. Tyr-W-MIF-1 (Tyr-Pro-Trp-Gly-NH_2) was first isolated from human frontal cortex,[11] as was Tyr-K-MIF-1 (Tyr-Pro-Lys-Gly-NH_2), and then from bovine hypothalamus.

Precursor/processing of MIF-1: Many years ago it was shown that MIF can be split from oxytocin by an exopeptidase present in a microsomal preparation,[5,32] although a group from Utrecht reported that oxytocin was not the source of MIF-1.[4] More recently, incubation of stable isotope-labeled oxytocin with brain tissue preparations showed that at least some MIF-1 could arise from oxytocin in the hypothalamus, but this probably does not explain the presence of MIF-1 in brain cortex.[25] Moreover, MIF-1 does not arise from Tyr-MIF-1 in blood[19] or brain homogenates.[20] The metabolism of MIF-1 is very unusual; like most peptides, it is rapidly degraded in rat blood, but unlike most peptides, it survives intact in human blood for several days.[19,28,32]

Salzet and Deloffre isolated MIF-1 from invertebrate leech brain in 2000, confirming "the very ancient origin of this peptide." Moreover, it should not be overlooked that essentially all cells in the body can synthesize the tripeptide glutathione *de novo*, but this possible method of synthesis has not been explored for MIF-1.

Precursor/processing of Tyr-MIF-1: Since the amino acid in oxytocin adjacent to MIF-1 is not tyrosine, it is unlikely that oxytocin is the precursor of Tyr-MIF-1. No precursor is known, although there are many possibilities shown by BLAST search. The metabolism of Tyr-MIF-1 differs in the cerebral microvasculature composing the blood–brain barrier obtained from different regions of the brain cortex, showing yet another mechanism by which the blood–brain barrier can regulate communication between the brain and body.[21]

Distribution of MIF-1: Mass spectrometry shows the hypothalamus to contain the highest concentrations of MIF-1 in mouse brain, followed by smaller amounts in the striatum, thalamus, cortex, and hippocampus.[25] After intravenous (iv)

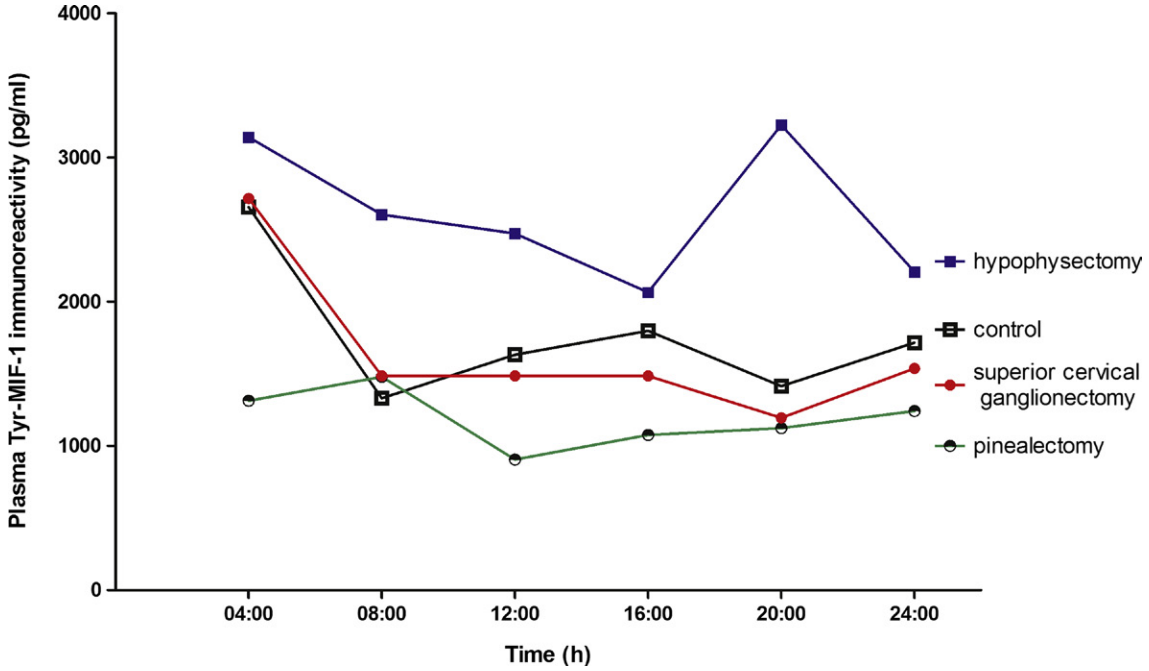

FIGURE 1 Effects of hypophysectomy, pinealectomy, or superior cervical ganglionectomy on the circadian variation of plasma Tyr-MIF-1 immunoreactivity in rats. The control rats showed a peak of Tyr-MIF-1 at 4 am and a nadir at 8 pm. Hypophysectomy changed the acrophase of the circadian rhythm whereas pinealectomy reduced the amplitude of circadian variation as well as changing the acrophase. Modified from Kastin et al.[18]

injection, most MIF-1 is found in the pineal and pituitary, with which MIF-1 interacts,[15] with lesser amounts in cortex, dorsal hippocampus, and hypothalamus.[8] MIF-1 enters the brain rapidly from blood by a saturable transport system, but once there is retained more than most peptides.[2]

Distribution of Tyr-MIF-1: By radioimmunoassay, the highest levels of Tyr-MIF-1 are found in the hypothalamus and pineal, followed by thalamus and striatum.[17] Hypophysectomy increases, and pinealectomy decreases plasma concentrations; circadian evaluation reveals the highest plasma at 0400 (Fig. 1), with the lowest brain concentrations then and at 2400 (Fig. 2).[18]

Tyr-MIF-1 is saturably transported out of the brain into blood faster than most peptides.[1] The system has highly specific structural requirements such that no component, including MIF-1, competes. Yet Met-enkephalin, having little if any structural similarity, saturably exits the brain by the same system. The P-glycoprotein system is not involved in this brain-to-blood transport.[22] Since Tyr-MIF-1 has antiopioid effects whereas Met-enkephalin has opioid effects, it seems intriguing that functional rather structural similarities prevail.

MIF-1 receptors and signaling: The highest concentration of MIF-1 binding sites has been reported to be present in the striatum, followed by the hypothalamus and cortex.[6] MIF-1 does not bind to opiate or Tyr-MIF-1 binding sites. After iv injection of MIF-1, there is a transient increase of pERK but a decrease of pSTAT3. These transient effects precede cFos activation that is highest is the cingulate cortex, nucleus accumbens, paraventricular hypothalamus, and parts of the thalamus.[24]

Tyr-MIF-1 receptors: The highest concentration of Tyr-MIF-1 binding sites is in the cortex, striatum, and amygdala;[33] MIF-1 does not bind to these sites. Tyr-Pro-opioids do bind to the Tyr-MIF-1 site, but ligands for the mu, delta, kappa, and sigma receptors do not.[34] Tyr-K-MIF-1 and Tyr-W-MIF-1 bind to the Tyr-MIF-1 binding site but Tyr-K-MIF-1 has its own binding site to which MIF-1, Tyr-MIF-1, Tyr-W-MIF-1, naloxone, and DAMGO do not interact. Tyr-MIF-1 and Tyr-W-MIF-1 are at least 200-times more selective for mu than delta or kappa opiate receptors, but Tyr-W-MIF-1 has about 20-times higher affinity than Tyr-MIF-1.[35] Single amino acid substitutions of Tyr-W-MIF-1 resulted in the isolation of the endomorphins discussed in the Opioid Peptides Section of this book.

CONFORMATION

MIF-1: R. Kostrzewa and colleagues including F. Bymaster, constructed a CPK (Corey–Pauling–Koltung) space-filling molecular model of MIF-1 and found it resembles that of dopamine in at least three different conformations. The amino group of the prolyl moiety of MIF-1 is separated from the N-terminal glycinamide oxygen atoms by the same distance as the dopamine amino group is separated from one of the catechol oxygen groups. This is compatible with

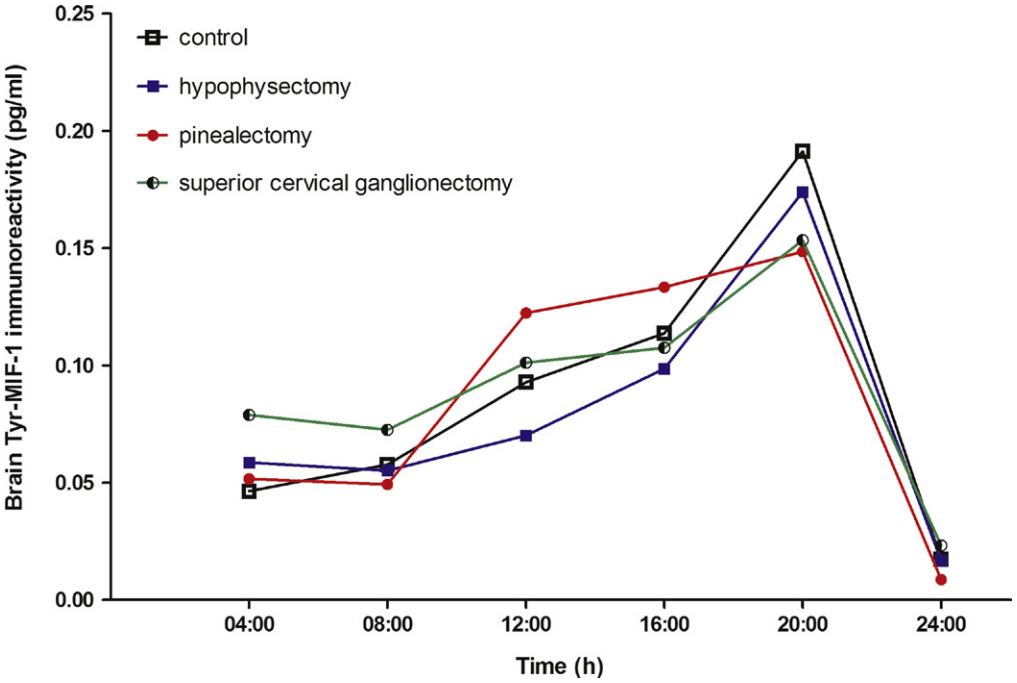

FIGURE 2 Circadian variation of brain Tyr-MIF-1 levels in rats after hypophysectomy, pinealectomy, or superior cervical ganglionectomy, in comparison with the controls. Endogenous Tyr-MIF-1 immunoreactivity peaked at 8 pm and the nadir was at 4 am. This was not changed significantly by surgery. Modified from Kastin et al.[18]

MIF-1 competing with dopamine at the postsynaptic dopamine receptor, or even modifying the receptor to enhance dopamine binding. Although this could explain some of the biological actions of MIF-1, evidence of this binding has only been found by the Utrecht group but not by us. There are conflicting reports on the effects of MIF-1 on turnover of dopamine in the striatum, on striatal tyrosine hydroxylase and dopa decarboxylase, and on enhancement of the actions of apomorphine. R.L. Johnson, R.K. Mishra, and associates have expanded this area with several studies designing and synthesizing MIF-1 analogs with dopamine receptor modulating activity.

Tyr-MIF-1: M. Petersheim and colleagues studied the conformation of Tyr-MIF-1 in aqueous solution by conventional one- and two-dimensional (COSY and NOESY) 1H nuclear magnetic resonance spectroscopy at 300 MHz. They found that Tyr-MIF-1 slowly exchanges between two conformers, probably determined by the cis and trans states of the proline residue. In the major conformation, the aromatic ring of tyrosine is close enough to interact directly with the proline pyrrolidine ring, as indicated by a strong temperature dependence of the proline C beta H, C delta H and C delta H' chemical shifts. By contrast, this interaction of the tyrosine and proline rings is absent in the minor conformation.

Biological actions: As with most chapters of this section, the biological actions of MIF-1 and Tyr-MIF-1 have been discussed in detail elsewhere with inclusive references.[23,27] They are active in animal models of depression and Parkinson's disease and in patients with these disorders. Both of these small peptides have opioid modulating properties, including antiopioid actions, a concept introduced with MIF-1 in 1979.[16]

Opioid actions: Whereas MIF-1 does not exert opioid effects, Tyr-MIF-1 has weak opioid activity. Its opioid potency and selectivity for the mu receptor is greater after the single amino acid substitution found in the isolated tetrapeptide Tyr-W-MIF-1, and additional single amino acid substitutions result in the endomorphins.

Antiopioid actions: The antiopioid actions of MIF-1 and Tyr-MIF-1 have been shown in several types of animals in a wide variety of test situations. Besides reversing the effects of exogenously administered substances like morphine, they can also reverse the effects of endogenous opioids, such as seen in forced warm water swimming, novelty, restraint, aggression, body rotation, and defeat. Some of these antiopioid effects follow an inverted-U shaped dose-response curve, as also seen in some tests of depression and parkinsonism. The antiopioid effects of MIF-1 have even been shown in healthy men.[9] For Tyr-MIF-1, its antiopioid actions are particularly evident when the opioid receptor reserve has been reduced by the administration of β-chlornaltrexamine (CNA) or induction of morphine tolerance.

Behavior: MIF-1 improves performance in the 12-choice Warden maze, extra-dimensional shift, brightness discrimination, and passive avoidance retention. The improved

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

learning in some of these tests is consistent with facilitated attention. It also lessens the effect of induced amnesia. Newborn mice injected with MIF-1 have accelerated development, including improved performance in the Lashley II maze when tested as adults.[7]

Temperature: MIF-1 blocks the hyperthermic effect of amphetamine. It also reverses the hypothermic effect of a phenothiazine, reserpine, morphine, and β-endorphin.

Parkinson's disease: As the first hypothalamic peptide to be tested for effects upon higher centers in the brain, MIF-1 is active in several older animal models of parkinsonism. These include the dopa-potentiation, oxotremorine antagonism, and deserpidine antagonism tests. Later it was shown to protect against the symptoms resulting from administration of the neurotoxin MPTP. More than ten clinical studies have shown the beneficial effects of MIF-1 in patients with Parkinson's disease. In a study published in the *Lancet*, Andre Barbeau reported the improvement after MIF-1 "was of such magnitude that it far surpassed the clinical effect of any of the numerous antiparkinson drugs which we have tested in our laboratory over the past 15 years, including levodopa alone."[3] Subsequently, the only clinical studies of MIF-1 in this disorder have been published in Chinese.

Depression: Many older animal models for Parkinson's disease, such as the dopa-potentiation test, are also considered animal models of mental depression. MIF-1 is active in all of these, even in animals lacking a pituitary gland, an observation illustrating the concept that hypothalamic peptides can exert extra-pituitary, extra-endocrine effects "up" on the brain as well as "down" on the pituitary. MIF-1 is also effective in the classic Porsolt test and its Nomura modification for mice with as little as 10 ng/kg body weight given intraperitoneally. A dose of 100 ng/kg MIF-1 is active in the prolonged Katz test of unpredictable chronic stress. In the small numbers of patients tested, the effects of MIF-1 in depression are dramatic. Even in patients with Parkinson's disease, some of the marked improvement in a wide range of symptoms include mental depression. Van der Velde compared oral MIF-1 with the tricyclic imipramine (10 patients each) and concluded that MIF-1 was "at least as effective as imipramine in this study, and that its anti-depressive effect was a rapid and often dramatic one."[30] Unlike depressed patients receiving the currently used antidepressant drugs, patients receiving MIF-1 show rapid and prolonged improvement starting within a few days.[10] It remains puzzling why the clinical actions of MIF-1 in mental depression and Parkinson's disease have not been extended, although the frequently observed U-shaped dose-response curve certainly did not encourage pharma. The potential of MIF-1 in depression is illustrated by the results of orally administered MIF-1 from clinical studies under the direction of Rudolph H. Ehrensing (Fig. 3).

Implications: MIF-1/Tyr-MIF-1 peptides have served to introduce several concepts into the brain peptide field. These include the first demonstration that hypothalamic peptides can exert extra-hypothalamic/extra-pituitary actions, that some of these actions follow an inverted dose-response pattern (illustrated in Fig. 3 below), that peptides can cross the blood-brain barrier, and that brain peptides can exert antiopioid actions. The possibility exists that some of the recently discovered actions of oxytocin may be caused by MIF-1, its C-terminal tail. It is hoped that the beneficial effects of these small peptides will be explored further.

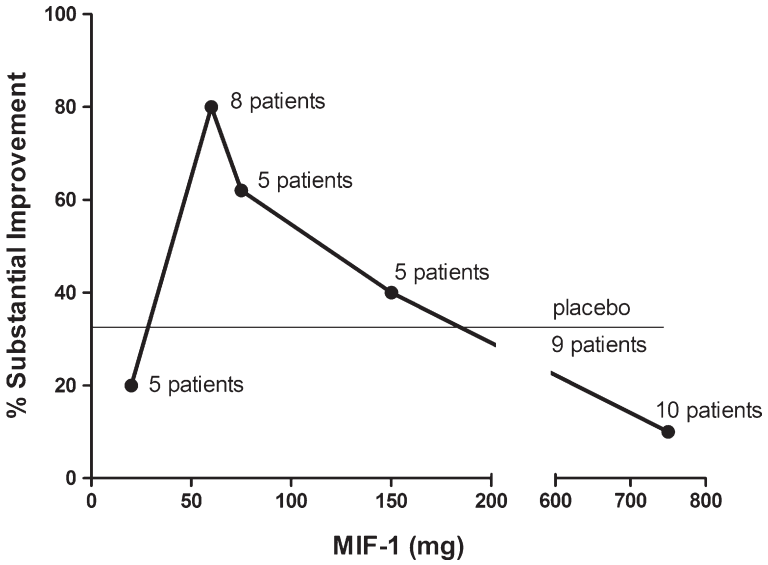

FIGURE 3 Early and dramatic improvement in small numbers of depressed patients at low but not high doses of MIF-1 given by mouth.

Chapter 113

Nesfatin-1

Andreas Stengel and Yvette Taché

ABSTRACT

Nesfatin-1 is a recently described 82 amino acid polypeptide derived from its precursor protein, nucleobindin2 (NUCB2). The peptide is widely distributed throughout the brain suggesting an expanding role in stress response, neuroendocrine regulation, autonomic control of viscera, and also onset of puberty in addition to the initially described inhibitory action on food intake. Although the understanding of nesfatin-1's actions in the brain have markedly advanced since its discovery in 2006, several important mechanisms still remain to be understood encompassing the regulation of NUCB2 processing leading to nesfatin-1 release in the brain as well as the identification of the nesfatin-1 receptor(s) and intracellular signaling pathways.

DISCOVERY

About two decades ago, a protein that promotes DNA antibody production was isolated from a large volume of mouse cell culture supernatant and human cell lines and named nucleobindin.[5] The 55 kDa protein was also termed NEFA (D*N*A binding/*EF*-hand/*a*cidic amino acid rich region) in keeping with features of its functional domains encompassing a basic putative DNA-binding domain, two Ca^{2+}-EF-hand motifs separated by an amino acid-rich leucine/isoleucine region and a leucine zipper motif in the C-terminal region.[5] The nucleobindin family so far comprises two members, nucleobindin 1 (NUCB1 or CALNUC) and nucleobindin2 (NUCB2 or NEFA).[5] The 420 amino acid protein NUCB2 contains a 24 amino acid N-terminal signal peptide and a 396 amino acid sequence highly conserved (>85%) in mouse, rat and human (Fig. 1A) implying a physiological significance across mammals. Nesfatin-1 was identified a few years ago in the rat hypothalamus by a subtraction-cloning strategy as an 82 amino acid peptide derived from NUCB2 and termed after *N*UCB2-*e*ncoded *s*atiety and *fat in*fluencing protein.[22]

STRUCTURE OF THE mRNA/GENE

The NUCB2 gene is located on chromosome 11 in humans, on chromosome 7 in mice and on chromosome 1 in rats, and contains 14 exons and 13 introns in humans.[31] The translation initiation site and putative signal sequence have been localized on exon 3.[31] Nesfatin-1 is encoded in the region between exons 3 and 5, while nesfatin-2 and -3 are encoded in regions between exons 5 and 14. The 3′-untranslated region has been identified in exon 14.[31] The translational start site forms clusters around 246 base pairs upstream of the start codon and the promoter region of human NUCB2 contains a CAAT box and several regulatory elements including nuclear factor 1, cAMP response element-binding protein-binding sites, as well as activator protein-1 and -2.[31]

PROCESSING OF THE PRECURSOR

The NUCB2 protein contains several cleavage recognition sites for prohormone convertases (PC). The proteolytic processing of NUCB2 by PC-1/3 is assumed to generate several products including nesfatin-1 (amino acids 1–82), nesfatin-2 (amino acids 85–163) and nesfatin-3 (amino acids 166–396, Fig. 1B).[22] In their landmark study, Oh-I and colleagues reported the presence of the 82 amino acid peptide in rat cerebrospinal fluid, whereas the mature peptide was not detectable in hypothalamic tissue.[22] Subsequent reports did not detect mature nesfatin-1 (9.7 kDa) in the brain[9,10] or plasma,[29] whereas full length NUCB2 as well as small amounts of exogenous synthetic nesfatin-1 were detectable by Western blot.[29] So far, most studies describing the expression at the protein level did not distinguish between NUCB2 and nesfatin-1 as the antibodies used recognized both molecules. Because of these findings, it remains to be clarified whether nesfatin-1 or full length NUCB2 is the biologically active molecule since NUCB2 also shows biological activity upon third ventricular injection in rats.[22] Among the known cleavage products, only nesfatin-1 influences food intake, whereas nesfatin-2 and nesfatin-3 do not.[22]

DISTRIBUTION OF THE mRNA/PEPTIDE

Initially, Oh-I and colleagues described the localization of NUCB2/nesfatin-1 immunostaining in several rat brain

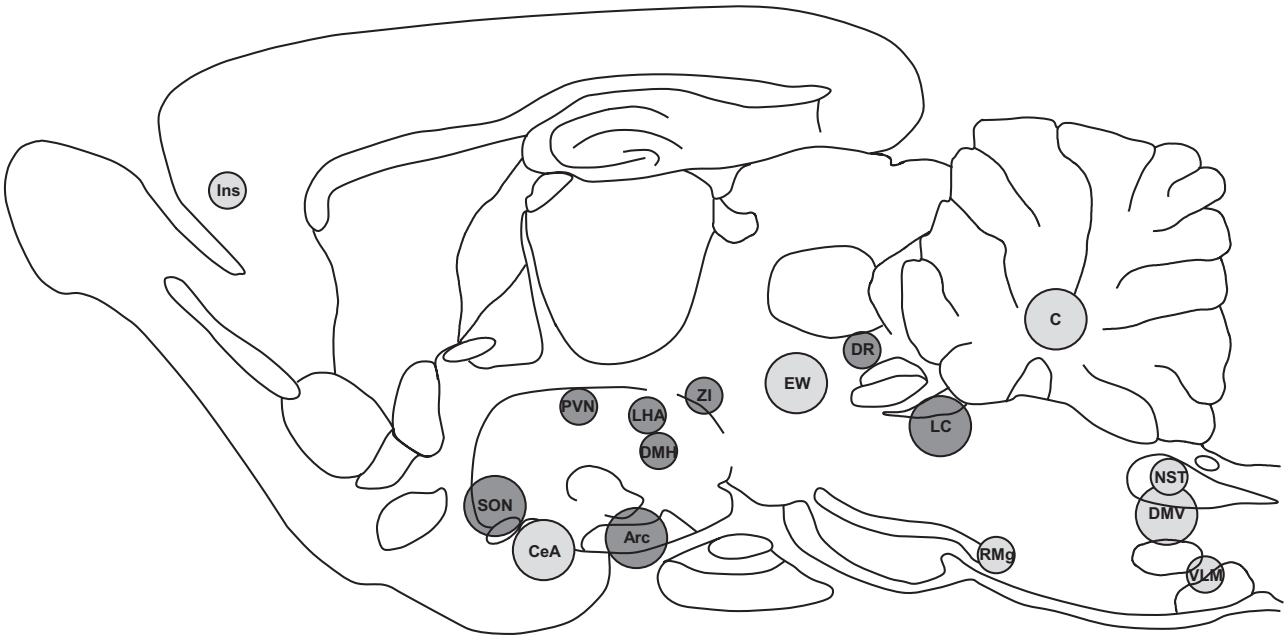

FIGURE 2 Expression of NUCB2/nesfatin-1 immunoreactivity in rat brain nuclei. Large circles represent high density and smaller circles moderate density of NUCB2/nesfatin-1-immunoreactive cells. Dark gray background represents intensive and light gray moderate intensive immunolabeling. Abbreviations: Arc, arcuate nucleus of hypothalamus; C, cerebellum; CeA, central amygdala; DMH, dorsomedial nucleus of hypothalamus; DMV, dorsal motor nucleus of the vagus nerve; DR, dorsal raphe nucleus; EW, Edinger–Westphal nucleus; Ins, insular cortex; LC, locus coeruleus; LHA, lateral hypothalamic area; NST, nucleus of solitary tract; PVN, paraventricular nucleus of hypothalamus; RMg, raphe magnus nucleus; SON, supraoptic nucleus; VLM, ventrolateral medulla; ZI, zona incerta.

nuclei implicated in the regulation of hunger and satiety encompassing the supraoptic nucleus, arcuate nucleus, paraventricular nucleus (PVN), lateral hypothalamic area, zona incerta and the nucleus of the solitary tract (NTS) (Fig. 2).[22] This neuroanatomical localization was confirmed in rats and mice by independent groups and extended to the insular cortex, central amygdaloid nucleus, dorsomedial hypothalamic nucleus, Edinger–Westphal nucleus, locus coeruleus, medullary raphe nuclei, dorsal motor nucleus of the vagus nerve, ventrolateral medulla, cerebellum, as well as preganglionic sympathetic and parasympathetic neurons of the spinal cord (Fig. 2).[8,9,11,12,16] Interestingly, in mice NUCB2/nesfatin-1 immunoreactivity was also detected in a previously undefined region which was named intermediate dorsomedial hypothalamus (Fig. 3).[11] Of note, however, at the cellular level the localization of NUCB2/nesfatin-1 immunoreactivity is confined to the cytoplasm and primary dendrites while not present in axons and terminals which is at variance with other brain neuropeptides.[8,9,12,17,22] This points toward non-axonal signaling, probably involving a paracrine or autocrine mode of action of NUCB2/nesfatin-1.

NUCB2/nesfatin-1-immunoreactive neurons colocalize with various brain neuropeptides in the hypothalamus and midbrain including 70–90% of cocaine- and amphetamine-regulated transcript (CART) or proopiomelanocortin (POMC),[9,15,23] 90% of urocortin-1,[23] 82% of melanin-concentrating hormone,[9] 64% of α-melanocyte-stimulating

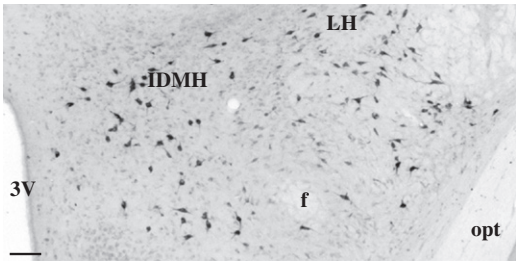

FIGURE 3 NUCB2/nesfatin-1-immunoreactive cells in the mouse intermediate dorsomedial hypothalamus. The scale bar represents 100 μm. for nesfatin-1's involvement in several biological processes related to energy homeostasis, stress, neuroendocrine and autonomic regulation.

RECEPTORS AND SIGNALING CASCADES

Structure activity relationship studies indicate that full length NUCB2 as well as nesfatin-1 exerts an anorexigenic effect after injection into the brain ventricle while nesfatin-2 and nesfatin-3 do not.[22] Several fragments of nesfatin-1, namely N-terminal nesfatin-$1_{1–29}$, the mid-fragment nesfatin-$1_{30–59}$ and the C-terminal nesfatin-$1_{60–82}$ (Fig. 1B) were also synthesized based on structural analysis of the α-helix of nesfatin-1 and tested for biological activity. Only the mid fragment is able to reproduce the anorexigenic effect of nesfatin-1 after peripheral injection in mice suggesting that this fragment may contain the active core of the peptide interacting with the receptor.[26] However, it remains to be established whether nesfatin-$1_{30–59}$ is generated *in vivo*.

Still to be identified is the receptor to which nesfatin-1 binds. One study showed that nesfatin-1 interacts with a receptor that has pharmacological characteristics of G protein-coupled receptors. This was based on *in vitro* results in cultured rat hypothalamic neurons showing that nesfatin-1 induces a fast rise in $[Ca^{2+}]_i$ which is abolished by pertussis toxin, indicating the involvement of a $G_{i/o}$ protein-coupled receptor and is also reduced by a specific protein kinase A inhibitor indicative of a role of protein kinase signaling.[8] The identification and consecutive pharmacological characterization of the nesfatin-1 receptor will represent an important leap forward to better understand nesfatin-1 signaling and physiology.

BIOLOGICAL ACTIONS WITHIN THE BRAIN (AND PITUITARY)

Effects of Nesfatin-1 on Food Intake

The initially described biological action of nesfatin-1 was the reduction of dark phase food intake after injection into the third brain ventricle in rats.[22] Subsequent studies showed that nesfatin-1 injected into the lateral brain ventricle reduces dark phase food intake with a delayed onset and long duration in rats, mice and goldfish.[13,27] Microstructure analysis using an automated food intake monitoring system in mice established that nesfatin-1 injected intracerebroventricularly reduces dark phase food intake by lowering meal frequency, increasing inter-meal intervals and reducing meal size.[13] Besides its anorexigenic action after injection into the forebrain where the PVN has been identified as a responsive site, nesfatin-1 injected into the hindbrain either into the cisterna magna or the fourth ventricle also reduces dark phase food intake in rats.[27]

The appetite suppressive action of intracerebroventricular injection of nesfatin-1 involves the activation of peptidergic anorexic circuitries as shown by the blockade of nesfatin-1's inhibitory effect by intracerebroventricular injection of the CRH_2 receptor antagonist, astressin$_2$-B,[27] the melanocortin 3/4 receptor antagonist, SHU9119[22] and an oxytocin antagonist.[33] Since the oxytocin and CRH receptor antagonists also block the α-MSH-induced reduction of food intake,[33] the signaling cascade could be nesfatin-1→α-MSH→oxytocin/CRH receptor activation. Lastly, inhibition of the orexigenic NPY pathways may also be involved in nesfatin-1's food intake reducing action based on *in vitro* experiments showing a hyperpolarization of NPY positive neurons by nesfatin-1.[24] By contrast, the anorexigenic action of nesfatin-1 is independent of leptin signaling as the food intake reduction after intracerebroventricular injection of nesfatin-1 is still observed in leptin receptor-deficient Zucker rats.[22]

Conclusive evidence supports the physiological relevance of NUCB2/nesfatin-1's action in the brain to curtail food intake. Expression of the NUCB2/nesfatin-1 mRNA in the PVN and supraoptic nucleus and the hypothalamic NUCB2 protein content are regulated by changes in metabolic status as indicated by the down-regulation after food deprivation for 24 h or chronic undernutrition at puberty in rats.[10,16,22] Conversely, food intake suppressing transmitters such as α-MSH or cholecystokinin increase hypothalamic NUCB2 mRNA expression[22] or activate NUCB2/nesfatin-1-immunopositive neurons in hypothalamic and brainstem nuclei.[20,27] Lastly, injection of an anti-NUCB2 antisense oligonucleotide into the third ventricle increases food intake[22] pointing toward an inhibitory tone on food consumption exerted by NUCB2/nesfatin-1. Nesfatin-1 selectively reduces dark phase food intake in *ad libitum* fed animals, whereas studies performed during the light phase investigating the feeding response after an overnight fast resulted in inconsistent findings and required higher doses to reduce food intake.[18,22,27] This may suggest that nesfatin-1 interferes more prominently with physiological processes of nocturnal feeding than those involved in the hyperphagic response to food deprivation.

Effects of Nesfatin-1 on Gastrointestinal Motility

Centrally acting peptides regulating food intake also affect gastrointestinal motility. Likewise, intracerebroventricular injection of nesfatin-1 delays gastric emptying in rats[27] and mice[2,11] and suppresses the fed pattern of gastroduodenal motility in mice.[2] Such alterations in gastric transit could contribute to the long lasting anorexigenic action of the peptide.

Involvement of Nesfatin-1 in Stress Responses

NUCB2/nesfatin-1's distribution in stress responsive brain neuronal circuitries including the PVN, central amygdaloid nucleus and locus coeruleus supports a potential role in the stress response. In addition, functional studies indicate that nesfatin-1 injected intracerebroventricularly, although at a higher dose than used for the feeding studies, induces anxiety and fear as indicated by characteristic behavior including less time spent in the open arms of the elevated plus maze test as well as increased startle response and freezing in an emotional response test.[19] It may be hypothesized that these effects are mediated by CRH in the PVN known to play a role in the induction of anxiety and depression. This is supported by the observation that brain injection of nesfatin-1 increases plasma adrenocorticotropin and corticosterone levels and cytosolic Ca^{2+} concentrations in CRH immunoreactive neurons isolated from the PVN.[17,32] Moreover, various stressors activate NUCB2/nesfatin-1 in specific brain nuclei as shown by double labeling with Fos used as a marker of neuronal activation. For instance, abdominal surgery, a physical stressor, induces a robust activation of NUCB2/nesfatin-1-immunoreactive neurons in the magnocellular neuroendocrine system, in the anterior parvicellular part of the PVN, the Edinger–Westphal nucleus, and nuclei of the catecholaminergic and serotonergic system.[28] Similarly, injection of lipopolysaccharide, an immunological stressor, activates NUCB2/nesfatin-1-immunopositive neurons in hypothalamic and hindbrain nuclei.[7] Also, restraint stress as a psychological stressor activates NUCB2/nesfatin-1-immunoreactive neurons in several hypothalamic and hindbrain nuclei.[14,17,23,30,32] Activation of these neurons may be part of mechanisms underlying the reduced food intake observed under these stress conditions.

Onset of Puberty

Hypothalamic nesfatin-1 may play a key role in driving the onset of puberty in female rats.[10] This is substantiated by the increased expression of hypothalamic NUCB2 mRNA and protein content during puberty transition and the delay of puberty by inhibition of NUCB2 synthesis after intracerebroventricular injection of an anti-NUCB2 antisense oligonucleotide.[10] In addition, intracerebroventricular injection of nesfatin-1 stimulates luteinizing hormone and follicle-stimulating hormone release into the circulation only in pubertal but not adult female rats.[10] These observations suggest that NUCB2/nesfatin-1 may be an important regulator of the hypothalamic gonadotropic axis at puberty.

PATHOPHYSIOLOGICAL IMPLICATIONS

Patients with newly diagnosed primary generalized epilepsy have elevated concentrations of NUCB2/nesfatin-1 in the circulation and saliva which decrease after treatment.[4] In addition, directly after a seizure, serum concentrations of NUCB2/nesfatin-1 are significantly increased.[3] Based on these results, nesfatin-1 could be used as a biomarker for the diagnosis of epilepsy, in case of a suspected recent seizure, but also for monitoring treatment outcome of the disease. Moreover, nesfatin-1 plasma concentrations are increased in patients with major depression,[1] a finding that was confirmed in the brain of depressed suicide victims who had higher NUCB2 mRNA levels in the Edinger–Westphal nucleus compared with the brains of control subjects with acute cardiac-respiratory failure or myocardial infarction as causes of death.[6]

In view of its proposed role as a tonic inhibitor of food intake, several clinical studies investigated the association of circulating NUCB2/nesfatin-1 and body weight. A positive correlation between plasma NUCB2/nesfatin-1 concentrations and body mass index (BMI) was reported with lower concentrations under conditions of anorexia nervosa[21] and higher concentrations in obese subjects,[25] indicating that circulating nesfatin-1 may be responsive to sustained changes in adipose tissue mass. In addition, three different single nucleotide polymorphisms in the NUCB2 gene have been identified in a large cohort of men that were associated with obesity[34] possibly representing a genetic cause for the increase of body weight.

Chapter 114

Neuromedin U

Preeti H. Jethwa, Caroline J. Small, Michael Patterson and Stephen R. Bloom

ABSTRACT

Neuromedin U (NMU) is one of the most abundant neuropeptides and has been found in significant concentrations in both the gastrointestinal tract and the central nervous system (CNS). Within the CNS, NMU cell bodies are found in the rostrocaudal part of the arcuate nucleus of the hypothalamus with more widespread distribution of NMU fibers in the nucleus accumbens, medial thalamus, brainstem, paraventricular nucleus, ventromedial nucleus, and dorsomedial nucleus, areas where the NMU2 receptor is expressed. Recently, NMU has been shown to be a potent anorexigenic peptide, and alterations of NMU signaling can predispose to obesity.

DISCOVERY

Neuromedin U (NMU) was first isolated from porcine spinal cord in 1985 and named for its potent contractile activity on the uterus.[23,24] Two molecular forms were purified; an icosapentapeptide (NMU-25) and an octapeptide (NMU-8) identical to the C-terminal of NMU-25.[23,34] Both these forms of NMU are biologically active. NMU has since been fully sequenced in several species, and most of the NMU peptides that have been isolated from different species are icosapentapeptides with the exception of rat NMU, NMU-23.[4]

STRUCTURE OF NMU mRNA

The human cDNA encoding the precursor protein for NMU has been sequenced.[2] The human NMU is an icosapentapeptide and has no internal dibasic cleavage site for the generation of a shorter version. The comparison of human and rat cDNA encoding NMU reveal about 70% homology between the two sequences suggesting that NMU is synthesized from a 174-amino acid precursor containing the NMU peptide within the C-terminus.[2,22] The precursor contains a hydrophobic signal peptide and several dibasic cleavage sites that give rise to a number of possible secreted peptides, including NMU (Fig. 1). Southern blot analysis of genomic DNA reveals that NMU is a single copy gene.[22]

NMU DISTRIBUTION AND PROCESSING

NMU shows remarkable conservation throughout evolution: the C-terminal pentapeptide (Phe-Arg-Pro-Arg-Asn-NH^2) is conserved across all species, and the heptapeptide (Phe-Leu-Phe-Arg-Pro-Arg-Asn-NH^2) is conserved throughout all mammalian species.[22] This degree of conservation suggests the importance of the carboxyl-terminus sequence for biological activity.

NMU is an abundant peptide, found in significant concentrations in both the gastrointestinal tract[1,3,6] and central nervous system.[3,6,9,14,16,17,31] It is also found in other tissues such as the pituitary gland,[6] the thyroid gland,[5] and the urogenital tract.[6]

In the rat brain, the highest levels of NMU-like immunoreactivity are found in the nucleus accumbens (Acb), hypothalamus, anterior pituitary, and thalamus.[6,7] NMU-immunoreactive cell bodies are found in the rostrocaudal part of the arcuate nucleus of the hypothalamus (Arc) with more widespread distribution of immunoreactive fibers in the Acb, medial thalamus, paraventricular nucleus (PVN), ventromedial hypothalamus (VMH), dorsomedial hypothalamus (DMH), and supraoptic nucleus (SON), and in the brainstem with dense terminals fields primarily in the nucleus of the solitary tract (NST) and parabrachial nucleus (PBN) (Fig. 4A).[3,14,16,31,32] In situ hybridization has shown NMU mRNA to be most abundant in the pituitary pars tuberalis and slightly less in the Arc and median eminence, the caudal brainstem (NST, area postrema (AP), and dorsal motor nucleus of the vagus (DMV), and the spinal cord.[14,16,17,31]

The presence of NMU mRNA in the median eminence was initially disputed, as some studies reported expression is localized to the par turberalis.[17] However, this was clarified when Graham et al.[9] showed that the expression of NMU mRNA is species dependent (Figs 2 and 3). In mice, NMU mRNA is detected in the Arc, DMH, VMH, and suprachiasmatic nucleus (SCN) in contrast to the expression of NMU mRNA in the rat in which it is absent from the median eminence, the VMH and the DMH but highly expressed in the pituitary par tuberalis.[9] In mice, NMU mRNA is located within the same region of the Arc as proopiomelanocortin

(POMC)/cocaine- and amphetamine-regulated transcript (CART) neurones, which play a key role in energy homeostasis, but there is no colocalization of CART and NMU mRNA.[9]

NMU RECEPTORS

In 1998, a G protein-coupled receptor (GPCR) FM-3 was cloned from human and murine cDNA libraries because of its homology with the growth hormone secretogogue receptor and the neurotensin receptor. Cloning enabled a subsequent "reverse pharmacological" approach for the identification of NMU as an endogenous ligand for the orphan human GPCR, FM-3.[8,13,15,16,30,31,33] NMU binds to and activates human FM3 with sub-nanomolar affinity and potency. Extracts from rat tissue contain the endogenous ligand for FM-3, the brain and small intestine extracts having the highest affinity. A 23-amino acid peptide identical to rat NMU-23 was subsequently chromatographically purified. A number of other potential ligands with homology to NMU were screened for receptor affinity but only NMU peptides activate the receptor. However, later a second high affinity ligand, Neuromedin S (NMS), has been identified.[26]

Simultaneously, a second NMU receptor, a GPCR, FM-4 was identified in humans and rodents.[15,16,30,31] FM-3 and FM-4 are cognate receptors and have been renamed NMU1R and NMU2R, respectively. Both receptors have

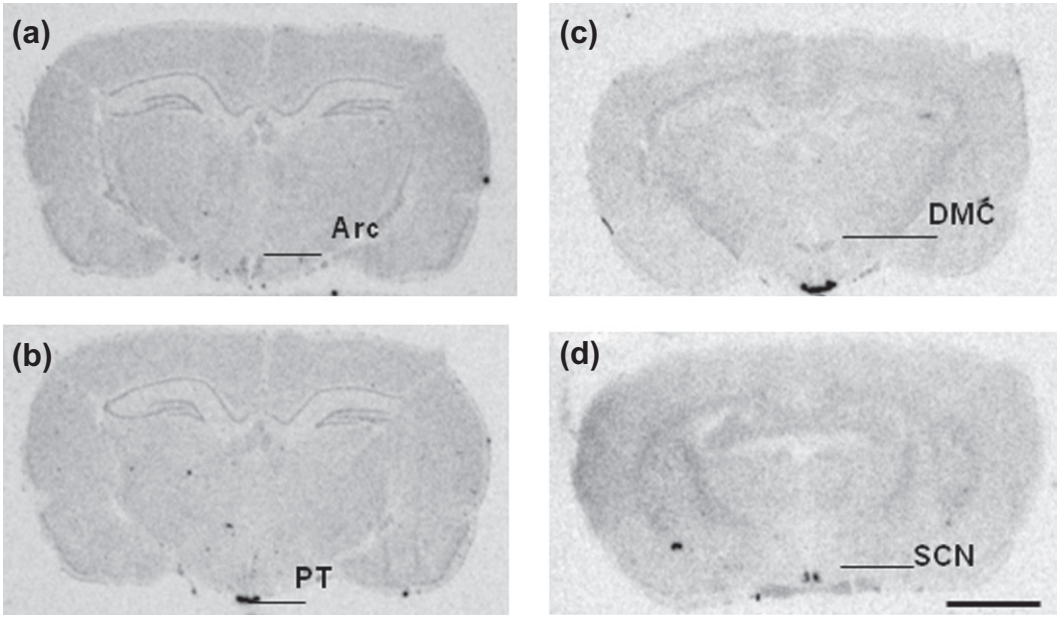

FIGURE 3 NMU expression in the rat hypothalamus Autoradiographs showing NMU mRNA expression in the rat hypothalamus (*ad libitum* fed hooded listers). NMU mRNA was detected in (a) the Arc (−2.8 to Bregma), (b) pars tuberalis (−3.6 to Bregma), (c) Dorsomedial compact zone of the DMH (−3.3 to the bregma), and (d) in the SCN (−1.4 to Bregma). Scale bar in (d) represents 2 mm.[9]

significant abilities to distinguish between different forms of NMU, and have species and tissue selectivity in the biological actions of NMU.[8,13,15,16,30,31,33] NMS is a second endogenous ligand for both receptors. NMU and NMS have a similar affinity for NMU1R, but NMS binds NMU2R with a slightly greater affinity.[26]

NMU1R

The gene for human NMU1R has been mapped to SHGC-33253, which is localized on chromosome 2q34–937[30] and is encoded by two exons.[31] Human NMU1R has a molecular weight of 44979 Da. The mRNA for NMU1R is expressed in a wide variety of tissues, but levels are the greatest in peripheral tissues in particular the small intestines and stomach. NMU1R mRNA is also present in relatively high levels in the pancreas, testis, adrenal cortex, liver, heart, lung, trachea, mammary gland, bone marrow, and peripheral blood leucocytes.[13,15,16,33] A similar distribution pattern exists in the rat with highest levels in the small intestine, lung and bone marrow.[8] NMU1R mRNA expression is also found in approximately 25% of the small/medium diameter neurons within the dorsal root ganglia.[35] There is relatively low expression of NMU1R in human or rodent brain.[8,16]

NMU2R

The gene for human NMU2R has been mapped to SHGC-8848, which is localized to chromosome 5q31.1–q31.1.[30] Human NMU2R has a molecular weight of 47450 Da. NMU2R mRNA in humans is confined predominantly to specific regions within the brain, with the greatest expression observed in the thalamus, substantia nigra, pontine reticular formation, medulla oblongata, and spinal cord. Moderate to high levels are present in the indusium griseum, vascular organ of the lamina terminalis, setophippocampal nucleus, CA1 region of the hippocampus, parafasicular thalamic nucleus, the PVN and the wall of the third ventricle in the hypothalamus and the dorsal raphe nucleus (Fig. 4B).[16] A detailed analysis of NMU2R expression is now complete for the rat.[9] The NMU2R gene is found in the medial postal region of the Arc adjacent to the third ventricle, isolated neurons in other portions of the Arc,[9] and the PVN. NMU2R is less abundant in the bed nucleus of the stria terminalis, subfornical organ, dorsal fornix, dorsal tuberomammillary nucleus, raphe obscurus, raphe pallidus nuclei, cunneate nucleus, and paratrigneinal nucleus.[16]

Peripherally, NMU2R is expressed in the testes with lower levels present in the GI tract, genitourinary tract, liver, pancreas, adrenal gland, thyroid gland, lung, trachea, spleen, and thymus.[16]

BIOLOGICAL ACTIONS OF NMU IN THE BRAIN

The Role of NMU in the Regulation of Energy Balance

Intracerebroventricular (icv) administration of NMU reduces nocturnal food intake and decreases body weight.[17,20,28,34] In addition, icv administration of NMU

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

antiserum increases food intake,[20] whereas fasting reduces the levels of NMU mRNA in the VMH.[16] NMU may also play a role in leptin-induced satiety; in rats, icv injection of anti-NMU antiserum partially attenuates the feeding effects of intraperitoneal leptin administration.[18]

Administration of NMU into specific hypothalamic areas potently reduces food intake. Wren et al.[34] showed a dose-dependent reduction of feeding 1 hour after the administration of NMU into the PVN and Arc. In addition to the immediate reduction in food intake observed after NMU administration into the PVN or Arc, NMU has a much delayed inhibitory (4–8 h postinjection) effect after administration into the medial preoptic area (MPOA) of the hypothalamus.[34] The MPOA is involved in the reproductive function and *c-fos* expression, and NPY levels increase after feeding, while αMSH reduces food intake after administration in the MPOA.[19] Thus, NMU may interact with other neuropeptides to mediate the delayed feeding effect.[34]

The decrease in food intake after a single icv injection of NMU is associated with a significant increase in gross locomotor activity, core body temperature, heat production, and oxygen consumption.[11,16,17,28,34] However, NMU does not cause shivering, suggesting that the effects on body temperature are mediated by changes in sympathetic outflow to brown adipose tissue and skeletal muscle. Ivanov et al.[17] proposed that the effects of NMU on feeding and energy expenditure are independent as they observed an increase in core body temperature in the absence of a decrease in food intake in satiated animals.

NMU null (NMU–/–) mice[12] and NMU overexpressing (NMU Tg) mice[21] have been developed. NMU–/– mice show increased body weight and adiposity, hyperphagia, and decreased locomotor activity and energy expenditure. Obese NMU–/– mice develop hyperleptinemia, hyperinsulinemia, late-onset hyperglycemia, and hyperlipidemia.[12] The NMU Tg mice, however, show decreased body weight and adiposity, hypophagia, and a modest increase in respiratory quotient during food deprivation and refeeding. Unlike the NMU–/ mice, the NMU Tg mice also show improved insulin sensitivity on both normal and high fat diet.[21] In addition, many neuropeptides important to the regulation of feeding are altered in these transgenic animals. In the NMU–/– mice, there is a decrease in POMC mRNA, while neuropeptide Y (NPY) and agouti-gene-related peptide (AgRP) mRNA levels remain unchanged.[12] However in the NMU Tg mice, both POMC and NPY mRNA levels are increased, while AgRP remains unchanged.[21] The phenotype of these animals suggests that alterations in the NMU system lead to altered energy metabolism.

The Role of NMU in Gastric Acid Secretion and Emptying

NMU icv reduces gastric acid secretion.[25] This CNS effect of NMU seems to be independent of vagal innervation because NMU significantly suppresses pentagastrin secretion in vagotomized rats. Prostaglandin E_2 reduces gastric acid secretion directly by inhibiting parietal cell secretion and indirectly by inhibiting gastric acid release. Peripheral administration of indomethacin, to block prostaglandin synthesis, prevents the inhibitory action of neuropeptides on gastric secretion. However, administration of NMU suppresses acid secretion in indomethacin-treated rats, suggesting that NMU acts independently of prostaglandin E_2.[25]

The Role of NMU in the Regulation of the HPA Axis and Stress Response

Corticotropin-releasing hormone (CRH) is another hypothalamic peptide located in the PVN, which decreases food intake, increases energy expenditure via stimulation of the sympathetic nervous system, induces stress responses, and increases locomotor and grooming behavior. Icv and intra-PVN administration of NMU increases plasma adrenocorticotropic hormone and corticosterone. In addition, the release of CRH and arginine vasopressin is increased from *ex vivo* hypothalamic explants incubated with NMU.[29] Consistent with these effects, NMU increases *c-fos* expression in CRH-containing neurons in the parvocellular region of the PVN and SON[17,29] and augments CRH mRNA expression in the PVN.[12]

The mechanism by which hypothalamic NMU alters feeding behavior and energy homeostasis is not clear. However, given that the icv effects of CRH appear to be similar to those observed after NMU administration Hanada et al.[10] hypothesized that the changes in feeding behavior and energy homeostasis with NMU may be via CRH. NMU icv does not alter dark phase food intake or fasting-induced feeding in CRH null ($CRH^{-/-}$) mice when compared with that in wild-type mice.[10] In addition, the increase in oxygen consumption, body temperature, and locomotor activity observed after NMU administration are suppressed in the $CRH^{-/-}$ mice. The effects of NMU are also abolished in wild-type mice pretreated with the CRH receptor antagonist alpha-helical-$CRH_{(9–41)}$ when compared with their controls.[11] Further supporting this, Hanada et al.[12] showed that CRH mRNA expression is reduced in the PVN of $NMU^{-/-}$ mice and show a lower plasma corticosterone level. However, surprisingly, NMU Tg mice show no changes in CRH mRNA expression,[21] although this may result from a differing method of detection.

To further support the hypothesis, NMU-induced inhibition of gastric acid secretion is blocked by pretreatment with anti-CRH IgG, suggesting that NMU-induced acid inhibition is mediated by CRH. CRH inhibits gastric acid secretion by activation of the sympathetic, noradrenergic nervous system and not vagal fibers. This finding supports the possibility that CRH mediates NMU-induced acid inhibition through a vagus-independent pathway. Icv administration

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

of NMU also inhibits gastric emptying in rats; although peripheral NMU has no effect.[25] This suggests that NMU mediates its effects on food intake and energy expenditure via hypothalamic CRH.

COMPARISON OF THE BIOLOGICAL ACTIONS OF NMU AND NMS

NMS was discovered in 2005 as an alternative ligand for the NMU receptors.[26] NMU and NMS share a common amidated C-terminal hexapeptide. Distribution of NMS seems more limited than NMU; in rats, high levels of NMS mRNA are only detected in the hypothalamus, testis, and spleen.[26] Within the hypothalamus particularly high levels of NMS are detected in the SCN suggesting a possible role in the regulation of circadian rhythms.[26] Like NMU, central administration of NMS suppresses feeding and stimulates the HPA axis. Nakahara et al.[27] compared the effects of NMU and NMS on feeding. When administered icv, both NMS and NMU increase CRH and POMC mRNA levels in the PVN and Arc.[27] Anti-NMS antisera block the feeding effects of leptin but in contrast to previous reports anti-NMU antisera have no effect.[27] Thus, it is probable the NMU system is involved in mediating the anorexi-

genic effects of leptin, but the contribution of each peptide requires further clarification. NMU and NMS elicit many of the same actions; however, significant differences in distribution suggest there may be discrepancies in their biological functions.

PATHOPHYSIOLOGICAL IMPLICATIONS

The development of the NMU null ($NMU^{-/-}$) mice[12] and the NMU overexpressing (NMU Tg) mice[21] further supports the role of NMU as an endogenous anorexigenic peptide. The $NMU^{-/-}$ mice develop an obese phenotype, whereas NMU Tg mice that have ubiquitous expression of the NMU transgene develop a lean phenotype. These findings suggest that NMU is an important regulator of energy balance as perturbation of NMU signaling can result in obesity. It is probable that NMU mediates its effects on body weight via alterations in hypothalamic CRH. Although this is an important and interesting hypothalamic circuit, it may not prove a useful antiobesity target. Stimulation would result in weight loss but also an overactive hypothalamic–pituitary–adrenal axis. Thus, NMU may not be useful as a long term antiobesity therapy.

Chapter 115

Neuropeptide B/W

Fumiko Takenoya, Haruaki Kageyama, Ki Sung Kang and Seiji Shioda

ABSTRACT

Neuropeptide B (NPB) and neuropeptide W (NPW) have been identified as endogenous ligands for GPR7 (NPBWR1) and GPR8 (NPBWR2), which belong to the orphan G protein-coupled receptor (GPCRs)family. In this chapter, we provide an overview of the distribution and localization of NPBWR-1 and -2, NPB/W mRNA and these transcripts in brain including human, rabbit, and rodent. NPB/W has various functions, such as feeding regulation and behavior, energy homeostasis, neuroendocrine function, and modulation of inflammatory pain. Therefore, the analysis of the functional significance of NPB and NPW may facilitate the development of therapeutic drugs. This chapter also discusses the morphological and physiological relationship between NPW and other neuropeptides in the central nervous system.

INTRODUCTION

In 1995, O'Dowd et al.,[17] by using oligonucleotides based on the opioid receptor and also on the structurally-related somatostatin receptor, identified two genes, GPR7 (NPBWR1) and GPR8 (NPBWR2), which were predicted to encode two GPCRs in the human brain. These two GPCRs share 70% sequence identity with each other and have a significant similarity with the sequences encoding transmembrane regions of the opioid and somatostatin receptors. NPBWR1 gene expression is found in both human and rodent brains, whereas the NPBWR2 gene is detected in human and rabbit brains, but not in rat or mouse brains.

IDENTIFICATION OF NPB/W

In 2002, Shimomura et al.[20] identified the endogenous ligand for NPBWR1 and NPBWR2 by exposing Chinese hamster ovary (CHO) cells to the porcine hypothalamic extracts while monitoring alterations in the level of cAMP. Moreover, when cell lines that expressed either NPBWR1 or NPBWR2 were incubated with the hypothalamic extracts, it seemed that the inhibition of forskolin induced cAMP production. NPBR-1 and -2 are reported to be coupled to the heterotrimeric Gi protein-mediated receptors. Further structural analysis of the ligands responsible for the inhibition of cAMP production led to the identification of a novel peptide NPW. NPW is named after the tryptophan residues (single-letter code W) appearing at both its N- and C-terminals in its two mature forms: NPW-30 (the 30-amino-acid form) and NPW-23 (consisting of 23 amino acids) (Fig. 1). These two peptides are derived from a common precursor peptide, proNPW, by proteolytic processing of two pairs of arginine residues at positions 24 and 25, and 31 and 32, respectively. At the same time, by using similar structural analysis methods, other research groups discovered NPB, which is also a ligand of NPBWR-1 and -2.[1,5,26]

The NPB cDNAs were cloned by Fujii et al.[5] at Takeda Chemical Industries to search for genes encoding proteins with the motif of the secretory signal sequence. They found a gene, NPB, which encoded a novel secretory protein. The purified endogenous ligand contains 29 amino acid residues and was modified with a bromine. The C-6 position of the indole moiety at the N-terminal tryptophan was brominated and therefore was named neuropeptide B. After the discovery of NPB, Tanaka et al.[26] fractionated acid–acetone extracts of bovine hypothalami and identified NPB and NPW. Similarly, Brezillon et al.,[1] using human NPB mRNA obtained by bioinformatic search of the EST database, discovered NPW's amino acid sequence. NPB is a 29-amino acid peptide with a brominated N-terminal tryptophan. In human tissues, a shorter 23-amino acid form (NPB-23) is generated by the proteolytic processing. NPW-23 and NPB-23 share a 61% amino-acid sequence homology, while NPW-30 and NPB-29 share a 66% amino-acid sequence homology.[1,5]

Distribution and Localization of NPB in Brain

In situ hybridization histochemical and immunohistochemical studies have shown that NPB mRNA is expressed in the hippocampus (CA1, CA2, CA3), lateral habenular nucleus (LHb), paraventricular nucleus (PVH), medial parvocellular subdivision (PaMP), Edinger–Westphal nucleus (EW), motor root of the trigeminal nerve (m5), sensory root of the trigeminal nerve (s5), lateral parabrachial nucleus (LPB)

anterior part (Sub CA), locus coeruleus (LC), noradrenergic cell group A5 (A5), and the inferior olive subnucleus B (IOB) in mouse brain.[26] In rat brain, RT-PCR analysis has shown that NPB mRNA is present in the cerebellum, hippocampus, hypothalamus, thalamus, substantial nigra, and in the spinal cord.[5,26] NPB-like immunoreactive (LI) staining is completely abolished by preabsorption of the primary antibody with NPB-29 but not with NPW-30. Dun et al.[3] have reported, using NPW-29 antiserum in an immunohistochemical study, that NPB-LI neurons are widely distributed in rat brain. In the frontal hypothalamic region, NPB-LI neurons are present in the PVH, supraoptic nucleus (SO), and suprachiasmatic nucleus (SCh), these areas being activated as part of the hypothalamic–pituitary–adrenal (HPA) in response to stress. In the caudal hypothalamic area, elevated expression of NPB is observed in cells of the supraoptic retrochiasmatic nucleus (SOR), zona incerta (ZI), lateral hypothalamic area (LH), dorsal hypothalamic area (DA), dorsomedial hypothalamic nucleus dorsal part (DMD), the tuber cinereum area, and caudal arcuate nucleus (ARC). Moreover, NPB-IL nerve fibers are intensely distributed in the median eminence. In the midbrain, NPB-IL cells are located in the EW, substantia nigra reticular part (SNR), lateral part (SNL), and medial part (SNM), as well as in the paranigral nucleus (PN), ventral tegmental area (VTA), and interfascicular nucleus (IF). The NPB mRNA is most abundantly expressed in the EW of the midbrain and many neurons in the EW actually project to the superficial dorsal horn. NPB-LI nerve fibers originating from the EW may be involved in nociceptive processing in the dorsal horn of the spinal cord. Schulz S. et al.[18] carried out a comparative analysis of the distribution of NPBWR1 mRNA, NPB mRNA, and NPB-LI in the rat hypothalamus. These areas show heightened expression in the ventral region of the zona incerta, anterior part of the dorsal thalamic nucleus, ventrolateral hypothalamic nucleus (VLH), and other areas of the ARC and SOR. Several regions in the hypothalamus and midbrain, such as the PVH, ARC, ventromedial nucleus (VMH), and dorsomedial nucleus (DMH) show an overlapping expression of NPB and NPBWR1 mRNAs, with these being important regions for energy and feeding regulation. Moreover, NPBWR1 mRNA and NPB/NPW-LI neurons are located in the SCh and SO, suggesting that the NPB/NPW system may be implicated in the modulation of circadian rhythms. The expression of NPB-LI in rodent brain is summarized in Fig. 2

Distribution and Localization of NPW in Brain

Quantitative RT-PCR results by Brezillon et al.[1] shows that NPW mRNA is highly expressed in the substantia nigra and spinal cord and moderately expressed in the hippocampus, amygdala, hypothalamus, corpus callosum (cc), cerebellum (Cb), and dorsal root ganglia in the human central nervous system (CNS). In rodents, in situ hybridization histochemistry has revealed that NPW mRNA is expressed in a few restricted brain regions including in rat brain of the periaqueductal gray (PAG), EW, dorsal raphe nucleus (DR), and dorsal part of dorsal raphe nucleus (DRD).[1,10,26] Kitamura et al.[10] reported that NPW mRNA in rat brain is confined to the specific nuclei in the midbrain and brainstem including periaqueductal gray and EW. However we have published articles by using RT-PCR analysis that NPW mRNA is expressed in the rat hypothalamic PVH, LH, ARC, and VMH.[23] In the peripheral tissues, NPW mRNA is also expressed in the urogenital system, including kidney, testis, uterus, ovary, and placenta.[5] Moreover, by using RT-PCR analysis, we have also confirmed the presence of NPW mRNA in the pituitary gland, adrenal gland, and stomach.[15,19] NPW may play an important role in the regulation of the endocrine system in response to stress by the activation of the HPA axis.[16,19]

Several immunohistochemical studies of NPW in the brain summarized in Fig. 2 shown that NPW-LI neuronal cell bodies are present in the various brain hypothalamic regions such as the PVH, especially in the parvocellular subdivisions, SO, accessory neurosecretory nuclei, dorsal and LH, perifornical nucleus (Pe), ARC, and anterior and posterior pituitary gland.[4] Moreover, NPW-LI cells seem to

(2006), Schulz et al.(2007), Takenoya et al. (2009).*

be more numerous in the male hypothalamus as compared with those of female ones.[4] Kitamura et al. have reported a heavy localization of NPW-LI cell bodies in the midbrain including the PAG and EW. However, our recent observation shows that NPW-LI cell bodies are found in many regions in the brain of rats.[23,24] In the forward part of the brain, NPW-LI cell bodies are found in the islands of Calleja (ICj), VLH, anterior parvocellular part (PaAP), medial parvocellular part (PaMP), PVH, DMD, VMH, ARC, and LH. In addition, NPW-LI cell bodies are also detected in the midbrain, and in the dorsal premammillary nucleus (PDM), dorsal tuberomammillary nucleus (DTM), PAG, EW, LPB, prepositus nucleus (Pr), and the raphe nucleus.[23] Moreover, we first identified at the electron microscopic level the presence of NPW-LI cell bodies in the PVH, VMH, and amygdala.[23] NPW-LI neurons in these regions make axosomatic and axodendritic synaptic contacts with unknown axon terminals in the PVH and ARC.[4,23]

NPW-LI nerve fibers have also been identified in the SO, retrochiasmatic nucleus, dorsal and LH, median eminence, amygdala, and posterior pituitary in rat brain,[4] as well as in the septum, BST, dorsomedial and posterior hypothalamus, central amygdaloid nuclei (CeA), CA1 field of the hippocampus, ARC, VMH, inferior colliculus, PBL, facial nucleus, and hypoglossal nucleus.[10] Simultaneously, NPW-LI axon terminals are shown in the POA, bed nucleus of the stria terminalis (BST), amygdala, PVN, ARC, VMH, LH, and PAG.[23] Dense staining of NPW axon terminals are found in the amygdala and BST. Given the abundant distribution of NPW-LI nerve fibers in the midbrain and limbic system such as in the CeA and BST, these observations suggest that NPW may play a role in the regulation of fear and anxiety as well as in feeding behavior.[8,10,23,24]

NPBWR1

The distribution of messenger RNA (mRNA) encoding NPBWR1 and NPBWR2 has been described in anatomical studies by the use of in situ hybridization histochemistry. In human beings, RT-PCR analysis has identified NPBWR1 mRNA located mainly in the hippocampus and amygdala of CNS. As compared with mouse and rat brains, NPBWR1 mRNA is highly expressed in the amygdala, hippocampus, neocortex, and hypothalamus.[11] Additionally, *in vitro*

autoradiography study has shown that NPBWR1 mRNA is abundantly expressed in the BST in rat brain, with expression levels yet to be determined in mouse brain. Furthermore, in situ hybridization histochemical studies have revealed that NPBWR1 mRNA is present in the rat hypothalamus, including in the ARC, VMH, PVH, and DMH, which are well known as centers for the regulation of feeding and energy homeostasis. These findings suggest that NPBWR1 receives feeding signals in the feeding-regulating center of the hypothalamus, and it is involved in the regulation of feeding behavior. To this extent, NPBW1 knockout mice show hyperphagia and adult-onset obesity.[9] Moreover, NPBW1R is detected in the midbrain including the LPB, dorsal tenia tecta (DTT), and laterodorsal tegmental nucleus (LDTg).[11,26]

With the aid of [125I]-NPW receptor autoradiography, significant expression of NPBW1 is detected in the amygdala and hypothalamus of the rat brain.[22] Radioactively labeled NPBW1 is also localized in other regions of the rat brain such as the BST, medial preoptic area (MPA), PAG, superficial gray layer of the superior colliculus (SuG), medial amygdaloid nuclei (MeA), and subfornical organ (SFO).[22] In general, NPBWR1 is most commonly expressed in brains at high levels in the amygdala.[10,21,22] Although the BST shows the highest level of NPBWR1 expression in small mammals, this phenomenon has not been shown in human beings. Kitamura et al.[10] have reported that NPBWR1 is most abundantly expressed in the CeA and BST, this may suggest that NPBWR1 is involved in the regulation of stress, emotion, fear, and anxiety. In addition, NPBWR1 is localized in the SCh and SO,[11] suggesting that NPB/W may be involved in the regulation of circadian rhythm via NPBWR1. On the other hand, NPBWR1 and NPBWR2 mRNAs are also localized peripherally in the pituitary and adrenal glands (in both the adrenal cortex and adrenal medulla).[14] These observations suggest that NPBWR-1 and -2 may be responded to stress by the hypothalamic–pituitary–adrenal HPA axis.[14,16] Moreover, NPBWR1 mRNA is expressed in the dorsal horn of the spinal cord, so it may be involved in pain regulation. On the basis of the distribution of NPBWR1, it is possible that species differences between human and rodent's CNS exist in relation to the physiological functions of NPB/NPW. The NPBR1 expression is summarized in Fig. 3.

Ziolkowska et al.[27] examined the expression of that system in cultured rat calvaria osteoblastlike cells (ROB) and its possible role in regulating ROB cell function. The results suggest that the system of NPW, NPB, and NPBWR1

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

directly regulates proliferative activity of cultured rat calvaria osteoblastlike cells.

NPBWR2

NPB is present in larger mammals and in rabbits but not in rats or mice. RT-PCR analysis has shown that NPBWR2 mRNA is highly expressed in the amygdala and hippocampus in human brain. Moderate levels of expression are found in the parietal cortex, thalamus, and caudate nucleus, and lower levels in the cerebellum, substantia nigra, and corpus callosum.[1] In the peripheral tissues, NPBWR2 mRNA is moderately expressed in the pituitary gland, adrenal gland, and testis, as well as in the cortical cells in the zona glomerulosa, fasciculata, and reticulata of the adrenal gland in human beings.[14]

NPW and Other Neuropeptides in the Hypothalamus

It is well known that the ARC, LH, and VMH in the hypothalamus are associated with energy homeostasis for feeding regulation. We have examined the neural colocalization of NPW with other feeding-regulating peptides. Typical orexigenic peptides are neuropeptide Y (NPY), orexin, and melanin-concentrating hormone (MCH) in the LH. Our results show very close neuronal interactions between NPW-containing nerve fibers and orexin- or MCH-containing neuronal cell bodies and nerve fibers in the rat brain.[25] On the other hand, using dual immunostaining method, Levine et al.[12] showed that c-Fos expression was induced in orexin-containing neurons in the perifornical region of the LH after intracerebroventricular infusion of NPW. In particular, c-Fos-LI was increased in the perifornical region of the LH after NPW infusion. Orexin is recognized as a peptide[6] that promotes feeding regulation and playing a role in the control of sleep/wakefulness. These findings suggest that the effect of NPW on food intake and sleep/wakefulness may be mediated via activation of the orexin pathway. Hirashima et al.[7] reported that NPB injection decreases the time spent in the waking state and increases the time spent in slow wave sleep during the dark phase. These results suggest that NPB may induce physiological slow wave sleep through NPBWR1 and modulate the occurrence of sleep/wakefulness. However, interactions between NPB- and orexin-containing neurons have not yet been shown by morphological studies.

The VMH is most commonly associated with the satiety center. However, most neurons have not yet been shown to be expressed in the VMH. We identified NPW-LI cell bodies in the VMH in the rat hypothalamus by immunohistochemistry. Leptin acts on the VMH where its receptors are abundantly expressed and reduces food intake via the signal transducer and activator of transcription-3 (STAT3) and suppressors of cytokine signaling (SOCS-3). Changes to the synaptic activity of projections from the VMH to proopiomelanocortin (POMC)-containing neurons in the ARC are known to inhibit food intake and to regulate glucose levels and energy homeostasis. Date et al.[2] have reported that leptin treatment promotes phosphorylation of STAT3 and then induces SOCS-3 in the NPW-containing neurons isolated from the VMH. It is possible that leptin mediates satiety signals via NPW neurons in the VMH. Moreover, using a double immunostaining method, NPW-containing neurons project to POMC-containing neurons in the ARC. Furthermore, treatment with NPW inhibits the firing of NPY neurons and decreases the frequency of spontaneous inhibitory postsynaptic current (sIPSCs) in POMC neurons in the ARC, as shown by loose patch extracellular recording of these neurons (identified by promoter-driven green fluorescent protein expression). These findings strongly suggest that NPW inhibits NPY and activates the POMC neuronal pathway, followed by inducing the suppression of food intake.

Based on the distribution of NPW-LI neurons in rat brain, we speculate that there are other functions of NPW in the brainstem because NPW-LI fibers abundantly project to the nucleus tractus solitarii (NTS) and parabrachial nucleus. Premotor neurons are well known to innervate the salivary glands and tongue. Neuroanatomical studies have shown that descending projections from the LH to the NTS and parabrachial nucleus contain the second- and third-order gustatory neurons, respectively.[13] Therefore, it is possible that NPW may be involved not only in the regulation of food intake but also in salivary secretion. Further studies are required to analyze precisely the neuronal networks underpinning each of these physiological functions.[24]

Chapter 116

Neuropeptide S

Rainer K. Reinscheid

ABSTRACT

Neuropeptide S (NPS) is one of the "youngest" members among the biologically active peptides. As such, description of its physiological functions and involvements in pathological conditions is still ongoing. NPS and its receptor NPSR1 are primarily expressed in the brain. In rodents, NPS precursor expression is restricted to a few brainstem nuclei, most intriguingly in a neuronal cluster adjacent to the noradrenergic locus coeruleus. NPSR1 transcripts are more widely expressed, with highest levels found in cortex, amygdala, thalamus, hypothalamus, and subiculum. Early preclinical investigations suggest that NPS might regulate arousal states, exploratory and anxiety-like behaviors, learning and memory, drug reward, feeding behavior, and sensory-motor gating. A functional polymorphism in human NPSR1 that changes the receptor's sensitivity for NPS has been associated with panic disorder and fear learning. These early results suggest that the NPS system may be an innovative drug target for the treatment of various mental illnesses.

DISCOVERY

Neuropeptide S (NPS) was first disclosed in a patent filed by Takeda Pharmaceuticals.[27] The patent reported that it had been isolated and purified according to the "orphan receptor strategy" by using its cloned receptor and ligand-induced second messenger activation as a bioassay.[5] The patent also disclosed the sequence of the receptor but contained no further data on tissue distribution, biological effects, or physiological functions. In 2004, we described the pharmacological characterization, tissue distribution and behavioral effects of this novel ligand/receptor system and suggested naming the peptide after the conserved N-terminal serine residue (single letter code: S; Fig. 1).[31] NPS is a 20 amino acid peptide that is found in the genome of all tetrapods but appears to be absent from fish and invertebrate genomes.[24] Recently however, a putative precursor protein encoding a truncated peptide that is identical with NPS 1–7 has been cloned from the cephalochordate *Branchiostoma floridae* (Fig. 1).[11] It is currently unclear if this peptide represents a species ortholog or is the result of convergent evolution. Intriguingly, the same seven terminal amino acid residues of NPS (SFRNGVG) are perfectly conserved across all species examined thus far (Fig. 1),[24] suggesting that the *Branchiostoma* peptide might represent an "early" evolutionary version of NPS. However, the absence of NPS-like sequences in the more complex and evolutionarily younger fish genomes is difficult to explain in this context.

STRUCTURE OF THE mRNA/GENE

NPS is encoded by a rather short, but typical, precursor protein. Including the signal peptide, the human NPS precursor is only 89 amino acid long (Fig. 2). Despite the short coding sequence, the human NPS gene contains at least 3 exons, with exon 1 encoding the 5′-UTR and the first two amino acids of the precursor protein, exon 2 encoding the signal peptide, and exon 3 coding for the remaining precursor sequence and the 3′-UTR. The absolute size of the NPS precursor mRNA has never been determined experimentally in any species, for example by Northern Blot analysis, but a search of the EST database in GenBank yields a bovine EST clone with a length of 669 bp (accession: DN276816) that contains the entire open reading frame and a substantial 3′ sequence. This suggests that the 3′-UTR of the NPS precursor mRNA might be at least 300 bp in size. The unprocessed NPS sequence is found at the C-terminus of the predicted precursor and is preceded by a pair of basic amino acids (Lys–Arg; Fig. 2), which are typically found as proteolytic processing sites in most neuropeptide precursors.

PROCESSING OF THE PRECURSOR

Processing of the NPS precursor protein has not yet been investigated systematically. Full length NPS 1–20 was isolated from rat and mouse brain extracts,[27] suggesting that proteolytic cleavage of the precursor must have occurred at the dibasic Lys–Arg motif immediately preceding immature NPS. A comparison of putative NPS precursor proteins from over 30 tetrapod species revealed that the protein "spacer" between the signal peptide and unprocessed NPS shows little conservation, suggesting that no other biologically active peptides may be encoded by this precursor protein, other than NPS itself.[24]

FIGURE 2 Alignment of human, mouse and bovine NPS precursor proteins. The putative signal peptide is underlined and the presumed signal peptide cleavage site is indicated by an arrow. The presumed dibasic proteolytic processing site is indicated by a box. Amino acids different from the human precursor sequence are shaded. Amino acid positions are given on the left.

Indirect evidence about the presumed processing of NPS precursors comes from a recent study of global gene expression in NPS-synthesizing neurons. Using NPS/EGFP-transgenic mice, NPS/EGFP-positive cells were harvested by laser-capture microdissection and mRNA was extracted and prepared for microarray gene expression analysis.[16] The results showed strong expression of the prohormone convertases Pcsk1, Pcsk2, Pcsk6, and nardilysin, that are presumably involved in neuropeptide maturation (see convertase chapters in Peptide Biosynthesis/Processing section of this book).

As a typical neuropeptide, NPS is most probably degraded by extracellular proteases after its synaptic release. The structures of degradation products and enzymes involved in NPS inactivation are, however, unknown at this time.

DISTRIBUTION OF THE mRNA/PEPTIDE

Currently, detailed expression results are only available from rat and mouse brain. Analysis of NPS distribution in rat tissues revealed that the precursor mRNA is strongly expressed in the brain. Peripheral tissues displaying NPS precursor mRNA expression are salivary and mammary glands, and thyroid.[31] NPS precursor transcripts are strongly expressed in three nuclei of the rat brainstem: the locus coeruleus (LC) area, principal sensory trigeminal nucleus (Pr5), and the lateral parabrachial nucleus (LPB) (Fig. 3). A more detailed investigation by double in situ hybridization in the LC region revealed a cluster of NPS-expressing neurons localized ventromedial to the noradrenergic neurons of LC proper that are situated in between the LC and Barrington's nucleus. This region is also referred to as the pericoerulear (periLC) area. The anatomical location of these NPS-producing neurons is unique and defines a previously unclassified cluster of neurons in the periLC region.[31,32] Neurochemical analyses show that the periLC NPS-expressing cells are mostly glutamatergic neurons with a small number of presumed cholinergic neurons. All NPS-producing cells in Pr5 are glutamatergic neurons, whereas in the rat LPB, NPS co-localizes with corticotropin-releasing hormone

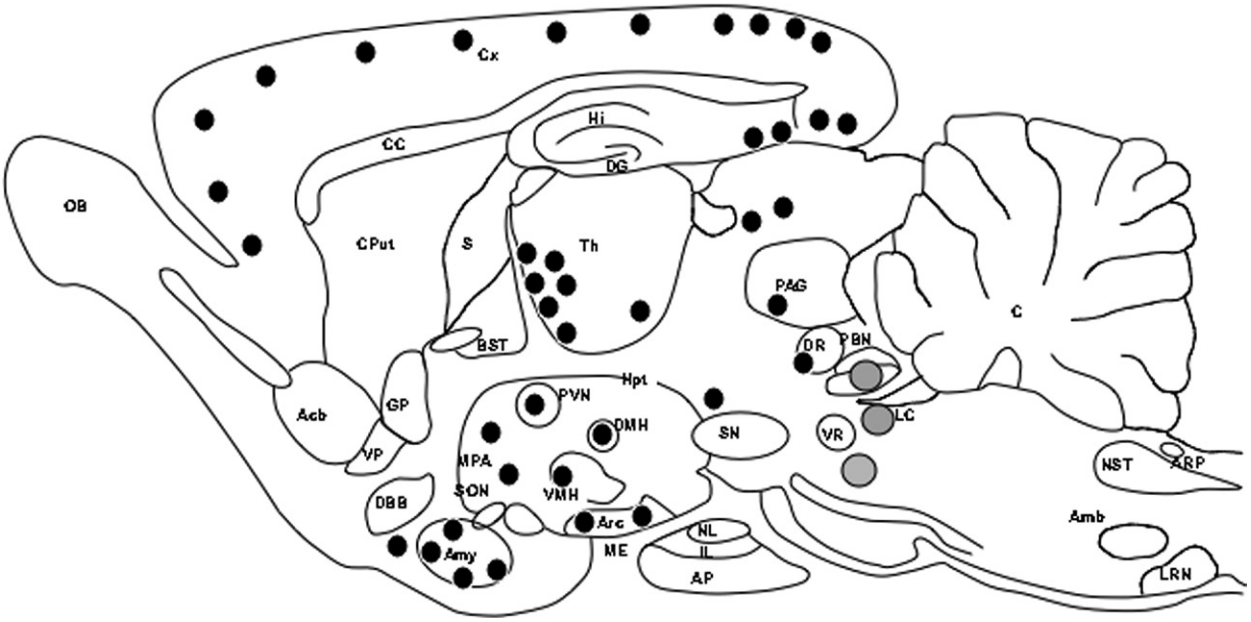

FIGURE 3 Schematic drawing of NPS precursor and NPSR1 transcript distribution in the rat brain. Gray circles depict areas of NPS precursor mRNA expression, while black circles indicate brain regions with high NPSR1 transcript expression.

(CRH).[32] The neurochemical profile of NPS-producing neurons suggests that the NPS system may have an excitatory role since NPS is predominantly found colocalized with excitatory transmitters. Besides the brainstem, only a few isolated cells expressing NPS precursor mRNA are found in the rat amygdala and hypothalamus.

In the mouse brain, strong NPS precursor mRNA expression is found in only two regions of the brainstem: the periLC and the Kölliker-Fuse (KF) nucleus that is located in the lateral parabrachial area.[6] Expression of NPS peptide in periLC and KF nucleus of the mouse brain was also confirmed by immunostaining. In contrast to the rat brain, mouse Pr5 does not appear to express NPS precursor transcripts or protein. Furthermore, no isolated neurons expressing NPS mRNA were found in hypothalamus or amygdala of the mouse brain. The location of periLC NPS-expressing neurons in rat and mouse brain appears to be very similar, indicating that this brainstem region might have equivalent functions in both rodent species. NPS-expressing neurons in the mouse KF nucleus are co-expressing CRH,[16] suggesting that this group of neurons might be the mouse equivalent to the more medially located LPB NPS-producing cells of the rat brain.

Projections of NPS-synthesizing neurons were studied in the mouse brain by immuno-staining with antisera raised against either the N- or C-terminus of NPS.[6] Dense NPS-immunopositive fiber projections were detected in hypothalamic and thalamic regions, while lower fiber densities were found in amygdala and forebrain structures. The distribution of NPS-immunopositive fibers overlaps well with NPSR1 mRNA expression in thalamic and hypothalamic regions. Mismatches between NPSR1 expression and NPS-immunoreactive fiber staining were observed in hippocampal, olfactory and cortical regions (Fig. 3).[6] This might result from insufficient sensitivity of the antisera, or activity-dependent regulation of NPS expression in neurons targeting these brain areas. Cell bodies of NPS-synthesizing neurons in the brainstem were clearly labeled by the antisera.[6,16]

RECEPTORS AND SIGNALING CASCADES

Like many formerly orphan receptors, NPSR1 was known under multiple names (GPR154, GPRA, VRR1) before the identification of its endogenous ligand. Analysis of available genomes suggests that only one NPSR1 gene exists in diploid tetrapods, with no closely related subtypes. NPSR1 is only distantly similar to vasopressin and oxytocin receptors. NPSR1 is however a very complex gene, divided into at least 9 exons and presumably spanning more than 300 kb on human chromosome 7p14-15. For human NPSR1, multiple splice variants (some of which cannot encode functional receptors) have been reported by Vendelin et al., 2005.[9] In addition, several coding polymorphisms have been identified in human NPSR1. In fact, NPSR1 was originally identified as a putative asthma-susceptibility gene using a positional cloning approach.[14] Several studies have independently replicated the association of certain NPSR1 haplotypes with asthma and possibly other forms of allergic immune disorders,[30] while others could not verify

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

these findings [e.g. Ref. 2]. Since the expression of NPSR1 in lung tissue has not been firmly established, the pathophysiological mechanism of NSPR1 function in asthma is currently discussed controversially. A recent study however suggests a neurogenic model by which NPSR1 activation may influence respiratory function.[33]

Expression of NPSR1 in HEK 293 cells or CHO cells reveals that NPS dose-dependently induces mobilization of intracellular Ca^{2+}, formation of cAMP, and activation of MAPK phosphorylation.[25,31] Structure-activity relationship studies show that the conserved N-terminal part of NPS (NPS 1-6) is absolutely critical for receptor activation while the C-terminal half of the peptide tolerates truncation or substitutions.[12,25] The glycine residue in position 5 of full-length NPS appears to play a critical role in ligand/receptor interaction, because substitution with bulky side-chain D-amino acids creates molecules with antagonistic profiles.[3] Finally, several studies have reported synthetic small-molecule antagonist structures with medium to high potency and selectivity for NSPR1,[19] for review see Refs. 7,19].

A coding polymorphism (rs324981, A/T) in human NPSR1 changes the amino acid at position 107 from asparagine to isoleucine ($N^{107}I$). Analysis of the pharmacological profile of the two receptor isoforms revealed that NPSR-N^{107} requires 5–10-fold higher concentrations of NPS for half-maximal activation than NPSR-I^{107}, suggesting that I^{107} (encoded by the T allele) represents a gain-of-function genotype.[25] The polymorphism occurs with surprisingly high frequency in the human gene pool and has been recently associated with panic disorder.[18] Interestingly, this polymorphism appears to be primate-specific, as all other tetrapod genomes encode only NPSR-I^{107}, suggesting that the N^{107} variant might confer some selective advantage to primates.

BIOLOGICAL ACTIONS WITHIN THE BRAIN

Since NPS was discovered only a few years ago, the description of its physiological functions is still at a relatively early stage. Nevertheless, a number of interesting brain functions have been identified that appear to be modulated by the NPS system. Since NPS is a peptide, most studies have used intracerebroventricular administration to investigate central functions of NPS. More recently, behavioral studies using NPSR1-selective antagonists or NPSR1 knockout mice are starting to complete the picture of biological effects produced by either NPSR1 over-activation or disrupted NSPR1 signaling.

Most consistently, central administration of NPS was found to increase arousal and produce wakefulness.[3,31] Despite this psychostimulatory effect, NPS was also found to attenuate anxiety-like behaviors.[15,26,31] This combination of anxiolytic and stimulatory effects of NPS implies that synthetic small-molecule agonists targeting NPSR1 could be the long-sought non-sedating anxiolytic drugs that the pharmaceutical industry has hoped to develop for a long time. Other studies suggest that NPS might modulate food intake,[28] although reports of conflicting findings make it currently difficult to interpret the role of NPS in feeding behavior. Several studies also linked activation of central NPS neurotransmission to the effects of rewarding or abused drugs, in particular to reinstatement of drug-seeking behaviors.[4,22] NPS appears to stimulate drug-seeking behaviors and is able to reinstate such behaviors even after extinction. Furthermore, NPS produces protective effects in animal models of pharmacologically induced psychosis: Central NPS administration is able to reverse neurotoxic, biochemical, and behavioral effects produced by the NMDA receptor antagonist MK-801, similar to the atypical antipsychotic clozapine.[20] Analysis of behavioral phenotypes in NPSR1 knockout mice reveals deficits in arousal, circadian activity, and mildly increased anxiety-like behaviors, suggesting that endogenous NPS signaling is required for these brain functions.[10]

A number of recent studies support a prominent role of NPS signaling in cognitive processes, in particular in processing of aversive memories. By enhancing glutamatergic neurotransmission, NPS accelerates fear extinction[13] and modulates expression of conditioned fear.[17] These effects were attributed to specific neuronal circuits within the amygdala and the adjacent endopiriform nucleus. Conversely, a synthetic NPSR1 antagonist is able to attenuate fear extinction.[13] Adding further evidence to the hypothesis that NPS may play an important role in cognition, we recently described a prominent function of NPS signaling in two different animal models of learning and memory.[21] Post-training central NPS administration enhances memory consolidation by interacting with noradrenergic systems in the brain. This pro-cognitive effect of NPS is evident for both aversive and neutral memory contents, and can last for several days after drug administration. Conversely, NPSR1 knockout mice display significant deficits in those memory paradigms, indicating that the endogenous NPS system is required for efficient memory processing.

In the obvious absence of approved synthetic drug molecules targeting NPSR1, no pharmacological studies involving humans are currently available to probe the role of NPS signaling in human brain functions. However, taking advantage of the above mentioned functional polymorphism in human NPSR1 and the hypothesized change in agonist sensitivity of the receptor, a number of recent studies have addressed the question: What functional consequences does attenuated NPS signaling have in humans? A recent study in healthy volunteers reported that NPSR genotypes influence processing and evaluation of fear memories.[23] The study used fear conditioning in humans and found that

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

T-carriers (coding for NPSR-I[107]) rated their subjective fear significantly higher than AA homozygotes (coding for NPSR-N[107]), who were expected to display attenuated NPS signaling. Acquisition and extinction of fear memories was accelerated in T-carriers, suggesting that the endogenous NPS system might be involved in these processes. These observations in humans are in line with recent findings in mice, showing that central NPS administration can enhance extinction of fear memories.[13] Neuroimaging by fMRI shows selectively higher activation of the dorsomedial prefrontal cortex and the dorsal anterior cingulate cortex in NPSR T-carriers during acquisition of fear memories,[23] indicating functional control over these two important brain structures by the NPS system. Similar neuroimaging observations were made in two separate studies on panic disorder patients or healthy human controls: T-carriers rate pictures with emotional facial expressions higher than AA homozygotes and showed increased activation of prefrontal cortical and amygdala structures.[8,9] These early results suggest, that, similar to preclinical animal models, the human NPS system might also be involved in processing of acute fear and formation of fear memories.

PATHOPHYSIOLOGICAL IMPLICATIONS

As mentioned above, NPSR1 was originally identified as an asthma-susceptibility gene that may also be associated with other forms of allergic diseases.[14] Numerous studies have replicated the initial findings while others did not. Despite the original report of upregulated expression of NPSR1 in asthmatic human or sensitized mouse lung tissue, subsequent studies could not firmly establish a physiological role for NPSR1 in lung or lung-associated immune cells.[1] A possible explanation for the discordance between strong genetic data implying certain NPSR1 haplotypes in asthma and the absence of functional responses of NPS in lung tissue was recently suggested by a study showing that central administration of NPS increased respiratory frequency and reduced airway responsiveness to methacholine in mice.[33] These new observations imply a neurogenic mechanism by which the NPS system may influence respiratory function and might thus be indirectly involved in the pathophysiology of asthma.

At this time, the most convincing evidence for an involvement of the NPS system in pathophysiological conditions comes from genetic data, linking NPSR1 to panic disorder. As mentioned earlier, T-allele carriers (coding for the more sensitive NSPR-I[107]) are found over-represented among panic disorder patients, as compared with healthy controls, while AA homozygosity appears to be a protective genotype.[18,9] The association was reported to be gender-specific in Japanese males,[18] while the second study used a German case/control cohort and reported no gender effects but a trend toward stronger association in females.[9] The reason for the gender discrepancy between the two studies is currently unclear, but certainly warrants further attention, including independent replication in other ethnic cohorts. Most importantly, another recent study in healthy volunteers may offer a mechanistic explanation for the association of NPSR1 genotypes with panic disorder. T-carriers were reported to over-rate their fear and form fear memories more efficiently, leading to "catastrophizing" fear reactions that involve NPSR genotype-dependent activation of the prefrontal cortex.[23] It is plausible that this effect may contribute to progressively enhanced panic responses.

The many physiological functions that have been attributed to NPS offer numerous therapeutic opportunities for developing drugs that target NPSR1. Thus far however, only synthetic NPSR1 antagonists have been reported[7] and none of them has entered clinical trials at this stage. Preclinical development is certainly still at an early stage since the NPS system was only discovered a few years ago, and it remains to be seen which therapeutic indications will emerge for compounds targeting NPSR1. However, the strong genetic results supporting a role for NPS signaling in panic disorder should make a compelling case for pharmaceutical development.

Chapter 117

Neurotensin/Neuromedin N

Paul R. Dobner and Robert E. Carraway

ABSTRACT

Neurotensin (NT) and neuromedin N, two bioactive peptides of brain and gut origin, are processed from a common precursor by prohormone convertases (PCs). Differential processing occurs in some tissues most probably resulting from the tissue-specific expression of distinct PCs, yielding large, N-terminally extended forms of the peptides. Two G protein-coupled receptors show preference for NT but bind both the peptides. NTR-1 signaling elevates intracellular [Ca^{2+}] and can also increase cGMP, cAMP, and arachidonic acid metabolites. NTR-1/sortilin (NTR-3) heterodimers seem to modulate NT signaling and trafficking of internalized receptors, but NT may also signal through sortilin. Intimately associated with dopaminergic systems, NT is most probably an endogenous antipsychotic and has also been implicated in the modulation of psychostimulant responses, pain perception, stress-induced analgesia, appetite control, stress responses, and reproductive functions. The development of NT agonists may provide new pharmaceuticals for the treatment of schizophrenia, drug addiction, and stress-related neuropathic pain syndromes.

DISCOVERY OF NEUROTENSIN

In 1967, Susan Leeman discovered that the extracts of bovine hypothalami induce vasodilation and anaphylactic shock in rats. Using this assay, her laboratory isolated, sequenced, and synthesized the active substance, a 13-residue peptide that they named neurotensin (NT).[6] NT is broadly expressed in the limbic nervous system and intestinal endocrine cells and is also found in various glands and in peripheral nerves.

NT is a member of a family of peptides that are strikingly similar in their C-terminal regions (Table 1). These peptides share C-terminal residues with NT that have been shown to be critical for NT function and display many of the same pharmacological properties for those that have been tested. For instance, the venom of the cone snail contains the NT-like peptide contulakin G, which is a potent analgesic in rats and dogs.[2] Several NT-related peptides are also present in neuronal cells of the protocordate *Ciona intestinalis* (Table 1).

NT most probably has multiple neuronal and endocrine signaling functions, including the modulation of dopamine (DA) signaling, stress-induced analgesia, energy balance, stress, and reproductive functions. This review focuses on the biosynthesis, distribution, receptor signaling, and potential functions of NT in the CNS.

STRUCTURE OF THE NEUROTENSIN/ NEUROMEDIN N PRECURSOR mRNA/GENE

The amino acid sequence of the NT precursor was first inferred from canine cDNA sequences and is highly conserved in vertebrates.[8] The predicted prepro form of the precursor ranges from 165 to170 amino acids in length, with NT and the related hexapeptide neuromedin N (NMN) lying in tandem near the carboxyl terminus of the precursor, bounded and separated by Lys-Arg processing sites (Fig. 1). The analysis of the rat, mouse, and human NT/NMN genes reveal that the coding region is spread over four exons, separated by three introns spanning just over 10 kb.[20] The gene is transcribed to yield two different transcripts (1.0 and 1.5 kb) that differ only in the extent of the 3'-untranslated region, most probably arising from the differential use of alternative polyadenylation signals. The two mRNAs are expressed in about equal amounts in the brain, but the 1.0 kb mRNA greatly predominates in the gastrointestinal tract. The sequences immediately upstream of the transcriptional start site contain a series of response elements (AP-1, CRE, and GRE) that are important for NT/NMN gene induction in response to environmental stimuli in PC12 cells. A variety of stimuli regulate NT/NMN gene expression in a brain region-specific manner.

NT/NMN mRNA EXPRESSION IN BRAIN

NT/NMN mRNA and its peptide products are expressed in many forebrain regions, with higher levels in limbic regions, including hippocampus and subicullum, VP, BNST, medial Acb, and Cput (Fig. 2).[1] NT/NMN mRNA-positive neurons are located mainly in the dorsomedial and ventral aspects of the Cput rostrally but are more evenly distributed in the caudal regions. A continuum of positive cells was observed

stretching from the S through the preoptic area, including the lateral S, DBB, lateral BNST, and lateral Hpt. Steroid hormones and neurotransmitters have been implicated in the regulation of NT/NMN mRNA expression in several regions of the brain, including the medial preoptic area, Arc, PVN, periventricular nucleus, amygdala, Cput, and Acb. In the brainstem, NT/NMN mRNA-positive neurons are most abundant in the PAG and DR and can also be found in adjacent lateral structures (cuneiform nucleus, microcellular tegmental nucleus).

PROCESSING OF THE PRECURSOR

The NT precursor is differentially processed by distinct prohormone convertases (PCs) in the brain and gastrointestinal tract (Fig. 1, reviewed in Ref. 22). PCs are described in detail in the Peptide Biosynthesis/Processing section of this book. In the brain, PC2 results in nearly complete processing of both the peptides, although brain NT levels are only decreased by ~15% in PC2 knockout mice. This is most probably because the precursor can also be processed by PC1 and PC5A, which are colocalized with NT and are capable of generating NT from the precursor. After liberation of the NT sequence from the precursor, the N-terminal Gln residue is converted into pGlu most probably through the action of glutaminyl cyclase. In the gastrointestinal tract, PC1 inefficiently cleaves the Lys-Arg pair amino terminal to NMN, resulting in the accumulation of amino-terminally extended NMN (large NMN in Fig. 1) that stretches from the signal peptide cleavage site to the carboxyl terminus of NMN (amino acids 23–147 in the rat sequence) and NT in gut endocrine cells. Similarly, colon cancer cell lines expressing both NT and PC5A produce predominantly amino-terminally extended forms of both NMN and NT (large NT in Fig. 1), similar to those found in the adrenal medulla, indicating that differential expression of distinct PCs can account for the observed tissue-specific processing of the NT precursor. The secretion of amino-terminally extended forms of NMN and NT may produce longer lasting biological effects because of their enhanced stability in the bloodstream compared with that of the fully processed peptides. A dibasic amino acid pair near the central region of the precursor is inefficiently processed in the brain and not used in the gastrointestinal tract, and complete processing of the NT precursor results in the production of a relatively stable fragment (Fig. 1, amino acids 24–140 of the human NT precursor) that extends from the signal peptide cleavage site through to the amino acid preceding the Lys-Arg amino terminal processing site of NMN.[11] This precursor fragment is detectable in serum from healthy individuals, is stable in both human plasma and serum, and is released into the serum after ingestion of an ordinary meal, opening the possibility that it may serve as a surrogate marker for NT secretion.

RECEPTORS AND SIGNALING CASCADES

Four NT receptors have been identified, two that are 7-transmembrane G protein-coupled receptors (NTR-1, NTR-2) and two primarily intracellular proteins related to yeast sorting receptors (NTR-3/sortilin, NTR-4/SorLA). NTR-1 displays the highest affinity (Kd, 0.1 nM) and seems to mediate NT effects on dopaminergic transmission, hot-plate latency, temperature regulation, and smooth muscle contractility (reviewed in Ref. 21). First described as a lower affinity receptor (Kd, 3 nM) with a differing specificity, NTR-2 has been implicated in the analgesic effects of NT (reviewed in Ref. 29). Although the role of NTR-3 is less clear, one possibility is that through binding and internalizing NT this receptor serves to regulate turnover of the peptide. Evidence supports the involvement of NTR-3 in the growth-promoting effects of NT and in NT-induced migration of brain microglial cells.

Signal transduction studies in transfected cell systems and cancer cell lines indicate that NTR-1 is primarily coupled to $G_{\alpha q}$ and signals via the activation of phospholipase C and the generation of IP_3, causing an elevation in intracellular $[Ca^{2+}]$ (reviewed in Ref. 21). Concomitant generation of DAG leads to the activation of PKC in some cells, stimulating MAP kinases and PI3 kinase via complex mechanisms that can involve EGF receptor transactivation. This

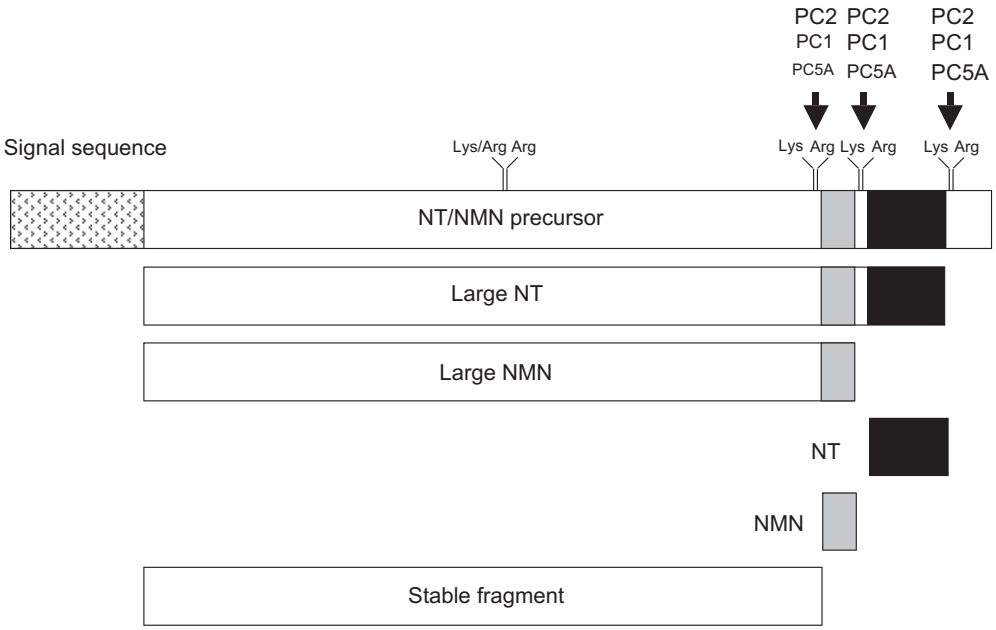

FIGURE 1 Schematic diagram of the NT/NMN precursor and its major processing products. The full length precursor is 165–170 amino acids long depending on the species and comprises 169 amino acids in the rat. The positions of the signal peptide (stippled fill, aa 1–23) and the NMN (gray fill) and NT (black fill) coding domains are indicated. The NMN and NT coding domains are bounded and separated by the indicated Lys-Arg processing sites. An additional Lys-Arg pair is located near the center of the precursor, but the available evidence suggests that this is not a major processing site. The prohormone convertases that have been shown to cleave the Lys-Arg processing sites are indicated and the extent to which they cleave a particular site is indicated by the size of the type, with the most efficient cleavage indicated by larger letters and the least efficient by smaller letters. PC1 cleaves the Lys-Arg pair located at the amino terminal end of NMN inefficiently but cleaves the sites surrounding NT efficiently resulting in the production of NT and Large NMN (intestinal pattern). PC5A cleaves the site at the carboxy-terminal end of NT efficiently, but the upstream sites less efficiently leading to the production of Large NT and Large NMN (adrenal pattern). PC2 cleaves all three sites efficiently resulting primarily in the production of NT and NMN (brain pattern).

signaling can have a feed forward component, in that NT-induced MAP kinase activation leads to the upregulation of EGF receptor. In neuroblastoma cells and rat brain slices, NT can elevate cGMP formation, inhibit cAMP synthesis and stimulate PI turnover, and evidence suggests that the third intracellular loop of NTR-1 is required for interactions with G_q, while the carboxy-terminal tail interacts with $G_{i/o}$ and G_s (reviewed in Ref. 21). Liposomal ceramide has been shown to decrease the interaction of NTR-1 with G_q within structured membrane microdomains, which inhibits the growth stimulatory effects of NT in MDA-MB-231 breast cancer cells. NTR-1 is inducibly palmitoylated on Cys^{381} and Cys^{383} (rat sequence), and inhibition of this process by site-directed mutagenesis and pharmacological strategies diminishes NT-induced ERK phosphorylation and reduces the ability of NT to protect against apoptosis in breast cancer cells.[17] NT activation of DA neurons appears to involve cAMP signaling, and NT potentiates cAMP formation (via NTR-1) in response to G_s-agonists by facilitating the activation of Ca^{2+}-dependent adenylyl cyclases. Perhaps secondary to its effects on $[Ca^{2+}]$, NT also activates PLA2 and DAG lipase, stimulating arachidonic acid release and the formation of bioactive metabolites via the cyclooxygenase and lipoxygenase pathways. This signaling could also be amplified by feed forward mechanisms because the expression of PLA2 is upregulated by the activation of MAP kinase (reviewed in Ref. 7). NT is the most potent substance known to stimulate leukotriene formation in rats, and the possible relevance of this to its central effects is not well investigated.

Signaling mechanisms for NTR-2 and NTR-3 are not yet clear. NTR-2 constitutively activates IP production, and this process is stimulated by the NTR-1 antagonist SR48692 but suppressed by NT (reviewed in Ref. 29). NTR-3 is primarily localized to ER-Golgi membranes but ≅10% is on the cell surface. NTR-3 can form heterodimers with NTR-1, decreasing the potency of NT to stimulate IP formation and to activate MAP kinase. Thus, NTR-3, which cannot promote either response, modulates these effects of NTR-1.

Results obtained by site-directed mutagenesis favor a model for NTR-1 activation in which binding of NT to key residues in EC loop 3 and TM 6 and 7 leads to a shift in IC loop 3 that enhances binding to G_q (reviewed in Ref. 21). The relative instability of NTR-1 in detergents has led investigators to use a systematic mutational approach to identify receptor mutants that display enhanced thermostability, resulting in the identification of an NTR-1 variant that is stabilized in an agonist binding conformation that presumably might be used with a wider range of detergent and buffer conditions for crystallization.[35]

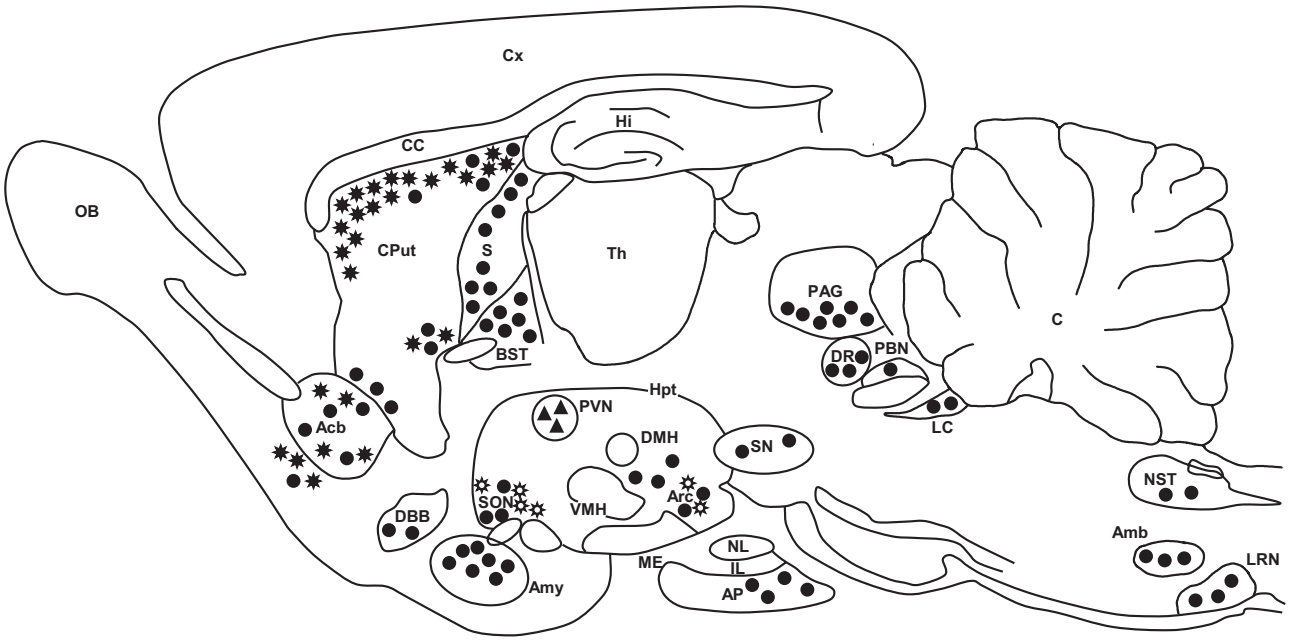

FIGURE 2 Schematic diagram of the distribution of NT-IR neurons in the rat brain. (●) NT-IR neurons detected after colchicine treatment. (▲) NT-IR neurons induced by stressful stimuli that are also detected after colchicine treatment. (✸) NT-IR neurons induced by either psychostimulants (dorsomedial CPu, Acc) or dopamine D_2 antagonists, including typical antipsychotic drugs (dorsolateral CPu, Acc). (✡) Estrogen-inducible NT-IR neurons in the female MPO and arcuate nucleus. NT gene expression in the rostal MPO nucleus is sexually dimorphic. Quantitative analysis of NT content by RIA (pmole/g wet weight tissue) provides a more comprehensive picture of the distribution of the peptide in various brain regions (OB, 3; Cx, 4-5; Acc, 29; CPut, 10; S, 73; BST, 172; Hi, 7; Th, 5-23; Hyp, 76-128; ME, 128; SN, 13; PAG, 42; LC, 54).

CONFORMATION

2D solid-state NMR spectroscopy has been used to study the conformational changes of NT8-13 on interaction with an N-terminally truncated form of rat NTR-1.[27] On binding to the receptor, the peptide rearranges to adopt a β-strand conformation, characterized by a ψ(Pro10) dihedral angle of 146±15°. The NMR spectrum of NT (8–13) in solution is also consistent with the presence of a type II β-turn, whereas the spectrum of a homolog that displays 40-fold less affinity for human NTR-1 does not.[34] Furthermore, a lactam-bridged analog of NT8-13 with ψ(Pro10) angles restricted to an angle (130°) close to the experimentally determined one exhibits ~1000-fold higher affinity for porcine NTR-1 than the stereoisomer (−130°), providing further evidence for the NMR-derived bioactive conformation.

BRAIN FUNCTIONS

Close Alliance between NT and Dopamine

NT has been broadly implicated in the modulation of DA signaling and can produce both psychostimulant- and antipsychotic drug (APD)-like effects after microinjection into different regions of the brain (reviewed in Ref. 5). Most midbrain DA neurons express high levels of NTR-1, and NT can stimulate these neurons to increase striatal DA release in the Acb. NT can also act presynaptically to potentiate DA release in both the Acb and Cput, most probably by antagonizing DA D_2 receptor autoinhibition. Consistent with these observations, NT microinjection in the VTA stimulates locomotor activity and repeated administration results in sensitization to not only NT but also psychostimulant drugs. Prolonged administration with the NT antagonist SR48692 lowers basal DA release in the Acc, consistent with the hypothesis that endogenous NT acts to augment DA release through NTR-1; however, basal and stress-induced DA release in the mPFC are unaffected. NTR-1, but not NTR-2, knockout mice are reported to be hyperdopaminergic with elevated basal DA release in the Cput, although release in the Acc and mPFC was not examined.[26] These differences could reflect regionally distinct roles for NT in the control of DA release, but could also result from either adaptive changes in NTR-1 knockout mice or unanticipated effects of prolonged NT antagonist administration.

NT can also produce neuroleptic-like effects when administered in the Acc, seemingly inconsistent with the evidence cited above indicating that NT acts presynaptically to augment DA signaling. The most probable explanation for this is that NT either acts postsynaptically or on other presynaptic afferents to oppose DA signaling and electron microscopic immunohistochemical analysis indicates that NTR-1 is expressed on both dopaminergic and excitatory afferents- and on postsynaptic neurons in the Acc; however, NTR-1 seems to be expressed primarily on striatal afferents

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

in the Cput. NTR-2 knockout mice have lower levels of basal striatal glutamate release and both NTR-1 and NTR-2 knockout mice display muted amphetamine-stimulated striatal glutamate release,[25] consistent with the hypothesis that endogenous NT modulates striatal glutamate release.

NT may be an Endogenous Antipsychotic

Considerable evidence suggests that NT mediates at least a subset of responses to certain APDs. APDs elevate striatal NT expression and NT administration in the Acb suppresses amphetamine-stimulated locomotor activity, similar to APDs, consistent with the idea that increases in NT signaling might be involved in APD actions (reviewed in Ref. 5). Although animal models of schizophrenia are necessarily limited, latent inhibition (LI) and prepulse inhibition (PPI) of the acoustic startle response measure aspects of sensorimotor gating that can be influenced by APDs. Enhanced DA transmission and isolation rearing disrupt PPI and APDs can restore PPI to control levels. In mice, APDs can also increase PPI above basal levels without prior disruption by DA agonists. There is increasing evidence that either pharmacological or genetic disruption of NT signaling can have a profound impact on APD responses in these animal models.

NT has been implicated in both the acquisition of LI and APD enhancement of LI. NT antagonist administration was shown to interfere with the acquisition of LI, and this was observed with both the relatively selective NTR-1 antagonist SR48692 and the NTR-1/NTR-2 antagonist SR142948A, indicating that NT signaling through NTR-1 may be particularly important (reviewed in Ref. 5). The suppressive effects of SR142948A are ameliorated by coadministration of the D_2 antagonist sulpiride, suggesting that NT antagonist treatment may increase DA D_2 transmission in the Acb or other key brain regions involved in LI. NT also seems to play a role in APD enhancement of LI, because SR142948A administration 1 hour before the last of 7 daily injections of haloperidol prevents augmentation of LI. Thus, NT likely plays a role in both basal and APD-enhanced LI, possibly through effects on DA D_2 signaling.

NT also appears to play a role in both basal and APD-enhanced PPI; however, results from NTR-1 and NTR-2 knockout mice suggest a more complicated picture. Preadministration of the NTR-1/NTR-2 antagonist SR142948A blocks the ability of both the typical APD haloperidol and the atypical APD quetiapine to restore PPI deficits in isolation-reared rats, without affecting basal PPI (reviewed in Ref. 5). Furthermore, NT mRNA levels are decreased by ~45% and NT receptor binding is increased by ~21% in the Acb shell in isolation-reared animals, and NT mRNA levels are restored to those observed in socially reared animals 4 hours after quetiapine treatment. Similarly, both haloperidol and quetiapine fail to augment PPI in NT knockout mice, which also have reduced basal PPI, although the response to clozapine is unaffected.[19] The decrease in basal PPI is modest and is not observed in either NTR-1 or NTR-2 knockout mice where it is instead elevated.[13,31]

The indirect DA agonist amphetamine disrupts PPI, but this effect is blocked in NT knockout mice,[19] suggesting that NT may play a crucial role in this process. Similar results have been reported for NTR-1 knockout mice;[31] however, another report indicates that amphetamine disruption of PPI is normal in these mice,[13] as it is in NTR-2 knockout mice.[31] These different results most likely reflect methodological differences, because both used NTR-1 knockout mice from the same source. These results provide a preliminary indication that NT signaling is required for amphetamine disruption of PPI in mice. NT participation in processes that either enhance or reduce PPI most likely reflects compartmental specificity in NT action within the circuits that modulate PPI, particularly the DA circuits. The analysis of amphetamine and haloperidol induction of striatal Fos expression has provided direct evidence for such compartmentalized NT signaling.[9,12]

NT and Psychostimulant Sensitization

As discussed above, NT is capable of modulating DA transmission at different levels. In addition to antipsychotic drug-like effects, NT produces psychostimulant-like effects after direct administration into the VTA and increases DA release in the Acb (reviewed in Ref. 5). Several different laboratories have reported that NT antagonist pretreatment blocks or attenuates amphetamine and can delay cocaine sensitization while sparing the acute locomotor stimulation produced by these drugs. By contrast, both amphetamine (PRD, unpublished observations) and cocaine[16] sensitization are augmented somewhat in NT knockout mice. Several other lines of evidence also suggest that NT acts to limit psychostimulant sensitization, including the observations that peripheral administration of the NT agonist, NT69L, suppresses nicotine sensitization, and that NT antagonist administration potentiates rather than blocks supersensitive locomotor responses to L-DOPA in dopamine-deficient mice. NTR-1 knockout mice show both increased basal and amphetamine-stimulated locomotor activity and striatal DA release, also consistent with the idea that NT acts to limit DA signaling, although psychostimulant sensitization was not examined.[26] However, both basal and cocaine-stimulated locomotor activities are similar to wildtype in NT knockout mice[16] and in rats treated with SR48692 (reviewed in Ref. 5). Thus, gene knockout and several other approaches favor a model in which NT acts mainly to limit psychostimulant sensitization, while experiments with NT antagonists indicate the opposite. Further work will be required to determine whether this discrepancy results from compensatory mechanisms in knockout animals or unanticipated antagonist effects, for instance agonist or partial agonist activity at NTR-2.

NT and Pain

Given centrally, NT enhances nociceptive responses at lower doses, but produces a potent analgesic response at higher doses that in most studies does not require μ-opioid receptor signaling (reviewed in Ref. 10). NT and NT receptors are expressed in the central descending circuitry involved in pain modulation and in the spinal cord, consistent with a possible role in pain modulation. The evidence to date indicates that endogenous NT plays a relatively minor role in basal nociception but is critical for at least certain aspects of stress-induced antinociception (SIAN). Remarkably, SIAN is totally absent in NT knockout mice, where water avoidance/cold-water swim stress instead results in a hyperalgesic response to colonic distension.[15] Similar results were obtained in rats pretreated with SR48692, indicating that SIAN probably requires NT signaling through NTR-1, and the defects observed in NT knockout mice are not because of developmental or compensatory changes resulting from the lifelong absence of NT signaling.[15] NTR-2 signaling has also been implicated in certain aspects of SIAN. NTR-2 knockout mice display a selective defect in SIAN after cold-water swim stress during the latter part of the second phase of the pain response in both the intraplantar formalin test and the paw withdrawal response to thermal stimuli, while nonstressed responses are comparable with wildtype.[23] Similar results occur in the paw withdrawal test after repeated administration of the NTR-1/NTR-2 antagonist SR142948A, indicating that the differences observed in NTR-2 knockout mice also do not result from developmental defects or compensatory changes resulting from the absence of NTR-2. Furthermore, intrathecal administration of both nonselective and NTR-2-selective NT agonists potentiate cold-water swim stress-induced SIAN in the paw withdrawal test. These results are consistent with the previous observations that NTR-2-selective agonists suppress pain responding in the intraplantar formalin test selectively during the latter part of the second phase of the pain response, influencing predominantly paw lifting while sparing paw licking, biting, and shaking behaviors. These results suggest that endogenous NT signaling through both NTR-1 and NTR-2 is particularly important for SIAN.

In contrast to SIAN, NT seems to play a relatively minor role in basal pain perception, where it seems to facilitate pain responses. Although both NTR-1 and NTR-2 knockout mice respond similarly to wild type in a variety of pain tests, NTR-2 knockout mice display longer jump latencies in the hot-plate test.[28] Viseromotor responses to colorectal distension are also diminished in both NT knockout mice and rats pretreated with SR48692.[15]

The evidence discussed above suggests that NT not only facilitates basal pain responses but it also plays a key role in SIAN and any theory of NT modulation of pain responses must take into account these seemingly contradictory results. Perhaps the simplest explanation is that the direction of pain modulation depends on the intensity of NT signaling, with basal NT signaling facilitating nociception and increased NT signaling being analgesic. The observation that cold-water swim stress increases NT mRNA levels in certain Hpt regions that project to the PAG is consistent with the idea that stress-induced increases in NT signaling to the PAG may underlie SIAN. Increased NT signaling could lead to the selective recruitment of neurons involved in analgesic responses, such as PAG "off" cells.

Appetite Control

NT has been implicated as a possible satiety factor and mediator of the central suppressive effects of leptin on food consumption (reviewed in Ref. 3). Leptin administration suppresses food consumption and weight gain, possibly through the decreased expression of orexigenic peptides and increased NT expression in the hypothalamus. Similarly, NT expression is decreased in specific Hpt regions in response to a high-fat diet that results in obesity. Combined central administration of NT and leptin potentiates both the short-term inhibitory effects of NT on spontaneous food intake and early, but not late (24 h) leptin effects. Because the leptin effect is blocked by pretreatment with either NTR-1 antagonist or NT antiserum, it has been suggested that NT mediates the central effect of leptin. Collectively, these results indicate that dynamic regulation of NT in specific Hpt nuclei in response to alterations in the levels of circulating leptin and perhaps other factors is involved in appetite suppression and body weight balance. Other results, showing that the anoretic effect of NT is antagonized by the H1 receptor blocker pyrilamine and in H1 knockout mice, suggest that the histamine H1 system, which is known to inhibit food intake, could be a final common mediator for the effects of both leptin and NT.[30]

NT and Stress Responses

Stress increases NT expression in several Hpt nuclei, suggesting that NT may modulate stress responses (reviewed in Ref. 14). Centrally administered NT was found to rapidly increase the levels of circulating ACTH and corticosterone and these increases were attenuated by corticotrophin-releasing hormone (CRH) antagonists and bilateral lesions of the PVN. Furthermore, SR 48692 administration in the PVN suppresses stress-induced increases in the plasma levels of ACTH and corticosterone and decreases CRH expression in the PVN. Both basal and stress-induced blood corticosterone levels are lower in NTR-2 knockout compared with those of control mice, consistent with NT playing a role in the control of corticosterone release.[23]

NT and Reproductive Functions

NT has been implicated in the preovulatory luteinizing hormone (LH) surge and the Hpt control of prolactin (PRL) release in rat (reviewed in Ref. 33). Estrogen increases NT mRNA and peptide expression in several Hpt regions that have been implicated in reproductive functions, and NT expression in these regions is sexually dimorphic. In addition, NT mRNA levels vary throughout the estrus cycle in female rats with NT mRNA-positive cells being ~3-fold more numerous at proestrus than at diestrus. These results coupled with microinjection data indicating that NT can augment LH release have led to speculation that NT might mediate the feedforward effects of estrogen on gonadotropin-releasing hormone (GnRH) release from rostral medial preoptic nucleus GnRH neurons expressing NTR-1 in the rat. However, this system may not operate in the mouse, because even though estrogen increases NT mRNA expression similarly in ovariectomized mice, icv NT administration does not augment LH release in ovariectomized mice treated with estrogen.[24] GnRH neurons are clearly subject to complex peptide control with kisspeptin playing a crucial role, and it remains to be determined how NT interacts with kisspeptin to modulate reproductive function. Kisspeptin neurons apparently express NTR-2 but not NTR-1 or NT.[24]

NT has also been implicated in both positive and negative regulation of PRL secretion from pituitary lactotropes. The evidence suggests that NT directly activates tuberoinfundibular DA (TIDA) neurons and mediates feedback inhibition of PRL release through the activation of these neurons.[18] Estrogen increases NT expression in TIDA neurons and NT is intensely expressed in virtually all TIDA neurons in nursing rats, but decreases markedly after removal of pups. Increased NT release from TIDA neurons in the median eminence would most probably counteract the inhibitory effects of DA on PRL secretion, because NT stimulates pituitary PRL release. NT knockout mice reproduce and successfully rear their young, indicating that NT is not essential for reproductive functions.[9]

PATHOPHYSIOLOGICAL IMPLICATIONS

There is now considerable evidence from animal models that endogenous NT signaling is both required for certain APD actions and that decreased NT signaling may underlie deficits in PPI. Comparison of NT levels in cerebrospinal fluid (CSF) from schizophrenics both before and after APD treatment indicates that low CSF NT levels are associated with more severe psychopathology and that clinical improvement is associated with increased CSF NT (reviewed in Ref. 5). Some NT agonists produce effects similar to those of atypical APDs and the relatively stable NT analog, NT69L, prevents drug-induced disruption of PPI in rats after either acute or chronic administration.[4] These results suggest that the development of NT agonists could provide an important new class of APDs. In the shorter term, there could be some therapeutic benefit associated with the use of NT-dependent (e.g. quetiapine, haloperidol) and NT-independent (e.g. clozapine) APDs in combination.

NT also seems to play an important role in stress-induced analgesia, suggesting that NT agonists could be effective in treating certain chronic pain syndromes associated with abnormalities in stress responses. The observation that cold-water swim/water avoidance stress in NT knockout mice results in hyperalgesia rather than analgesia is particularly interesting in this regard.[15] Stable NT agonists may prove to be particularly effective in treating stress-related and neuropathic pain.[32]

Chapter 118

NPY

Yvan Dumont and Rémi Quirion

ABSTRACT

Neuropeptide Y (NPY) is one of the most abundant peptides found in various brain structures and one of the most evolutionary conserved ones. NPY and its homologs (peptide YY and pancreatic polypeptide) have been implicated in several biological processes including food intake, anxiety and depression-related behaviors, neuronal excitability and seizures, circadian rhythms, alcohol consumption, neuroendocrine secretions, nociception, and cardiorespiratory functions. The various effects of NPY in the central nervous system are mediated by the activation of at least five receptor subtypes designated as Y_1, Y_2, Y_4, Y_5, and y_6, the last one not being functionally expressed in human and rat. Clinical and preclinical studies suggest that NPY plays a major role in obesity, epilepsy, anxiety, depression, and cardiovascular disorders.

DISCOVERY OF NPY AND HOMOLOGS

The discovery of this peptide family started with the isolation of a 36 amino acid peptide from the chicken pancreas in 1975 that was termed avian pancreatic polypeptide (aPP). Later on, a strong PP-immunopositive signal was observed in the central nervous system (CNS) of several species. These results were subsequently confirmed by other investigators, suggesting the presence of a PP-like protein in mammalian brains. However, the isolation of genuine PP proteins from the CNS remained unproductive. The nature of the PP-like immunoreactive (ir) materials detected in the CNS was resolved in 1982 with the discovery of two peptides isolated from porcine intestine and brain extracts; the first one was called peptide YY (PYY); while the second became known as neuropeptide Y (NPY).[30] These two peptides contain a tyrosine residue at their N-and C-termini, and 36 amino acids with structural homologies to the PPs. All three peptides are thus included in the same family usually designated as the Y, NPY, or PP family. Further information on this peptide family is provided in the Ingestive and Gastrointestinal Peptides sections.

Antibodies were developed against NPY, and immunohistochemical and radioimmunoassay techniques revealed the presence of very high amounts of NPY-like immunoreactive (ir) materials in the mammalian CNS, including brain, and established that the PP-like ir previously observed in brain tissues resulted from cross-reactivity of the antibody used with NPY.[12] Thus far, NPY has been exclusively found in the central and peripheral nervous systems, while PYY and PPs are mostly restricted to endocrine cells of the intestine and pancreatic gland.

STRUCTURE OF THE PRECURSOR mRNA/GENE

The human gene coding for NPY is located on chromosome 7 and nonisotopic in situ hybridization revealed that it is on 7q15.1 in proximity to the HOXA cluster (7q15-q14). It exists as a single-copy gene.[5] Early analysis of the gene sequence revealed that the transcription unit spans about 8000-base pairs (bp) divided in four exons separated by three introns of about 965-, 4300-, and 2300-bp as well as 5′ and 3′-untranslated domains (Fig. 1). The 5′-nontranscribed region of the NPY gene regulates the expression of the NPY mRNA and contains the sequence ATAAA or TATA box, as well as nucleotide sequences for DNA-binding proteins such as CAAT, AP1, and several SP1.[5] The mRNA transcript includes the first exon, which contains the 5′-untranslated domain; the second exon, which codes for the initiating codon and the main part of the mature NPY sequence up to glutamine 34; the third exon, which codes for the last two amino acids, the glycine amine donor site, the dibasic cleavage site, and the main portion of the carboxy terminal peptide of neuropeptide Y (CPON); and the fourth exon, which includes the end of CPON and the 3′-untranslated region, including the polyadenylation recognition signal AATAAA (Fig. 1). The NPY mRNA consists of 551-bp and translates for a 97 amino acid precursor protein (Fig. 2). Comparable NPY gene organization has been reported in various species.[5]

PROCESSING OF THE NPY PRECURSOR

As for most low-molecular-weight peptides, NPY is synthesized as a precursor protein containing a hydrophobic

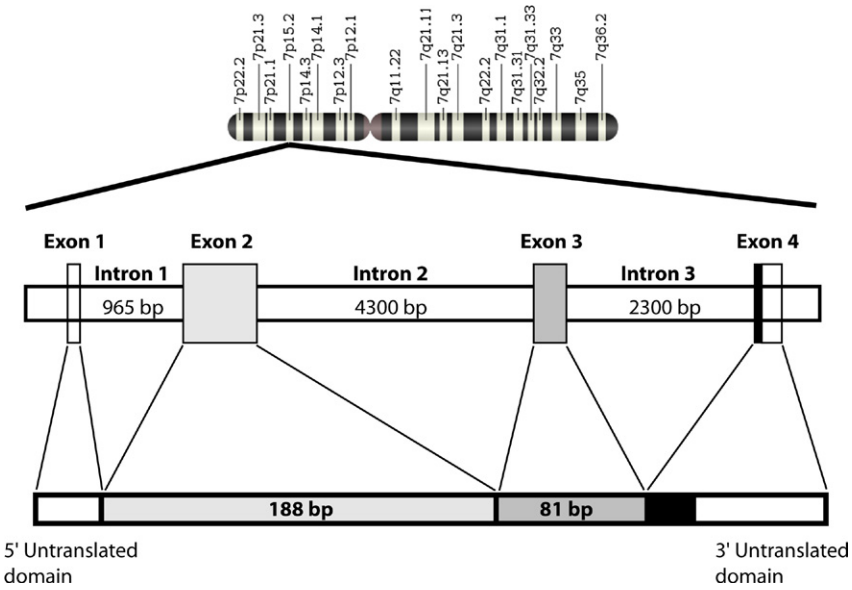

FIGURE 1 Schematic representation of the human NPY gene organization.

signal peptide, the mature peptide NPY, the amidation-proteolytic site, and the carboxy-terminal extension CPON (Fig. 2).[5] The signal sequence has two main functions. In the early stage of translation, as the first amino acid residue of the nascent polypeptide emerges from the large subunit of the ribosome, this region of interacts with the signal recognition particle, a ribonucleoprotein, resulting in slowing down translation in the cytoplasmic space.[5] The complex (ribosome-nascent chain-signal recognition particle) is then targeted to the endoplasmic reticulum, where it interacts with the signal recognition particle receptor. This event reactivates the translation process and ensures that the translation of the polypeptide coding mRNA occurs at the surface of the rough endoplasmic reticulum. The second function of the signal sequence is to facilitate the passage of the nascent polypeptide through the lipid bilayer of the endoplasmic reticulum into the lumen to be packed into secretory vesicles.[5] The 97 amino acid pre-pro-NPY is then cleaved by signal peptidases to generate a 69 amino acid peptide, or pro-NPY, and the signal peptide.[5] The pro-NPY is next processed by enzymatic cleavage to generate a 39 amino acid peptide that contains NPY and the amidation proteolytic site motif (glycine-lysine-arginine) and a 30 amino acid residue peptide usually referred to as CPON.[5] The C-terminal lysine and arginine are removed by a carboxypeptidase from the immature NPY and the glycine residue donates its amino group to generate the amide of the C-terminal tyrosine residue of NPY[5] (see carboxypeptidase chapter in Peptide Biosyntheis/Processing section of this book). NPY and CPON are then stored in vesicles and co-released upon stimulation. In contrast to NPY, the role of CPON is still unknown.

DISTRIBUTION OF NPY mRNA AND PROTEIN

Anatomical studies have demonstrated the presence of important quantities of NPY-like ir material and NPY mRNA in the brain of multiple species including the rat, mouse, and human, and a high degree of similarity in the distribution of NPY-ergic neurons is observed between species.[12] In situ hybridization and immunostaining studies revealed that NPY mRNA and immunoreactive materials are distributed very similarly.[12] In mammalian brain, NPY-ergic neurons are found in interneurons, as well as long projection neurons. While interneurons are mostly located in the forebrain, projection neurons are located, for example, in the arcuate nucleus, lateral geniculate nucleus, and various brain-stem nuclei.[12]

NPY, one of the most abundant brain peptides, is expressed in numerous brain regions where it is often colocalized with either norepinephrine, GABA, somatostatin. or the agouti-related protein. Schematic distribution of NPY-ir is presented in Fig. 3. Enrichment in NPY-ergic neurons varies between different cortical areas, with the highest concentrations found in the cingulate and temporal cortices and the lowest in the occipital lobe. Cortical NPY-positive cells are mostly interneurons.[12] In the hippocampus, large quantities of NPY-containing cells are located in the hilus of the dentate gyrus, striatum, and orien layers of the CA2 and CA3 subfields, and near or within the stratum pyramidale of the CAl subfield.[12] Most of this innervation is from local projections, but some NPY-like ir terminals may have extrahippocampal origins. In the striatum, the majority of NPY-ergic neurons are interneurons with the

highest densities located in the nucleus accumbens and the bed nucleus of the stria terminalis.[12] The anterior olfactory nucleus, olfactory tubercle, islands of Calleja, lateral septum, and tenia tecta also contain important amounts of NPY-like ir neurons. The hypothalamus is the structure that expresses the highest levels of NPY. NPY-like ir and mRNA cell bodies are mainly found in the arcuate nucleus and lateral hypothalamus,[12] while fibers and terminals spread throughout this region. The suprachiasmatic nucleus is innervated by NPY axons originating from the ventral lateral geniculate nucleus.[12] NPY innervation of the paraventricular nucleus of the hypothalamus arises from the brainstem with shorter projections originating in the arcuate nucleus.[12] The amygdaloid complex is also an area that contains several NPY-like ir cell bodies and numerous fibers. On the other hand, no or very low levels of NPY-like material are expressed in most thalamic nuclei and the cerebellum. The only thalamic nucleus that contains significant amounts of NPY is the lateral geniculate nucleus, with fibers projecting to the suprachiasmatic nucleus. Significant amounts of NPY-like ir neurons are also found in the inferior colliculus, central gray area, medulla oblongata, lateral reticular nucleus, raphe nuclei, and locus coeruleus. The dorsal horn of the spinal cord also expresses significant amounts of NPY, especially under pathological conditions.

STRUCTURE OF NPY-LIKE PEPTIDES

A few studies have evaluated the secondary and tertiary structures of NPY and homologs. Using a combination of molecular modeling and structural dynamics, comparison of the possible structure of NPY with that of aPP has shown that structural elements found in aPP are maintained in NPY.[2] In the model proposed, N-and C-termini are stabilized by the intramolecular association of the hydrophobic moieties of the polyproline type II helix (residues 1–9) and the amphiphilic α-helix (residues 14–30), these two structures being connected by a type II β-turn.[2] This confers a hairpin-like structure to the NPY molecule, where the tyrosine residue in position 1 and amino acid residues 30–36 are located in close proximity to each other, a structure often referred to as the PP-fold. Structure activity studies have also shown that the central segment of NPY, amino acid residues is important in conferring the helical conformation and ensuring high affinity for various NPY receptor subtypes.[3]

RECEPTORS AND SIGNALING CASCADES

There are 7 receptor subtypes in vertebrates, of which 5 exist in mammals, and these are designated Y_1, Y_2, Y_4, Y_5, and y_6.[22] They all belong to the subfamily of seven transmembrane G protein-coupled receptor type 1.[22] They are expressed in all mammalian brains except for the y_6 subtype which is restricted to only a few species including the mouse, rabbit, and dog.[22] Rather surprisingly, NPY receptors display relatively low sequence homologies between themselves and appear to be among the most divergent receptor families.[19] Some NPY receptor subtypes even have higher homology for other families of G protein-coupled receptors. The detailed CNS distribution of the various NPY receptor subtypes has also been evaluated in various species. Generally, the Y_1 and Y_2 subtypes are the most abundant NPY receptors expressed in the CNS, especially in all cortical areas, thalamic nuclei, hippocampus, and brainstem nuclei while the Y_4 and Y_5 classes are found in much lower amounts.[8]

NPY receptors are usually coupled to Gi/o leading to the inhibition of the production of cyclic AMP (cAMP). However, coupling to other signal transduction pathways can also occur. In HEK293 cells transfected with the human Y_1 receptor cDNA, the receptor couples to a pertussis toxin-sensitive G protein that mediates the inhibition of cAMP accumulation while in CHO cells this same receptor is associated with the elevation of intracellular Ca^{++} levels.[22] Likewise, transfection of different cell types with the human Y_2 receptor cDNA can generate a receptor that can couple to a pertussis toxin-sensitive G protein mediating the inhibition of cAMP production and the elevation of intracellular Ca^{++} levels.[22] Similar findings have been reported for the human and rat Y_2 receptor.[22] It has also been shown that some of the effects of NPY are mediated by protein kinase C (PKC3),[6] and its downstream cascade extracellular signal-regulated kinase (ERK)1/2 and CAMP responsive element binding protein.[29,35]

BIOLOGICAL ACTIONS

Numerous studies have addressed the biological functions of NPY and homologs in the CNS and shown a broad range of effects after intracerebroventricular (icv) injections of NPY as well as by direct administration of this peptide into specific nuclei including: the paraventricular, perifornical hypothalamic nuclei, hippocampus, and brainstem nuclei. NPY has been reported as the most potent substance known thus far to stimulate feeding behavior and water consumption in various species including rat, mouse, sheep, pig, rabbit, and pigeon. NPY also increases the respiratory quotient indicative of increased carbohydrate utilization as energy substrates, revealing its role in catabolism. NPY can facilitate learning and memory processes, modulate locomotor activities, produce hypothermia, decrease sexual behavior, shift circadian rhythms, modulate cardiorespiratory parameters, produce antinociceptive effects, and generate anxiolytic-like effects; it also has been implicated in bone formation. Additionally, NPY alters secretion of neuroendocrine hormones such as gonadotropin-releasing hormone, and corticotropin-releasing hormone. Furthermore, NPY has been shown to modulate the neuronal activity of glutamatergic, adrenergic, serotonergic, GABAergic and dopaminergic neurons. In amphibians, NPY inhibits α melanocyte-stimulating hormone release. The various effects of NPY have been reviewed in various publications; see for example, Refs. 9, 14, 20, 26, 32, and 33.

PATHOPHYSIOLOGICAL IMPLICATIONS

Based on results obtained by use of NPY antibodies, receptor antagonists, antisense oligonucleotides, siRNA, and genetically modified animals, it has been suggested that NPY could be implicated in various pathophysiological disorders including feeding and satiety, cardiovascular functions, memory impairment and cognition, anxiety- and depression-related behaviors, pain, epilepsy, alcohol consumption, and drug dependence. For example, neutralizing endogenous NPY effects by the administration of NPY antibody into specific brain regions such as the hippocampus induces amnesia in the rat,[27] while NPY antibodies administered in the ventromedial or paraventricular hypothalamic nuclei decrease food intake.[7] Similarly, blocking the synthesis of NPY by icv administration of NPY antisense oligonucleotides results in decreased food intake and attenuation of the progesterone-induced LH surge.[14] Injection of an NPY Y_1 receptor antisense induces marked anxiogenic-like behavior.[11] Moreover, NPY-deficient mice show mild spontaneous seizures, while kainate-induced seizures result in death in these animals, which can be prevented by the exogenous administration of NPY.[33] Furthermore, NPY-deficient mice are alcohol preferring and less sensitive to the sedative effect of alcohol, while transgenic mice overexpressing NPY drink less alcohol.[31] Additionally, young and old transgenic rats are less anxious than wildtype rats.[4] Furthermore, Y_1 knockout mice display highly aggressive behaviors,[16] whereas NPY Y_2 knockout mice show anxiolytic-like behavior and drink less alcohol as compared with wildtype mice.[4] Similar results are observed with Y_2 receptor antagonists.[4,13] More recently, the therapeutic potential of Y_2 receptor antagonist in anxiety and depression-like behaviors has been confirmed.[1,6,23] In fact, evidence suggests that Y_1, Y_2, Y_4 and Y_5 receptor subtypes can be implicated in the pathophysiology of feeding[15,21] and anxiety and depressive disorders.[10,24] In humans, Karvonen and collaborators[17] have identified a 1128 T-C polymorphism that results in substitution of leucine by proline at residue 7 in the peptide part of preproNPY, and its frequency is higher in alcohol-dependent subjects.[18] Additionally, recent studies in humans have suggested that NPY could be implicated in the ability to cope with stressful events. Specifically, research with US Special Forces military personnel exposed to an extremely stressful training experience has shown that effective coping is correlated with higher blood levels of NPY.[25,34] Interestingly, men with combat-related PTSD have low levels of NPY in the cerebrospinal fluid as compared with control subjects.[28] These results point to a potential role for NPY in resilience to stress. Hence, it would appear that NPY and its receptors can be associated with various aberrant CNS behaviors, suggesting their possible relevance in the development of new therapeutic avenues to treat neurological and mental illnesses.

Chapter 119

PACAP

David Vaudry, Tomoya Nakamachi, Magali Basille, Olivier Wurtz, Alain Fournier, Hubert Vaudry and Seiji Shoida

ABSTRACT

Pituitary adenylate-cyclase-activating polypeptide (PACAP) is a 38- or 27-amino-acid peptide belonging to the VIP/secretin/GHRH/glucagon superfamily that was discovered from hypothalamic extracts for its ability to stimulate cAMP formation in anterior pituitary cells. PACAP and its 3 receptor subtypes are widely expressed in the brain, suggesting that this peptide may exert numerous functions in the central nervous system. In the developing brain, PACAP controls progenitor proliferation, migration, and differentiation. In the adult brain, PACAP regulates circadian rhythms, food intake, water drinking, locomotor activity, pain, and stress responses. PACAP is able to protect brain tissue from neurodegenerative diseases and stroke by inhibiting neuronal cell death and by stimulating neurogenesis. The diversity and complex effects of PACAP can be accounted for by the existence of at least 14 splice variants for the PACAP specific receptor, PAC1, which can modulate the coupling to various second messengers.

DISCOVERY

In an attempt to isolate novel hypophysiotropic neuropeptides, Akira Arimura and coworkers screened fractions from an extract of 4300 ovine hypothalami, by monitoring their ability to induce cAMP production in cultured rat anterior pituitary cells. Using this approach, they isolated a 38-amino-acid C-terminally α-amidated peptide that they named pituitary adenylate-cyclase-activating polypeptide [PACAP; Ref. 21]. A shorter form of PACAP encompassing only 27 amino acids (PACAP27) has subsequently been characterized. PACAP and its receptors are widely expressed in the central nervous system (CNS) and in most peripheral organs. In humans, the sequence of PACAP27 shares 68% identity with that of vasoactive intestinal polypeptide (VIP), identifying PACAP as a member of the VIP/secretin/GHRH/glucagon superfamily.[33] The primary structure of PACAP has been extremely well conserved in vertebrates, including mammals, birds, reptiles, amphibians, and fish, suggesting that this peptide may exert vital biological functions.[28] Indeed, PACAP induces vasodilation and bronchodilation, activates intestinal motility, increases insulin and histamine secretion, and modulates immune responses. In the central and peripheral nervous systems, PACAP acts as a neurotransmitter, neuromodulator, and/or neurotrophic factor.[1]

STRUCTURE OF THE mRNA/GENE

PreproPACAP encompasses 176 amino acids in humans, sheep, and mice, and 175 amino acids in rats.[33] The sequence of PACAP is located in the C-terminal region of the precursor and is identical in all mammalian species studied so far. The precursor also contains a 24-amino-acid signal peptide and a 29-amino-acid peptide, exhibiting moderate sequence homology with PACAP27, termed PACAP-related peptide (PRP; Fig. 1).

In humans and mice, the PACAP gene comprises five exons, the sequence of PRP being encoded by exon 4 and that of PACAP by exon 5 (Fig. 2). The overall structural organizations of the PACAP precursor and gene exhibit strong similarities with those of VIP, confirming that they originate from a common ancestral sequence through exon and gene duplications.[28,33] PACAP is constitutively expressed, but its transcription can be enhanced by cAMP, phorbol diester, dexamethasone, progesterone, and even PACAP itself. The promoter region of the mouse PACAP gene (ADCYAP1) is schematically represented in Fig. 2. In humans, the PACAP gene is localized on the P11 region of chromosome 18,[4] which is associated with holoprosencephaly and psychiatric disorders,[25] suggesting that PACAP may be involved in the control of brain development and/or the etiology of psychiatric disorders.[13]

PROCESSING OF THE PRECURSOR

Endoproteolytic cleavage of the PACAP prepro-protein at three dibasic sites (i.e. Arg^{79}-Arg^{80}, Lys^{129}-Arg^{130}, and Arg^{170}-Arg^{171}) by prohormone convertases generates a large PRP form (big PRP) and a glycine-extended form of PACAP38 (Fig. 1). Cleavage at the single Arg^{110}

seem to include at least PC1, PC2, and PC4, all discussed in the section of the book).[15]

DISTRIBUTION OF THE mRNA/PEPTIDE

The mapping of PACAP-expressing neurons has been investigated by immunocytochemistry and *in situ* hybridization in mammals. The highest densities of PACAP-producing neurons are found in the hypothalamus, especially in the paraventricular and supraoptic nuclei.[33] However, PACAP expression is not restricted to hypothalamic neurons but is widely distributed throughout the brain (Fig. 3). In particular, numerous populations of PACAP-expressing neurons are found in the cerebral cortex, amygdala, hippocampus, pineal gland, substantia nigra, cerebellum, and pons (Fig. 3). A dense network of PACAP-immunoreactive fibers is found in the thalamus and septum (Fig. 3). The overall distribution of PACAP-immunoreactivity is very similar in nonmammalian vertebrates.[33] In all brain structures, PACAP38 is by far the predominant form, PACAP27 representing <10% of the peptide content.[2]

In peripheral organs, the highest concentration of PACAP is found in the rat testis where the total mRNA content is higher than in the whole brain. PACAP is expressed in other endocrine glands such as the pituitary, the adrenal, the parathyroid, and the endocrine pancreas (see the PACAP chapter in the Endocrine Peptides section of the book). PACAP-immunoreactive fibers are also found in nonendocrine tissues such as the urinary bladder, the airways (see the PACAP chapter in the Respiratory Peptides section), and the retina. In peripheral organs, in contrast to the CNS, PACAP, and VIP often seem to be coexpressed by the same cells.

RECEPTORS AND SIGNALING CASCADES

Three PACAP/VIP receptors, which belong to the class B family of seven-transmembrane (TM) G protein-coupled receptors (GPCR), have been cloned and termed, respectively, PAC1, VPAC1, and VPAC2, according to their relative affinity for PACAP and VIP.[11] PAC1 recognizes PACAP27 and PACAP38 with 1000-fold higher affinity than VIP, whereas VPAC1 and VPAC2 exhibit similar affinity for both PACAP and VIP. All three receptors stimulate adenylyl cyclase (AC) through coupling to the Gαs protein, but the receptors have some variations in their signaling cascades and binding affinities.[14]

The PAC1 was first cloned from the rat pancreatic acinar carcinoma cell line AR4–2J, and subsequently in humans, cows, rats, and mice. The human PAC1 cDNA encodes a 525 amino acid GPCR with seven TM helices, which exhibits 30–50% sequence identity with the glucagon, secretin, parathyroid hormone, corticotropin-releasing hormone (CRH), and calcitonin receptor cDNAs. PAC1 has

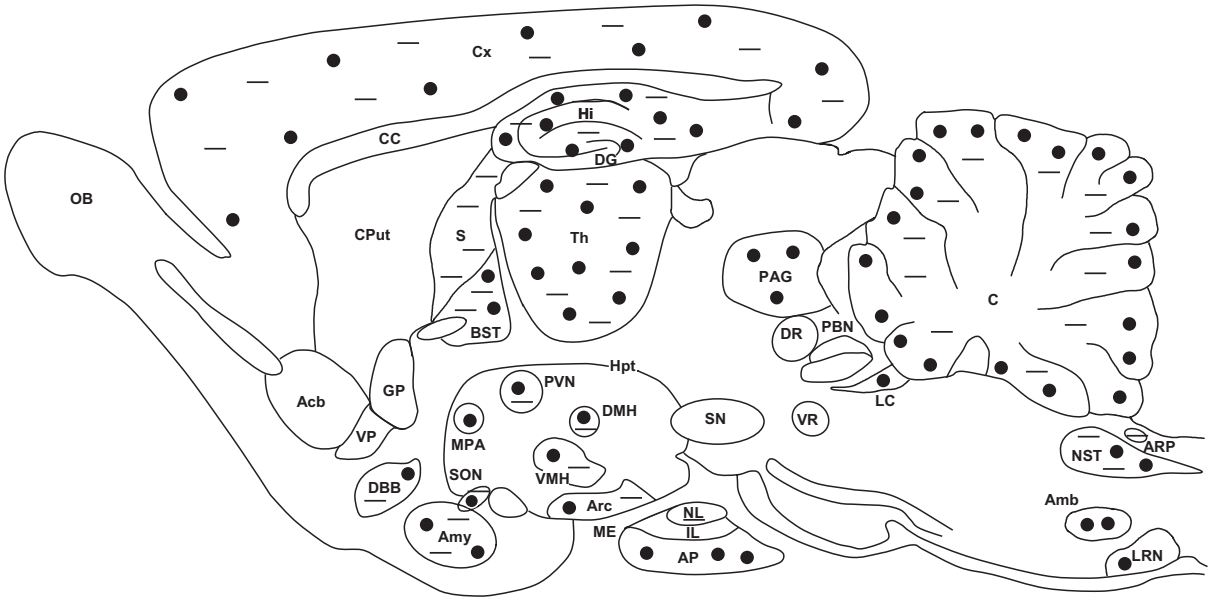

FIGURE 3 Localization of PACAP cell bodies (●) and fibers (–) in the rat brain. Adapted from Ref. 7. various splice variants that can modulate the coupling of the receptor to specific signaling pathways. In particular, splice variants with or without hip and hop cassettes in the third intracellular domain have been identified (Table 1). Both the short and hop variants stimulate AC and PLC. By contrast, PLC activation and subsequent Ca^{2+} response is impaired in the presence of the hip variant, which indicates that the various cassettes are involved in different coupling mechanisms to second messengers.

Besides the hip and hop cassettes, other variants such as the PAC1-TM4 subtype have been identified. This variant exhibits substitution and deletion of two amino acids in the fourth TM domain as well as two other substitutions in the second TM domain and N-terminal region of the receptor. The PAC1-TM4 causes an increase in $[Ca^{2+}]_i$ by enhancing calcium influx through L-type voltage-sensitive calcium channels, but it has no effect on AC or PLC activation. Two very short variants of PAC1 (PAC1-vs1 and PAC1-vs2) with a deletion of 21- or 57-amino acids, respectively, in the N-terminal extracellular domain have also been reported. In contrast to PAC1-s, PAC1-vs variants bind to PACAP38 and PACAP27 with similar affinity and have equal potency to stimulate AC and PLC. Another splice variant of PAC1 (PAC1-3a) with the insertion of 24 amino acids (exon 3) in the N-terminal extracellular domain was cloned. The transcripts for PAC1-3a are preferentially expressed in the developing rat brain and in cultured astrocytes but are undetectable in the adult brain. The PAC1-3a variant has a sixfold higher affinity for PACAP38 than PAC1-s, but the two variants show similar affinity for PACAP27. PAC1-3a is coupled to both cAMP and inositol phosphate signaling pathways although with lower response when compared with PAC1-s (Table 1).

Stimulation of AC or PLC pathway is classified by the EC50 values for PACAP, +++: 5 nM <, ++: 50 nM <, +: 500 nM <, -: 500 nM >.

Lutz and coworkers[16] identified 14 PAC1 splice variants in the human SHSY-5Y neuroblastoma cell line, including the hip and hop cassettes. They found deletions of exon 5, exon 5 and 6, and exons 4–6, which are responsible for shorter N-terminal extracellular loops, called δ5, δ5,6 and δ4,5,6 variants. Deletion of exon 14–17 regions by frame shift also results in the loss of amino acid residues in TM6, extracellular loop 3, TM7, and carboxyl tail named variants δ14,15,16,17. Investigation of the coupling of these variants to cAMP and calcium signaling in COS7 cells revealed that PACAP38 is approximately 30-fold more potent than VIP in activating cAMP and inositol phosphate mobilization in the δ5,6 variants. By contrast, PACAP does not stimulate cAMP level in cell expressing the hPAC1-δ5,6,14,15,16,17 variant (Table 1).

The VPAC1, cloned from rats and humans, consists of 459 and 457 amino acids, respectively. In cells transfected with the VPAC1 cDNA, PACAP and VIP activate AC with similar potency. VPAC2 has been cloned from rat, mouse, and human cDNA libraries. VPAC2 has similar affinity for PACAP and VIP as VPAC1. VPAC2 is known to activate AC and can also in some cases stimulate inositol phosphate production and induce calcium mobilization. Bokaei and collaborators identified novel five-transmembrane (5TM) forms of both human VPAC1 and VPAC2. These VPAC1 and VPAC2 variants lack 88 and 74 amino acid residues in the third intracellular loop, the fourth extracellular loop, and TM6–7, which results in impaired activation of AC. The signaling pathways associated with activation of these various receptor variants are summarized in Table 1.

PACAP receptors are widely expressed in the CNS. In the rodent brain, a high density of PAC1 is found in the olfactory bulb, cerebral cortex, hippocampus, thalamus, hypothalamus, substantia nigra, and cerebellum (Fig. 4).[6,17] VPAC1 and VPAC2 are mainly expressed in the olfactory bulb, cerebral cortex, dendate gyrus, pineal gland, and thalamus (Fig. 4).[17]

BIOLOGICAL ACTIONS WITHIN THE BRAIN

PACAP exerts pleiotropic biological activities as a neurotrophic factor, neurotransmitter/neuromodulator, and neurohormone. PACAP regulates both proliferation and differentiation of neurons during development.[29] PACAP and its receptors are expressed in germinative regions of the brain, and PACAP plays an important role in neural tube patterning and neurogenesis.[33] On gestational day 9.5, the pattern of PAC1 expression in the mouse is very similar to that of the transcription factor Math 1 known as a major neural progenitor marker. In rat embryos, on gestational day 10.5, PACAP contributes to neural tube formation by down-regulating sonic hedgehog and gli-1 gene expression. On gestational day 13, PACAP stimulates proliferation of cortical precursor neurons whereas, on gestational day 18, PACAP suppresses cell proliferation and stimulates differentiation of neurons. In the cerebellar cortex, PACAP inhibits granule cell migration.[3] Although the effect of PACAP on cell migration is robust, it lasts for only approximately 2 h because of a desensitization process. The different effects of PACAP on brain development can probably be ascribed to temporal expression of specific splice variants of PAC1 in developing neurons. PACAP promotes the differentiation of embryonic stem cells into neurons and the differentiation of neural stem cells into astrocytes.[22] Taken together, these observations indicate that PACAP contributes to brain development suggesting that selective agonists may prove useful for neuronal regeneration to repair brain lesions.

Indeed, many reports indicate that PACAP exerts neuroprotective effects *in vivo* and *in vitro*.[30,34] PACAP application on cultured neurons prevents damages induced by hypoxia, withdrawal of nerve growth factor, excitotoxicity, oxidative stress, gp120 (from human immunodeficiency virus), and other neurotoxins.[26] The neuroprotective activity of PACAP on neuron/glia cocultures occurs at subpicomolar and subnanomolar concentrations, whereas the antiapoptotic effect of PACAP on PC12 cells and cerebellar granular neurons

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

is only seen at nanomolar concentrations.[32,34] These findings suggest that glial cells contribute to the neuroprotective effect observed at very low concentrations of the peptide. The neuroprotective activity of PACAP on cultured granule neurons involves Gαs signaling, coupled to the AC/PKA pathway.[34] PACAP also induces phosphorylation of ERK through Rap1 and Ras activation, which stimulates the expression of the antiapoptotic factor B-cell lymphoma 2 (Bcl-2). This increase of Bcl-2 suppresses cytochrome *c* release from mitochondria, which in turn reduces caspase-9 activation, causing long-lasting inhibition of caspase-3 activity that is responsible for the neuroprotective action of PACAP.[31,34] *In vivo*, the neuroprotective effect of PACAP has been well characterized in rodent models of stroke and Parkinson's disease.[24,26,27] Ischemic death of hippocampal and cerebral cortex neurons can be prevented by intracerebroventricular infusion of low doses of PACAP. Systemic administration of PACAP38 also reduces infarct volume in the brain after transient focal ischemia induced by occlusion of the middle cerebral artery in rats.[27] This indicates that a therapeutic concentration of PACAP can be reached in the brain parenchyma after systemic intravenous administration of the peptide. Despite the relatively large size of the peptide, PACAP38 is translocated from the blood to the brain across the blood brain barrier with a high efficacy transport system in a saturable manner. Indeed, the efficacy of the transport mechanism is 6 times greater for PACAP38 than for morphine. PACAP38 protects hippocampal neurons from apoptosis by inhibiting the c-Jun N-terminal kinase 1 (JNK)/stress-activated protein and p38 signaling pathways. The antiapoptotic effect of PACAP38 after ischemia is indirect and involves IL-6 release.[24] PACAP stimulates the production of various neurotrophic factors in astrocytes such as IL-6 and macrophage inflammatory protein 1 (MIP1), regulates the activation of normal T expressed and secreted (RANTES) and activity-dependent neuroprotective protein (ADNP), and suppresses astrocytic cell death.[22] In Parkinson's disease model, PACAP administration attenuates 6-hydroxydopamine and 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine-induced mesencephalic dopaminergic neuronal death.[27] To summarize, PACAP can rescue injured neural cells from apoptosis, suggesting that PACAP derivatives could be useful for the treatment of stroke or neurodegenerative diseases.

The role of PACAP in the regulation of the circadian rhythm has been widely documented in mammals.[20] PACAP stimulates melatonin secretion by the rat pineal gland and cultured pinealocytes through phosphorylation of cAMP-responsive element-binding protein (CREB). The effect of PACAP on CREB phosphorylation culminates in the first part of the dark period of the 24-h cycle together with the peak of PACAP level in the pineal gland. Circadian variations in PACAP content occur in the rat pineal gland, and a high density of PACAP binding sites is present in the pineal, suggesting that PACAP is involved in the regulation of the rhythmicity of melatonin production.[33] The main biological clock center in the brain is the suprachiasmatic nucleus (SCN). PACAP causes phosphorylation of CREB in the SCN during the light period, and the effect of PACAP on CREB is suppressed by melatonin. Similarly, melatonin blocks PACAP-induced stimulation of cAMP production in the rat SCN, indicating that the hypothalamus is a site for functional interaction between PACAP and the pineal hormone melatonin. PACAP interacts with glutamate to induce light resetting of the circadian clock.[9] Thus, in rodents, PACAP enhances the phase delay provoked by glutamate in the early night, and blockade of PACAP neurotransmission inhibits the effect of glutamate. PACAP also activates clock genes such as Clock or Cry1.[10] Taken together, these results indicate that PACAP from the retinohypothalamic tract acts as a neurotransmitter to phase shift the SCN circadian rhythm in a manner similar to light.

Central administration of PACAP induces many behavioral effects in rodents. In particular, there is now clear evidence that PACAP is involved in the control of feeding behavior. Intracerebroventricular injection of PACAP decreases food intake in a dose-dependent manner.[18] In mice, the anorexigenic action of PACAP is mediated through the melanocortinergic system. Injection of PACAP in the vicinity of the perifornical lateral hypothalamus stimulates drinking and, reciprocally, water deprivation causes an increase in PACAP immunoreactivity in the subfornical organ. These observations show that PACAP plays a role in the regulation of feeding and drinking behavior.

The most abundant population of PACAP-containing neurons and the highest density of PACAP binding sites are found in the hypothalamus. In particular, a dense accumulation of PACAP-immunoreactive neurons and PACAP receptors are present in the magnocellular region of the PVN and SON, where the neurosecretory perikarya producing oxytocin and vasopressin are located. Administration of PACAP within the PVN or SON increases the firing rate activity and causes membrane depolarization of magnocellular neurons. Intracerebroventricular and intracisternal injections of PACAP induce a dose-dependent elevation of plasma vasopressin. In the neural lobe of the pituitary, PACAP stimulates the release of oxytocin and vasopressin through the activation of the cAMP/PKA signaling pathway. Collectively, these observations indicate that PACAP is a potent activator of hypothalamic magnocellular neurons.

PACAP modulates the activity of various other hypothalamic neuronal populations. Specifically, intracerebroventricular injection of PACAP provokes a significant increase in GnRH, somatostatin, prolactin, and CRH mRNA expression in the hypothalamus. PACAP injection also stimulates

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Fos expression in CRH neurons in the PVN, leading to a substantial increase in plasma corticosterone concentration and inducing stress-like behavior. In the ovariectomized ewe, infusion of PACAP in the arcuate nucleus reduces plasma prolactin concentration. A single administration of PACAP to neonatal female rats delays the onset of puberty by influencing the GnRH neuronal system through PAC1. Taken together, these results indicate that PACAP may act within the hypothalamus as a neurotransmitter or neuromodulator to regulate the secretion of hypophysiotropic neurohormones (see the PACAP Chapter in the Endocrine Peptides section of this book).

PATHOPHYSIOLOGICAL IMPLICATIONS

Pharmacological experiments support the view that PACAP is involved in various pathophysiological conditions. The PACAP- or PAC1-deficient mouse strains that have been established in different laboratories provide additional evidence for the involvement of PACAP in vital biological functions. For instance, most PACAP-deficient mice die within the first two weeks after birth with abundant lipid droplets in liver, heart, and skeletal muscle cells.[8] Premature death of PACAP-deficient mice occurs when the animals are raised at 21°C and can be prevented by placing the animals at an environmental temperature of 24°C.[8] When 7-day-old PACAP-KO mice are separated from their mother and placed at 21°C, they show a greater loss in body temperature compared with the wild-type littermates, indicating an impaired thermal adaptation in PACAP-deficient mice. Adaptive thermogenesis is mediated by norepinephrine, which is released from sympathetic nerve endings innervating the brown adipose tissue. The importance of (nor)epinephrine in thermogenesis is supported by the finding that mice deficient in dopamine β-hydroxylase, the enzyme that catalyzes the conversion of dopamine to norepinephrine, are highly cold sensitive. These findings provide important information regarding the physiological role of PACAP in the adaptation of the organism to a cold environment, through adaptive thermogenesis by the brown adipose tissue. The adaptive effect to low temperature and the protective action of PACAP to other stresses seem to be mediated by the ability of the peptide to sustain the production of catecholamines in sympathetic nerves and the adrenal medulla.

PACAP-null and heterozygous mice exhibit severer neurological defects, higher mortality rate and larger infarct volume after permanent middle cerebral artery occlusion, compared to wild-type animals.[23] These deficits could be improved by either intracerebroventricular or intravenous administration of PACAP. PACAP acts by inhibiting cytosolic cytochrome *c* release and stimulating Bcl-2 expression as well as STAT3 and ERK phosphorylation. Using an oligo-antisense strategy, Banks and colleagues[5] showed that the peptide transport system-6 (PTS6) was responsible for the efflux from the brain to the blood of PACAP27. They also revealed that accumulation of endogenous PACAP into the brain could reduce the infarct volume and neurological deficit score after ischemia. Collectively, these results indicate that endogenous PACAP acts as a neuroprotective agent in the case of stroke.

Behavioral studies with PACAP- and PAC1-mutant mice provide evidence for the involvement of PACAP in the control of psychomotor behavior. PAC1-deficient mice exhibit increased locomotor activity, reduced anxiety-like behavior, and markedly impaired social behavior, suggesting that PAC1 signaling plays a role in the development and/or function of neural pathways associated with pheromone processing and regulation of social interaction. Similarly, PACAP-deficient mice display behavioral abnormalities, including increased locomotor, exploratory, and explosive jumping activity in the open field.[12] These mice also show deficit in prepulse inhibition of the acoustic startle response, an operational measure of sensorimotor gating. Some behavioral abnormalities found in PACAP-deficient mice are reminiscent of schizophrenia-like behavior, and these abnormalities can be reversed by treatment with the atypical antipsychotic drug risperidone.[13] Noteworthy, cognitive dysfunctions in schizophrenic patients correlate with a reduction of hippocampal volume and a decrease of hippocampal neurogenesis, which occur in the brains of both schizophrenic patients and animal models of the disease, suggesting that the neurogenic dysfunction in the hippocampus contributes to the etiology of schizophrenia. Interestingly, intracerebroventricular administration of PACAP stimulates hippocampal neurogenesis in adult mice[19] and PACAP increases the expression of Disrupted-In-Schizophrenia 1 (DISC1), which is a susceptibility gene for schizophrenia. DISC1 is prominently expressed in the adult hippocampus and acts as a regulator of neurogenesis. These studies imply that PACAP could play a role in schizophrenia, possibly by altering hippocampal neurogenesis.

Targeted deletion of PAC1 alters learning and memory in rodents.[33] Mutant mice harboring either complete or forebrain-specific inactivation of PAC1 suffer from a deficit in contextual fear conditioning, a hippocampus-dependent associative learning paradigm. In contrast, water maze spatial memory is unaffected in PAC1 mutants. Long-term potentiation (LTP) in the dentate gyrus of PAC1-deficient mice and PACAP-heterozygous mice is induced by both suprathreshold and threshold tetanic stimulation. However, the population spike at threshold but not suprathreshold LTP decreases significantly in both PAC1-deficient and PACAP-heterozygous mice. These findings suggest that PACAP, acting through PAC1, may play a pivotal role in learning and memory functions.[33]

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

PACAP-deficient mice exhibit significant impairment in the magnitude of response to brief light exposures with altered light-induced phase delays and advances of the circadian system. Light stimulation at early night results in a larger phase delay in PAC1-knockout mice than in wild-type animals.[10] PAC1-knockout mice under a more natural light stimulation regimen disclose a significantly decreased phase delay of the endogenous rhythm at early night.[9] At late night, the phase advance observed after light stimulation is attenuated in PACAP-deficient mice and converted into a phase delay in PAC1-knockout animals. Time-dependent dysfunctions of photic entrainment in PACAP-knockout mice can be counteracted by infusion of PACAP38. Altogether, these observations indicate that PACAP regulates particular nonvisual light responses by conveying parametric light information. Thus, dysfunction of the PACAP/PAC1 system produces selective deficits in the light response, especially during the light-to-dark transition period of the circadian system.

As indicated above, analysis of the phenotype of PACAP- and PACAP receptor-knockout mice indicate that the peptide must exert important physiological and pathophysiological functions *in vivo*. However, some phenotype changes can only be observed under pathological conditions, as PACAP has been shown to be released in the presence of psychogenic and metabolic stressors. The difficulty in some cases to detect phenotypic changes occurring in PACAP-knockout animals also arises from the fact that PACAP belongs to a superfamily of genes, including VIP and secretin, which can have partially overlapping functions. Undoubtedly, future studies will continue to disclose novel and unexpected functions of PACAP, which may lead to further clinical studies and applications for the treatment of various diseases.

Chapter 120

Prolactin-Releasing Peptide

Shuji Hinuma and Norio Iijima

ABSTRACT

Prolactin (PRL)-releasing peptide (PrRP) was discovered as a specific ligand for hGR3 /GPR10 in the course of a search for ligands of orphan G protein-coupled receptors. PrRP has an arginine-amidated phenylalanine in its C-terminus. Peptides with such a structure are referred to as RFamide peptides. The first RFamide peptides to be discovered in mammals were neuropeptides FF and AF. PrRP was thus the second RFamide peptide discovered in mammals. The discovery of PrRP indicated that various RFamide peptides and their genes exist in mammals as a family. Although PrRP was originally reported to stimulate PRL secretion, accumulated evidence demonstrates that PrRP has a variety of regulatory functions including hormone secretion, food intake, stress, blood pressure, and pain. Recent studies indicate that RFamide peptides show crossreactive binding to each others' receptors. The critical functions of PrRP should be considered as part of a network of RFamide peptides/receptors.

DISCOVERY

The discovery of prolactin (PRL)-releasing peptide (PrRP)[8] can be considered in the light of two historical viewpoints. Because PrRP is a member of the RFamide peptide family, one viewpoint would be that of the history of RFamide peptides (i.e., bioactive peptides with arginine and amidated phenylalanine at the C-terminus). The second viewpoint would be that of research into orphan G protein-coupled receptors (GPCRs) (i.e., GPCRs whose ligand is unknown), because PrRP would not have been discovered in the absence of a search for their ligands. The discovery of PrRP could therefore be considered to have happened at a crosspoint of studies on RFamide peptides and orphan GPCRs.

In the 1970s, Price and Greenberg discovered the first RFamide peptide, the tetrapeptide FMRFamide, in the ganglia of the clam, where it functions as a cardioexcitatory peptide. Since then, a number of RFamide peptides have been isolated from invertebrates, and it was expected that FMRFamide-like peptides would exist not only in invertebrates but also in vertebrates. The first report of an RFamide peptide in a vertebrate was the LPLRFamide that was isolated in 1983 from chicken brain by the use of antibodies specific for the C-terminus of FMRFamide.[6] The first discovered mammalian RFamide peptides were neuropeptide FF (NPFF) and neuropeptide AF (NPAF) that were purified from bovine brain extracts. It was later demonstrated that both of these peptides are encoded by a single gene.[27] PrRP, which was reported in 1998, was therefore the second RFamide peptide to be identified in mammals. In addition, it should be noted that the identification of the fish RFamide peptide (C-RFa) made an important contribution to the discovery of mammalian RFamide peptides.[6] To date, a total of five RFamide peptide genes and seven RFamide peptides have been discovered in mammals. Fig. 1 shows the alignment of the seven human RFamide peptides. It is evident from a comparison of their amino acid sequences that these mammalian RFamide peptides share similar primary structures, not only in their C-terminal regions but also in their N-terminal regions.

A breakthrough in the discovery of mammalian RFamide peptides was brought about by the use of a reverse pharmacological approach for the identification of ligands for orphan GPCRs. There are about 800 GPCR genes in the human genome. Half of these genes encode sensory receptors, of which most are olfactory. The other half of these genes are believed to encode receptors that regulate cell functions. There are a number of GPCRs whose ligands are still unknown and these receptors are therefore referred to as orphan GPCRs. When we started our studies of orphan GPCRs in the early 1990s, the exact number of GPCR genes in the human genome was unknown. With the progress of the human genome project, it is now possible to exactly determine the number of GPCR genes in the human genome. Even at present, there remain about 100 orphan GPCRs in the human genome, not including sensory GPCRs. In the mid-1990s, we established a general strategy for the identification of orphan GPCR ligands based on the detection of signal transduction that was induced after stimulation of cells that expressed a targeted orphan GPCR with test samples. Although it is difficult to predict what kind of signal transduction will occur after stimulation of a specific orphan GPCR, we noticed that at least one of three cellular responses was invariably induced by the activation of any regulatory GPCR: (1) an increase in

calcium ions; (2) an increase in cAMP; or (3) a decrease in cAMP. Thus, in principle, signal transduction by most orphan GPCRs should be detectable by these three assays. PrRP was discovered during such a search for orphan GPCR ligands. Although we eventually succeeded in determining ligands for various orphan GPCRs, PrRP was the first specific ligand that we identified for an orphan GPCR, hGR3 (now referred to as GPR10). The reasons why we decided to search for ligands of GPR10 was because of the unique distribution of this receptor (GPR10 mRNA is particularly abundant in the pituitary) and because its amino acid sequence shows significant homology with neuropeptide Y receptors. We first constructed GPR10-expressing Chinese hamster ovary (CHO) cells. We then used an arachidonic acid metabolite (AA)-releasing assay to search for a GPR10 ligand because, at that time, convenient methods for the direct detection of Ca^{2+} signaling in multiple samples were unavailable. We purified the obtained ligand from bovine brain extracts using a combination of various chromatographic steps and later named this ligand PrRP based on its ability to induce PRL production by pituitary cells. All of the recently discovered mammalian RFamide peptides, except for NPFF and NPAF, the first of these peptides to be discovered, have been identified in the course of a search for ligands of orphan GPCRs. The discovery of PrRP therefore provided an important clue to explore the existence of other novel mammalian RFamide peptides.

STRUCTURE OF THE PrRP mRNA/GENE

The genomic structure of the mouse PrRP gene is illustrated in Fig. 2.[32] The mouse and human PrRP genes are located on chromosome number 1 and 2, respectively. Both the mouse and the human PrRP genes consist of two exons. Cloning of human, bovine, rat, and mouse PrRP cDNAs showed that mature PrRP is produced from a precursor protein (Fig. 3). Because we purified peptides of two different lengths from bovine hypothalamic tissue extracts, PrRP31 and PrRP20, we predicted that at least two forms of PrRP are produced from this precursor protein. As shown in Fig. 3, the structure of the PrRP precursor protein can be divided into four parts: (1) the N-terminal signal peptide sequence, (2) the mature PrRP protein sequence, (3) an amidation and proteolytic cleavage motif (GRRR), and (4) the C-terminal portion, which is not included in the mature PrRP sequence. Of these four parts, the GRRR motif is completely identical, and the mature PrRP protein sequence is highly conserved between species. The signal peptide sequences are also relatively conserved, whereas the homology of the C-terminal portion that follows the GRRR motif is apparently lower than the homology of other parts of the precursor protein. These results accord very well with what is known regarding molecular evolution, that is, that functionally important amino acid sequences remain highly conserved during the evolution process. Interestingly, the position at which the intron splits the PrRP gene into two exons exactly matches the position of the N-terminus of PrRP20 (noted by an arrowhead in Fig. 3), suggesting that PrRP20 is not merely an artifact resulting from degradation of PrRP31 during the purification procedure.

PROCESSING OF THE PrRP PRECURSOR

As shown in Fig. 3, PrRP precursor proteins derived from human, bovine, rat, and mouse have typical N-terminal signal peptide sequences of 21 or 22 amino acid residues that are important for extracellular secretion. By analyses of

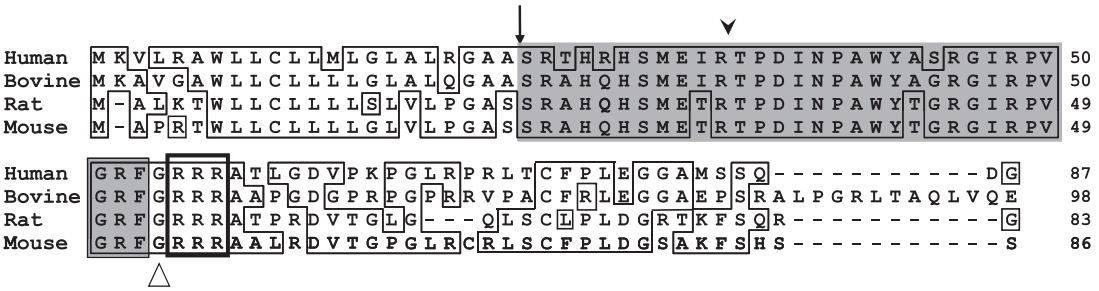

FIGURE 3 Amino acid sequences of human, bovine, rat and mouse precursor proteins containing PrRP. PrRP precursor protein sequences deduced from cDNAs are aligned, and mature PrRP sequences are indicated in gray. The arrow and arrowhead indicate the amino termini of PrRP31 and PrRP20, respectively. The open triangle indicates a glycine residue, which is presumed to react as an amide donor to produce amidated C-termini. Triplet basic amino acid residues constituting the typical motif of a proteolytic cleavage site are boxed with a bold line. Amino acid residues with identical sequences in at least two of the species are boxed.

the N-terminal sequences of active peptides purified from bovine tissue extracts, it has been shown that the N-terminus of one of the mature bovine peptides, PrRP31, starts from S^{23} just after the signal sequence, while that of the other peptide, PrRP20, starts from T^{34}. Because the precursor protein sequences are highly conserved in all species examined, it is expected that mature PrRPs will be produced from these precursor proteins in a similar manner in all species. The process by which mature PrRP is generated from the precursor protein is speculated to be consistent with that of other RFamide peptides. A possible scenario for the production of mature PrRP is illustrated in Fig. 4. First, the signal peptide is removed from the PrRP precursor protein, followed by cleavage of the basic amino acid repeat of R^{55}, R^{56}, and R^{57}. After these basic amino acids have been removed by carboxypeptidase, F^{53} at the carboxy terminus of the mature PrRP is amidated by peptidyl α-amidating monooxygenase (see the chapter on this enzyme in Peptide Biosynthesis/Processing section of this book) through a reaction with G^{54} as an amide donor. Because the amount of PrRP31 obtained from bovine tissue extracts appeared to be greater than that of PrRP20, PrRP31 would be predominantly produced from the precursor protein,[8] though it is unknown at which point of the process to produce mature PrRP, PrRP31 switches to PrRP20.

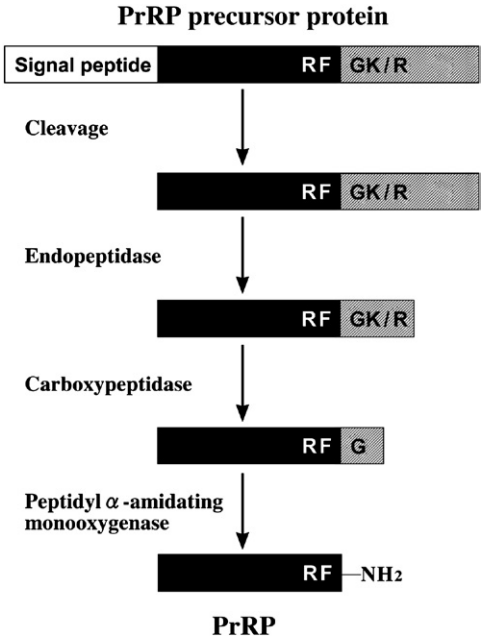

FIGURE 4 Schematic representation of the processing of the PrPR precursor protein leading to mature PrPR.

DISTRIBUTION OF THE mRNA/PEPTIDE

The distribution of immunoreactive PrRP in the brain of rats is shown in Fig. 5. The highest expression of PrRP mRNA in both rats and humans has been detected in the medulla oblongata, whereas moderate levels of mRNA are expressed in the hypothalamus,[26] where the highest concentration of bioactive PrRP has been detected in rats.[20,22] In humans, high levels of immunoreactive PrRP have been reported in both the hypothalamus and the medulla oblongata.[31] In situ hybridization analyses indicate that PrRP mRNA is localized in the neurons of the ventromedial and dorsomedial nuclei of the hypothalamus (VMH and DMH). The strongest PrRP mRNA signals are found in the nucleus of the tractus solitarius (NTS), whereas moderate levels are seen in the lateral reticular nuclei (LRN) of the medulla oblongata.[9,10,28] In rat embryos, PrRP mRNA is seen in the NTS at E18, and in the LRN at E20. On the other hand, PrRP mRNA is first detected by in situ hybridization in the hypothalamus on postnatal day 13. The distribution of PrRP-positive fibers differs considerably between neonatal and adult rat brains. In addition, gonadal steroid hormones regulate PrRP gene expression in the medulla oblongata of rats.[11] Although a high level of PrRP immunoreactivity is detected in the hypothalamus under normal conditions, PrRP-positive nerve fibers are barely detectable in the external layer of the median eminence, which is known

to be the release site of the classical hypothalamic hypophysiotropic neurohormones.[9,20] Thus, the pathway of the action of PrRPs on the pituitary, where its receptors are abundantly expressed, remains unclear. Extensive colocalization of PrRP and tyrosine hydroxylase immunoreactive neurons in the A1/A2 areas in the NTS and LRN suggests that PrRP is produced in noradrenergic neurons.[1,34] In peripheral tissues, immunoreactive PrRP has been detected in the adrenal gland.[5,21]

PrRP RECEPTORS AND SIGNALING CASCADES

As mentioned above, PrRP was discovered in the course of a search for specific ligands of the orphan GPCR GPR10 by use of an AA-releasing assay and CHO cells that expressed GPR10.[8] Interaction of a GPCR with an agonistic ligand is considered to induce the following signaling cascade in cells. (1) The binding of agonistic ligand to the GPCR integrated into the cell membrane induces conformational changes in the GPCR. (2) These changes induce activation of receptor-coupling with G proteins, either with Gαq and/or Gαi/o 003F subunits, in the case of GPR10. (3) Activation of G proteins causes subsequent activation of enzymes such as phospholipase A_2 and/or phospholipase C. (4) These activated enzymes catalyze the hydrolysis of membrane phospholipids resulting in the production of AA and/or other metabolites. (5) These events simultaneously cause both Ca^{2+} influx and a decrease in the cAMP content of cells. Based on such assumptions, we succeeded in identifying PrRP as a GPR10 ligand that could induce evident AA release in CHO cells expressing GPR10. Such an approach for the identification of a receptor ligand is referred to as reverse pharmacology. We later confirmed that PrRP induces Ca^{2+} influx and a decrease in cAMP production in CHO cells expressing GPR10. In addition, PrRP stimulates the activation of extracellular signal–regulated protein kinase (ERK), and this PrRP-induced ERK activation was completely blocked by pertussis toxin, which inactivates Gαi/o,[12] indicating that GPR10 couples to both Gαq and Gαi/o. These results indicate that intracellular signaling cascades induced by the interaction of GPR10 and PrRP are almost identical to those induced by other GPCRs. The K_d value of the binding of [^{125}I]-labeled PrRP to GPR10 expressed in CHO cells has been determined to be 26 nM. The binding of PrRP20 and PrRP31 to GPR10 is

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

of a similar high affinity. However, both the AA-releasing and receptor-binding activities of PrRP are dramatically decreased in the absence of C-terminal amidation, indicating that the amidated C-terminus is essential for the binding of PrRP and GPR10. It has been reported that the PrRP receptor contains a sequence that closely resembles a PSD-95/Discs-large/ZO-1 (PDZ) domain binding motif in its C-terminal tail and that the PrRP receptor does in fact bind with PDZ domain proteins that are known to interact with α-amino-3-hydroxy-5-methlisoxazole-4-propionic acid receptors.[17] The promoter region of the PrRP receptor gene contains several putative binding sites for transcription factors, including pituitary-specific transcription factor (Pit-1), which is involved in pituitary-specific gene expression, although the 5′-flanking region of the promoter region reportedly shows promoter activity not only in pituitary-derived cells but also in nonpituitary cells.[12,13]

NPFF-2 was originally identified as one of the receptors (NPFF-1 and NFFF-2) for NPFF and NPAF. It has been reported that human PrRP31 has a significantly higher affinity for human NPFF-2 (Ki = 19 nM) than NPFF (Ki = 5.2 nM).[3] Because NPFF-2 can bind to a wide spectrum of RFamide peptides including FMRFamide, its ligand specificity seems to be ambiguous. By contrast, it has also been reported that NPFF does not display any noticeable interaction with GPR10, whereas human PrRP binds to GPR10 with high affinity (Ki = 0.68 nM), indicating that the GPR10 receptor is highly specific for PrRP.[6]

The tissue distribution of the PrRP receptor differs from that of PrRP (Table 1). The unknown hypothalamic receptor-1 (UHR-1), a rat ortholog of human GPR10, was originally isolated from the hypothalamic suprachiasmatic nucleus. UHR-1/GPR10 mRNA is widely distributed throughout the brain, and its highest level of expression is in the anterior lobe of the pituitary.[4] High expression of GPR10 mRNA has also been detected in the normal pituitary and in pituitary adenomas.[35] In situ hybridization analyses have indicated that the highest expression of GPR10 mRNA is in the reticular nucleus of the thalamus and that prominent signals are also detected in the paraventricular nucleus of the hypothalamus (PVH), periventricular nucleus (PeVH), DMH, NTS, and area postrema (AP).[9,18,28] Binding of PrRP to the reticular nucleus of the thalamus has been reported. Although a low level of PrRP binding is also observed in the PeVH, no specific labeling has been detected in any other brain region.[28] In peripheral tissues, GPR10 mRNA has been detected in the adrenal gland, stomach, and femur by reverse transcription-polymerase chain reaction (RT-PCR) analyses.[4] In situ hybridization has revealed that GPR10 mRNA is expressed in the adrenal medulla in rats.[28]

The other PrRP receptor, NPFF-2, is strongly expressed in the central nervous system (CNS), in areas such as the spinal cord, medulla oblongata, and hypothalamus (Table 1).[6] The distribution of NPFF-2 is thus apparently distinct from that of GPR10 and PrRP.

BIOLOGICAL ACTIONS OF PrRP WITHIN THE BRAIN (AND PITUITARY)

PRL-Releasing Activity

We were the first to report that PrRP dose dependently enhances the secretion of PRL from a rat pituitary adenoma-derived cell line, RC-4B/C, and from rat anterior pituitary cells. Since then, accumulated evidence has supported the PRL-releasing activity of PrRP. However, the physiological roles of PrRP are highly controversial. Typical contentious points are as follows: (1) PrRP seems to be less potent in releasing PRL than thyrotropin-releasing hormone (TRH), although the *in vivo* effect of PrRP is strongly affected by the estrous cycle and by gender.[24] (2) PrRP-positive fibers are not apparent in the external layer of the median eminence, where classical hypothalamic hormones acting on the pituitary are detected, under normal conditions. (3) An increase in PrRP mRNA expression in the brain is not detected during lactation in some animals.[16] These results indicate that PrRP clearly differs from known hypothalamic releasing factors that act on the pituitary. In teleost fish, fibers that are immunoreactive with C-RFa (an ortholog of mammalian PrRP) project into the pituitary and terminate close to PRL-producing cells in the rostral pars distalis. Moreover, intraperitoneal injection of C-RFa significantly increases the circulating levels of PRL in fish. C-RFa is therefore considered to be a physiologically relevant candidate stimulator of PRL release in teleost fish. However, recent reports suggest that PrRP plays different roles in PRL release in different species.[14] Therefore, the role of PrRP in PRL secretion remains controversial, even from an evolutionary viewpoint.

Mediation of Stress Responses

PrRP has been proven to affect the hypothalamic–pituitary–adrenal axis by potently stimulating corticotropin-releasing hormone (CRH) neurons in the PVH.[18,21,23] The release of corticosterone and adrenocorticotropic hormone (ACTH) after central administration of PrRP is evoked not only by the modulation of CRH release but also by the release of other ACTH secretagogues such as oxytocin or vasopressin.[23] The highest expression of PrRP mRNA has been detected in the medulla oblongata, while immunoreactive PrRP has been detected in the A1/A2 noradrenergic neurons, which mediate stress signals in the CNS.[1] Water immersion-restraint stress increases c-Fos protein accumulation specifically in PrRP/TH-double immunoreactive cells in A1/A2 neurons.[21] Exposure to acute

foot shock also activates substantial numbers of medullary neurons that express PrRP mRNA.[21] In other studies, some PrRP-immunoreactive neurons showed synaptic contact with oxytocin-positive cell bodies in the hypothalamus. Indeed, intracerebroventricular (i.c.v.) administration of PrRP stimulates oxytocin release from the rat pituitary. These results suggest that PrRP-positive noradrenergic neurons that project into the hypothalamus mediate oxytocin release from the pituitary in response to stressful stimuli and demonstrate that PrRP plays an important role in regulating stress responses.

Suppression of Food Intake

PrRP and GPR10 have been detected in the DMH, which is closely involved in the regulation of feeding and energy homeostasis. It was found that PrRP mRNA expression is reduced in both the DMH and NTS during lactation and fasting in rats.[16] I.c.v. administration of PrRP causes a reduction in food intake in free-moving and fasted male rats without affecting water intake. This effect of PrRP is observed when PrRP is injected into the DMH, but not when it is injected into the PVH, indicating that the DMH is important for the inhibitory effect of PrRP on food intake.[29] Analyses of PrRP gene- and PrRP receptor (GPR10) gene-knockout (KO) mice have provided more direct evidence that the PrRP system is involved in the regulation of food intake or energy balance. PrRP KO mice show adult-onset hyperphagia and obesity that are accompanied by impaired glucose tolerance and insulin resistance.[32] Obesity induced by the disruption of PrRP or GPR10 gene seems to be consistent between PrRP and GPR10 KO mice, although the mechanisms responsible for this phenotype are not necessarily identical.[7] In the experiments using PrRP KO mice, there are no significant differences neither in body temperature changes during exposure to a cold environment nor in the cold exposure-induced UCP1 mRNA changes between PrRP-deficient and wild-type mice. Thus, the fact that PrRP KO mice gain more weight than wild-type mice do seems to be a result of their increased food intake rather than reduced energy expenditure. PrRP-positive neurons in the rat brain reportedly possess leptin receptors, and i.c.v. administration of PrRP together with leptin causes additive reductions in nocturnal food intake. These results indicate that PrRP plays important roles in the regulation of food intake.

What is the Physiological Role of PrRP?

As explained above, PrRP has been demonstrated to function in PRL release, as a stress mediator, and in the regulation of food intake. In addition, other functions of PrRP have been reported;[6] (1) induction of the secretion of not only PRL but also of other hormones including growth hormone, somatostatin, luteinizing hormone, and gonadotropin-releasing hormone; (2) induction of an increase in blood pressure and regulation of the cardiovascular system; (3) effects on sleep; and (4) pain control.[15,18] However, although various functions have been reported for PrRP since its discovery, physiological functions exclusive to PrRP have not yet been established. What does this finding mean? We would like to propose the following hypothesis as to how the crucial physiological role of PrRP can be elucidated. PrRP is a member of the RFamide peptide family. To date, seven RFamide peptides, encoded by five distinct genes, have been reported in mammals (Fig. 1). Because RFamide peptides are widely found in both invertebrates and vertebrates, it is speculated that these peptides have evolved through gene duplication. Thus, one or a few ancestral peptides with the same or similar functions have diversified during evolution into the present peptides, which have different functions. The functional differentiation of RFamide peptides continues, even at the present moment. From an evolutionary point of view, it is understandable that some RFamide peptides might have duplicated or redundant functions. Indeed, some peptides share the same receptors. For instance, recent studies indicate that NPFF-2 can bind not only NPFF but also PrRP, RFRPs, kisspeptin, and QRFP /26RFa (Table 2), suggesting that RFamide peptides and their receptors function as a network and that they possibly compensate for each other if one component of the network happens to fail. Indeed, naturally occurring GPR10-deficient rats are not impaired in food intake suppression induced by PrRP administration.[2] In addition, it is shown that PrRP induces high blood pressure and increases the heart rate via NPFF-2 *in vivo* in rats. However, some RFamide peptide/receptor pairs may have specific functions. In the case of kisspeptin and its receptor (GPR54), loss-of-function mutations of the GPR54 gene are known to cause the absence of puberty onset and hypogonadotrophic hypogonadism in humans.

TABLE 2 Cross reaction of Mammalian RFaminde Peptides with Receptors

RFamide peptide[a]	Receptors[a]
NPFF and NPAF[b]	NPFF-1/OT7T022, NPFF-2 /HLWAR77
PrRP	HGR3/GPR10, NPFF-2
RFRP-1 and RFRP-3[b]	NPFF-1, NPFF-2
Kisspeptin	GPR54, NPFF-2
QRFP/26RFa	AQ27/GPR103, NPFF-2

[a]*Representative nomenclature is used here according to the previous report listing RFamide peptides and their receptors.[6] Additional data are obtained from recent articles.[19]*
[b]*The two peptides are derived from a single gene. Alternative name is shown with a slash.*

Similar phenotypes are produced in kisspeptin-KO and GPR54-KO mice. Kisspeptin and its receptor GPR54 are therefore believed to have differentiated so that they play a selective role in reproduction, which cannot be carried out by other RFamide peptides and their receptors. If this assumption that RFamide peptides and their receptors principally function as a network and complement each other to a certain extent is valid, then a single gene-targeting technique would not always be effective in delineating the physiological functions of the RFamide peptides/receptors. It is expected that analyses of multigene KO animals will be an important approach in the future for resolving the enigma concerning the functions of RFamide peptides and their receptors, especially in the case of PrRP.

PATHOPHYSIOLOGICAL IMPLICATIONS

PrRP receptor (GPR10 or its ortholog) mRNA has been detected in various tumor cell lines including pituitary adenomas, and PrRP stimulation induces the secretion of PRL or other factors from some tumor cells.[30,35] It is probable that the hormone secretion-stimulatory activity of PrRP influences the characteristics of tumors, although there is no direct evidence that PrRP and its receptor are closely related to the growth and phenotypes of tumor cells.

It could be speculated that the regulation of food intake by PrRP and its receptor is related to obesity and/or diabetes. A human genetic study has suggested that polymorphism in GPR10 is associated with high blood pressure, and it was demonstrated, in a strain of rats used as an animal model of diabetes, that a mutated GPR10 gene is responsible for hyperphagia, dyslipidemia, and obesity.[33] In addition, it was found that PrRP gene expression is downregulated in experimental diabetic rats, and that this phenomenon is reversed by insulin or leptin treatment.[25] These reports suggest that PrRP and its receptors are involved in obesity, diabetes, hypertension, and dyslipidemia

Chapter 121

Relaxins

Andrew L. Gundlach, Craig M. Smith, Philip J. Ryan, Anna Blasiak, Francisco E. Olucha-Bordonau and Sherie Ma

ABSTRACT

The relaxin family of peptides comprises relaxin-1/2, relaxin-3, and insulin-like peptides (INSL) 3–6. Three of these peptides and their native receptors are present in the brain. Relaxin-1 is expressed by neurons within the anterior olfactory nucleus, piriform/neocortex, hypothalamus, and hippocampus of rat brain, whereas relaxin-3 is highly expressed by discrete populations of neurons in the brainstem of rodents, nonhuman primate, and other species; relaxin-3-positive axons and fibers/terminals are widely distributed throughout the forebrain. By contrast, INSL3 is detected in relatively low levels and only in neurons in some midbrain/brainstem areas. Two types of G protein-coupled receptors—RXFP1 and RXFP2, and RXFP3 and RXFP4—preferentially interact with individual relaxin-family peptides and, apart from RXFP4, are broadly but differentially expressed in the forebrain. Experimental studies implicate relaxin-3/RXFP3 signaling in physiological roles including arousal, stress, and cognition. By contrast, functions of relaxin/RXFP1 and INSL3/RXFP2 signaling within the brain are yet to be clearly identified.

DISCOVERY

The relaxin peptide family consists of seven peptides: relaxin-1/2, relaxin-3, and insulin-like peptide 3-6. Relaxin is a 5 kDa peptide hormone, which was first isolated in 1926 and named for its ability to relax the pubic symphysis. Relaxin was also one of the first genes cloned and contains a highly conserved, characteristic sequence 'RXXXRXX(I/V)' within its B-chain, which was subsequently discovered to be essential for binding to different cognate relaxin receptors. It was this sequence that was used many years later to search the Human Genome and lead to the discovery of the relaxin-3 gene.[2] Similar genomic strategies were used to identify other members of the relaxin peptide family—INSL4-6—all of which have been shown to have distinct biological actions (see Ref. 17 for a review). Insulin-like peptide 3 (INSL3) (also known as relaxin-like factor) is a 57 aa peptide hormone that was discovered in the early 1990s. The *INSL3* gene was subsequently cloned from human, pig, mouse, and rat with high expression in the testis. INSL3 was initially recognized as a powerful regulator of testicular development and function, before more recent studies identified roles in other tissues including kidney and brain (see Ref. 17 for a review).

After years of searching for a presumed tyrosine kinase receptor for relaxin (based on its insulin-like structure), recently four formerly 'orphan' G protein-coupled receptors were identified and characterized as cognate receptors for the relaxin-family peptides: LGR7 (now classified as RXFP1) for relaxin; LGR8 (RXFP2) for INSL3, GPCR135 (RXFP3) for relaxin-3, and GPCR142 (RXFP4) for INSL5 (see Ref. 3 for a review). The leucine rich repeat containing GPCRs, LGR7, and LGR8 were initially identified as receptors for relaxin by Hsu and others;[10] and GPCR135 and GPCR142 were identified by Liu et al. as receptors for relaxin-3.[12] Subsequent intensive characterization using recombinant receptors, chimeric peptides, and/or information from natural and experimentally generated gene deletion mouse models revealed that LGR8 is the native receptor for INSL3 and GPCR142 is the preferred receptor for INSL5 (see Ref. 3 for a review). The relative affinity and cross reactivity of the different relaxin-family peptides (human, rat, and mouse) for the different receptors has been systematically analyzed, and in recent years agonists with far better selectivity for RXFP3 over RXFP1/2 than native relaxin-3[13] and high-affinity RXFP3 antagonists[8,11] have been developed, allowing studies of the respective biological actions of the different ligand-receptor combinations.

STRUCTURE OF THE mRNA/GENE

Relaxin-3

The structure/sequence of the preprorelaxin-3 gene is highly conserved among vertebrates (human, chimpanzee, dog, mouse, and rat). The human relaxin-3 gene (*RLN3*) is located on chromosome 19p13.2, and the rat and mouse genes (*Rln3*) are located on chromosomes 19q11 and 8, respectively (http://www.ncbi.nlm.nih.gov/gene/?term=relaxin 3). The relaxin-3 gene is evolutionarily conserved with 73% homology between

Copyright Elsevier 2024

RLN3 and *Rln3* in the C-peptide domain and 93% homology in the A- and B-domains.[2] There is little homology, however, in the C-peptide domain (<20%) of relaxin-3 and other insulin- and relaxin-family members in human and mouse, which may reflect differences in C-peptide function(s). Phylogenetic analysis indicates that relaxin-3 (also known as insulin-like peptide 7, INSL7) emerged before the divergence of fish and all relaxin-family peptides evolved from an ancestral peptide that was relaxin-3-like. The relaxin-3 gene is under strong purifying selection, indicating a highly conserved and important function.[35]

Relaxin and INSL3

The preprorelaxin gene (*RLN1/2*) is located on human chromosome 9p24.1, and the rat and mouse genes (*Rln1*) are located on chromosomes 1q52 and 19 21.0, respectively (http://www.ncbi.nlm.nih.gov/gene/?term=relaxin). *RLN1* and *RLN2* share high sequence homology, whereas relaxin sequences in different mammalian species vary by up to 42–60%, despite a high similarity in biological activity. The peptide encoded by *RLN2*, relaxin-2, is the predominant stored and circulating form of relaxin in humans and is the functional equivalent of relaxin-1 (or 'relaxin') in rodents, whereas the peptide encoded by *RLN1* is only expressed in humans and great apes in the decidua, placenta, and prostate. *RLN1* and *RLN2* were derived through recent duplication events and are evolutionarily divergent to *RLN3*. The *INSL3*/(*Insl3*) gene is located on human chromosome 19p13.2-p12 and the equivalent rat and mouse genes are located on chromosome 16p14, and chromosome 8 33.0, respectively (http://www.ncbi.nlm.nih.gov/gene/?term=INSL3).

PROCESSING OF THE PEPTIDE PRECURSOR

Relaxin-3

The precursor peptide, preprorelaxin-3, is approximately 23kDa and is organized in a signal sequence-B-C-A domain configuration. The mature peptide is produced by proteolytic cleavage of the C-chain and formation of three disulfide bonds between six highly conserved cysteine residues present on the A- and B-chains (24 and 27 residues, respectively). Solution NMR structure of human relaxin-3 reveals an arrangement in which the A-chain forms two helical segments that are separated by an extended region and lie antiparallel to each other in a U-shape. The B-chain adopts a third helix that lies across the face of the U enclosing a hydrophobic core in an arrangement stabilized by the disulfide array.[2]

Relaxin and INSL3

The precursor peptides, preprorelaxin-1/2, and prepro-INSL3 are processed in a similar way to relaxin-3. There is very little homology between mouse *Rln1* and *Rln3*, other than the key core binding elements required of relaxins in the B-chain, and key structural elements in the A-chain.

DISTRIBUTION OF THE mRNA/PEPTIDE

Relaxin-3

Relaxin-3 mRNA and peptide have been mapped in several species, including mouse, rat, and nonhuman primate. Relaxin-3 mRNA expression is restricted to a relatively small number of neurons in the brainstem, but their extensive projection patterns results in a widespread presence of relaxin-3 in nerve fibers/terminals throughout the CNS, with similar distributions observed amongst all species studied (see Ref. 28 for a review). Because the rat and mouse are the major 'experimental' species, their relaxin-3 expression pattern is described here. A strong correlation exists between areas expressing relaxin-3 mRNA (assessed by in situ hybridization) and areas containing relaxin-3 peptide (assessed by immunohistochemistry) in the two species.[16,27,33] Furthermore, the site of relaxin-3 expression seems to be evolutionarily conserved, as there are analogous populations of neurons in zebrafish (see Ref. 28).

In rodents, relaxin-3 mRNA- and peptide-positive neuronal *cell bodies* are present: (i) in the nucleus incertus pars compacta and dissipata (or nucleus O) of the medial pontine central gray; (ii) in the adjacent pontine raphe nucleus; (iii) scattered along the entire rostrocaudal extent of the ventromedial regions of the periaqueductal gray (PAG), and; (iv) in a region dorsal to the substantia nigra (Fig. 1).[16,27]

Relaxin-3 positive *fibers* are observed in areas immediately adjacent to relaxin-3 soma and in a large number of forebrain and some brainstem areas. Very dense relaxin-3 fiber networks are present in various nodes of the septo-hippocampal pathway, including the median raphe, interpeduncular and supramammillary nuclei, and in the medial septum/nucleus of the diagonal band and hippocampus (ventral>dorsal).[16,27,33] Relaxin-3 fibers are also present in the dorsal raphe nucleus, PAG, tegmentum and tectal areas, in several areas of the hypothalamus, including preoptic and periventricular nuclei and 'lateral hypothalamic area,' and in the extended amygdala (medial/central amygdala, bed nucleus of stria terminalis, and lateral septum) and the amygdalohippocampal area. Medium densities of relaxin-3 fibers are present in the anterior/posterior cingulate and retrosplenial cortices, and midline intralaminar thalamic nuclei, while descending fibers are present in the inferior olive and nucleus of solitary tract.[16,27]

Relaxin-3 neurons are GABAergic (as reflected by the expression of glutamic acid decarboxylase). Based on earlier anatomical studies and data in the Allen Brain Atlas <http://www.brain-map.org/>, relaxin-3 probably coexists with other neuropeptides in nucleus incertus (NI) neurons and

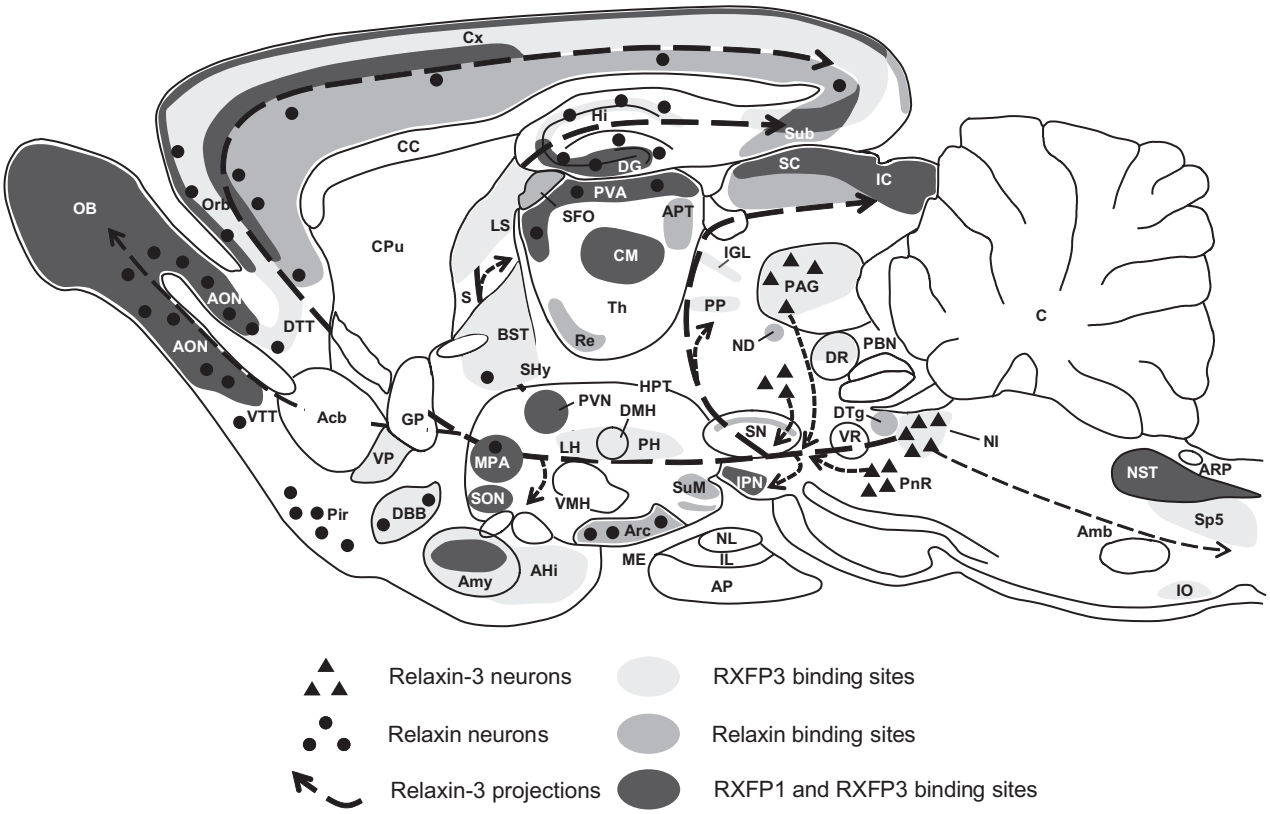

FIGURE 1 Schematic representation of the contrasting distribution of relaxin-3 and relaxin neurons and their receptor distributions in rat brain. In a stylized parasagittal brain section, neurons that express mRNA and immunoreactivity for relaxin-3 (black triangles) and relaxin (black dots) are illustrated, along with the approximate localization of the main relaxin-3 projections (black arrows). The relative distribution of RXFP1 and RXFP3 binding sites and areas in which their regional, but not precise cellular, presence overlaps are also illustrated (different gray shadings).

presumably in the other identified populations. Although a comprehensive and systematic histochemical study has not been conducted, candidates for coexpression with relaxin-3 in NI include cholecystokinin, neurotensin, and neuromedin-B, and a range of other putative markers have been identified, including different receptors, calcium-binding proteins, and transmitter-related enzymes (see Ref. 24 for a review).

Relaxin and INSL3

Relaxin and INSL3 also have a quite restricted expression profile in rat and/or mouse brain. Neurons expressing high levels of relaxin mRNA (as defined as readily detectable by in situ hybridization) are present in the hypothalamic arcuate nucleus and the anterior olfactory nucleus and piriform (or primary olfactory) cortex of rat brain. Relaxin mRNA is also detectable in tenia tecta, orbital cortex, and more generally throughout the cerebral cortex, and in dentate gyrus and CA1-3 fields of hippocampus (Fig. 1) (see Ref. 17 for a review). In contrast to the presence of relaxin-3 in nerve fibers throughout the brain, relaxin immunoreactivity, although detectable in mRNA-expressing neurons and in some fibers within the median eminence, is not observed in fiber networks associated with RXFP1-rich areas and projection target areas for the arcuate nucleus or piriform cortex.[14] This suggests a probable difference in mechanism of action of the relaxin 'peptide hormone,' compared with the 'neuropeptide' relaxin-3, that requires investigation.[17]

Similarly, using oligonucleotide-based in situ hybridization it was not possible to detect neurons expressing INSL3 mRNA in the brain of rats.[25] However, in more recent studies, we have used a characterized INSL3 antiserum to detect INSL3-positive neurons in the midbrain of mice. In a similar fashion to relaxin, INSL3 immunoreactivity is visible within the cytoplasm of the soma, but is not reliably observed in nerve fibers in adjacent or distant areas that contain high levels of RXFP2.[25]

RECEPTORS AND SIGNALING CASCADES

Extensive research using *in vitro* cell-based systems, recombinant and native receptors, and second messenger or associated reporter assays has shown that the different relaxin-family peptide receptors can couple to a variety of signal transduction pathways (see Ref. 7 for a review); however, technical challenges associated with targeting

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

these low abundance receptors in complex ex vivo tissue or in intact animals has meant that confirming these findings in endogenous neural systems has proven difficult. INSL5-RXFP4 interactions are more relevant to peptide actions in the gastrointestinal tract, as both INSL5 and RXFP4 are highly expressed in the large intestine. [RXFP4 is a pseudogene in the rat and there is a lack of convincing evidence that INSL5 and RXFP4 are expressed in mouse brain].[31] Nonetheless, independent studies have consistently shown that after activation by relaxin, which involves both the large ectodomain and the transmembrane loops, RXFP1 acts via excitatory G_s-proteins to activate adenylyl cyclase (AC) and cellular cAMP levels and subsequently protein kinases A and C, phosphatidylinositol 3-kinase, and extracellular signaling regulated kinase (ERK1/2), as well as nitric oxide signaling. These events are complex and ligand concentration dependent and are affected by the nature of the intracellular networks available.[7] RXFP2 can couple to G_s-protein and stimulate cellular cAMP levels and has also been reported to couple to inhibitory $G_{i/o}$-proteins and inhibit AC/cAMP in cell lines and native tissues, suggesting a possible influence of the G-protein repertoire of the cell on coupling. RXFP3 has consistently been shown to interact with inhibitory $G_{i/o}$-proteins and reduce cellular cAMP levels activated by forskolin, and relaxin-3 activation of RXFP3 also activates the ERK1/2 pathway. ERK1/2 phosphorylation requires the activation/recruitment of $G_{i/o}$ proteins through receptor internalization and/or compartmentalization into lipid-rich environments.[7] By contrast, Callander et al.[6] reported that RXFP1 does not internalize via conventional β-arrestin-coupled mechanisms, which is consistent with a long, sustained period of activation by relaxin of rat subfornical organ neurons recorded in a brain slice preparation (see Ref. 17 for details). Long-lasting receptor activation/signaling would also favor the maximum effectiveness of low levels of neuropeptide hormone produced in brain or that might enter the brain across the blood-brain barrier from the periphery.

DISTRIBUTION OF mRNA/PROTEIN

The central distribution of the three brain relaxin family receptors has been mapped by in situ hybridization and is described for the rat[15,16,25] (Fig. 1). RXFP1 mRNA is widely distributed in the olfactory bulb, cerebral cortex, thalamus, hippocampus, hypothalamus, midbrain, pons, and medulla, with transcripts most abundant in the basolateral amygdala, subiculum, deep layers of cingulate, somatosensory and motor cortices, and in intralaminar/midline thalamic nuclei. These areas also contain very high densities of [^{33}P]-relaxin binding sites, suggesting a largely somatic localization of RXFP1 and site of action of relaxin.[15]

RXFP2 mRNA is present in a distinct distribution in forebrain, with rich expression in the thalamus. High densities are detected in the parafascicular nucleus, the dorsolateral, ventrolateral and posterior thalamic nuclei, and in the medial habenula. RXFP2 transcripts are also present in frontal and motor cortices. The comparative distribution of RXFP2 protein examined by autoradiography of [^{125}I]-human INSL3 binding sites detected high densities in the thalamus, especially in the parafascicular nucleus, and in the entire striatum – the caudate putamen, islands of Calleja, olfactory tubercle, nucleus accumbens – with lower levels in the distinct layers of cerebral cortex. In contrast to RXFP1, RXFP2 is axonally transported and expressed presynaptically, as well as on neuronal soma, consistent with a different mechanism of action for INSL3-RXFP2 and relaxin-RXFP1 signaling.[25]

The regional pattern of distribution of RXFP3 mRNA (and [^{125}I]-R3/I5 binding sites) largely overlaps with that observed for relaxin-3 positive fibers.[16,30,31] Areas of particular functional interest that contain relaxin-3 fibers *and* RXFP3 mRNA/binding sites include preoptic, periventricular and lateral hypothalamus, paraventricular and supraoptic nuclei; nodes of the septohippocampal pathway—the septum, hippocampus, and median raphe, interpeduncular and supramammillary nuclei; the superior colliculus and PAG; and the extended amygdala, including the bed nucleus of stria terminalis and central/medial amygdala. Some species-based differences in distribution have been identified, where the distribution has been mapped thoroughly in rat and mouse (see Refs. 16, 27 for details).

BIOLOGICAL ACTIONS WITHIN THE BRAIN

Relaxin-3

Relaxin-3 has a proposed role in the control of a range of brain circuits related to behavioral state and arousal, which, in turn, regulate a number of related physiological actions and behaviors, but a full review of all possibilities is beyond the scope of this chapter. Instead, a brief discussion of its proposed role in several key functions will be presented (see Ref. 28 for further details). The neuroanatomical distribution of the nucleus incertus/relaxin-3 system displays a strong similarity to existing or 'characterized' ascending arousal systems. The nucleus incertus lies dorsal and caudal to the median raphe and medial to locus coeruleus and lateral tegmental nucleus, and relaxin-3 positive fibers and RXFP3 are present within areas in which populations of arousal-related neurons are located (although notably, not in locus coeruleus), suggesting relaxin-3/RXFP3 networks act in parallel with the norepinephrine system and in parallel and/or in series with other major arousal systems.

Strong, independent, and consistent pharmacological evidence has shown the ability of exogenous relaxin-3 (and RXFP3-selective agonists) to influence food consumption

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

and body weight gain in the rat. There is also some experimental evidence for modulatory actions associated with arousal, circadian rhythm and sleep/wake states, spatial and emotional memory, and responses to stress and affective behavior. Relaxin-3 has not been associated with any particular pathological conditions, but relaxin-3 expression is increased by strong neurogenic stressors[24,28] and relaxin-3 neurons are strongly activated after central administration of corticotropin-releasing hormone (CRH).[33]

Many early 'functional' studies administered human relaxin-3 into the lateral cerebral ventricle or into specific brain areas. However, relaxin-3 can activate RXFP1 and RXFP3 *in vitro* and *in vivo*, and this has increased the value and importance of using agonist peptides selective for RXFP3 over RXFP1 and RXFP2 in studies assessing effects of exogenous peptides *in vivo* that aim to deduce endogenous functions of relaxin-3/RXFP3 signaling.

Feeding and Metabolism

Central (intracerebroventricular, icv) administration of relaxin-3 strongly activates food consumption in satiated adult rats.[19] A similar phagic action has been shown after targeted injections of relaxin-3 into various feeding-related hypothalamic nuclei, including the paraventricular (PVN), and arcuate hypothalamic nuclei.[19] The selective RXFP3 agonist, R3/I5,[13] and the recently developed minimized agonist, RXFP3-A2 agonist[26] also increase food intake after acute icv injection in rats; while prior administration of the RXFP3 antagonists, R3(BΔ23-27)R/I5 or R3B(1-22)R and RXFP3-A3 block R3/I5- and RXFP3-A2-induced feeding, respectively.[11,26] Chronic icv infusion of relaxin-3 (via osmotic minipump) increases food consumption and body weight over a 14-day infusion period, with no marked effect observed on locomotor activity.[9] In a similar study, chronic R3/I5 infusion significantly increases food consumption (~40%) and body weight gain (~10% higher after 14 days). The increased food consumption in the R3/I5 group is reflected in increased epididymal fat, as well as increased plasma insulin and leptin concentrations.[32] Furthermore, when administered in the early part of the light/(inactive) phase, R3/I5 causes a dose-related increase in motor activity over a 2-h period.[32] However, R3(BΔ23-27)R/I5 has no significant effect on locomotor activity, even when given during the dark/active phase, and it does not block food consumption in fasted rats, suggesting that endogenous relaxin-3 does not play a primary role in basal locomotor or feeding behavior. Lastly, in a further chronic study, rats injected centrally with an adeno-associated virus (AAV) capable of producing active RXFP3 agonist secretion into the extracellular space display significantly increased food intake and higher weight gain than do controls over an extended period of >6 weeks (Ganella DE et al., unpublished data).

Despite these consistent pharmacological actions of RXFP3 activation, there is currently no clear evidence that relaxin-3 signaling is essential for the maintenance of 'normal'/basal food consumption and body weight, such as significant alterations in expression produced by fasting, as observed for other key orexigenic peptides such as neuropeptide Y. It has not been determined whether rats injected with relaxin-3 display any preference for fat or carbohydrate intake over other macronutrients, as seen with peptides such as galanin.

Furthermore, in contrast to findings in rats, in normal mice, icv administration of high doses of relaxin-3 or the selective RXFP3 agonist, R3/I5 has no acute stimulatory effect on feeding. Also, despite an early report of metabolic and associated neuroendocrine disruption in a mixed background strain of relaxin-3 null mutation mice, genetically more similar (C57BL/6 backcrossed) relaxin-3 knockout (KO) mice display an identical food consumption and body weight phenotype to wild-type littermates.[29] At present, relaxin-3 overexpressing (OE) mice have not been generated, but it would be interesting to determine whether these display an 'obese' or metabolic phenotype. Exploratory studies of acute and chronic RXFP3 activation or inhibition on feeding and body weight under different dietary conditions or in leptin-deficient obese (*ob/ob*) mice or similar strains might also provide further insights. It will also be important to determine which peptides/transmitters/hormones implicated in feeding control are directly or indirectly altered by RXFP3 activation, particularly under conditions of altered diet and stress such as during the reproductive cycle, and determine the nature of species-specific responses.

In summary, current evidence suggests that although relaxin-3 can modulate feeding, this should not necessarily be thought of as a 'primary' endogenous role of the peptide, and orexigenic effects of exogenous relaxin-3 administration may be best interpreted in terms of the putative overall function of relaxin-3 as an arousal transmitter.

Water Drinking

Several studies have shown rapid increases in water drinking after icv injection of relaxin-3 in rats.[4,19] This effect is, however, similar to that seen after icv injection of human relaxin,[4] and probably results primarily from the activation of RXFP1 in the subfornical organ by high concentrations of exogenous relaxin-3.[16]

Release of Hypothalamic and Pituitary Hormones

Available anatomical results and initial pharmacology studies indicate that relaxin-3 plays a modulatory role in neuroendocrine control—as relaxin-3 positive fibers and

RXFP3 are present in relevant hypothalamic sites, including magnocellular (and parvocellular) PVN and SON, and in the anterior and posterior periventricular areas. For example, in the hypothalamic–pituitary–gonadal (HPG) axis, icv relaxin-3 increases plasma luteinizing hormone (LH) concentrations, possibly via direct actions on hypothalamic GnRH neurons.[21] Specifically, human relaxin-3 (5 nmol, icv) and intra-PVN (0.5–1.6 nmol) in adult male Wistar rats significantly increase LH plasma levels by 2- to 3-fold 30 min postinjection. This effect is blocked by pretreatment with a peripheral GnRH antagonist. Central administration of human relaxin-2 has no effect on plasma LH levels. In hypothalamic explants, relaxin-3 dose dependently stimulates the release of GnRH by 20–30% above basal values. Relaxin-3, at high doses, stimulates GnRH release from a GT1-7 GnRH hypothalamic neuronal-cell line that express RXFP3. However, these cells also express RXFP1, a possible confound for a simple interpretation of the results. Nonetheless, the probable modulatory effect of relaxin-3 on aspects of reproduction in different species warrants further examination.

McGowan et al.[20] also reported that acute and chronic intra-PVN relaxin-3 injections produces a decrease in plasma thyroid-stimulating hormone (TSH) levels, suggesting a putative role modulating the hypothalamic–pituitary–thyroid axis and energy expenditure.

Central administration of native relaxin-3 also stimulates the hypothalamic–pituitary–adrenal (HPA) axis, increasing CRH expression in the PVN and increasing plasma adrenocorticotropic hormone (ACTH) and corticosterone.[34] Administration of the RXFP3-selective agonist, R3/I5, also increases plasma ACTH and corticosterone levels.[32] Finally, the effect of central relaxin-3 on other hypothalamic peptides and hormone-releasing factors and pituitary hormones has been examined, with reports of decreased plasma growth hormone (GH) levels. Chronic icv delivery of R3/I5 also produces an elevation in plasma testosterone[32] (see Ref. 28 for a review).

Overall, these studies suggest that relaxin-3/RXFP3 signaling may act as an ascending signal to regulate the hypothalamic coordination of appetite and growth, and thyroid and adrenal function, in relation to stress and reproductive status,[20] but further studies are required to better establish the precise mechanisms.

Arousal, Circadian Rhythm, and Sleep

Relaxin-3/RXFP3 networks are present in several brain areas, including the preoptic and lateral hypothalamus and dorsal raphe nucleus that are functionally related to the control of 'arousal' and on this basis the relaxin-3 system has been suggested to act in parallel and/or in series with these other arousal networks.[28] In the lateral hypothalamus, RXFP3 activation may result in altered activity of orexin neurons and in turn, relaxin-3 neurons express receptors for orexin and are activated by this peptide *in vitro* (Blasiak A, unpublished observations). Sleep-active GABA/galanin-containing neurons are located in the subregions of the preoptic area (POA), with a high density in the median preoptic nucleus (MnPN) and the ventrolateral (vl) POA and these areas contain RXFP3.[16,27] Convincing evidence indicates that POA neurons promote sleep onset and maintenance by inhibitory modulation of multiple arousal systems via projections from vlPOA and MnPN to multiple monoaminergic arousal systems in the posterior/lateral hypothalamus and the brainstem and are involved in homeostatic regulation of rapid eye movement (REM) and non-REM sleep. It will be of interest, therefore, to further assess the effect of sleep disturbances on the activity of relaxin-3 neurons in rat and mouse models. Furthermore, relaxin-3/RXFP3 elements are present in the intergeniculate leaflet and suprachiasmatic nucleus (the 'circadian pacemaker'), which receive retinal inputs and integrate photic and nonphotic sensory inputs. In line with this, a preliminary study reported that relaxin-3 mRNA expression varied over the 24-h circadian cycle, with a peak at 2000h (during dark/active phase) and a trough at 0800h (during early light/inactive phase), and RXFP3 activation alters the activity of intergeniculate leaflet neurons *in vitro*.[5] Whether relaxin-3 contributes to the generation of circadian rhythm, or is 'downstream' of these processes, is currently unknown.

In functional studies in rats, icv infusion of R3/I5 increases wakefulness and wakeful behaviors such as locomotor activity/exploration,[32] possibly indicative of increased general arousal. These findings are consistent with the results in two separately C57B/6J backcrossed cohorts of relaxin-3 KO mice, whereby relaxin-3 deficiency leads to increased time spent sleeping during the dark ('active') phase.[28,29]

Motivation and Reward

A primary 'reward pathway' within the brain consists of dopaminergic neurons in the ventral tegmental area that project to the nucleus accumbens, and it is activated when an animal engages in pleasurable behavior such as eating food or mating. It is also involved in the motivational drive to engage in such behavior. Relaxin-3/RXFP3 signaling may impinge directly or indirectly on this dopaminergic pathway and related limbic regions including the amygdala; and preliminary studies in relaxin-3 KO mice suggest that relaxin-3 can modulate motivated behaviors, as KO mice run less far on voluntary running wheels.[29]

Spatial and Emotional Memory

Limited studies of relaxin-3/RXFP3 signaling in learning and memory have been reported. The effect of icv injections

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

of RXFP3 agonist or antagonist has not been assessed, but the effect of intraseptal administration of relaxin-3 analogs was explored as part of a wider study to examine the anatomical and functional association of these networks with the septum and the septohippocampal system.[24] Intraseptal injection of the RXFP3 antagonist R3(BΔ23-27)R/I5[11] reduces the performance of adult, male Sprague–Dawley rats in a spatial working memory test (spontaneous alternation task), and this effect is reversed by coinfusion of the RXFP3 agonist, R3/I5.[18] In light of these and related anatomical findings, septal RXFP3 activation is postulated to alter the balance of GABA and acetylcholine release from septal afferents in the hippocampus, but these studies and others pertaining to the direct/indirect actions of RXFP3 activation on hippocampal GABA (inter)neuron and pyramidal neuron physiology and hippocampal-associated learning have not yet been completed. More recently, we also observed a strong inhibitory effect of intraamygdala injection of R3/I5 on fear expression in an auditory fear conditioning model (Ma et al., unpublished data) consistent with the high density of RXFP3 in this region.[16] Further studies are now required for the effect of RXFP3 activation and inhibition on spatial and emotional memory and of the ability of RXFP3 modulation to inhibit or potentiate memory enhancing actions of other drugs in validated preclinical memory tasks.

Relaxin-3 KO mice have been investigated in some learning and memory paradigms—relaxin-3 KO mice display no difference to their wild-type littermates in the Y-maze test—but it will be of interest to assess their performance of more difficult elements of experimental learning and memory tasks available, including Morris water maze (spatial), social transmission of food preference (olfactory), and fear conditioned freezing on the trace-fear conditioning task (emotional). Such studies should better elucidate the precise effects and mechanisms of action of RXFP3 modulation and may reveal the potential of relaxin-3-related drugs as treatment for aged-related memory deficits, perhaps as an adjunct to other treatments.

Stress Responses and Behavioral Activation

Relaxin-3 expression increases markedly after water immersion/restraint stress and repeat forced swim stress,[1,33] and on the basis of this and related findings, relaxin-3 is proposed to play a role in the coordinated stress response, which could include activation of forebrain arousal systems. In this respect, nucleus incertus (NI) relaxin-3 neurons express a high level of CRH-R1 in rat and are activated by CRH;[24] and we have obtained electrophysiological evidence that NI relaxin-3 neurons are activated by oxerins, in line with observations of orexin receptor mRNA in NI (see Ref. 28 for a review).

Relaxin and INSL3

Relaxin is well known for its actions in peripheral systems. Relaxin is produced by the ovary and targets the mammalian reproductive system to ripen the cervix, elongate the pubic symphysis, and inhibit uterine contraction. Additional roles have been proposed in enhancing sperm motility, regulating blood pressure/heart rate, and releasing oxytocin and vasopressin. Relaxin has well-characterized effects on osmotic homeostasis during pregnancy via actions of circulating relaxin on neurons in the circumventricular organs, but its actions within the brain are less well characterized.

Similarly, despite well-described roles for INSL3 in gonadal tissue function in males and females, including development of urogenital tract and female fertility, regulation of growth, and differentiation of gubernaculum and intraabdominal testicular descent, the precise roles of INSL3/RXFP2 signaling in brain are not well characterized. However, available anatomical data on the distribution of relaxin and INSL3 in distinct neuron populations in forebrain, combined with the broad and contrasting distribution of their receptors throughout sensory and motor systems and neuroendocrine networks in rat and mouse brain,[14,15,23,25] suggest that exploring their neurobiological effects in appropriate experimental models will be informative. Central administration of human relaxin inhibits feeding in rats during the early dark phase;[22] but little information is available regarding the regulation of endogenous brain relaxin or INSL3 expression by other peptides/hormones associated with metabolic or reproductive state, including leptin, insulin, and thyroid hormone and estrogen/testosterone, respectively.

Feeding and Metabolism

In initial comparative studies of the effects of relaxin-3 and human relaxin-2 (H2), little or no effect of H2 was reported,[19] but central and peripheral administration of H2 reduces food intake in male, adult Wistar rats.[22] Icv and intra-PVN administration of H2 (180 and 18–540 pmol, respectively) decrease 1-h food intake in the early dark phase by 50–70% and increase grooming and 'head down' behavior, suggesting effects within the PVN and other brain regions.[22]

Water Drinking Behavior and Pregnancy

Relaxin has a well-characterized dipsogenic effect in the brain after iv or icv administration via direct actions on the circumventricular organs (subfornical organ/OVLT), which lie along the rostral border of the third ventricle outside the blood-brain barrier and have neural axonal projections to other regions (MPO, SON, and PVN) that subserve vasopressin secretion and water drinking. Relaxin is thought to activate these brain pathways via angiotensin II signaling. In the

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

pregnant rat, injection of a relaxin monoclonal antibody into the brain negates the normal increase in drinking observed during the second half of pregnancy. Exogenous relaxin effects in the rat also vary with time of injection during the light–dark cycle, whereby dose-dependent water drinking caused by relaxin is maximal at night compared with that during the day. This effect, while perhaps predictable in nocturnal animals, may suggest an involvement of relaxin in this and other circadian-based functions (see Ref. 17 for details).

Learning and Emotional Memory

RXFP1 is concentrated in limbic regions including the hippocampus, subiculum, entorhinal cortex, and basolateral amygdala (BLA), known to participate in emotional processing, and learning and memory. The BLA is well characterized with regard to its neural connections and its involvement in modulation of fear memory. Experiments using an aversively motivated, inhibitory avoidance paradigm revealed that infusions of relaxin into the BLA (but not adjacent areas) immediately after a footshock training session significantly impaired 48-h memory retention performance in a dose-related manner.[14] These results indicate relaxin can alter early memory consolidation processes, although further studies are required to investigate the neurochemical mechanisms underlying this effect and whether endogenous relaxin alters BLA function.

Somatosensory and Motor Behavior

Preliminary studies of central administration of different doses of INSL3 (80–320 pmol icv in mice and 10–40 pmol intrastriatal in rats) indicate that INSL3 has complex pharmacological effects on locomotor activity and complex behavior.[17] In light of the presence of low levels of INSL3 in midbrain neurons (in red nucleus and substantia nigra pars reticulata) and the intriguing juxtaposition of these cells to neurons expressing abundant RXFP2 in somatosensory networks,[25] exploring their interaction in appropriate experimental models should help reveal the basis of their neurobiological actions.

PATHOPHYSIOLOGICAL IMPLICATIONS

It is established that transmission systems in the brain can release a cocktail of signaling molecules, including classical transmitters, gases and hormones, and neuropeptides, which are often recruited after severe stress or aversive/pathological events to modulate transmission and promote plasticity and neural repair. Human studies have also shown that dysregulation of neuropeptides is probably of importance for a plethora of neurodegenerative and neuropsychiatric disorders. Although not as extensive as for other similar systems, available anatomical, neurochemical, and pharmacological evidence provides substantial support for the further exploration of relaxin-3-related ligands with good RXFP3 selectivity as treatments for the pathology or associated physiological/behavioral symptoms of stress-related anxiety and depression, forms of addiction, and cognitive impairments associated with such disorders. There is no conclusive evidence linking genetically based alterations in the relaxin-3 system with specific brain pathophysiological disorders, despite some preliminary reports. By contrast, there is the possibility of therapeutically exploiting widespread RXFP3 signaling networks to alleviate the pathophysiology and symptoms of a range of psychiatric conditions. Although speculative in nature, this is considered here for some relevant disorders such as chronic stress and anxiety, mood/sleep disturbances and depression, drug addiction and relapse, and cognitive deficits associated with neurodevelopmental and neurodegenerative diseases.

Relaxin-3

Feeding and Metabolism

Administration of RXFP3 agonists into the brain produces a robust stimulation of food consumption and further studies using rat models of obesity or pathological weight loss are warranted. Studies of ‘life-long’ relaxin-3 deficient mice have provided no strong evidence for the involvement of relaxin-3/RXFP3 signaling in the physiology or pathology of energy balance and related disorders, but conditional relaxin-3- or RXFP3-KO strains or other transgenic lines such as relaxin-3 OE mice may be useful for illustrating any undiscovered role of endogenous relaxin-3 under normal and pathological metabolic conditions. Importantly, chronic secretion of a bioactive relaxin-3 analog into the hypothalamus have produced increased food intake and weight gain over an extended period, indicating that further studies of relaxin-3/RXFP3 signaling related to eating and body weight/obesity disorders may provide new insights.

Stress, Anxiety and Fear

Relaxin-3 modulates the response to stressors, as well as anxiety-like behavior (see Ref. 28 for a review). RXFP3 is expressed in various stress-related brain regions, including the PVN, where it may regulate CRH and vasopressin/oxytocin, which are critical regulators of the HPA or ‘stress’ axis under different physiological conditions. Relaxin-3 expression is increased in nucleus incertus (NI) neurons by neurogenic stressors and NI neurons can be activated by swim stress, social stress, treadmill exercise, and immobilization, and this may act physiologically to promote arousal and alertness. Central relaxin-3 injections increase parvocellular PVN CRH neuron activity, suggesting a positive feedback mechanism,[34] but the precise details of this effect are currently unclear and actions on extra-hypothalamic CRH neurons have not been explored.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Mood, Reward, Depression, and Addiction

The distribution of relaxin-3 and RXFP3 in key limbic circuits suggests exogenous relaxin-3 analogs and/or endogenous relaxin-3 signaling can modulate arousal, mood, and reward. Given the involvement of the monoamine transmitters, serotonin, and norepinephrine in these modalities, it will be important to determine their interaction with relaxin-3/RXFP3. Relaxin-3 neurons in rat brain express the serotonin-1A receptor ($5HT_{1A}$) and the chronic 'global' depletion of brain serotonin is reported to increase relaxin-3 mRNA in the NI, suggesting a potential inhibitory regulation of relaxin-3 neurons by serotonin-$5HT_{1A}$ transmission.[28] The nature of this interaction and the effect of relaxin-3/RXFP3 signaling on serotonin neurons in the dorsal, median, and pontine raphe nuclei warrants further investigation, as $5HT_{1A}$ receptor function is strongly implicated in depressive-like behaviors.

Preliminary studies with RXFP3-selective peptides suggest relaxin-3/RXFP3 signaling may modulate 'depressive-like' behavior. RXFP-A2[26] injected icv decreases depressive-like behavior (i.e. immobility in the forced swim test), but this needs to be independently verified and shown to be RXFP3 mediated. Mixed background relaxin-3 KO mice display increased 'depressive-like' behavior (i.e. increased immobility in the forced swim test) and further testing of relaxin-3 KO mice in other 'depression' paradigms and an examination of the efficacy of an RXFP3 agonist in validated mouse (and rat) models of depressive symptoms would be valuable. Lastly, relaxin-3 signaling appears to act via RXFP3 as a positive regulator of reward in alcohol-preferring rats, as central RXFP3 agonist administration attenuates alcohol self-administration and inhibits cue-induced reinstatement of drug-seeking behavior (Ryan et al., unpublished data). Thus, further experimental studies in these areas have implications for clinical conditions such as insomnia, depression, and addiction.

Relaxin and INSL3

It is not possible to comment definitively on the involvement of relaxin/RXFP1 and INSL3/RXFP2 signaling in specific disease-based brain pathologies, as there is very little published data available on their neurobiological roles. One can only speculate on such a possibility based purely on the presence of RXFP1 and RXFP2 in different excitatory networks in cortex and subcortical thalamic, hypothalamic, and limbic areas, and the established links between other peptide/hormone systems and the neuropathology of emotional and affective disorders. However, more details about the precise nature of neural actions of these peptides/receptors will facilitate more directed research, and these systems offer some therapeutic potential for disorders associated with sensorimotor deficits and possibly conditions linked to the HPG axis and reproductive behavior and physiology.

ACKNOWLEDGMENTS

The authors wish to acknowledge the contribution of current and former staff and student members of the Gundlach laboratory and our local and international collaborators in generating the experimental data reviewed in this article. Original research in the Gundlach laboratory reviewed in this chapter was supported by NHMRC (Australia); Johnson & Johnson Pharmaceutical Research & Development, LLC, USA; the Howard Florey Biomedical Foundation (USA); the Besen Family and Pratt Foundations; and the Victorian Government's Operational Infrastructure Support Program.

Chapter 122

26RFa

Jérôme Leprince, Cindy Neveu, Benjamin Lefranc, Laure Guilhaudis, Isabelle Segalas-Milazzo, Jean-Claude do Rego, Manuel Tena-Sempere, Kazuyoshi Tsutsui and Hubert Vaudry

ABSTRACT

The neuropeptide 26RFa/43RFa (also termed QRFP) is the latest member of the Arg-Phe-NH_2 peptide family discovered in vertebrates. 26RFa/43RFa recognizes the previously orphan G protein-coupled receptor GPR103. In the brain of mammals, 26RFa and GPR103 mRNAs are actively expressed in the dorsolateral and mediobasal hypothalamic areas. Intracerebroventricular injection of 26RFa provokes a dose-dependent increase of food intake. 26RFa also stimulates the gonadotropic axis, inhibits glucose-evoked insulin secretion, increases locomotor activity, and induces analgesic effects. Finally, GPR103-deficient mice suffer from osteopenia indicating that 26RFa plays a physiological role in bone formation.

DISCOVERY

RFamide peptides constitute a superfamily of regulatory peptides that share the Arg-Phe-NH_2 motif at their C-terminus. Numerous RFamide peptides have been identified in various classes of invertebrates (see the Invertebrate Peptides Section in this book), but only 5 groups of RFamide peptides have been characterized in vertebrates: neuropeptides FF/AF (NPFF/NPAF), prolactin-releasing peptide (PrRP, see the chapter on PrRP in this section of the book), gonadotropin-inhibitory hormone (GnIH)/RFamide-related peptide (RFRP) (see the chapter on GnIH in this section), kisspeptin (see the chapter on kisspeptins in this section), and 26RFa/43RFa.[5]

26RFa was initially isolated from the brain of the frog *Rana esculenta* using a nonselective antibody against the RFamide motif.[6] The sequence of 26RFa markedly differs (except for the C-terminal Arg-Phe-NH_2 signature) from all the known vertebrate RFamide peptides, indicating that 26RFa belongs to a new family of RFamide peptides. The amino acid sequence of frog 26RFa was used to characterize the cDNA sequences of the 26RFa precursors in rats and humans.[6] Concomitantly, two groups, using a bioinformatics approach, have identified the 26RFa precursors (that they termed QRFP) in the rat, mouse, bovine, and human genomes and have paired 26RFa with the orphan receptor GPR103.[10,12] Subsequently, the cDNAs encoding the 26RFa precursors have been characterized in goldfish,[17] quail,[25] chicken,[25] and zebra finch[24] indicating that the 26RFa gene is present in virtually all the classes of vertebrates. In the brain of mammals, 26RFa mRNA is primarily expressed in hypothalamic nuclei involved in the control of feeding behavior.[4,6,10,12] Consistent with this observation, intracerebroventricular (icv) injection of 26RFa or 43RFa stimulates food consumption in birds[24,25] and rodents.[6,7,13,14,18,22]

STRUCTURE OF THE 26RFa PRECURSOR

The human 26RFa cDNA encodes a 136-amino acid prepropeptide including a 17-amino acid signal peptide, a 73-amino acid N-terminal flanking peptide and the C-terminally located 43-amino acid peptide 43RFa (Fig. 1).[10,12] The general structure of the 26RFa cDNA has been preserved during evolution although the goldfish precursor sequence (168 residues) is substantially longer than the mammalian ones (120–136 residues).[26] The human 26RFa precursor, but not the precursor of other species, encompasses an additional putative RFamide nonapeptide within the cryptic polypeptide that is delimited by two single Arg residues at its N-(Arg^{79}) and C-terminal (Arg^{90}) extremities (Fig. 1).

PROCESSING OF THE PRECURSOR

The human 26RFa precursor encompasses 5 potential cleavage sites (Arg^{79}, Arg^{90}, Lys^{107}, Arg^{124}-Lys^{125}-Lys^{126}, and Arg^{135}-Arg^{136}) suggesting that processing by prohormone convertases may generate several RFamide peptides (see the chapters on Prohormone convertases in the Peptide Biosynthesis/Processing section of this book). The presence of glycine residues upstream the C-terminal basic cleavage sites (Gly^{89} and Gly^{134}) predicts that two peptides are potentially amidated (Fig. 1). Thus, cleavage at Arg^{90} and Lys^{107} has the potential to generate 43RFa and 26RFa, respectively. Indeed, the mature peptides have now been isolated and sequenced in several representative vertebrate species: in the frog *R. esculenta* and the quail *Coturnix japonica*, the mature

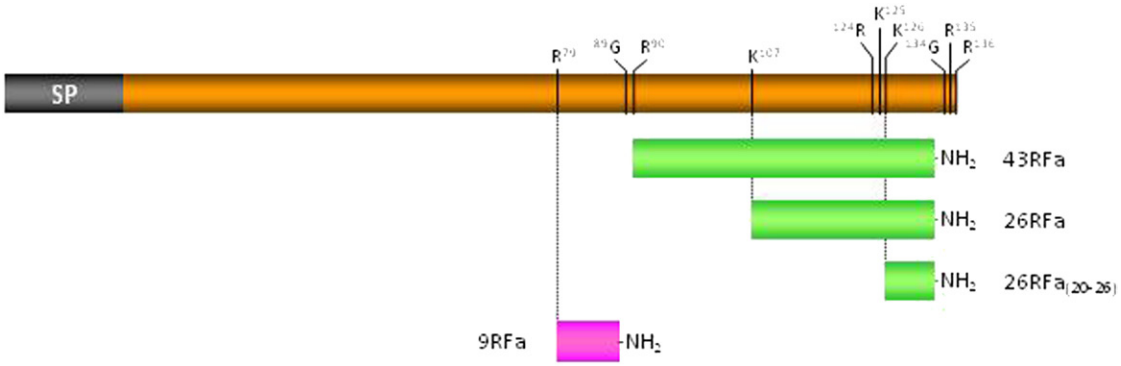

FIGURE 1 Schematic representation of the human prepro26RFa. Potential mono/polybasic cleavage sites that may lead to the generation of RFamide peptides are indicated by vertical bars. G, glycine; K, lysine; R, arginine; SP, signal peptide.

forms of the peptide are 26RFa[6] and its 27 amino acid homolog,[25] respectively, whereas in the rat brain, the mature form is 43RFa.[22] High-performance liquid chromatography analysis combined with radioimmunoassay quantification indicates the existence of both 26RFa- and 43RFa-immunoreactive peptides in the human hypothalamus and spinal cord.[4] The occurrence of a tribasic cleavage site (Arg-Lys-Lys or Arg-Arg-Lys) within the mammalian (except for the duck-billed platypus), avian, reptilian, and amphibian 26RFa sequences (Fig. 2) suggests that 26RFa could be further processed to generate the highly conserved C-terminal heptapeptide $26RFa_{(20–26)}$. Moreover, the presence of two isolated basic residues in the cryptic region of the human precursor (Arg^{79} and Arg^{90}) together with the Arg-Phe-Gly signature at positions 87–89 suggests that the 26RFa precursor could generate an additional RFamide nonapeptide (termed 9RFa) in humans (Fig. 1). However, neither $26RFa_{(20–26)}$ nor 9RFa has been detected in tissue extracts so far.

DISTRIBUTION OF 26RFa mRNA

In rats, 26RFa-expressing neurons are located in the lateral hypothalamic area, the ventromedial hypothalamic nucleus, the lateral aspect of the arcuate nucleus, and the retrochiasmatic area (Fig. 3),[6,10,12] whereas in mice, the expression of 26RFa is restricted to the lateral hypothalamic area and the periventricular nucleus.[22] In humans, 26RFa-containing neurons are present in the ventromedial hypothalamic nucleus and the paraventricular nucleus.[4] The 26RFa gene is also expressed in other extrahypothalamic human brain structures such as the cerebellum, the brainstem, and the dorsal and lateral horns of the spinal cord.[4] In quail, 26RFa mRNA occurs only in the anterior hypothalamic nucleus,[25] whereas in zebra finch, 26RFa transcript is also present in the ventromedial nucleus of the hypothalamus and the lateral hypothalamic area.[24] In teleost fish, the 26RFa gene is expressed in the optic tectum and the hypothalamus.[17]

DISTRIBUTION OF GPR103 mRNA AND SIGNALING CASCADES

26RFa and 43RFa are the ligands of the formerly orphan GPR103, also designated AQ27 or SP9155, a class A G protein-coupled receptor (GPCR).[10,12] Although GPR103 shares substantial sequence similarity with other RFamide receptors, and to a lesser extent with the Y2 neuropeptide Y (NPY) receptor, galanin receptor (Gal-R1), orexin, and cholecystokinin (CCK) receptors,[12,15] it binds selectively 26RFa and 43RFa. In contrast, 26RFa displays a moderate affinity for NPFF-2 and a low affinity for NPFF-1, two other receptors for RFamide peptides.[11] GPR103 exhibits several characteristic features of class A GPCRs including (i) the existence of an Asp residue within the second transmembrane region (TM2) that plays a pivotal role for G protein coupling, (ii) the conserved Glu-Arg doublet sequence at the N-terminal extremity of the second intracellular loop (IL2), (iii) a disulfide bridge between the two Cys residues located in the first and second extracellular loops, and (iv) three conserved residues, that is, Phe, Pro, and Asn, within TM6 and TM7 that are crucial for receptor activation (Fig. 4). GPR103 binds 26RFa and 43RFa with high affinity (IC_{50} = 3.2 and 0.52 nM, respectively).[10,12] In GPR103-transfected CHO cells, 26RFa and 43RFa inhibit cAMP formation with similar efficacy.[10] 26RFa and 43RFa also induce a robust increase in intracellular calcium concentration ($[Ca^{2+}]_i$) in a PTX-independent manner, suggesting that GPR103 is coupled to a $G_{i/0}$ and/or to a G_q protein.[10] The affinity and potency of the C-terminal heptapeptide $26RFa_{(20–26)}$ are several orders of magnitude lower than those of 26RFa indicating that this heptapeptide is not a good ligand for GPR103.[10,16]

Although only one GPR103 gene is found in the human genome, two isoforms of the receptor have been cloned in rodents. These isoforms have been termed GPR103A and GPR103B in mouse[22] and QRFP-r1 and QRFP-r2 in rat.[13] 26RFa binds mouse GPR103A and GPR103B with the same affinity[22] and stimulates inositol triphosphate in rat QRFP-r1 and QRFP-r2 with a similar efficacy.[13]

To maximize structural similarity, a residue deletion denoted by (•) has been introduced into the guinea pig sequence. *, Peptide sequence deduced from the cDNA sequence.

The distribution of 26RFa binding sites and GPR103 mRNA has been studied by autoradiography and in situ hybridization, respectively. In the rat brain, 26RFa binding sites are widely distributed, the highest densities of recognition sites being found in the granular cell layer of the olfactory bulb, the piriform cortex, the hippocampal formation, the amygdaloid complex, several hypothalamic nuclei, the inferior colliculus, the dorsal raphe, and the accessory abducens, ambiguus, parasolitary, and Roller's nuclei of the medulla oblongata.[3] A very high density of binding sites is also observed in the dorsal horn of the rat spinal cord.[3] QRFP-r1 mRNA is actively expressed in the arcuate, ventromedial, and paraventricular nuclei of the hypothalamus and the amygdala, whereas QRFP-r2 mRNA is particularly abundant in the reuniens and parafascicular nuclei of the thalamus, the medial preoptic area, and the hypoglossal nucleus (Fig. 3).[13] Differential expression of the two receptor isoforms is also observed in the mouse brain: GPR103A mRNA is abundant in the olfactory bulb and the nucleus of the solitary tract, whereas GPR103B mRNA is primarily

found in the paraventricular hypothalamic nucleus, the magnocellular nucleus of the lateral hypothalamus, the median mammillary nucleus, and the reticular nucleus.[22]

GPR103 is also expressed in several peripheral organs such as the pituitary, the eye, the zona glomerulosa of the adrenal cortex, and the testis in rat,[10] and the eye and bones in mouse.[1] In the human brain, the highest concentrations of GPR103 are observed in the cerebral cortex, hypothalamus, and vestibular nuclei.[12] In human peripheral organs, the GPR103 gene is expressed in the retina, pituitary, heart, kidney, testis, and bone.[1,10,15]

SOLUTION CONFORMATION

The three-dimensional structure of 26RFa has been elucidated by circular dichroism and molecular modeling under NMR constraints in various media.[23] In methanol, 26RFa adopts an α-helical conformation in its central region from Pro^4 to Arg^{17} while the N- and C-terminal extremities are apparently not structured (Fig. 5). The strong conservation, from amphibians to mammals, of the amino acids responsible for the amphipatic characteristic of the α-helix and those of the flexible C-terminal tail suggest that these two regions play a pivotal role in the interaction of 26RFa with GPR103 and/or in receptor activation.

STRUCTURE–ACTIVITY RELATIONSHIPS

Structure–activity relationships of 26RFa have been assessed by measuring the Ca^{2+}-mobilizing activity of human 26RFa-related analogs in *h*GPR103-transfected CHO cells. Peptide truncation studies indicate that the biologically active domain of 26RFa is located in the C-terminal region and that $26RFa_{(20–26)}$ is the shortest analog that retains full efficacy to increase $[Ca^{2+}]_i$ in GPR103-transfected cells.[16] Systematic replacement of each amino acid of $26RFa_{(20–26)}$ by an alanine (Ala scan) or its D-enantiomer (D scan) shows that the last three C-terminal residues are very sensitive to these modifications while position 23 tolerates both substitutions rather well.[16] Most importantly, replacement of Ser^{23} by a norvaline leads to an analog, $[Nva^{23}]26RFa_{(20–26)}$, which is 3-fold more potent than the native heptapeptide.[16]

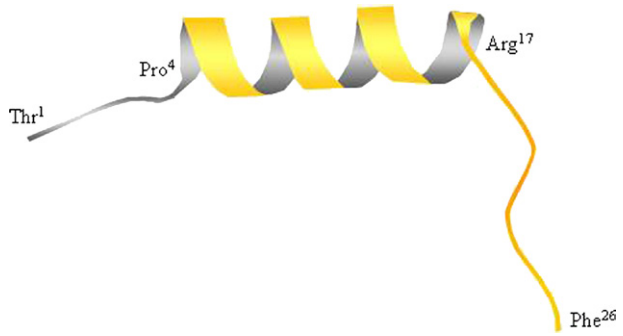

FIGURE 5 Three-dimensional NMR structure of human 26RFa in methanol. 26RFa consists of an α-helix between residues Pro^4 and Arg^{17} flanked by two nonstructured N- and C-terminal segments.

BIOLOGICAL ACTIONS WITHIN THE BRAIN (AND PITUITARY)

The occurrence of 26RFa mRNA, 26RFa immunoreactivity and GPR103 mRNA in hypothalamic nuclei controlling appetite and feeding behavior prompted several groups to investigate the effect of 26RFa and related peptides on food consumption. Acute icv injection of low doses of 26RFa induces a dose-dependent stimulation of food intake in mice.[6,22] 43RFa and the C-terminal fragment $26RFa_{(20–26)}$ both mimic the stimulatory effect of 26RFa on feeding.[7,18] Chronic infusion of 43RFa in mice provokes hyperphagia associated with a significant increase in body weight and fat mass.[18] In rat, icv injection of 26RFa moderately stimulates feeding in normally fed rat without modifying energy balance parameters.[13] 43RFa increases food intake when the animals are fed a high-fat diet but has no effect on rat under regular diet conditions.[20,21] In mouse,[22] as in rat,[14] 26RFa/43RFa-induced food intake is blocked by Y1 receptor antagonists indicating that 26RFa/43RFa exerts its orexigenic effect through activation of NPY neurons.

Reciprocally, energy balance influences 26RFa gene expression. Thus, 26RFa mRNA is upregulated in genetically obese *ob/ob* and *db/db* mice.[22] 26RFa mRNA expression is also enhanced in fasting mice as compared with that of normally fed mice.[22] In rat, 26RFa mRNA level is increased in the ventromedial and arcuate nuclei in animals fed a high-fat diet.[21] Surprisingly, however, 43RFa peptide concentration is higher in rats fed a low-fat diet than in rats under regular diet and is undetectable in rats fed a high-fat diet.[2] In goldfish, food deprivation significantly increases 26RFa and NPY gene expression in the hypothalamus.[17] Finally, in a perfused rat pancreas model, 26RFa inhibits glucose- and arginine-evoked insulin secretion.[8] Altogether, these observations suggest that 26RFa/43RFa plays a physiological role in the regulation of food intake and energy homeostasis.

26RFa and related peptides exert multiple actions on the hypothalamic–pituitary–gonadal axis. Thus, icv injection of 43RFa, 26RFa, or $26RFa_{(20–26)}$ induces an increase in plasma luteinizing hormone (LH) and follicle-stimulating hormone (FSH) concentrations in rat.[19,20] Because high concentrations of GPR103 mRNA and 26RFa binding sites occur in the preoptic area[3] where gonadotropin-releasing hormone (GnRH) neurons are located (see chapter on GnRH in this section of the book), these results suggest that 26RFa may activate the gonadotropic axis through the stimulation of GnRH release. In addition, 43RFa, 26RFa, and $26RFa_{(20–26)}$ stimulate basal and GnRH-induced LH and FSH secretion from rat pituitary explants.[19] This observation, together

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY
Copyright Elsevier 2024

with the presence of GPR103 mRNA in the pituitary,[10,12,19] indicates that 26RFa may act at the pituitary level to stimulate gonadotropin secretion. Finally, GPR103 mRNA is expressed in the testis,[10] suggesting that 26RFa may regulate gonadotropic function through a direct action on the testis. In the goldfish, intraperitoneal injection of 26RFa causes a transient increase in plasma LH concentration, but 26RFa has no effect on LH release from pituitary cells in primary culture,[17] suggesting that, in fish, the peptide may stimulate the gonadotropic axis by acting exclusively at the hypothalamic level.

In the rat, the highest concentration of GPR103 mRNA is found in the adrenal gland.[10] Consistent with this observation, intravenous (iv) injection of 43RFa causes a dose-dependent increase in plasma aldosterone levels.[10] The fact that 43RFa does not modify corticosterone secretion[10] indicates that the peptide acts specifically on zona glomerulosa cells of the adrenal cortex.

The GPR103 gene is actively expressed in the spinal cord of mice.[12] In the spinal cord of rats, high concentrations of GPR103 mRNA and 26RFa binding sites are found in the superficial layers of the dorsal horn.[3] In the human spinal cord, 26RFa mRNA is abundant in the dorsal horn.[4] These observations strongly suggest that 43RFa/26RFa could be involved in nociceptive transmission. In support of this hypothesis, intrathecal administration of 26RFa in rats significantly reduces the frequency of agitation behaviors in the paw formalin injection test and attenuates the level of mechanical allodynia in the paw carrageenan injection test.[28] The analgesic effect of 26RFa in the formalin test is also observed after icv injection of the peptide[27] indicating that 26RFa also modulates nociceptive transmission at a supraspinal level.

Central and peripheral administrations of 26RFa and related peptides induce several other biological responses. In particular, icv injection of 26RFa or 43RFa in mice exerts a dose-dependent stimulatory effect on locomotor activity.[7,22] The action of 26RFa/43RFa on locomotion is not mimicked by the C-terminal heptapeptide $26RFa_{(20–26)}$, suggesting that the effects of 26RFa on food intake and on locomotor activity may be mediated through distinct receptors.[7] Central injection of 43RFa in mice causes a rise in blood pressure and heart rate.[22] Iv injection of 26RFa in anesthetized rats induces a biphasic effect on blood pressure (i.e., hypotension followed by hypertension) associated with tachycardia.[9] The pressure response is inhibited by α- and β-adrenoreceptor antagonists, while the tachycardia response is attenuated by cervical vagotomy and a β-adrenoreceptor antagonist,[9] suggesting that the peripheral cardiovascular effects of 26RFa are mediated via the vagal nerve and involve a (nor)adregernic pathway.

PATHOPHYSIOLOGICAL IMPLICATIONS

Phenotype analysis of GPR103A-deficient mice reveals that homozygous mutant mice are viable and fertile but suffer from severe osteopenia accompanied by a decrease in bone density that is more pronounced in females than in males.[1] In addition, $GPR103A^{-/-}$ mice exhibit pronounced kyphosis similar to patients with osteoporosis.[1] Histological analysis indicates that the decrease in bone density in KO mice results from a reduction in the number of osteoclasts and a deterioration of the osteochondral plate. It thus seems that the activation of GPR103A by 26RFa is involved in bone formation through direct action at the osteochondral plate. Four single-nucleotide polymorphisms (SNPs) have been identified in the osteopenic SAMP6 mouse genomic DNA. In particular, one SNP is found in the promoter region of the 26RFa gene that generates a novel neuron-restrictive silencing factor binding site, a repressor that decreases gene expression in non-neuronal tissues.[29] Accordingly, a significantly lower expression of the 26RFa transcript has been found in lumbar spine, but also in the hypothalamus of SAMP6 mice compared with that of wild-type mice,[29] suggesting that a decrease in 26RFa production may contribute to the osteoporosis phenotype of SAMP6 mice.

Chapter 123

Secretin

Stephanie Y.L. Ng, Carrie Y.Y. Cheng and Billy K.C. Chow

ABSTRACT

Since its initial discovery, secretin is now coined as a classical hormone with widespread distribution. In particular, numerous studies have demonstrated the abundant expression of secretin and its receptor within various brain areas sparking interest of its potential as a brain peptide. With gene knockout animals becoming widely available, recent physiological studies have provided a glimpse of secretin's role in appetite control and osmoregulation, establishing its potential as a brain peptide. This chapter focuses on secretin and its receptor, reviewing our current knowledge in the structural and molecular aspects, central effects and the pathophysiological implications in cognitive behavior.

DISCOVERY

The discovery of secretin in the beginning of the last century introduced the concept of hormone and hence initiated the field of endocrinology. Ivan Petrovich Pavlov showed that the pancreatic secretion was stimulated by the acidity in chyme rather than food, and he believed that the secretion was control by nerves. However, the hypothesis was challenged when researchers showed that the introduction of acid was able to excite pancreatic secretion even after denervation. In 1902, two British physiologists, Ernest Starling and William Bayliss, observed that intravenous injection of a mucosal extract, produced in the duodenum on acid infusion in an anesthetized dog, stimulated pancreatic secretion. This study clearly indicated the presence of an active substance originated from the intestinal mucosa and carried as a blood-borne agent to stimulate pancreatic secretion. This active substance was later named as secretin, and the term "hormone" has been coined ever since, meaning chemical messenger transmitting information from one organ to another via blood circulation.

STRUCTURE OF THE mRNA/GENE

Since its discovery, the secretin genes have been characterized in different species (Fig. 1). Among species, a conservation of gene environment is revealed by chromosomal synteny analysis and a common four-exon structure is also shared (Figs. 2 and 3). In the rat genome, the secretin gene is 813 nucleotides in length. The first exon encodes for the signal peptide and part of the N-terminal peptide; the second exon encodes entirely for the biologically active secretin peptide and processing signal sequences; and the remaining two exons encode for the C-terminal peptide of the prosecretin. Comparison of the secretin gene with genes within the same peptide family reveals similar structural organization suggesting that they are evolved from a common ancestral gene. In particular, a high degree of similarity is shared in the exon(s) encoding the biologically active peptides that are physiologically important, while the C-terminal peptide-encoding exons show a lower level of similarity. In contrast to the active peptides of gastric inhibitory polypeptide (GIP) and growth hormone-releasing hormone (GHRH) that are encoded in two exons, active secretin alongside with other superfamily peptide members (glucagon, glucagon-like peptides (GLPs), vasoactive intestinal peptide (VIP), pituitary adenylate cyclase-activating polypeptide (PACAP), peptide histidine methionine, and PACAP-related peptide (PRP)) are encoded by one exon. Among its superfamily, the SCT gene is unique in encoding for only a single copy of biologically active peptide and lacking a sequestering intron between the transcriptional and translational start sites.

PROCESSING OF THE PRECURSOR

The structure of secretin's precursor has been deduced from a range of mammalian cDNA sequences. In the pig, the precursor consists of a signal peptide, a short N-terminal flanking sequence, a 27 amino acid secretin peptide which is followed by a Gly-Lys-Arg cleavage and amidation sequence

and a 72 amino acid C-terminal extension peptide.[33] This was initially believed to be the sole secretin precursor form to exist. However, analysis of porcine intestinal RNAs soon suggested otherwise with findings of at least two scarcer and shorter transcripts whereby in one form a single arginine residue replaces a 32 amino acid sequence preceding the Gly-Lys-Arg motif;[33] and another form which lacks the third exon and only encodes a 44 amino acid C-terminal extension peptide.[33] Differential splicing has then been suggested to be the mechanism responsible for generating these variant transcripts.[33] These transcripts, together with the longer form, have full bioactivity and are the precursor molecules (preprosecretin) from which the 27 amino acid C-terminally amidated secretin (secretin-27) and its Gly (secretin-28), and Gly-Lys-Arg (secretin-30) C-terminally extended intermediates are synthesized from. Two alternative processing pathways are involved such that the different bioactive secretin forms are representatives of intermediate products in the biosynthetic pathway.[4] In the first step of preprosecretin processing, signal peptidase targets the Ala-Arg bond in positions −10 and −9 upstream from secretin's N-terminus to produce an 80 amino acid prosecretin, which then proceeds into one of the two alternative pathways. In one pathway, the signal peptide and N-terminal flanking peptide are cleaved to produce a 71 amino acid intermediate form consisting of secretin extended by the Gly-Lys-Arg amidation region and a C-terminal extension peptide. A trypsin-like peptidase subsequently targets the dibasic site; cleaving C-terminally of the amidation site to produce secretin extended by Gly-Lys-Arg. Secretin-Gly is then obtained by the removal of the latter two residues by carboxypeptidase (see the carboxypeptidase chapter in Peptide Biosynthesis Processing section of this book). Lastly, peptide amide monoamine oxygenase (see the PAM chapter in same section just mentioned) then acts on the intermediate to produce the final product of secretin with a C-terminally amidated valine residue. Alternatively, prosecretin can also be processed first at its C-terminal end before cleavage of its N-terminal flanking peptide.

DISTRIBUTION OF THE mRNA/PEPTIDE

In recent years, our understanding of secretin functioning as a neuropeptide has advanced considerably. Many studies have reported and confirmed the widespread occurrence of secretin protein and transcript in the central nervous system (CNS) by reverse transcriptase-polymerase chain reaction (RT-PCR), Northern blot, in situ hybridization and immunohistochemistry studies. Before 1981, secretin immunoreactivity had been mapped in the CNS of the rat and pig with a highly specific radioimmunoassay. Secretin concentrations are high in the olfactory bulb, thalamus and hypothalamus, moderate in the striatum, septum, hippocampus, midbrain, and cerebellum, and low in the cerebral cortex, medulla oblongata and pons. By using RT-PCR, secretin precursor mRNA was detected in the olfactory bulb, thalamus, hypothalamus, cerebral cortex, hippocampus, midbrain, cerebellum, medulla oblongata, pons, and pituitary. Contrary to the findings of previous studies, the expression level of secretin precursor mRNA is highest in the medulla oblongata, pons and the pituitary at levels comparable with those in duodenum. Secretin has subsequently been found in other brain regions including the brainstem and the sensory ganglia.[19]

Aside from a general view of the expression of secretin in the brain, cellular localization of secretin in some of the brain regions have also been studied in detail. In the cerebellum, secretin immunoreactivity is found in Purkinje cells, basket cells, central cerebellar nuclei, and the superior cerebellar peduncle.[19] On closer examination, secretin is present in the soma, dendrites and axon[19] inside Purkinje cells. In the hypothalamus, secretin is expressed in several hypothalamic nuclei including the paraventricular nucleus (PVN), supraoptic nucleus (SON),[19] and arcuate nucleus (Arc).[7] Secretin is also colocalized with angiotensin type 1 receptors in the PVN.[21] In the cerebral cortex, secretin is found in the hindlimb area of the motor cortex and also pyramidal cells in both external and internal pyramidal layers.[19] In the brainstem, secretin immunoreactivity is present in the mesencephalic nucleus of the trigeminal nerve, the superior olivary nucleus, and scattered cells of the reticular formation.[19]

The distribution of secretin was not only studied in the adult brain but also during embryonic development. Secretin transcripts have been detected in the central amygdala, hippocampus, cerebellum, area postrema, and the nucleus of the solitary tract (NTS) during postnatal day 7 (P7) to P60 in rats. Within most brain regions, secretin transcripts are more abundant in postnatal day 7 and 14 rats when compared with P21, P30, and P60 rats, suggesting that the expression of the secretin gene is developmentally regulated during the first few weeks after birth.[31] The ontogeny of secretin expression has also been studied in the mouse brain. Siu et al. showed that secretin transcripts are expressed as early as at E10.5 in the midbrain and hindbrain regions. In the midbrain region, secretin transcripts and peptides are present in the cephalic mesenschyme at E10.5 and E12.5 and the mesencephalic flexure and tegmentum at E14.5 and E16.5. In the hindbrain region, secretin transcripts and peptides are found in the cerebellar primordium from E10.5 to E16.5 and in the choroid plexus from E12.5 to E16.5.[30] Another research group has also shown the expression of secretin transcripts in discrete areas of the mouse brain during development, including the gigantocellular reticular nucleus, the raphe magnus nucleus, and the lateral paragigantocellular nucleus.[23] These studies complement the previous results on the expression of secretin in the brain of adult mammals and also suggest a functional role of secretin during embryonic development.

Like its ligand, secretin receptor is also widely expressed throughout the CNS. Within the cerebellum, positive signals for secretin receptor knockout (SCTR) are present in Purkinje

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

cells and basket cells. Aside from the cerebellum, SCTR is also found in various brain regions. By the use of autoradiography with I^{125}-secretin, it was shown that intense binding is present in the accumbens nucleus, laterodorsal thalamic nucleus and NTS, whereas there is moderate binding in the olfactory bulb, caudate/putamen, lateral septal nucleus, amygdale, hippocampus, hypothalamus, dorsal raphe nucleus, and locus coeruleus, pineal gland, and pituitary (Fig. 4).

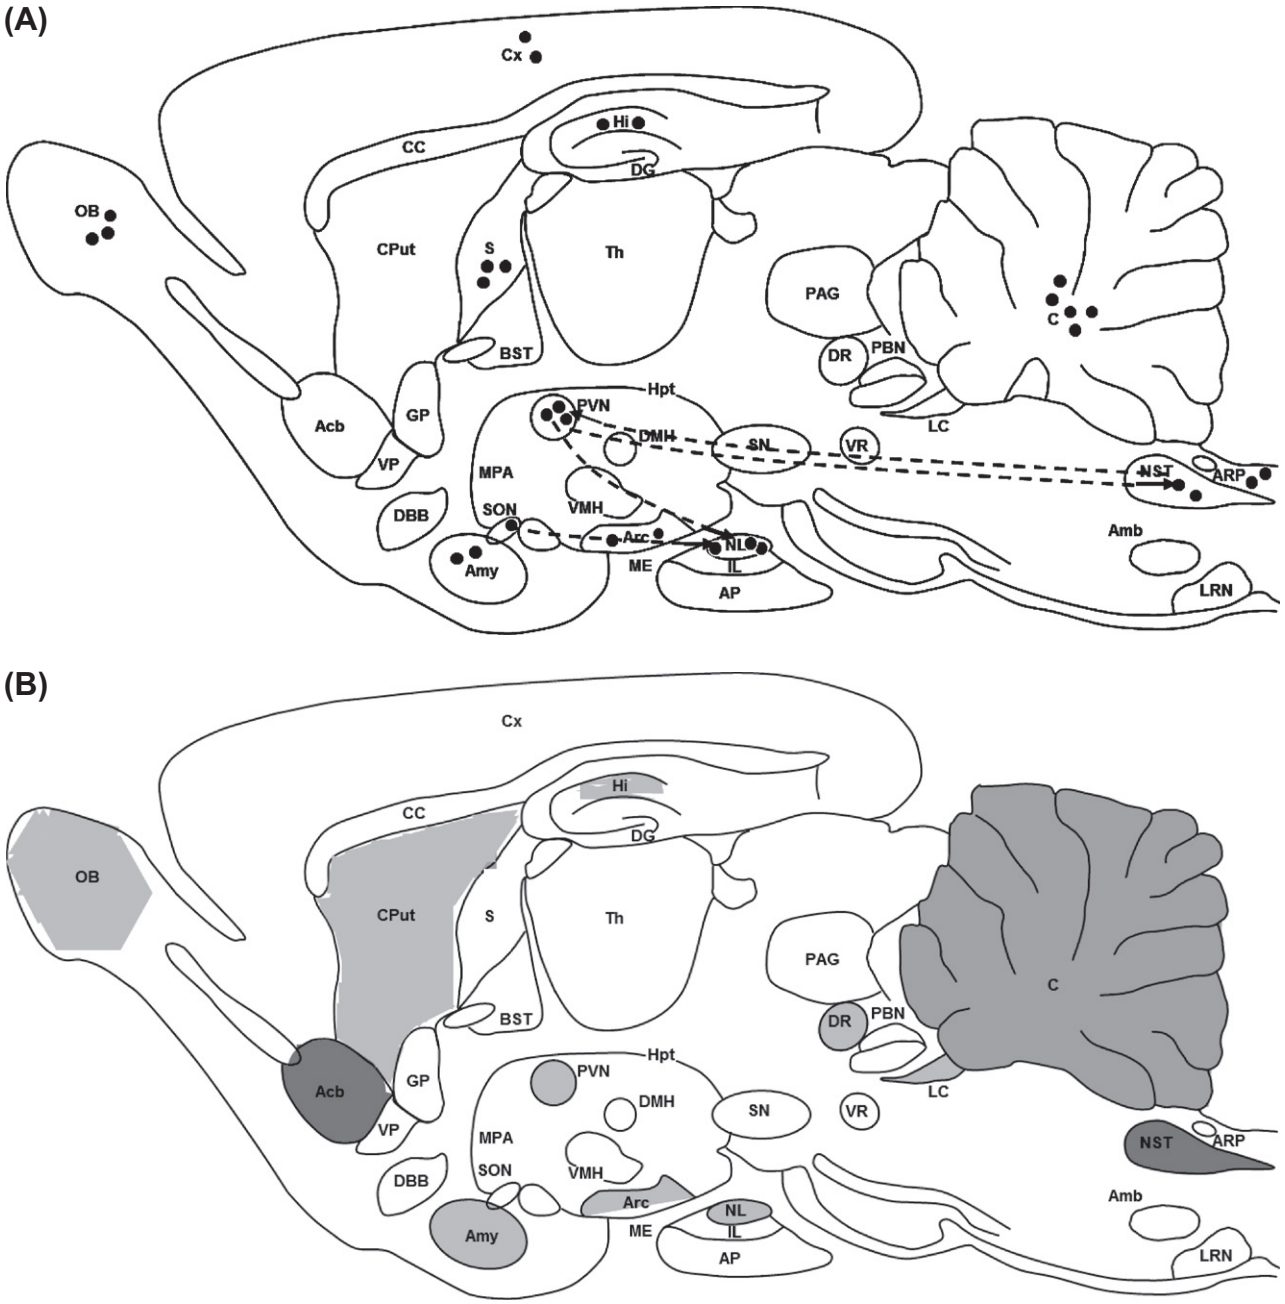

FIGURE 4 Distribution of (A) secretin and (B) secretin receptor in a parasagittal section of the rat brain. Secretin positive perikarya are denoted by black circles, fibers/projections by stippled lines. Regions with positive signals for secretin receptor are denoted by shading ▬ represents regions showing intense binding to I^{125}-secretin; ▭ represents regions showing moderate binding to I^{125}-secretin. Abbreviations: Acb, nucleus accumbens; Amb, nucleus ambiguus; Amy, amygdala; AP, anterior pituitary; Arc, arcuate nucleus of hypothalamus; ARP, area postrema; BST, bed nucleus of stria terminalis; C, cerebellum; CC, corpus callosum; CPut, caudate putamen; Cx, cerebral cortex; DBB, diagonal band of Broca; DG, dentate gyrus; DMH, dorsomedial nucleus of hypothalamus; DR, dorsal raphe nucleus; GP, globus palidus; Hi, hippocampus; Hpt, hypothalamus; IL, intermediate lobe of pituitary; LC, locus coeruleus; LRN, lateral reticular nucleus; ME, median eminence; MPA, medial preoptic area; NL, neural lobe of pituitary; NST, nucleus of solitary tract; OB, olfactory bulb; PAG, periaqueductal gray; PBN, parabrachial nucleus; PVN, paraventricular nucleus of hypothalamus; S, septum; SN, substantia nigra; SON, supraoptic nucleus; Th, thalamus; VMH, ventromedial nucleus of hypothalamus; VP, ventral pallidum; VR, ventral raphe nuclei.

THE SECRETIN RECEPTOR AND ITS SIGNALING CASCADES

The Structure

By chronological order, the secretin receptor cDNA was first cloned in the rat followed by human, rabbit, and most recently in the lungfish (*Protopterus dolloi*) and frog (*Xenopus laevis*). The secretin receptors cDNAs encode for a 21–28 amino acid residues long N-terminal signal peptide, a single 1320–1392 base pair open reading frame encoding for a 440–464 amino acid mature protein. Among the secretin receptors, 62.6–69.0% sequence identity is shared with most similarity in the ligand binding and seven TM domains, and to a lesser extent in the signal peptide and C-terminal tail domains.

Of the range of secretin receptors, the detailed structure of mammalian forms, particularly of the rat has been most extensively studied. By truncation, site-directed mutagenesis, and chimeric receptor studies on the rat secretin receptor, the large extracellular N-terminal receptor domain has been shown to be a structurally independent, highly folded, disulfide-bonded domain, playing a direct role in recognition with the C-terminal portion of secretin.[12] Included are a series of six conserved cysteine residues ($Cys^{24,44,53,67,85,101}$) and one cysteine (Cys^{11}), which is present only in the most closely related family members. Together, they form three extracellularly located disulfide intradomain bonds that are implicated to be important for both receptor architecture and function.[2] Five putative N-linked glycosylation sites (NXS/T) are also distributed in the N-terminal ectodomain and second exoloop, and are essential in maintaining high affinity binding sites, which ultimately affect receptor function.[28] Secretin receptor structure is further supported by conserved charged amino acids in the extracellular region, namely, Asp^{49}, Arg^{83} in the N-terminus, Asp^{174} and Lys^{194} in the first exoloop, and Arg^{255} in the second exoloop.[10] At least four of the aforementioned amino acids are conserved throughout the secretin receptor superfamily and mutation of any of these residues results in severe reduction in secretin affinity and potency, and the receptor maximal response. Within the third endoloop, two conserved basic motifs, KLR and RLAR/K, have been found crucial in receptor conformation and functionality.[5] Mutagenesis studies reveal KLR to be necessary for efficient G protein coupling while RLAR/K contains the conformational determinant for receptor maturation and stability. Besides structurally supportive components, several regions have also been shown to be associated in ligand binding. These include amino acid residues 1–30, 34–41, and 103–110 distributed throughout the N-terminal domain and complementation by the first and second extracellular loops and the first, second, and sixth transmembrane domains to allow efficient secretin binding and receptor activation.[24]

Receptor Signaling and Regulation

On binding of secretin to its receptor, conformational change is induced to present an α-helical amphiphilic cationic receptor structure that interacts with heterotrimeric G proteins (α, β, and γ). G protein activation subsequently initiates the dissociation of guanosine triphosphate bound to the Gα subunit in exchange for guanosine diphosphate and ultimately triggers a series of downstream signaling cascades. Initially, it was believed that the secretin receptor coupled solely to $G\alpha_s$, stimulating the adenylyl cyclase (AC) pathway to accumulate cAMP. However, it was later discovered that high concentrations of secretin not only resulted in maximal cAMP formation but also transiently increased intracellular calcium (Ca^{2+}) levels in pancreatic acinar cells.[32] As a result, the secretin receptor is now also recognized to mediate independently through $G\alpha_q$ coupling and thereafter activating the inositol triphosphate, intracellular Ca^{2+} and diacylglycerol pathways.

Like some members of the β-adrenergic family of G protein-coupled receptors (GPCRs) where receptor phosphorylation has been identified to be the key, the secretin receptor is also desensitized in a similar fashion in response to agonist stimulation. Alternatively, the secretin receptor has also been suggested to undergo phosphorylation-independent internalization based on findings of restimulation with secretin failing to elicit cAMP response in CHO cells transfected with rat secretin receptors.[16] With later studies using cytosensor microphysiometry on the human secretin receptor, a clearer elucidation of receptor regulation has been postulated, whereby desensitization may be rapidly followed by resensitization.[26]

Receptor Dimerization

GPCRs were previously believed to exist and function as monomeric units; however, mounting evidence now documents the ability for receptors to traffic and signal within higher-order complexes. In fact, dimerization of GPCRs is now a widely accepted constitutive mechanism for both regulation and functional modification. In the past few years, Miller's group has concentrated much effort in exploring the dimerization status of SCTR, making it the most extensively studied class II B GPCR member (see his chapter on secretin in the Gastrointestinal Peptides section of this book). This aspect of receptor association has been investigated predominantly by fluorescence or bioluminescence resonance energy transfer (FRET/BRET) technology, using C-terminally tagged receptors with either *Renilla* luciferase or yellow fluorescent protein. By morphologic FRET microscopy, the secretin receptor has been shown to be capable of agonist-independent self-association (homodimerization), beginning as early as the start of biosynthesis with distribution in organelles (including the endoplasmic

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

reticulum, Golgi clusters) of the maturation pathway, and in the plasma membrane.[22] The detailed molecular determinants to secretin receptor homodimerization were later studied with the lipid exposed segment of TM4 (particularly Gly^{243} and Ile^{247}) deemed as an important interface and necessary for efficient stimulation of the AC signaling pathway.[15] Furthermore, cysteine-scanning mutagenesis of 14 TM4 residues provides some information regarding the secretin receptor dimeric state: only three (Gly^{241}, Trp^{242}, and Pro^{245}) of the fourteen cysteine mutated TM4 residue constructs suffered loss in proper trafficking and signaling, and only three (Gly^{243}, Ile^{247}, and Ala^{250}) of the five lipid-facing cysteines exposed to cuprous phenanthroline to induce disulfide bonding were able to stabilize in the high affinity state.[11] In particular, the SCTR does not exist as a higher-order oligomer [13] but is able to heterodimerize with other secretin superfamily members.[14] Clearly, secretin receptor dimerization provides new insights into the molecular components involved in enhancing receptor function.

BIOLOGICAL ACTIONS WITHIN THE BRAIN (AND PITUITARY)

Cerebellum

Among various brain regions, the function of secretin in the brain has been best studied in the cerebellum. In 1981, the presence of secretin in cerebellum was detected by radioimmunoassay, and it was later confirmed by other studies using in situ hybridization and immunohistochemistry. These techniques further detail the cellular location of secretin, showing the expression of secretin in Purkinje neurons of adult humans and rats.[34] Inside Purkinje cells, secretin immunoreactivity is found in both the soma and dendrites.[34] For the secretin receptor, in situ hybridization reveals its expression in the GABAergic interneurons (basket cells) in addition to Purkinje cells.[34] The pattern of expression in the cerebellum suggests that Purkinje cells synthesize secretin which then targets Purkinje cells themselves and also the nearby basket cells. By use of whole-cell patch-clamp recordings from identified Purkinje neurons in acute rat cerebellar slices, it was found that secretin modulates synaptic input to Purkinje cells. Secretin increases the frequency and amplitude of evoked and spontaneous inhibitory postsynaptic currents (IPSCs) as well as the frequency of the miniature IPSCs originating from basket cells.[34]

Taken together, these results indicate an action of secretin in the cerebellum. Depolarization of Purkinje cells triggers the release of secretin from somatodendritic region. Secretin then binds to its receptor located on presynaptic basket cells to facilitate GABA release and thereby stabilize excited Purkinje cells in a negative feedback manner.[34] In addition to direct activation of presynaptic secretin receptors on basket cells, another mechanism of how secretin facilitates the inhibitory neurotransmission in the cerebellum has been suggested. The released secretin acts on an unknown glutamate source causing the release of glutamate which then enhances the release of GABA by activating presynaptic AMPA receptors.[20] Preliminary results also show that secretin may bind to its receptors on the same or nearby Purkinje cells; nevertheless, the function has not yet been identified.

Hippocampus

An earlier study has shown that secretin increases glutamate and GABA levels within the extracellular spaces in the hippocampus.[9] A study using secretin receptor knockout ($SCTR^{-/-}$) mice reveals the importance of secretin and its receptors in hippocampal synaptic plasticity, and social and cognitive behavior.[27] Hippocampal long-term potentiation (LTP) is a use-dependent increase in synaptic efficacy and is widely considered as one of the major cellular mechanisms that underlies memory. Hippocampal LTP was induced by the stimulation of the Schaffer collateral pathway in the CA1 area. In the study, Nishijima et al. showed that loss of secretin receptors causes deficits in synaptic transmission at Schaffer collateral synapses. In addition, loss of secretin receptors also provokes a significant reduction in LTP induction and maintenance, showing the necessity of secretin receptors for normal hippocampal function. The reduced synaptic transmission may correlate with the reduction in the density of dendritic spines displayed in the mutant mice, which is the primary place for connecting excitatory neuronal axons and for synaptic modification. The behavioral consequences brought about by the defect in synaptic plasticity include altered social behaviors and cognitive behaviors.[27]

Amygdala

Fos mapping shows that neurons in the central and medial amygdala are activated by intravenous, intraperitoneal, and intracerebroventricular administrations of secretin, suggesting that secretin may participate in the primary role of the amygdala in emotional learning. Consistent with this notion, it was shown that peripheral administration of secretin dose dependently decreases the magnitude of fear-potentiated startle in rats.[19] In humans, consistent results were also obtained. A functional magnetic resonance imaging (fMRI) study using blood oxygen level dependent (BOLD) changes in response to different facial stimuli showed that secretin treatment causes significant activation of the right amygdala during the viewing of fearful faces,[35] suggesting that secretin alters amygdala responsiveness to affective stimuli. The human and animal studies both suggest the role of secretin in modulating social behavior and recognition.

The amygdala has also been implicated in playing a stimulatory role in pancreatic exocrine secretion via the

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

vagus nerve. Electrical stimulation of the medial amygdaloid nucleus significantly increases pancreatic secretion of water and bicarbonate output on secretin or intraduodenal HCl infusion in rats. However, medial amygdaloid stimulation is ineffective in stimulating pancreatic secretion in the control group receiving saline infusion,[19] thus implying that a certain level of plasma secretin is essential for the stimulatory effect of amygdala in pancreatic secretion.

Hypothalamus

The biological role of secretin in body water homeostasis has been studied for many years but not fully substantiated because of inconsistent findings regarding the renal functions of secretin. Recent studies using transgenic mice shed light on the role of secretin in body water homeostasis. *SCTR*$^{-/-}$ mice exhibit polyuria and polydipsia; they drink more water and produce more urine than their wildtype littermates. The underlying mechanism is similar to the way secretin promotes transepithelial solvent flux in cholangiocytes; it induces expression of AQP2 and stimulates trafficking of this water channel from intracellular vesicles to the plasma membrane in renal collecting tubules under hyperosmotic conditions. To regulate water homeostasis, secretin actually works at multiple levels including the hypothalamus and pituitary in addition to the kidneys. Chu et al.[8] showed that chronic hyperosmolality leads to an increase in plasma secretin level. By electrical stimulation of the PVN but not nearby sites in the hypothalamus, secretin is released from the posterior pituitary into the systemic circulation. In hypothalamic and pituitary explants, high concentrations of K^+ in the culture medium leading to K^+-evoked depolarization is able to stimulate secretin release via the activation of L-, N-, and P-type high-voltage-gated calcium channels.[19] Collectively, these results indicate that chronic hyperosmolality could lead to the release of secretin from the posterior pituitary into the systemic circulation by activating magnocellular neurons in the PVN of the hypothalamus. In addition, secretin could upregulate vasopressin expression level in the hypothalamus and stimulate vasopressin release from the hypophysial axis to the circulation.

As a brain-gut peptide, secretin is also involved in appetite control.[7] Central and peripheral secretin injections reduce food intake in wildtype mice but not in *SCTR*$^{-/-}$ mice, implying that secretin exerts its anorectic action via the secretin receptor. Secretin and its receptor are expressed in hypothalamic nuclei including the Arc and PVN that are the primary brain sites engaged in regulating body energy homeostasis. In the Arc, the secretin receptor is expressed in POMC neurons, which are powerful anorexigenic neurons. Consistent with this, secretin injection causes neuronal activation in these two areas, showing the importance of these two hypothalamic nuclei for secretin to control appetite. More importantly, both intraperitoneal and intracerebroventricular secretin are able to modulate transcript levels of several appetite-related genes in these two areas, including activating POMC transcripts in the Arc and melanocortin receptor 4 (MC4R) transcripts in the PVN. Previous injection of the MC4R antagonist, SHU9119, into the PVN is able to significantly reduce secretin-induced anorexia. Taken together, the results show that the anorectic function of secretin is mediated, at least in part, via the hypothalamic melanocortin system.

Lamina Terminalis

As mentioned above, there is a growing body of evidence showing that secretin is important in body fluid homeostasis. It works at multiple levels, including pituitary, hypothalamus, and kidney, to regulate water balance. Very recently, the use of transgenic mice has also revealed the involvement of the secretin/secretin receptor axis in the angiotensin II osmoregulatory pathways in maintaining fluid balance in the body.[21] The lamina terminalis consists of the organum vasculosum of the lamina terminalis (OVLT), the median preoptic nucleus (MnPO), and the subfornical organ (SFO), critical sites for regulating water intake. It has been proposed that angiotensin II stimulates the expression of secretin and its receptors in the SFO and OVLT under hypertonic conditions. The synthesized secretin then induces vasopressin expression and release into the circulation and eventually increases water reabsorption from the kidney. The centrally produced angiotensin II can also stimulate vasopressin and secretin expression and release in the PVN.

Other Brains Areas

In addition to the brain areas discussed above, secretin and its receptors have also been detected in other brain regions including olfactory bulb, septum, striatum, the NTS, and sensory ganglion. Mapping of Fos activation followed by intracerebroventricular injection of secretin reveals that this peptide can influence central networks involved in behavioral, endocrine, and autonomic regulation. Secretin-activated regions include the area postrema, dorsal motor nucleus, medial region of the NTS, lateral tegmentum, locus ceruleus, ventral periaqueductal gray, and paraventricular thalamic nucleus.[19] In the NTS, other than inducing Fos expression, secretin also exerts direct effects on the excitability of the neurons via activation of a nonselective cationic conductance (NSCC), which allows passage of cations (Na^+, K^+, or Ca^{2+}) in varying proportions.[19] The NTS is a pivotal region involved in the integration of cardiovascular, respiratory, gustatory, hepatic, and renal control mechanisms; it receives afferent input from the periphery and sends efferent output to many CNS areas. Consistent with this, previous studies have shown that intracerebroventricular injection of secretin in rats could increase defecation, alter the respiratory rate, and decrease blood pressure.[6]

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Therefore, the NTS might represent an important CNS site where endogenous and/or systemic secretin could act to influence central autonomic regulation and other brain-mediated activities.

PATHOPHYSIOLOGICAL IMPLICATIONS

Autism

Presenting at an early childhood age and having lifelong persistence, autism is a common disorder of neural development characterized by core deficits in social, communicative and behavioral skills. In 1998, the beneficiary effects of secretin in autistic treatment was reported with significant improvements in speech, eye contact, and attention after intravenous secretin treatment trials in three autistic children.[17] This initial success with secretin sparked popularity for its research in the treatment of autism. Despite this, further clinical studies yielded negative results including those with synthetic human secretin and double-blind trails. Although the direct benefits of secretin for autistic treatment remain controversial, experimental results provide support. Autism has been hypothesized to be a hypoglutamatergic disorder, and secretin may be a candidate in autistic treatment with experimental evidence showing its ability when peripherally administered to increase extracellular glutamate and GABA levels in the rat hippocampus.[9] Further, secretin knockout mice show abnormal social and cognitive behavior and impairment in hippocampal synaptic plasticity specifically in the CA1 area,[19] suggesting the involvement of secretin in synaptic function and possible therapeutic value in ameliorating the symptoms of autism. Despite the encouraging results, the most recent information available from controlled trials in autistic children show a lack of impact of secretin in improving various social, communicative and behavioral skill deficits.[18]

Schizophrenia

With the overlap of phenotypic features between autism and schizophrenia, it is not surprising that secretin's potential in alleviating schizophrenia-related disorders has also been explored. This was first shown in a 2004 double-blind study whereby single intravenous injections of secretin in 22 schizophrenia patients was able to significantly improve symptoms more than in those treated with placebo based on the clinical global impression scale.[29] In the same year, the beneficiary effects of secretin was further shown in a patient with chronic undifferentiated schizophrenia and prominent autistic features.[1] Experimentally, the rat has also been used as an animal model for study, and it has been found that secretin is able to dose dependently reverse the phencyclidine-induced impairment in prepulse inhibition, which in schizophrenic patients is in the abnormal range.[25] Secretin administration has also been shown to markedly improve eye-blink conditioning, which is associated with loss of effective associative learning, one of the many symptoms in schizophrenia.[3] With the mounting evidence of secretin improving schizophrenic symptoms, a possible role in enhancing cerebellar function and thus classically conditioned learning has been suggested and deserves further studies.

Chapter 124

Somatostatin/Cortistatin

Jacques Epelbaum, Cécile Viollet and Raphaelle Winsky-Sommerer

ABSTRACT

Somatostatin-14 was originally characterized as a hypothalamic neurohormone responsible for the inhibition of pituitary growth hormone secretion. In mammalian brain, two genes encode for the prosomatostatin-derived peptides, somatostatin-14 and somatostatin-28, and procortistatin-related ones, respectively. Each peptide binds with similar affinities to the five cloned sst receptors that belong to the GPCR family and cortistatins bind specifically to MrgX2. Besides the initial neuroendocrine role, somatostatin and cortistatin peptides serve as neuromodulators in the CNS, influencing differently sensory processes, sleep, motor activity, and cognitive functions, as well as playing a role in brain diseases such as affective disorders, epilepsia, and Alzheimer's disease.

DISCOVERY

Somatostatin (SRIF: somatotropin-release inhibiting factor) was discovered in 1972 by Roger Guillemin and his colleagues who were engaged in the quest to purify and characterize the hypothalamic neurohormones involved in the control of pituitary hormone secretion.[29] They were aiming for a growth hormone (GH)-releasing-hormone (GHRH) (see the GHRH chapter in this section of the book) but ended with a 14-amino acid peptide, which actually inhibited GH release from pituitary cells in monolayer culture. Rapidly thereafter, SRIF immunoreactivity was localized in the pancreas and gastrointestinal tract as well as in the brain. Two biologically active forms arise from the C-terminal portion of a single propeptide: SRIF14, originally described in the hypothalamus,[29] and the amino-terminally extended SRIF-28, discovered later in the gut[22] (Fig. 1). SRIF-14 is predominantly produced by neurons and secretory cells in the central and peripheral nervous system, and SRIF-28 in the gastrointestinal tract (see the Somatostatin chapter in Gastrointestinal Peptides section of this book). However, many additional expression sites have been described in other endocrine and exocrine cells, the placenta, the kidney, the retina, and in cells of the immune system.[12]

Cortistatin (CST) was discovered in 1996 by Luis de Lecea[6] who used directional tag PCR subtractive hybridization techniques to fish out genes selectively involved in long-term potentiation (LTP), a phenomenon probably corresponding to cellular memory at the neuronal level. Among several candidates, he sequenced a novel 112-amino acid polypeptide with a striking homology to somatostatin at its distal C-terminal end.[4] The cloning and localization of the gene on human chromosome 1 at 1p36.3–p36.2 increased the complexity of the somatostatin-signaling system. Sharing 11 amino acids with somatostatin, CST is predicted to occur in a 14- (CST-14) or 17-amino acid form (CST-17) in rodents and humans, respectively, and a longer one of 29 amino acids (CST-29) in rats and humans (Fig. 1). In the central nervous system, CST mRNA expression is mainly restricted to the cerebral cortex and the hippocampus. In mouse brain, small levels of preproCST mRNA have been detected in the amygdala and the hypothalamus, an important SRIF expression site.

A novel peptide, neuronostatin (LRQFLQKSLAAAA-NH_2), encoded by the somatostatin gene, has more recently been identified based on bioinformatic analyses of evolutionarily conserved sequences.[26] It is mostly concentrated in spleen, pancreas, and brain, and seems to be involved in cardiovascular, metabolic, and neuronal functions. Some of its actions seem to be mediated through the central melanocortin system.

STRUCTURE OF THE PRECURSOR mRNA/GENES

The preproSRIF gene structure and regulation have been extensively reviewed elsewhere.[30] The SST (human) and Sst (rat and mouse) somatostatin genes are, respectively, located in 3q28, on chromosome 11q23 and 16. The organization of the human, mouse, and rat genes is very similar. A single intron interrupts the two exons encoding preproSRIF. SRIF-14 and SRIF-28, located at the carboxy-terminus of the precursor, are generated by posttranslational enzymatic processing. In brain cells, transcription is regulated positively by many factors acting on *cis*-regulatory elements: bZip proteins acting on a cAMP response element (CRE),

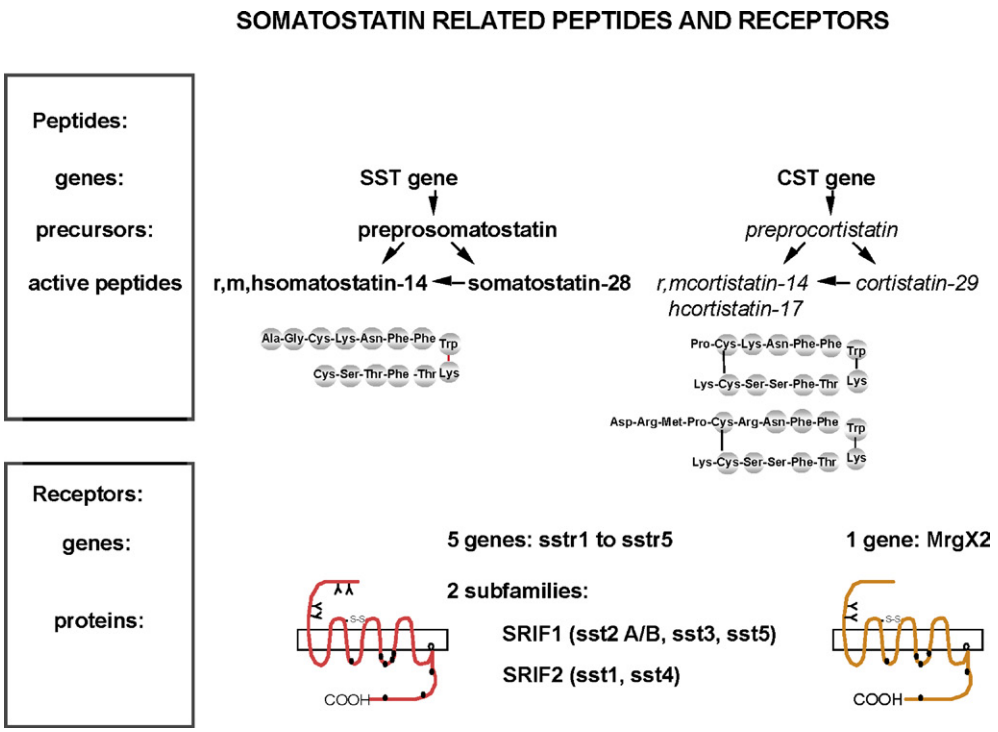

FIGURE 1 Somatostatin-related peptides and receptors. The somatostatin gene gives rise to two bioactive peptides somatostatin-14 and somatostatin-28, the former being totally conserved in mammals and representing the majority of somatostatin immunoreactivity in brain. In contrast, cortistatin gene-derived putative peptides are different in murine and primate species and, according to remaining levels in *Sst*−/− mouse, represent only a minority of somatostatin immunoreactivity in the brain. Somatostatins and putative cortistatins can bind to the six somatostatin receptors which, according to their operational properties, can be subdivided in two families, SRIF1 and SRIF2. Cortistatins can also bind to a formerly orphan receptor, MrgX2, which is highly expressed in dorsal root ganglia.

and homeodomain proteins such as Pdx-1 or bHLH proteins (such as *Sim1* and *arnt2*) on TAAT elements.[20] Transcription is negatively regulated by two proximal silencers, which may be active in cerebrocortical but not hippocampal cells. SST gene regulation seems to be notably different in brain and pancreas since enhancers in the latter (SST-TAAT1, SST-TAAT2 and SST-UE-B) act as silencers in neural cells.

The human CORT and mouse Cort genes are located in 1p36.3–1p36.2 and on chromosome 4, respectively. Very few results are available concerning their regulation.

Although the sequences of SRIF-14 and SRIF-28 are identical in all mammals tested so far, cortistatin sequences vary notably within this lineage, indicating a much more rapid rate of evolution for the latter gene.[4]

DISTRIBUTION OF THE mRNAs AND PEPTIDES

SRIF immunoreactivity is largely distributed in many neurons in mammalian brain, including the human brain (Fig. 2). The highest levels are found in the mediobasal hypothalamus and median eminence, amygdala, preoptic area, accumbens nucleus, cerebral cortex, striatum, olfactory regions, and brainstem. Two main categories of neurons can be identified: those that project to a distance from their soma (long projecting) and short GABAergic interneurons coexpressing the neuropeptide either alone (cortex and hippocampus) or together with neuropeptide Y (striatum and a few cells in the cortex).[32] Preprocortistatin mRNA-expressing neurons are mostly localized in a subset of cortical and hippocampal GABAergic interneurons, which partially colocalize with SRIF-positive neurons. In *Sst*−/− mouse, the levels of immunoreactive material remaining in the brain, which probably correspond to CST, is below the sensitivity of the assay, while CST expression does not change.[18] No study has yet reported the distribution of CST peptides in mammalian brain with selective antibodies, which do not recognize SRIF moieties.

In the rat cortex, a subset of cortistatin-positive neurons contains parvalbumin, whereas SRIF interneurons, which mostly correspond to Martinotti cells, contain calbindin. In the mouse, however, SRIF Martinotti interneurons contains calretinin.[34]

Long-projecting neuronal somatostatinergic systems can be differentiated according to their localizations:

- Hypophysiotropic somatostatin neurons projecting to the median eminence are located within the rostral periventricular nucleus (Pev) and the parvocellular

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

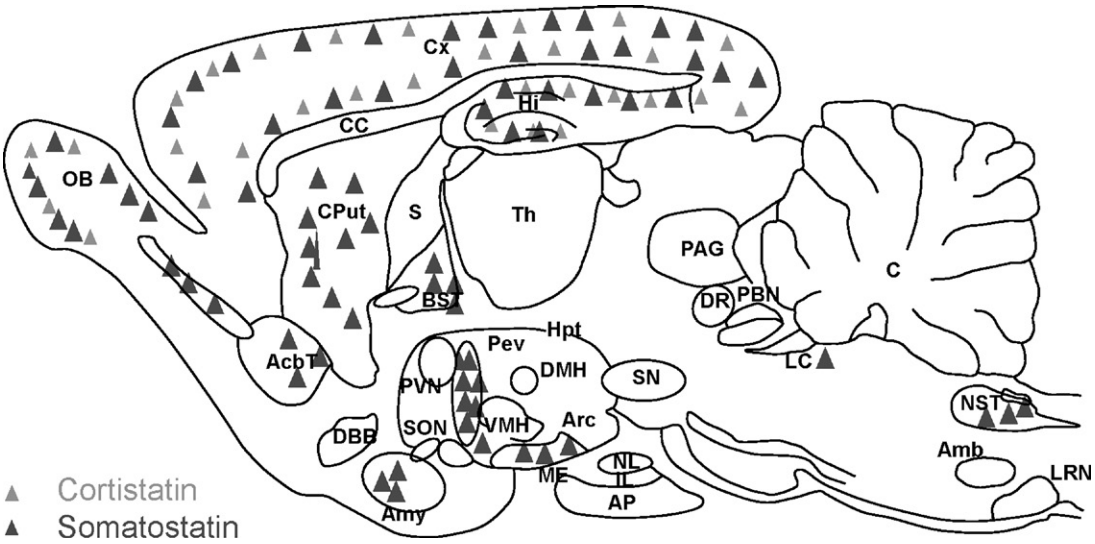

FIGURE 2 Schematic distribution of somatostatin (dark grey) and cortistatin (light grey) neurons in mammalian brain. In adults, somatostatin neurons are essentially distributed in the forebrain (OB, BST, Acb, claustrum, all parts of Cx including HI, entopeduncular nucleus, Amy, and Hpt) and the lower brainstem (central gray, para- and lateral lemniscal nuclei, reticular formation next to the prepositus hypoglossal nucleus, suprageniculate nucleus and NST). Cortistatin neurons are essentially present in the Cx and HI.

paraventricular nucleus. These cells are located close to the third ventricle, in three or four layers that are parallel to the ventricle wall and their axons run laterally and turn caudally through the retrochiasmatic area to enter the median eminence where they make contact with the fenestrated capillary loops of the portal vasculature from which they reach pituitary somatotrophs directly. SRIF cells in the Pev also project to many limbic (olfactory tubercle, septum, habenula, hippocampus) and mesencephalic (substantia nigra and locus coeruleus) regions. Cocaine–amphetamine-regulated transcript (CART) colocalizes in 38% of the somatostatinergic neurons, and CART is the only neuropeptide produced by hypophysiotropic somatostatinergic cells.

- Some hippocampal CA1 somatostatin neurons innervate the subiculum and lateral septal nucleus and also cortical, limbic, and olfactory regions.
- Amygdaloid somatostatin neurons connect the different nuclei of the amygdala with the noticeable exception of central nucleus ones, which innervate many limbic regions through the stria terminalis.
- Solitary tract neurons, through their projections to the ambiguus nucleus, control esophagean motility and, through their ascending projections to magnocellular hypothalamic neurons, cardiovascular processes. These neurons are the only ones in the brain to contain only SRIF-28 (and possibly neuronostatin) but not SRIF-14.
- PreBötzinger complex somatostatin neurons, which are essential for the generation of normal breathing, send widespread projections specifically targeted to other brainstem regions also implicated in the control of breathing.

PROCESSING OF THE PRECURSORS AND DEGRADATION OF THE PEPTIDES

The convertases furin and PACE-4 seem to be involved in the constitutive pathway to generate SRIF-28. In secretory vesicles, proSRIF is a physiological substrate of PC1 and/or PC2, and generation of SRIF-14 in human brain requires this latter convertase. Processing of proSRIF is severely impaired in pancreatic islets of PC2–/– mice pancreatic islets. Further, PC1 and PC2 immunoreactivities are localized in numerous human cortical neurons, and their topographic and cellular distribution broadly coincides with that previously reported for SRIF-containing neurons, that is, mainly in the cortical layers II, III, as well as in V and VI. SRIF peptides are degraded primarily by two endopeptidases: EC.3.4.24.15 (Thimet oligopeptidase) and EC.3.4.24.16 (neprilysin). The former is a soluble enzyme, whereas the latter is membrane associated. Subsequently, exopeptidases, such as aminopeptidases A and M, are able to cleave the N-terminal fragments. SRIF seems also cleared from brain interstitial space by sequestration within microvessels.

No data are available concerning proCST processing and degradation mechanisms in mammalian brain. All these enzymes are discussed in detail in the Peptides Biosynthesis/Processing section of this book.

RECEPTORS AND SIGNALING CASCADES

SRIF mediates its biological functions by at least six receptor subtypes, termed sst1, sst2A, sst2B, sst3, sst4, and sst5, all of which belong to the family of seven transmembrane domain G-protein-coupled receptors.[20] Truncated human sst5-variants with 4 or 5 transmembrane domains are present in a few normal and some tumoral tissues but they do not seem to be highly expressed in brain.[9] The natural ligands of the different somatostatin receptor subtypes, SRIF-14 and SRIF-28 and CST, bind to all somatostatin receptor subtypes with high affinity. Nonetheless, it has not been shown that CST mediates sst receptor activation *in vivo*. A putative CST receptor has been identified as MrgX2, a member of the Mas-related gene family, which is highly expressed in dorsal root ganglion.[24] Surprisingly, CST also seems to be able to interact with the ghrelin receptor, although this is not the case for SRIF.

The recent generation of specific antibodies against each somatostatin receptor variant allows a precise cellular and subcellular localization of somatostatin receptor subtypes in the central nervous system, which also provides important insights into somatostatin signaling. The development of specific somatostatin analogs and antagonists and the results of experiments investigating genetically modified mice also contribute to a better understanding of the individual somatostatin receptor characteristics.

Many detailed studies[8] have examined, especially in rodents, the pattern of expression of individual sst receptor subtype mRNAs in brain. Sst1–5 receptor transcripts are widely distributed throughout the CNS and the pituitary, displaying distinct but overlapping patterns of expression. However, mRNA levels do not necessarily reflect receptor protein expression. Today, immunolocalization of the sst1–5 proteins in mammalian brain and pituitary has been achieved using selective antibodies (Fig. 3).

Contrasting with the broad distribution of sst1 mRNAs, the sst1 protein seems to be essentially restricted to the rostral part of the periventricular hypothalamic nucleus from the organum vasculosum laminae terminalis extending caudally to the rostral part of the median eminence when using a C-terminally directed antibody. In contrast, a broad distribution of the presumptive deglycosyled form of the sst1 receptor protein in rat brain has been reported, using an antibody directed against the N-terminal sequence. Further experiments are needed to resolve this discrepancy. It remains also to be established whether the presumptive nonglycosylated sst1 form is functional. At any rate, the localization of the sst1 receptors and functional studies in the basal ganglia and retina are consistent with its role as a presynaptic inhibitory autoreceptor.

Using C-terminally directed antibodies, sst2A receptor immunoreactivity seems to be widely distributed, in keeping with the regional distribution of both sst2 mRNA and

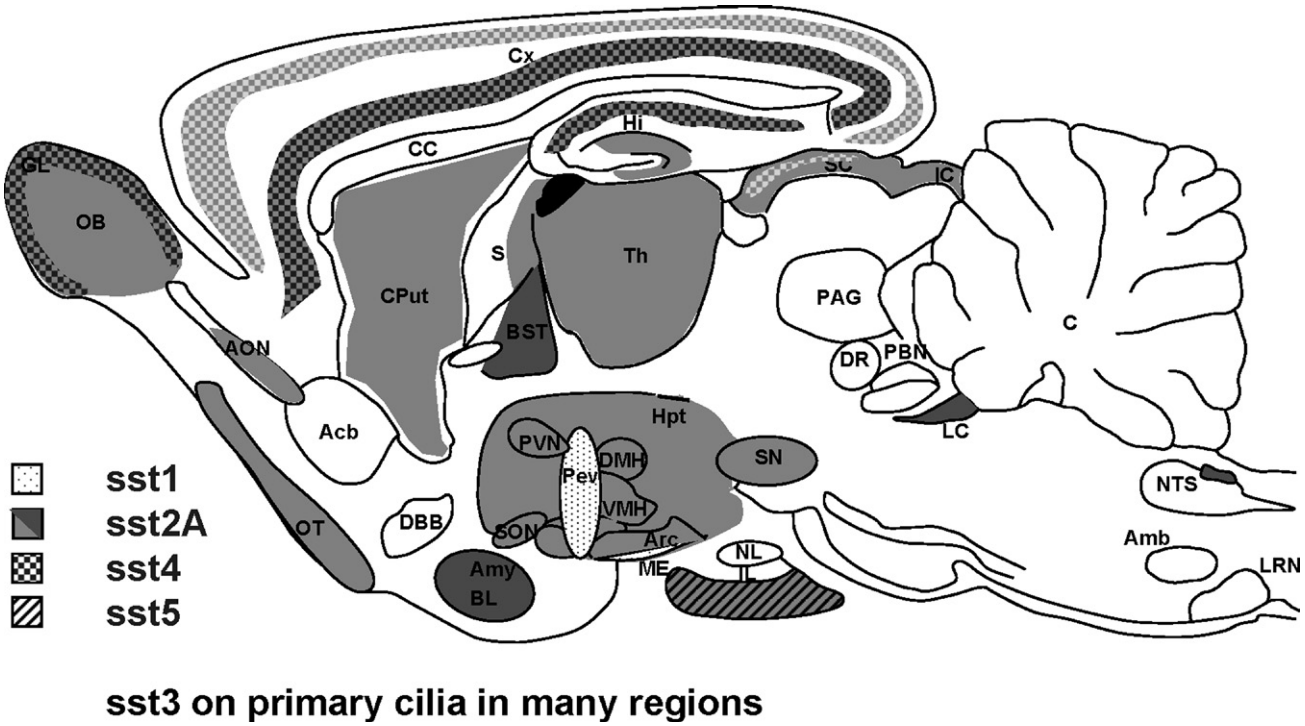

FIGURE 3 Schematic representation of somatostatin receptor immunolocalization in mammalian brain. Color intensity is proportional to the levels of SSTR2A receptor. Same abbreviations as in Figure 2.

SRIF-1 binding sites. Rostrally, numerous strongly immunoreactive nerve cell bodies are observed throughout the pyramidal layer of the olfactory tubercle, extending into the polymorph layer. More sparse and less intensely labeled nerve cell bodies are also found in layer II of the piriform cortex. Diffuse but intense immunoreactive labeling is present in the endopiriform, anterior olfactory, and lateral olfactory tract nuclei. In the cerebral cortex, the frontal, parietal, temporal, and occipital lobes exhibit prominent perikaryal immunostaining in layers II–III. A few less intensely immunoreactive cell bodies are also evident in layer V. Diffuse but intense sst2A labeling is found in layers V–VI of the cerebral cortex. High densities of immunoreactive perikarya and dendrites are detected in the lateral division of the bed nucleus of the stria terminalis. Low densities of sst2A-positive cells are also found in the vertical limb of the diagonal band of Broca. In the habenula, immunoreactive cell bodies are detected among a dense network of immunoreactive processes in the medial part while the lateral one seems devoid of any positive signal. Moderate densities of immunoreactive nerve cell bodies and proximal dendrites are encountered throughout the ventrolateral and caudal segments of the neostriatum, within the core and the shell divisions of the nucleus accumbens and in the dorsolateral part of the septum. Diffuse but intense immunoreactive labeling is observed in the claustrum.

Within the hippocampus, pyramidal cells including their basal and apical dendrites of CA1–CA2 fields are intensely stained. A few labeled perikarya are also observed in the stratum radiatum. Diffuse but intense immunoreactive signal is present in the stratum lacunosum moleculare and the subiculum and is also apparent, albeit less prominently in the molecular layer of the dentate gyrus. The CA3 subfield remains consistently immunonegative. Both high densities of perikaryal and diffuse labeling are detected in the amygdaloid complex, the former in the central and the latter in the basolateral nucleus. Moderate densities of immunoreactive nerve cell bodies are also encountered in the medial and cortical nuclei. The endopiriform nucleus displays diffuse but intense immunolabeling.

In the hypothalamus, only sparse immunoreactive perikarya are detected except in the tuberomammillary nucleus in which they form a tight cluster of moderately immunoreactive cells. Diffuse labeling is apparent in a few nuclei including the arcuate and paraventricular nuclei. In the midbrain, low densities of labeled cell bodies with long and fine processes are evident in the deep layers of the superior colliculus as well as in periaqueductal gray matter. Additionally, diffuse labeling is found in the dorsal and lateral segment of periaqueductal gray, gray layers of the superior colliculus, pars compacta of the substantia nigra and ventral tegmental area. In the pons, intensely labeled perikarya and processes are detected in the locus coeruleus. Labeled cell bodies are also apparent in the lateral dorsal tegmental area and parabrachial nucleus. More caudally, moderate densities of immunopositive cell bodies are visible in the dorsal motor nucleus of the vagus and in the lateral reticular nucleus. Diffuse labeling is found in the nucleus tractus solitarius and medial vestibular nucleus. The cerebellar cortex and deep cerebellar nuclei are devoid of immunostaining. In the spinal cord, sst2A immunoreactivity is exclusively found in the dorsal horn. A dense network of immunoreactive processes is present in the substantia gelatinosa (Layer II), whereas immunoreactive cells are apparent in the border zone between layers I and II. Only occasional cell bodies are stained in layer VI. Double labeling immunohistochemistry for pituitary hormones and the sst2A receptor reveals an almost complete colocalization of the sst2A receptor with GH expressing cells. Only a small percentage of lactotroph cells (<10%) bear the sst2A receptor, whereas a substantial overlap of the receptor is found with gonadotrophs (LH/FSH) (40–50%), corticotrophs (<60%), and thyrotrophs (<30%).

Sst3 receptor mRNAs are broadly expressed in mammalian central nervous systems. However, SSTR3 is immunolocalized exclusively in neuronal cilia.

Sst4 mRNAs are expressed in a relatively restricted number of rat brain areas, in contrast to the rather broad expression pattern of sst1, sst2, and sst3 receptors. Expression of the sst4 receptor mRNA is the greatest in the pyramidal cells of the CA1 region of the hippocampus, lower in other hippocampal regions, the olfactory bulb, and the cortex and is absent from the striatum, cerebellum, and hypothalamus. SSTR4 immunoreactivity is essentially restricted to the cerebral cortex and CA1 of the hippocampus.

Sst5 receptor immunoreactivity is only sparsely present in neuronal perikarya and proximal dendrites limited to the rostral part of the brain, but the protein is clearly present in the pituitary.

MgrX2 is moderately expressed in susbsets of CA2–4 neurons in the hippocampus, but it is not detected in the cerebral cortex.

SRIF/CST interaction with their cognate receptors in the brain may trigger the recruitment of many intracellular effectors.[20] The five sst receptors can inhibit the adenylyl cyclase–cAMP–protein kinase A pathway through pertussis toxin-sensitive G proteins such as Gαi1–3. Many potassium channels (inward rectifier, noninactivating voltage-sensitive, ATP-sensitive, large conductance Ca^{2+}-activated, M-current) can be opened, either directly or through activation of the phospholipase C-protein kinase C pathway and phospholipase A2–arachidonic acid pathway. By these mechanisms, somatostatin can hyperpolarize cell membranes, therefore reducing $[Ca^{2+}]i$. It may also modulate Ca^{2+} influx either directly through voltage-sensitive Ca^{2+} channels (L-, N- P/Q-types) and Gαo proteins or indirectly

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

through the guanylate cyclase-cGMP-dependent-protein kinase pathway. In addition, sst1 receptors can also recruit pertussis toxin-insensitive G proteins such as the Na^+/H^+ exchanger. Stimulated sst receptors can also activate tyrosine (PTP)- and serine/threonine-phosphatases, some of the latter, PP2A and calcineurin (PP2B), being involved in synaptic plasticity processes. Finally, sst receptors seem able to inhibit the mitogen-activated protein kinase pathway, possibly through the activation of PTPs. Such mechanisms may contribute to the monitoring of tumor growth by SRIF. All the previously mentioned signal transduction pathways seem to be effectively modulated by the cloned receptors (see Table 1 for further details). However, it seems that multiple sst receptor subtypes can be expressed in single neurons, the best examples being hypothalamic neurons on which somatostatin can either enhance (through a sst1 pertussis toxin-independent mechanism) or decrease (through a sst2 pertussis toxin-dependent one) AMPA/kainate receptor mediated responses to glutamate, depending on their ability to modulate $[Ca^{2+}]i$.

SRIF receptors can be differentiated by their ability to internalize. With the noticeable exception of sst4, all subtypes internalize in various cellular models after agonist treatment. In the brain, this has only been shown *in vivo* for sst1[27] and sst2[5] receptors. In transfected cell models, SRIF receptors have also been reported to homo- and heterodimerize and interact with PDZ-containing proteins.[20] Such receptor-multidomain protein complexes are likely to intervene in the cell- and tissue-specific modulation of SRIF/CST-mediated signaling processes.

TABLE 1 Characteristics of Human Somatostatin Receptors. Summary of the HSSTRs Characteristics

INFORMATION ON ACTIVE AND/OR SOLUTION CONFORMATION

SRIF and CST are disulfide bridged peptides, and the receptor pharmacophore lies in the four amino acid sequence: Phe–Trp–Lys–Thr, totally conserved amongst peptides. The lysine and D-tryptophan side chains in cyclic hexapeptide analogs exist in an equatorial orientation relative to the backbone of the peptides. SMS 201-995 [(D)-Phe–c[Cys–Phe–(D)-Trp–Lys–Thr–Cys]–Thr-ol, octreotide] was the first SRIF analog in clinical use for the treatment of acromegaly, and several other endocrine and malignant disorders. It binds predominantly to hsstr2 and hsstr5 and with low affinity to hsstr3, it has no or low affinity to sst1 and sst4, but it also binds to mu-opioid receptors. Octreotide exists in solution in two conformational families, differing mainly by the conformation of the C-terminal tail. The molecule adopts an overall antiparallel ß-sheet conformation, with a type II″ ß-turn centered at the (D)-Trp8–Lys9 region. In one conformational family, the residues after this ß-turn continue the ß-sheet structure. Based on elaborate studies of various somatostatin analogs, it was concluded that this family contains the active conformation(s). In the second conformational family, the residues after the ß-turn adopt a 3–10 helical conformation. A cyclic hexapeptide SRIF substitute, SOM230 c-[(2-amino-ethyl-carbamoyl)-Hyp1–Phg2–DTrp3–Lys4–(4-O-benzyl)-Tyr5–Phe6], pasireotide, has been designed by analogy with octreotide. It binds with high affinity to sst1, sst2, sst3, and sst5 receptors. Strikingly, pasireotide conformers correspond to the two main X-ray structures in the asymmetric unit of SMS 201–995. However, due to a wider range of action and a longer half-life, pasireotide is more potent (longer acting) than octreotide on hormonal inhibition and antiproliferative effects.[15]

BIOLOGICAL ACTIONS WITHIN THE BRAIN AND PITUITARY

The best-characterized action of brain SRIF is the inhibition of pituitary hormone secretion, most notably GH, and also TSH and, in some cases ACTH and TSH.[12] Moreover, SRIF is a widely distributed neuromodulator substance in the brain. Experimental depletion of somatostatin by cysteamine disrupts avoidance learning and decreases locomotor activity, while somatostatin agonists induce the opposite effects. Somatostatin also exerts anxiolytic- and antidepressant-like effects (see Ref. 32 for review, and the Behavior chapter in the last section of this book).

CST shares several functional properties with SRIF such as the depression of neuronal activity. However, some biological functions of CST are unique, for example, the induction of slow-wave sleep and reduction of locomotor activity.[7] Intracerebroventricular (icv) administration of CST-14 induces a twofold increase in deep slow wave sleep (sws) amounts during both light and dark periods; CST mRNA levels depend on the physiological demand for sleep as they oscillate during the light/dark cycle and are induced fourfold on total (but not REM) sleep deprivation, returning to basal levels after 8 hours of rebound sleep. Interestingly, and also in contrast to SRIF, CST antagonizes the effects of acetylcholine at the cortical level (system related to alertness) to promote cortical synchrony and to control sws/wakefulness/sws transitions. These data suggest that CST is a specific sleep factor, which accumulates during wakefulness to generate sleep pressure and then is released during sleep. In contrast to SRIF, CST produces a reduction of locomotor activity. Also unlike SRIF, expression of CST mRNA is not upregulated in response to kainic-acid-induced seizure activity *in vivo*.

Receptor-selective control of several cognitive and sensory processes have been dissected using pharmacological and genetic approaches. In mice, intrahippocampal injection of the sst4 agonist L-803,087 dramatically impairs place memory formation (alike SRIF), whereas sst1–3 agonists do not induce any mnemonic effects. Unlike SRIF, the sst4 agonist also enhances the use of a cue-based memory and acquisition of another striatum-dependent memory task. Hippocampal sst4 thus seems to selectively control the use of cognitive strategies by switching from hippocampus-based multiple associations to simple striatum-based behavioral responses. Selection of striatum-dependent strategies, however, requires a functional cooperation between sst2 and sst4 receptors.[13]

Data on the effect of *sst1–4* and *Sst* gene deletion on brain activity in mice are summarized in Table 2. A change in basal GH release from somatotroph cells has been reported in *sst1−/−* mice, while somatostatin inhibition is reduced in *sst2−/−* mice. Sexual dimorphism in GH pulsatile secretion and ACTH/corticosterone secretion no longer exists in *Sst−/−* mice. Subtle changes in motor and cognitive behavior have been also observed in *sst2−/−* mice. Studies also show that *sst1*, *sst2*, *sst4*, and *sst* gene deletions modify seizure sensibility. *Sst2−/−* mice seem to be less sensitive to ischemia and display disturbed olfactory processing. *Sst3−/−* mice are severely impaired in discriminating novel objects, whereas they retain normal memory for object location. *Sst4−/−* mice display increased sensitivity to seizures. Although the mice have been developed, no report on brain activity is available for *sst5−/−* mice at the present.

PATHOPHYSIOLOGICAL IMPLICATIONS

Long-acting sst2 preferring agonists such as octreotide and lanreotide are used for the clinical management of acromegalic patients, gastroenterological or pancreatic tumors, and other gastrointestinal disorders. Specifically designed

analogs are also used for tumor imaging and in development for radiotherapy. Not surprisingly, the physiopathological implications for neuropsychiatric diseases are less developed. Nevertheless, changes in SRIF and sst receptors have long been known to be associated with dementia, epilepsy, and major affective disorders.[12,13]

Concerning affective disorders, one of the most consistent neuropeptide alterations in depression has been a state-dependent decrease of CSF SRIF. This decrease does not seem to be specific to depression, as it is also observed in other patient populations where cognition is impaired, such as in schizophrenia, Alzheimer's dementia, drug refractory epilepsy, and active multiple sclerosis.[14] The SRIF decrease in affective illness and active multiple sclerosis has been considered state dependent, in that levels normalize with recovery from the acute episode or treatment. In contrast, increased SRIF levels have been reported in psychiatric illness where cognition is accelerated, as in mania, or ruminative, as in obsessive compulsive disorder.

Temporal lobe epilepsy (TLE) is characterized by hippocampal sclerosis together with profound phenotypic changes of different classes of interneurons. Evidence from human studies suggests that hilar SRIF interneurons undergo extensive degeneration in patients with hippocampal sclerosis. Therefore, SRIF receptors may represent potential therapeutic targets for temporal lobe epilepsy. Indeed, SRIF is released under conditions characteristic of seizures; seizures induce changes in the levels of the peptide; SRIF and its analogs affect seizures. However, information on the precise contribution of each SRIF receptor on the SRIF-induced inhibition of epileptiform activity is still limited. Although the sst_2 receptor is the candidate likely to mediate the anticonvulsant effects of SRIF in the rat hippocampus, in the mouse hippocampus, recent observations support a central role of sst4 and/or sst_1 receptors in mediating SRIF inhibition of epileptiform activity.[3,19,23]

Finally, in Alzheimer's disease cortical SRIF deficiency correlates with the dementia score in frontal cortex and with some indices of severity of the illness. Selective assays indicate that somatostatin-related but not cortistatin-related peptides are mainly involved in these deficits.[13] However, overexpression of the human ß-amyloid precursor protein downregulates CST mRNA in PDAPP mice.[33] Pierotti et al. observed that the proportion of proSRIF is significantly lower in the temporal cortex of Alzheimer patients with SRIF-28 proportions significantly elevated.[21] These results suggest that total SRIF deficiency may be related to a reduction in the rate of biosynthesis and/or to a change in the proteolytic processing of the precursor form to yield the bioactive peptides SRIF-28 and SRIF-14 but not through PC2 protein convertases.[13] Monitoring brain SRIF levels may be of interest since the neuropeptide seems to be the only one out of nearly 50 reagents which increases neprylysin[25] activity thereby promoting the degradation of the amyloid ß peptide Aß 42, which is supposed to be a major pathogenic factor in the disease.

Chapter 125

Tachykinins

Nigel M. Page

ABSTRACT

The mammalian tachykinins constitute a family of peptides that all share the common C-terminal sequence, FXGLM-NH_2, and that act as neurotransmitters and neuromodulators in the brain. They mediate their biological actions through interactions with three known tachykinin receptors (NK_1, NK_2, and NK_3) that are located widely and in distinct locations in the brain. They are implicated in the control of several autonomic, affective, and higher cerebral functions and in the pathophysiology of some neurogenerative, psychiatric, and reproductive disorders.

DISCOVERY

The history of the tachykinins can be traced back to 1931 with the discovery of substance P (SP) by von Euler and Gaddum. A 'preparation' (and hence the 'P' of SP) was purified from equine brain and intestine that was found to cause vasodilatation and stimulation of gut mobility in rabbits (see the chapter on SP in Gastrointestinal Peptides Section of this book). Numerous attempts to isolate the pure form of SP over the next forty years were unsuccessful. Nonetheless, in 1967, a peptide named sialogen that stimulated salivation was discovered in the bovine hypothalamus, and in the following year, Lembeck and Starke suggested that this peptide might be the same as SP. In 1970, upon purification and comparison of sialogen's biological properties with those of impure preparations of SP, it was realized that these two peptides were indeed the same. This enabled the chemical structure of SP to be determined as that of an amidated undecapeptide (Table 1), allowing its chemical synthesis and the production of a specific radioimmunoassay. Over the next ten years, SP was believed to be the only mammalian tachykinin even though there were indications that this might not be entirely the case. Inference was drawn from the detection of immunoreactive tachykinin-like activity in mammalian tissues other than SP. Additionally, eledoisin and physalaemin, two tachykinins isolated in the early sixties from the Mediterranean octopus and the South American frog, respectively, were found to produce greater pharmacological responses on mammalian tissues than those produced by SP. In 1983, these suppositions gave way to the confirmation of the existence of two further members both isolated from the porcine spinal cord and designated neurokinin A (NKA) and NKB. Two biologically active N-terminally extended forms of NKA—neuropeptide K (NPK) and neuropeptide gamma (NPγ)—were also later discovered in the mid-1980s. More recently (2000 onward), additional species-divergent members have been discovered including hemokinin-1 (HK-1) in the mouse and rat, endokinin-1 (EK-1) in the rabbit, and endokinin A (EKA) and EKB in humans. Furthermore, in 2003/2004, tachykinin gene-related peptides were identified: in rabbit, EK-2, and in humans, EKC and EKD.[21]

STRUCTURE OF THE mRNA/GENE

The mammalian tachykinins are encoded on three different genes, termed preprotachykinin (*TAC*) 1, *TAC*3, and *TAC*4 (Fig. 1). *TAC*1, the first to be cloned in 1983 from bovine brain, was initially believed to be two different genes, one containing SP (*TAC*1) and the second also containing NKA (*TAC*2). In the following year, it was realized that a discrete genomic segment encoded NKA by alternative RNA splicing of the same gene to yield α*TAC*1 and β*TAC*1.[19] The β*TAC*1 splice transcript was determined to be encoded by seven exons with exon 3 and exon 6 containing SP and NKA, respectively. Exon 6 is lacking from α*TAC*1. Existence of a third *TAC*1 precursor was later found in the rat with the elucidation of a sequence corresponding to the precise deletion of exon 4 (γ*TAC*1). In addition, a fourth splice variant δ*TAC*1 lacking both exon 4 and exon 6 was identified. Therefore, in essence, the alternative splicing of exon 6 of *TAC*1 produces either SP alone (α, δ*TAC*1) or along with NKA (β, γ*TAC*1). The differential inclusion or exclusion of exon 4 into β and γ*TAC*1 allows the potential formation of the two extended NKA peptides, either NPK or NPγ, respectively. Marked species-dependent differential expression of the *TAC*1 splice variants has been found, although within a given species no established evidence of tissue-specific alternative splicing has yet been reported. The gene organization for *TAC*3 encoding NKB, like *TAC*1, is composed of seven exons with exon 5 encoding the sequence for NKB. In the bovine mRNA, two

*TAC*3 transcripts have been reported that differ only at the 5′ extremity of their untranslated regions. In humans, three *TAC*3 transcripts (α, β,γ*TAC*3) are found that differ in their C-terminal coding region.[25] Nevertheless, a thorough investigation of *TAC*3 has concluded that it encodes only the single tachykinin. The gene structures of *TAC*1 and *TAC*3 are highly conserved across the mammalian species when compared with the highly species-divergent structure of *TAC*4. Mouse *TAC*4 is encoded by 4 exons, rat by 5, of which exon 2 in both encodes HK-1. In the rabbit, alternative splicing produces α and β*TAC*4, whereas the alternative splicing of exons 3 and 4 in humans produces α, β, γ, and δ*TAC*4. These splicing events allow either a tachykinin (EK-1, EKA, or EKB) to be synthesized alone or in conjunction with one of the tachykinin gene-related peptides (EK-2, EKC, or EKD). The tachykinin gene-related peptides are not predicted in the mouse or rat genome.[21]

PROCESSING OF THE PRECURSOR

The tachykinin peptides are synthesized as large precursor proteins, which undergo posttranslational proteolytic processing to generate the mature peptide products. It is alternative mRNA splicing that leads to the distinct tachykinin precursor proteins. Each precursor has a strongly hydrophobic signal peptide sequence at its N-terminus, responsible for translocating it to the endoplasmic reticulum. Cleavage of this signal sequence in the endoplasmic reticulum forms the procursor, which is further cleaved, normally at dibasic (or monobasic) amino acid residues by prohormone convertases to yield the smaller tachykinin peptides. Each tachykinin is typically flanked upstream (except human EKA and EKB) and downstream by potential dibasic cleavage sites and all possess an adjacent glycine at their C-terminus for amidation. Typically, following prohormone convertase action (see Peptide Biosynthesis/Processing Section later in book), a carboxypeptidase removes the C-terminal dibasic residues and a peptidylglycine α-amidating enzyme converts the exposed glycine into a C-terminal amide. Intermediate products of this process, including SP-glycine and SP-glycine-lysine, can be found throughout the rat brain where the levels of these extended products are the lowest in the amygala and highest in the medulla.[15] Such differences are believed to be an indicator of different rates of tachykinin synthesis coupled to utilization within the different brain regions. However, the most significant differences in tachykinin processing are found at their N-termini. In SP, where the N-terminal dibasic cleavage site is adjacent to a proline residue and because of the resistance of arginine–proline bonds to prohormone converting enzymes, an arginine residue from the dibasic cleavage site is exceptionally maintained. Additionally, in the case of SP, many studies have shown that further processing can occur including the production of SP(1-4) and SP(1-7), which are biologically active SP metabolites. There is also evidence of differential processing at the N-terminal dibasic cleavage site of NKA with such processing responsible for the production of both NPK and NPγ. Indeed, early evidence from the late 1980s noted that although SP cleavage seemed to be easily handled, the fact that multiple peptides were derived from the NKA portion of the *TAC*1 precursor indicated that multiple enzymes might be involved in the cleavage of the different NKA tachykinins. Likewise, the apparent loss of the N-terminal dibasic processing site of EKA and EKB with a monobasic cleavage site could be due to the evolutionary pressure of differential processing.

DISTRIBUTION OF THE mRNA/PEPTIDE

In the brain, distribution of the tachykinins has been most extensively studied in the rat, where widespread and distinct regions containing labeled *TAC*1 and *TAC*3 neurons are found.[20] In the case of rat *TAC*1, these are

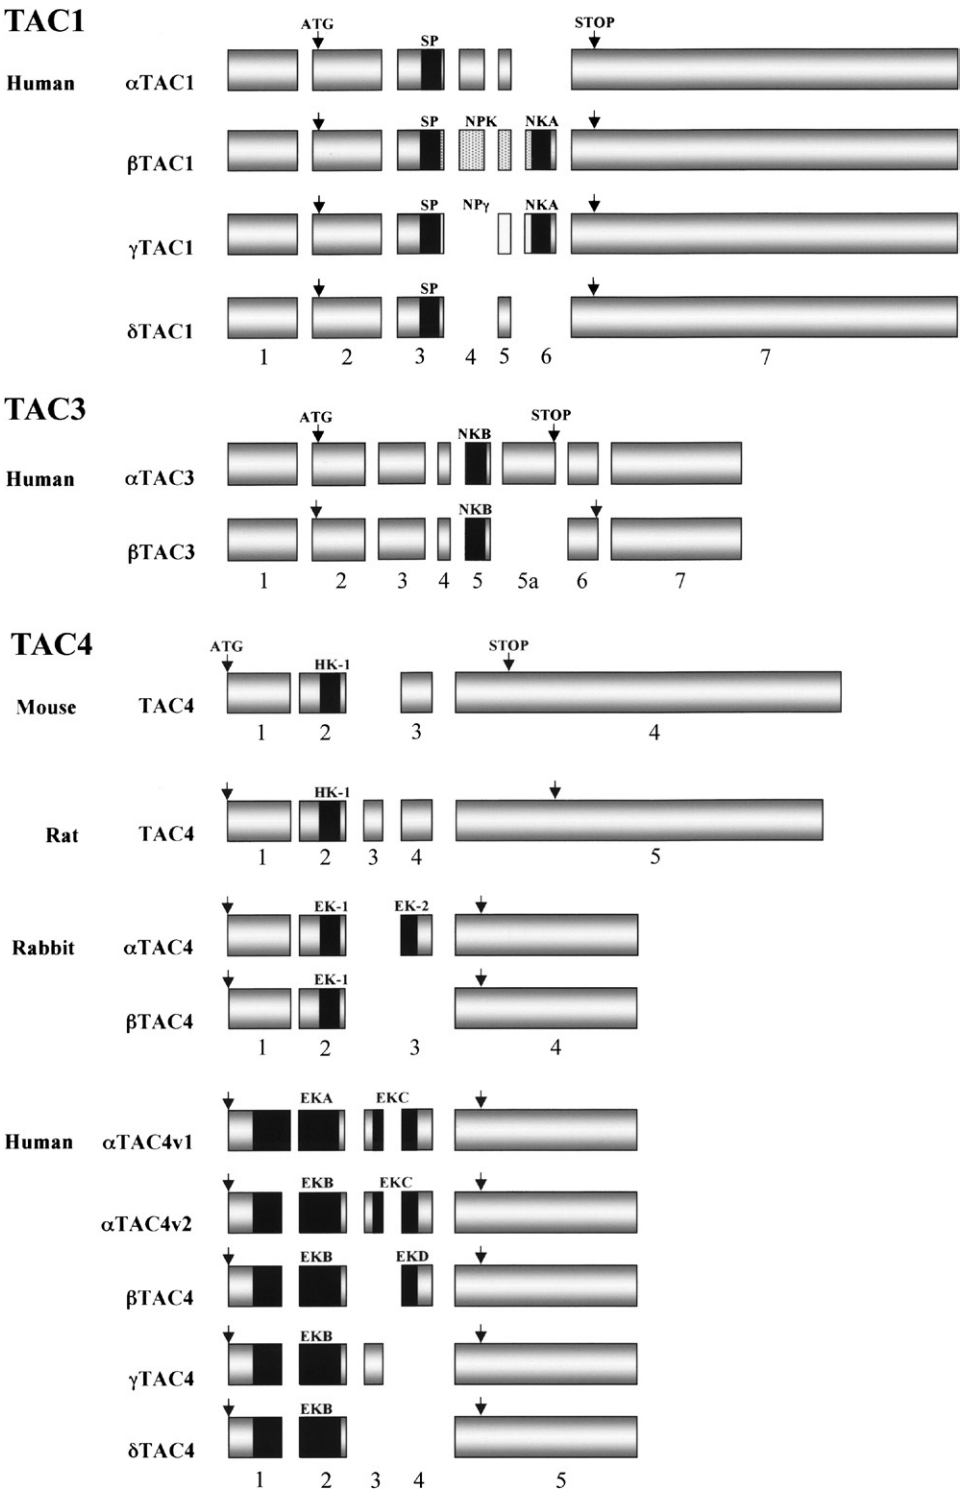

FIGURE 1 Exon organization of the human *TAC*1, human *TAC*3, and mouse, rat, rabbit and human *TAC*4 genes showing the positions of the predicted peptides *(Adapted from Ref. 22)*.

in the anterior olfactory nucleus, olfactory tubercle, the islands of Calleja, the nucleus accumbens, the caudate putamen, amygdala, hypothalamus, the medial habenular nucleus, nuclei of the pontine tegmentum, raphe nuclei, portions of the reticular formation, and the nucleus of the solitary tract.[9] The characterized positions of the SP- and NKA-containing cell groups and fibers in the rat brain are shown in Fig. 2, where it is generally believed that SP is cosynthesized, colocalized, and cosecreted with NKA. Levels of *TAC*1 have also been measured during the

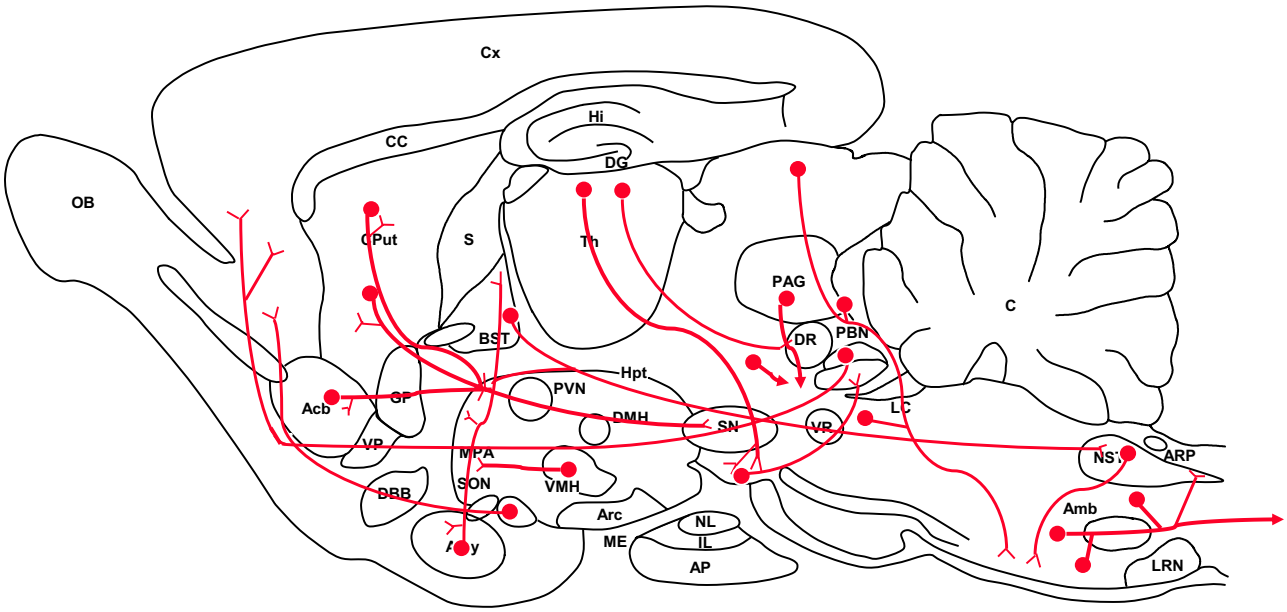

FIGURE 2 Parasagittal section of the rat brain showing substance P and neurokinin A cell groups and fibers.

development of rat brain from embryonic day 15 to adult indicating significant changes in region and time-specific regulation of the *TAC*1 gene, particularly in the cingulate cortex.[1] In the case of rat *TAC*3, neurons are located in the cerebral cortex, the hippocampal formation, the amygdaloid complex, the bed nucleus of the stria terminalis, the ventral pallidum, the habenula, the medial preoptic area, the arcuate nucleus, and the lateral mammillary bodies.[16] In the human brain, there is a distinct and complementary distribution pattern of *TAC*1 and *TAC*3 neurons observed in the hypothalamus and basal forebrain. *TAC*3 is the predominant tachykinin in the rostal hypothalamus, whereas *TAC*1 predominates in the posterior hypothalamus.[3] Numerous *TAC*3 neurons are identified in the magnocellular basal forebrain, the bed nucleus of stria terminalis, and the anterior hypothalamic area with scattered neurons in the infundibular and paraventricular nuclei, paraolfactory gyrus, posterior hypothalamic area, lateral division of the medial mammillary nucleus, and amygdala.[3] Numerous neurons expressing *TAC*1 are identified in the premammillary, supramammillary, and medial mammillary nuclei, the posterior hypothalamic area, and the corpus striatum. Scattered SP neurons are also observed in the preoptic area, the infundibular, intermediate, dorsomedial, and ventromedial nuclei, the infundibular stalk, the amygdala, the bed nucleus of stria terminalis, and the paraolfactory gyrus.[3] The expression levels for *TAC*1 and *TAC*3 have been translated into respective amounts of immunoreactive peptides by immunoassay, which have proved largely confirmatory of the mRNA expression sites. In the different regions of rat brain, the amounts of SP are generally greater than those of NKA, which are in turn greater than those for NKB. *TAC*4 has been found to be predominantly expressed in the periphery. Nevertheless, the analysis of numerous regions of the murine brain (including the brain stem, cerebellum, cortex, caudate, hippocampus, middle brain, hypothalamus, and thalamus) has revealed a similar regional distribution to that for brain *TAC*1, although it is present at consistently (around 100-fold) lower levels, except in the cerebellum that has a 10-fold higher expression level of *TAC*4 than *TAC*1.[5] In terms of some earlier peptide studies of SP in the brain, it is highly possible that these may have also detected HK-1 and EK as some established and commercially available antibodies to SP have been found subsequently to have a 100% crossreactivity with the common C-terminal decapeptide of the HK and EK peptides.[21]

RECEPTORS AND SIGNALING CASCADES

In the early 1980s, after intense pharmacological investigations, the existence of three tachykinin receptors was proposed, termed NK_1, NK_2, and NK_3 (reviewed in Ref. 21). Final confirmation was provided in the late 1980s with the cloning of each subtype from a number of different mammalian species. The receptors all constitute members of the G protein-coupled receptor family and are encoded on five exons. For example, the tachykinin NK_1 receptor contains seven putative hydrophobic α-helical transmembrane domains where the first two extracellular loops are joined by a disulfide bridge. Its extracellular N-terminus contains two predicted asparagine glycosylation sites and its intracellular

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

C-terminal tail contains predicted sites of palmitoylation and a series of potential serine and threonine phosphorylation sites. The order of potency of the tachykinin receptors for each tachykinin is as follows: NK_1, SP = HK-1 = EKA/B ≥ NKA > NKB; NK_2, NKA > NKB > SP = EKA/B, and NK_3, NKB > NKA > SP = EKA/B.[24] NPK and NPγ preferentially bind to the NK_2 receptor. However, there is significant opportunity for the crossselectivity of each receptor subtype with each different tachykinin owing to their common 'activating' C-terminal motif, allowing them to act as full agonists at each receptor subtype. Overall, the signal transduction mechanisms of the three tachykinin receptors have been studied in transfected Chinese hamster ovary (CHO) cells. Here, all these receptors markedly activate phospholipase C-β via a pertussis toxin insensitive G protein ($G\alpha_q$ and/or $G\alpha_{11}$), leading to the hydrolysis of membrane-bound inositol phospholipids and elevation of intracellular calcium.[8] Receptor activation can also promote the arachidonic acid cascade; however, the stimulation of adenylate cyclase is less efficient and requires about one order of magnitude higher concentrations of each tachykinin.[18]

The NK_1 receptor has been found distributed in the dorsal striatum, nucleus accumbens, hippocampus, raphe nuclei, medulla oblongata, and cerebral cortex.[20] In the central nervous system, binding sites for NKA were reported despite the finding that NK_2 receptor mRNA transcripts could not be located. Indeed, NK_2 receptors are only expressed in a few regions of the brain such as the nucleus of the medial septum/diagonal band. The NKA binding enigma eventually gave way to the realization that alternative conformations of the NK_1 receptor existed (reviewed in Ref. 23). In CHO cells overexpressing the NK_1 receptor, 'classic' NK_1 receptor binding sites were found coupled to adenylate cyclase whereas 'septide-sensitive' NK_1 receptor sites were found coupled to phospholipase D. At 'classic' NK_1 binding sites, SP was found to be the only endogenous tachykinin to display high affinity, whereas NKA, NPK, NPγ, and NKB, instead exhibited a high affinity for the 'septide-sensitive' NK_1 binding site. However, *in vivo*, 'classic' NK_1 receptor binding sites are associated with phospholipase C, and rarely with adenylate cyclase. Consequently, each NK_1 receptor subtype represents a different receptor conformation that can be coupled to a distinct transduction system with the capacity to activate different functions. Furthermore, the NK_1 receptor also exists as a truncated isoform without its C-terminal tail; this possesses different receptor binding efficiencies and effector system interactions.[7] The full-length NK_1 receptor isoform has been reported to be the most prevalent throughout the human brain, whereas in peripheral tissues, the truncated isoform is the most represented.[2] Nonetheless, more recently, Lai et al.[13] have reported that, in some parts of the brain including the cingulated cortex, nucleus accumbens, and locus coeruleus, mRNA levels of the truncated NK_1 receptor isoform are significantly higher than those of the full-length receptor. In addition to these isoforms and subtypes, it should be noted there are marked species differences in the localization of the central tachykinin receptors, which are also accompanied by significant species-dependent variability in the homologies of the NK_2 and NK_3 receptors when compared with the highly species conserved NK_1 receptor.[23,28]

BIOLOGICAL ACTIONS WITHIN THE BRAIN

There is substantial evidence that, in the brain, tachykinins play very important roles as neurotransmitter, neuromodulatory, and neurotrophic agents. They occur particularly in large quantities in the areas involved in the control of several autonomic and endocrine functions, of affective and emotion responses, and of higher cerebral functions. They are also often colocalized with other neurotransmitters such as dopamine, endomorphin, and serotonin.

The biological actions of tachykinins have been recorded in a number of different brain regions and some of the more defined are summarized here:

1. In the *cerebral cortex*, SP has been found to excite 91% of the spontaneously active neurons tested.[26]
2. In the *striatum*, tachykinins are released by high potassium concentrations. SP has been reported to increase the firing of some striatal neurons and to evoke the release of dopamine, Met-enkephalin, and acetylcholine.
3. In the *globus pallidus*, microinjection of tachykinin antagonists into the entopeduncular nucleus has been shown to reduce muscle tone in genetically spastic rats, suggesting that SP-dependent mechanisms can regulate muscle tone.[29]
4. In the *substantia nigra*, SP is released in a calcium-dependent manner in response to depolarizing stimuli and upon electrophoretic application to produce long-lasting excitation. SP infusion into the substantia nigra produces marked increases in stereotyped behaviors such as grooming, sniffing, and rearing. In addition, SP has also been suggested to have an excitatory regulation on nigrostriatal dopamine release. NKA is also believed to exert potent excitatory action on nigral dopaminergic and nondopaminergic neurons.[12]
5. In the *ventral tegmental area*, a close relationship between dopamine and SP has been suggested. SP infusion into the ventral tegmental area causes a marked increase in locomotion and rearing that can be completely blocked by infusion of dopamine antagonists. An important role for NKA in the ventral tegmental area has also been suggested as it has been found to be 10 times more potent than SP in producing an increase in motor activity.[10]

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

6. Dopamine neurons richly innervate the *nucleus accumbens*, where evidence suggests that tachykinins can modulate dopamine release through presynaptic mechanisms. The activation of this pathway is believed to cause an increase in locomotor activity. In addition, SP injection into this nucleus exerts memory-promoting effects.
7. In the limbic system, the *hippocampus* and *amygdala* have been implicated in memory processing, where NKA and NPK administered intracerebroventricularly after footshock avoidance training enhanced memory attention in mice. Localization studies also showed that NPK improved memory when injected directly into the hippocampus and amygdala. The amygdala has also been implicated in the regulation of sexual behavior with higher levels of SP being found in male rather than female rats, and with castration of adult rats reduces amygdala SP staining. It has also been suggested that the medial amygdala is a site of action for a NK_3 mediated mechanism to inhibit salt intake. Weidenhofer et al.[31] have also shown that NK_1 receptors are widely distributed in the amygdala and could be involved in emotion and fear processing. Furthermore, intraseptal activation of all three NK receptors, especially the NK_2 receptor, has been implicated in stress-induced hippocampal acetycholine release.
8. In the *hypothalamo–hypophysial* system, it has been suggested that SP may be secreted directly into the portal circulation to reach the anterior pituitary. In doing so, SP may affect the release of anterior pituitary hormones. Such released SP is believed to inhibit the release of rat growth hormone, whereas SP antagonists increase the concentrations of plasma growth hormone. Also, SP applied to pituitary cells exerts a stimulant effect on prolactin secretion. In the hypothalamus, SP has been shown to act as an orexigenic substance and promotes weight gain via coupling to the NK_1 receptor.[11]
9. In the hypothalamic *infundibular/arcuate nucleus*, NKB and the NK_3 receptor are shown to be the essential elements of the human reproductive axis being coexpressed with kisspeptin, dynorphin, and the estrogen receptor α in a variety of mammalian species.[27] There is evidence in humans that these neurons regulate estrogen negative feedback on gonadotropin-releasing hormone secretion and have been implicated in hypogonadotropic hypogonadism and the menopause.

Furthermore, a number of biological actions of tachykinins in the brain are demonstrated by direct intracerebroventricular injection. These are summarized:

1. *Cardiovascular* responses promoted by SP and NKA typical of a defense reaction that increases blood pressure, heart rate, sympathetic efferent activity, visceral vasoconstriction, and hindlimb vasodilation. These responses are accompanied by behavioral defense reactions including increased locomotion, scratching, skin biting, and grooming.
2. NK_3 agonists that elicit dose-related inhibition of *gastric secretion*, *gastric emptying*, and *colonic propulsion*.
3. The administration of eledoisin that affects the *drinking behavior* evoked by angiotensin II intracerebroventricular injection, which acts by inhibiting water uptake and causing water deprivation and cell dehydration. Injection of eledoisin also causes the release of vasopressin with ensuing antidiuresis and independently displays a potent and lasting inhibitory effect on salt uptake.
4. Changes in *respiration* caused by the dose-dependent administration of SP leading to minute ventilation, due to increased volume stimulated respiration.
5. An increase in *anxiety* with the infusion of NK_1 agonists causing long-lasting and pronounced vocalization in guinea pigs.
6. The administration of SP and some of its N-terminal derived peptides that are shown to control *behavior*. SP(1-7) inhibited not only nociception but also aggressive and grooming behavior, while, like SP, stimulating investigative motor activities.
7. Intrathecal administration of EKA/B is shown to evoke scratching behavior and thermal hyperalgesia through the NK_1 receptor.[32]

PATHOPHYSIOLOGICAL IMPLICATIONS

Tachykinins have been implicated in a number of centrally mediated disease states. These include, among others, the neurodegenerative disorders of Parkinson's and Alzheimer's disease. Parkinson's disease, which is a serious motor disorder, is caused by the degeneration of dopamine neurons in the substantia nigra. However, there are lines of evidence to indicate a role for tachykinins in its pathogenesis.[4] First, decreases of *TAC*1 and SP-immunoreactivity are found in the nigral and striatal regions of animal and post mortem Parkinson's disease patients. Second, tachykinins have been found to exert neuroprotective effects on neurons. In addition, several NK_1 and NK_3 receptors are localized in the dopaminergic neurons of the basal ganglia indicating these neurons are under the physiological regulation of tachykinins. Furthermore, in an animal model of Parkinson's disease, tachykinin receptor agonists were found to modulate motor activity. In the case of Alzheimer's disease, SP function has been related to memory and learning where it is highly expressed in several brain areas from the forebrain to hindbrain.[6] In this regard, the basal forebrain, particularly the nucleus of Meynert, has received attention, as it is these SP-containing nuclei that have been shown to degenerate in the senile dementia of Alzheimer's disease. SP has also been found to interact with the cholinergic ascending system of the nucleus of Meynert and patients with Alzheimer's disease show a marked loss

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

of cholinergic neurons from the nucleus of Meynert to the cortex and diminished brain SP immunoreactivity.

SP has also received particular focus in its role in psychiatric disorders. This rationale has been based on the observation that, like clinically used antidepressant/anxiolytic drugs, SP antagonists suppress anxiety-related behaviors and defensive cardiovascular changes in rodents. In addition, mice with selective deletions of the gene encoding the NK_1 receptor or SP itself showed decreased anxiety-related behaviors. More recently, aversive and stressful stimuli have been shown to change SP levels and NK_1 receptor binding with increase SP influx into specific limbic structures such as the amygdala and septum with the magnitude of the response dependent on the severity of the stressor. The mechanism by which SP antagonists bring about their effects is not fully understood, but SP is found in close association with 5-hydroxytryptamine and norepinephrine-containing neurons that are targeted by currently used antidepressant drugs. The NK_1 antagonist MK-869 was shown to display antidepressant activity comparable with that of the selective serotonin reuptake inhibitor paroxetine but with a better side effect profile. However, further research is needed to ascertain the relevance of NK_1 antagonists in depression after the subsequent discontinuation of MK-869 from Phase III trials, after it was shown to be no more effective than placebo. Nevertheless, there still remains an interest in the role of SP in psychiatric illnesses, which also extends to conditions such as panic disorder, obsessive-compulsive disorder, generalized anxiety disorder, and posttraumatic stress disorder. Interestingly, MK-869 has recently received regulatory approval for use as an antiemetogenic therapy in cancer chemotherapy patients along with a combination of $5\text{-}HT_3$ antagonist and dexamethasone. SP is found in neurons of the brain stem and is believed to suppress the centrally controlled vomiting reflex. Because tachykinins are well known for producing marked behavioral changes in animals, they are plausible candidates for playing roles in other pathological behavioral states including schizophrenia and bipolar mood disorders. Changes in brain levels of SP and SP-binding sites have been implicated in schizophrenia. Significant reductions of *TAC*1 mRNA expression are detected in the basal, lateral, and accessory basal amygdaloid nuclei in patients with schizophrenic or bipolar disorders. It has been hypothesized that the involvement of tachykinins in mood disorders and schizophrenia suggests a generalized impairment of the SP system in the amygdala. NK_1 antagonists have also been used in the study of acute migraine where it is believed that SP is a mediator of pain and inflammation through the NK_1 receptor. SP binding to postcapillary NK_1 receptors in the brain vasculature is believed to produce plasma extravasation, platelet aggregation, and white cell endothelial adhesion. These effects could mediate both the inflammatory process and pain reported in migraine. Furthermore, NK_1 antagonists are very effective in animal models of inflammation, thought to be the indicators of activity in acute migraine. SP antagonists have also been implicated as a therapeutic approach for improving the outcome following traumatic brain injury,[30] where SP is released after acute injury leading to not only direct neuronal cell death but also to the development of vasogenic edema. The ability of SP to also augment immune responses of glial cells has important ramifications to the progression of damaging inflammation.[17] Furthermore, in glial cells, SP-NK_1 receptor interaction is involved in glioma development and progression, and NK_1 receptor antagonists may serve as an anticancer therapy.[14]

Chapter 126

TRH

A. Eugene Pekary

ABSTRACT

Thyrotropin-releasing hormone (TRH) was the first of the hypothalamic releasing factors to be fully characterized. It consists of the tripeptide pGlu-His-Pro-NH_2 that is derived from a precursor protein with multiple copies of the progenitor sequence Lys-Arg-Gln-His-Pro-Gly-(Lys/Arg)-Arg. PreproTRH is distributed throughout the animal kingdom, occurring in species lacking a pituitary. In addition to its neuroendocrine release from the hypothalamus of mammals, resulting in the secretion of TSH and PRL from the anterior pituitary, it functions as a neurotransmitter, neuromodulator, and neuroprotective agent in the central and peripheral nervous systems. Unlike hypothalamic preproTRH mRNA levels and TRH content that are subject to thyroid hormone negative feedback inhibition, extrahypothalamic brain TRH biosynthesis and release are unresponsive to thyroid hormone status. TRH suppresses glycogen synthase kinase-3β (GSK-3β) expression, a process that may lead to treatments for Alzheimer's disease, depression, bipolar disorder, and diabetes. TRH is also an important regulator of lean body mass.

DISCOVERY OF TRH

The nearly simultaneous reporting of the structure of the first hypothalamic releasing factor, thyrotropin-releasing hormone (TRH), as pGlu-His-Pro-NH_2, by Roger Guillemin and Andrew Schally, was the culmination of a five-decade effort to validate the neuroendocrine hypothesis.[5] This story contains elements of intense rivalry between competing research groups, serendipitous combinations of events, and sheer luck that the substance being isolated contained only three amino acid residues, Glu, His, and Pro. During the synthesis of all possible tripeptides containing these amino acids, Glu-His-Pro was found to have a low, but unmistakable, activity in the dispersed anterior pituitary bioassay being used to detect TSH-releasing activity in chromatographic fractions of hypothalamic extracts. Given that almost all the other hypophysiotropic hormones are much larger than TRH[30] and often require amidation of the C-terminal residue, complete characterization of these other releasing hormones using the technology and funding available at the time would have been nearly impossible. Acceptance of Neuroendocrinology as a legitimate research discipline could have been long delayed but for this extraordinary confluence of chance, rivalry, and scientific skepticism.

STRUCTURE OF THE PRECURSOR mRNA/GENE

Genes for fish, frog, chicken, rat, mouse, and human preproTRH contain three exons and two introns. The first exon codes for the 5′-untranslated region; the second exon contains the signal sequence and most of the N-terminus. The remainder of preproTRH is coded by the third exon (Fig. 1). Two closely related preproTRH genes have been identified in frogs, with sequence differences occurring primarily within the 5′-flanking regions. This may provide additional opportunities for tissue and cell-specific regulation of TRH synthesis in this species, which produces extraordinarily high levels of TRH in its skin.[11] Each preproTRH mRNA contains multiple TRH progenitor coding sequences: 6–8 in teleosts, 7 in frogs, 6 in humans, 5 in rats and mice, and 5 in chicken.[33] Interestingly, one of the 5 TRH progenitor sequences in chicken preproTRH is not flanked by pairs of basic amino acid residues. Peptide sequences connecting some of the TRH progenitors in rat preproTRH have been shown to have biological activity,[20] but these are not strongly conserved among species.[33]

DISTRIBUTION OF PREPROTRH mRNA AND PREPROTRH-DERIVED PEPTIDES

PreproTRH mRNA is expressed at very high levels in mouse hypothalamus and testis.[28] Immunohistochemical staining with antibodies to intervening sequences of rat preproTRH showed staining in neuronal perikarya and processes in all the regions of the brain previously demonstrated to immunostain for TRH, including dense

innervations of the external zone of the median eminence. Immunocytochemical and in situ hybridization studies localize TRH-producing perikarya in extrahypothalamic brain areas such as the olfactory system, reticular thalamic nucleus, and amygdaloid complex (Fig. 2). Rat preproTRH (160–169) is readily measured in the hippocampus, piriform cortex, amygdala, striatum, and anterior cortex.[20] High levels of TRH immunoreactivity are also found in the posterior pituitary, retina, pineal gland, spinal cord, reproductive, and immune systems.[13,22,30]

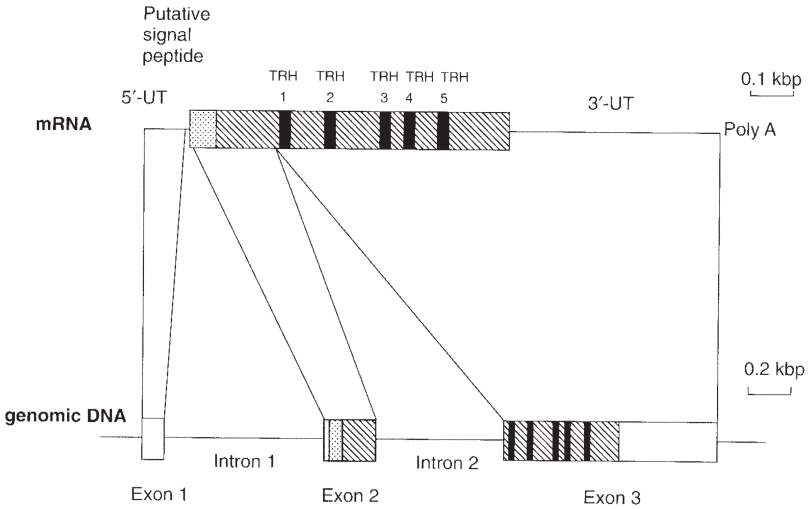

FIGURE 1 Structure of rat preproTRH gene: schematic diagram of the messenger RNA (mRNA) (top line) and genomic DNA (bottom line). The 5′-untranslated region (5′-UT) and 3′-untranslated region (3′-UT) are shown by the solid line (top) and open boxes (bottom). The signal peptide is indicated by a stippled box. The striped boxes indicate connecting and terminal peptides. The solid boxes indicate the TRH progenitor-coding regions. (Ref. 30 with permission from MIT Press).

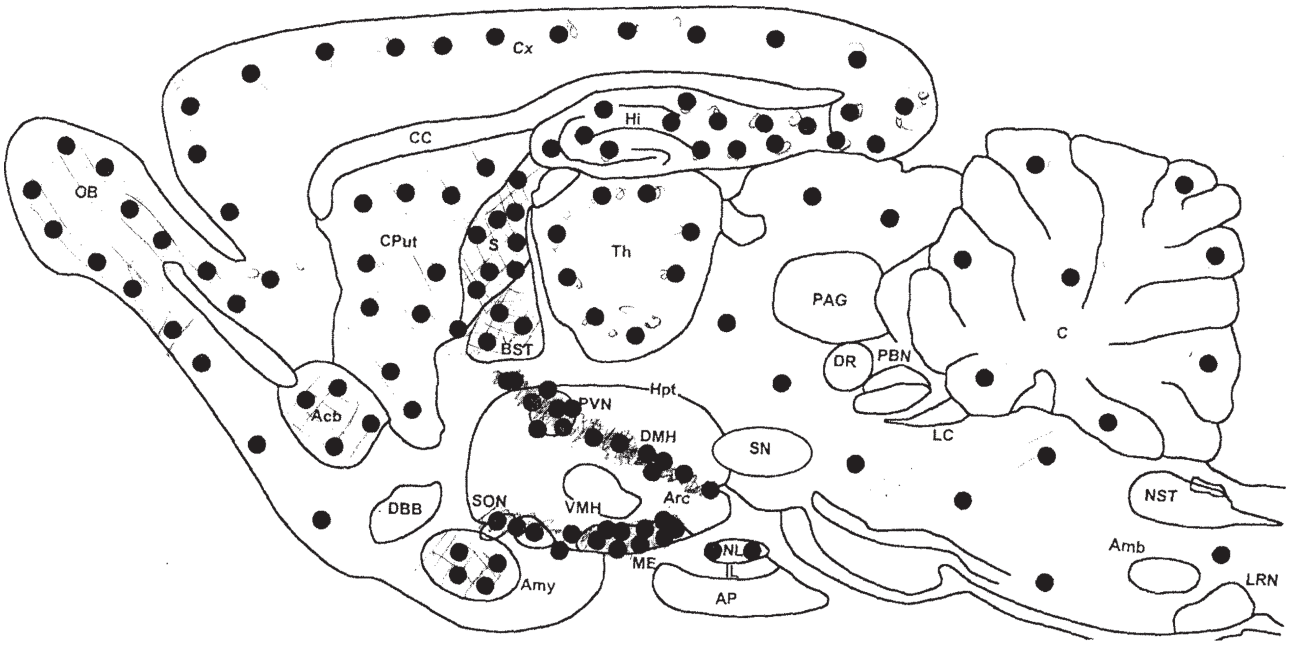

FIGURE 2 PreproTRH mRNA, expressed protein, and derived peptides are widely distributed in rat brain.[7,19,20,26,28,30] However, the extent of processing of the preproTRH precursor protein to form tripeptide TRH, before its extracellular release, is limited in some brain areas but is nearly complete in the hypothalamus.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

PROCESSING OF THE TRH PRECURSOR

Processing of preproTRH begins with the removal of the signal peptide during its passage into the lumen of the rough endoplasmic reticulum.[19] The dibasic amino acid residues flanking the N-terminus and C-terminus of the repeated TRH progenitor sequence Gln-His-Pro-Gly are cleaved by serine proteases, PC1 and PC2, which are constituent membrane proteins of the large dense core vesicles (LDCV) into which preproTRH is packaged after synthesis in the endoplasmic reticulum. The C-terminal basic residues are removed by the zinc-dependent carboxypeptidase H. The remaining C-terminal Gly is cleaved by the copper, ascorbate, and oxygen-requiring peptidylglycine alpha amidating monooxygenase (PAM). The N-terminal Gln is cyclized to pyroglutamate with the aid of an N-glutaminyl cyclase.[19,30]

DISTRIBUTION OF TRH RECEPTORS AND THE TRH DEGRADING ENZYME

Four different receptors for TRH have been reported to occur in a teleost; three in frog; two in rat, mouse; and one in chicken, pig, human, sheep, and cow.[12,18] Three of the teleost TRH receptor genes consist of two exons, whereas the forth consists of 5 exons.[18] The distribution of the rat mRNA for the TRH receptor 1 (TRH-R1) and receptor 2 (TRH-R2) has been studied in detail.[7] TRH-R2 mRNA is widely distributed throughout brain with highest mRNA levels in the thalamus, cerebral and cerebellar cortex, medial habenulae, medial geniculate nucleus, pontine nuclei, and the entire reticular formation. Consistent with the endocrine function of TRH, TRH-R1 predominates in hypothalamic nuclei, the anterior pituitary thyrotrophs, mammotrophs (PRL-secreting cells), and to a lesser extent in somatotrophs (GH-secreting cells).[30] TRH-R1 in brainstem regions and spinal cord motoneurons is involved in autonomic and somatomotor control.[2,5] An overlapping distribution of the TRH degrading enzyme (TRH-DE) mRNA[1] with TRH-R2 mRNA is consistent with the involvement of TRH in higher cognitive functions as well as effects on arousal, locomotor activity, and pain perception.[1,7,8,30]

TRH RECEPTOR SIGNALING CASCADES

TRH-R1 and TRH-R2 are typical G-protein-coupled receptors that bind TRH and N-methyl-TRH with high affinity and specificity.[8] TRH-R3 from frog binds TRH, and other TRH-like peptides weakly, suggesting that it is an orphan receptor (Hinkle and Pekary, unpublished results[16]). TRH-R1 couples to G_q and G_{11},[4] pertussis-toxin-insensitive G proteins that activate phosphoinositide-specific phospholipase C-β (PPI-PLC).[1] PPI-PLC is the enzyme that hydrolyzes phosphatidylinositol 4,5-bisphosphate ($PIPP_2$) to generate two second messengers, inositol 1,4,5-triphosphate and 1,2-diacylglycerol. Inositol trisphosphate binds to the inositol trisphosphate receptor, a calcium channel on the endoplasmic reticulum, resulting in an increase in the cytoplasmic calcium levels.[34] Diacylglycerol, along with calcium, activates protein kinase C (PKC) resulting in the increased phosphorylation of Ser and Thr on a variety of second messenger enzymes.[4] Altered phosphorylation of ion channel, cytoplasmic and plasma membrane proteins, and nuclear transcription factors modify gene expression in the cell nucleus thereby transducing the TRH receptor binding signal.[1]

BIOLOGICAL ACTIONS OF TRH WITHIN THE BRAIN AND PITUITARY

TRH is the principal regulator of the "set point" for thyrotropin (TSH) synthesis and secretion by the anterior pituitary thyrotrophs.[24,32] TSH stimulates the thyroid gland to produce T_4 and T_3, which provide a negative feedback suppression of hypothalamic TRH and pituitary TSH synthesis. Thyroid hormones also accelerate TRH degradation.[19,32] This regulatory network is summarized in Fig. 3. Knock out of the preproTRH gene results in hypothyroidism and diabetes mellitus.[35] Hypothalamic TRH release is altered in many conditions including thyroid disease, cold stress, the onset of sleep, and changes in hormone, monoamine, and cytokine levels resulting from physical or emotional stress or severe illness.[1] Inhibition of "leak" potassium (K^+) channels is a widespread mechanism by which neurotransmitters induce slow excitation of neurons.[31] Transmitter modulation of cellular excitability has been attributed to TASK-1, a two-pore domain K^+ channel, coupled to TRH-R1.[31]

It has long been assumed that TRH has other functions besides the control of TSH given its wide distribution throughout the brain and peripheral tissues, its occurrence in vertebrate and invertebrate species lacking a pituitary, and the unresponsiveness of TRH mRNA and peptide levels of the limbic system to changes in thyroid status.[24] In fish, TRH stimulates growth hormone (GH) and prolactin (PRL) release but does not affect TSH secretion. In amphibians, TRH is a marginal stimulator of TSH release in adult frogs, not in tadpoles, and a major releasing factor for GH and PRL. In birds, TRH induces TSH and GH secretion. In mammals, TRH triggers TSH, GH, and PRL release. In fish and amphibians, TRH also potently stimules α-melanocyte-stimulating hormone release.[3]

TRH has neurotransmitter and neuromodulatory functions.[30,31] It is colocalized and cosecreted with other

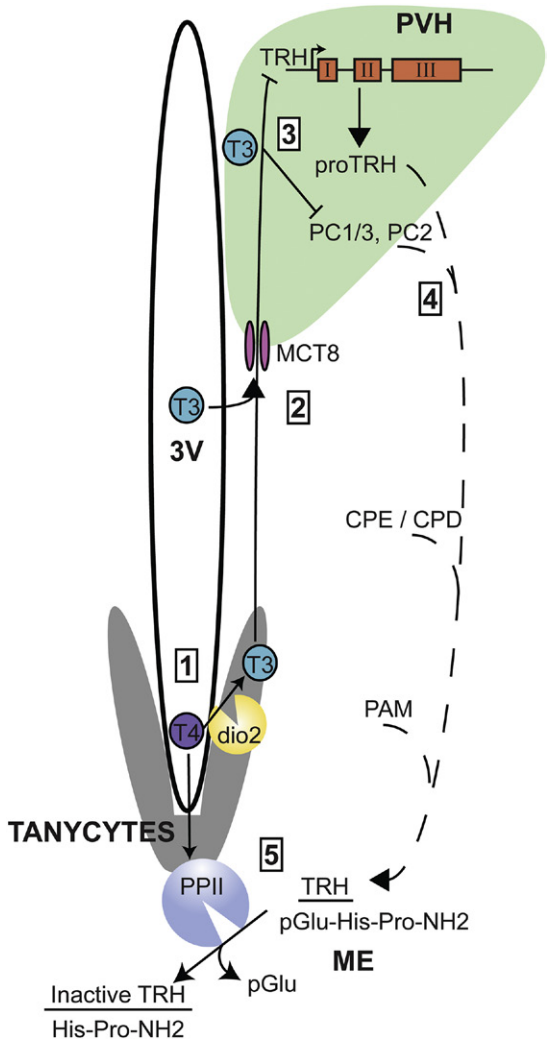

FIGURE 3 Thyroid hormone regulates TRH transcription, posttranslational modification, and degradation through the assistance of tanycytes. 1, tanycytes take up T_4, which is converted to T_3 by type 2 deiodinase (dio2). 2, hypophysiotropic TRH neurons in the paraventricular nucleus of the hypothalamus (PVH) receive T_3 from tanycytes or from the circulation through the monocarboxylate transporter 8 (MCT8). 3, TRH, prohormone convertases 1/3(PC 1/3), and 2 (PC2), are inversely regulated by T3. 4, posttranslational modifications to proTRH by PC1/3 and PC2, carboxypeptidases E and D (CPE and CPD), and peptidyl glycine α-amidating monooxygenase (PAM) occur as it travels down the axon (dashed line). 5, TRH is released in the median eminence (ME) where it can be degraded by tanycyte-bound pyroglutamate aminopeptidase II (PPII), which is positively regulated by thyroid hormone. (Ref. 32 with permission from the Endocrine Society).

neurotransmitters in a variety of different nerve cell types located in both CNS and peripheral tissues.[9,30] CNS regulation of autonomic functions, including arousal, blood flow, heart rate, blood pressure, breathing, thirst, hunger, pain, exocrine and endocrine pancreas functions, gastrointestinal motility, and gastric acid secretion mediated at least in part by TRH release within the CNS.[2,3,5,6,10,14] Interestingly, high levels of TRH also occur within the β-cells of the pancreatic islets[26,35] and Leydig cells of the testis[22] of all mammals so far tested.

PATHOPHYSIOLOGICAL IMPLICATIONS

TRH has an essential neuroprotective function that is partly mediated by its suppression of glycogen synthase kinase-3β (GSK-3β) expression in neurons.[17] This enzyme is responsible for the hyperphsphorylation of tau that results in neurofibrillary tangles that are associated with the neuropathologies of Alzheimer's and other dementias and regulates microtubule assembly in nerve axons and dendrites.[25]

A signal transduction pathway for TRH downregulation of GSK-3β has been proposed.[17] This ability of TRH to suppress GSK-3β has implications not only for Alzheimer's disease but also severe depression, bipolar disorder, diabetes mellitus, stroke, prostate cancer, and aging. GSK-3, in turn, modulates the release of TRH. Antidepressants and the major mood stabilizers for bipolar disorder, lithium and valproate, also inhibit GSK-3β and can reverse the associated neurologic damage with glia and neurons in brain regions associated to mood regulation [see Ref. 25 and references therein]. TRH and TRH-like peptides can be viewed as endogenous antidepressants, anticonvulsants, analeptics, and neuroprotectants.[8,21] Because TRH is rapidly degraded by TRH-DE,[29] development of TRH-DE-resistant TRH analogs,[2,29] use of naturally occurring TRH-like peptides with antidepressant properties,[8,21] or development of nontoxic, selective PAPII inhibitors[29] will be required for practical treatments.

Centrally administered TRH analog has a protective effect on cerulin-induced acute pancreatitis in rats. TRH and TRH receptors are distributed throughout the immune system and play an important role in both normal and pathological responses to bacterial and viral infection.[13]

Genomewide association and replication studies have identified TRHR1 as an important gene for lean body mass.[15] This is consistent with the central role played by the hypothalamic–pituitary–thyroid axis in the regulation of metabolism, muscle development, and maintenance.[15] Chronic ip injection of TRH can mobilize triglycerides, decrease serum leptin, and induce weight loss in obese mice without inducing hyperthyroidism.[27] Leptin and ghrelin, hormones that inhibit and stimulate feeding, respectively, may use TRH and TRH-like peptides in their downstream signaling[23] (Fig. 4).

Chapter 127

Urotensin II Peptides

Isabelle Lihrmann, Hervé Tostivint, Howard Bern†, and Hubert Vaudry

ABSTRACT

Urotensin II (UII) is a cyclic neuropeptide initially isolated from the urophysis of teleost fish. In the central nervous system (CNS) of tetrapods, UII is almost exclusively produced in motoneurons located in brainstem nuclei and in the ventral horn of the spinal cord. Three paralogs of UII have also been characterized, namely urotensin II-related peptide (URP) both in tetrapods and fish, and URP1 and URP2 in fish. The cyclic region of UII and URPs, which has been fully conserved during evolution, plays a crucial role for the biological activity of these peptides. A single receptor for UII and URP, called the UT receptor, has been identified so far. In agreement with the widespread distribution of UT receptor in the CNS, UII and URP exert a large array of activities in the brain and in peripheral organs.

DISCOVERY

The caudal neurosecretory system of teleost fish incorporates a neurohemal organ called the urophysis, which contains various regulatory factors including neurotransmitters and neuropeptides (Fig. 1). Urotensin II (UII) is a cyclic neuropeptide that has been originally isolated from the goby urophysis on the basis of its ability to induce contractions of the trout hindgut.[2] In all species of fish investigated, the UII sequence encompasses 12 amino acids with a fully conserved cyclic region at position 6–11 that exhibits some structural similarity to somatostatin. It had long been thought that UII was the apanage of the fish urophysis.[2] However, characterization of UII from the brain of the European green frog[7] has revealed that a UII-encoding gene actually exists in certain species of tetrapods and that this gene is not only expressed in the caudal portion of the spinal cord but also in brain nerve cells.[33] Consistent with these notions, the cDNAs encoding the UII precursors have been cloned in various mammalian species,[33] including human.[1,10] Subsequently, a paralog of UII named urotensin II-related peptide (URP) has been characterized in the rat brain and the URP cDNAs have been cloned in mammals, birds, and teleosts fish.[30] Two additional UII paralogs, designed URP1 and URP2, have been recently identified in teleosts.[26] The occurrence of UII, URP and their receptor in the CNS, together with the variety of their behavioral effects, suggest that these peptides act as neurotransmitters and/or neuromodulators.

STRUCTURE

Gene Structure and Evolutionary Aspects

The gene encoding preproUII, also named *uts2*, comprises five exons and maps on human chromosome 1p36. In human, two distinct precursor isoforms with 139 (isoform a) and 124 (isoform b) amino acids have been characterized.[1,10] These two isoforms only differ in their N-terminal extremity and give rise to the same mature UII peptide (Fig. 2). In all other mammalian species studied so far (mouse, rat, pig, and monkey), only isoform b has been identified.[33] In fish, two variants of isoform b are expressed as a result of genome duplication. The *uts2d* gene encoding prepro-URP has five exons and maps on human chromosome 3q23. The human URP precursor consists of 119 amino acids and exhibits very low sequence identity with the UII precursor (<20%). Two additional genes, designed URP1 and URP2, have been characterized in teleost fish, which are not the orthologs of the URP gene.[26] The four distinct UII/URP genes present in vertebrates, namely UII, URP, URP1, and URP2 genes, probably arose during the two rounds of whole genome duplication before the emergence of gnathostomes. However, the URP1 and URP2 genes are thought to have been lost in the tetrapod lineage (Fig. 3). Comparative genomics has further shown that urotensin II and somatostatin gene families likely arose from a common ancestral gene.[31]

Processing of the Precursors

The general organization of the UII and URP precursors is identical, the sequence of each peptide being located at the C-terminal extremity of the protein[1,9,10,26,30,31] (Fig. 2). Somatostatin-14, which possesses structural similarity to UII in the

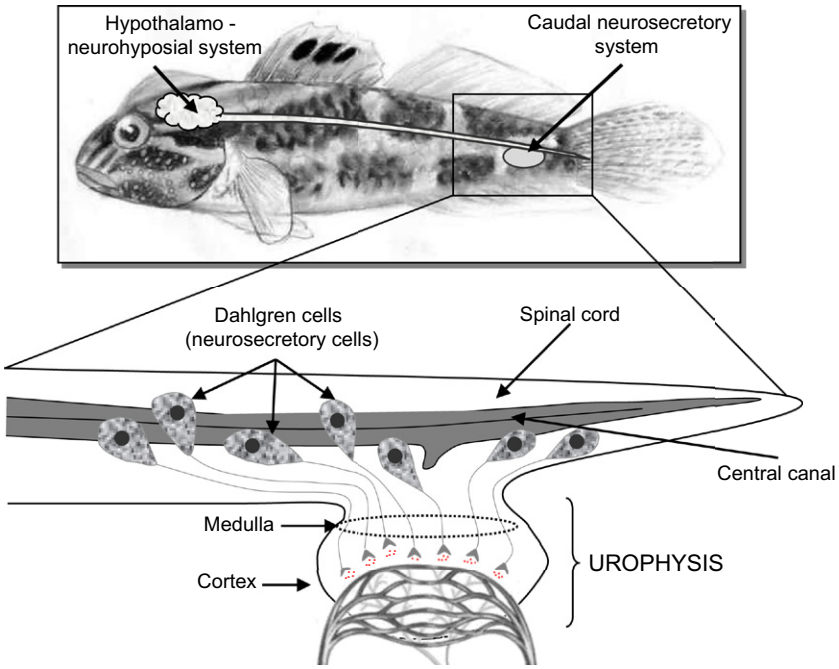

FIGURE 1 The fish caudal neurosecretory system consists in UII-immunoreactive Dahlgren cells located in the caudal portion of the spinal cord in the last (~5 to 6) preterminal vertebrae. Large unmyelinated axons from these cells extend lateroventrally and turn caudally to join the spinal-urophysial tract. UII is released in the vicinity of fenestrated capillaries in the urophysis and ultimately join the renal portal system.

biologically important cyclic region, is also located at the C-terminal end of its precursor (see chapter on Somatostatin in this section of the book). Proteolytic cleavage of proUII and proURP at dibasic (Arg-Lys) or tribasic (Lys-Lys-Arg) sites has the potential to generate mature peptides whose sequences may vary from 8 (tetrapod lineage URP) to 17 (mouse UII) amino acids in length. In tetrapods, up to now, the structure of UII has only been determined in the frog brain[7] and in the human and porcine spinal cord.[5,33] Additional molecular forms have been isolated in the human brainstem[5] which may correspond to large processing products at one of the upstream Arg-Lys dibasic sites. A UII-converting enzyme with furin-like activity has been partially characterized in human epicardial mesothelial cells, vascular endothelial cells, and cardiac fibroblasts by studying the processing of the 25 amino acid C-terminal fragment of proUII.[28]

Peptide Structure

Strong evolutionary pressure has acted to preserve the primary structure of the C-terminal portion of UII and URPs while the N-terminus is highly variable.[22,33] (Fig. 4). Thus, in all species examined, the amino acid sequence of the cyclic region of UII and URPs (Cys-Phe-Trp-Lys-Tyr-Cys) has been fully conserved.[33] In the UII sequence, the cyclic portion is preceded by an acidic residue (Asp or Glu) and is flanked at its C-terminus by a hydrophobic residue (Val or Ile). In URP sequences of tetrapods, the cyclic region is flanked by an Ala residue at its N-terminus and a Val or an Ile residue at its C-terminus. Fish URP1 and URP2 sequences differ from the others by the replacement of the C-terminal Ala by a Val in URP2 and the presence of an N-terminal extension in URP1 and URP2 (Fig. 4).[26]

LOCALIZATION

In the CNS of tetrapods, UII and URP are almost exclusively expressed in motoneurons located in the brainstem and the dorsal horn of the spinal cord.[5,8–10,13,24] In particular, in the rat brain, a high concentration of UII mRNA has been observed in motoneurons located in the trigeminal, abducens, facial, ambiguus and hypoglossal nuclei[9] (Fig. 5). Similarly, intense expression of the UII gene occurs in the ventral horn of the spinal cord in developing rat.[9] UII mRNA is also detectable, albeit at a much lower level, in various human and mouse cerebral structures, including amygdala, hypothalamus, and cerebellum.[9,13] Globally, the profiles of expression of the UII and URP genes in the CNS of mammals are similar.[13,30] except in the human spinal cord where preproURP levels are much lower.[30] In the mouse spinal cord, the UII and URP precursors are expressed within the same motoneuron cell bodies.[24] By contrast, several brain regions in mouse contain mostly URP mRNA. They include the locus coeruleus, the rostroventrolateral medulla, the lateral paragigantocellular nucleus, and the dorsal nucleus of the vagus.[13]

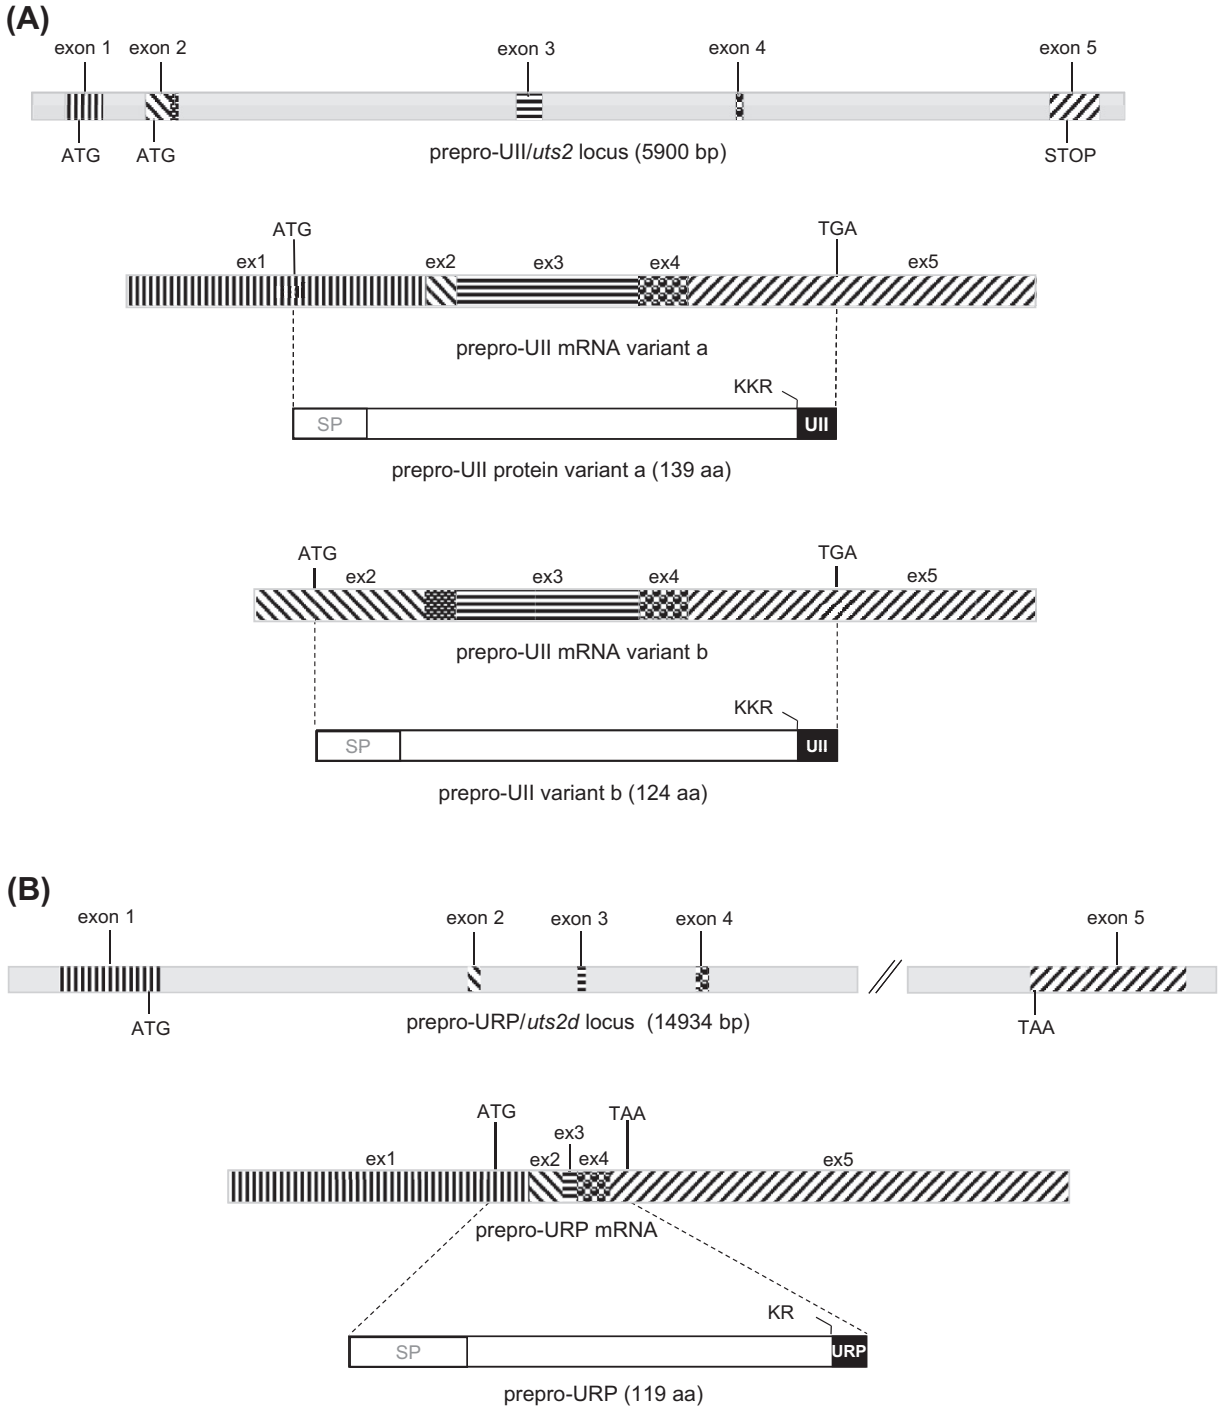

FIGURE 2 Structure of the human preproUII and preproURP genes. **(A)** The preproUII gene comprises five exons and encodes two precursor isoforms (variants a and b) that only differ at their N-terminal extremity. The same mature UII peptide is generated from both isoforms a and b after proteolytic cleavage at a tribasic site (KKR). **(B)** The preproURP gene comprises five exons. The URP sequence is located at the C-terminal extremity of the URP precursor and the mature peptide is generated by proteolytic cleavage at a dibasic site (KR).

In fish, while expression of the UII gene is restricted to the caudal neurosecretory system,[2] the URP1 gene is expressed most abundantly in the medulla oblongata and to a lesser extent in the spinal cord. URP2 mRNA-containing cells are found below the fourth ventricle and at the ventral side of the central canal in the spinal cord. These URP2-expressing cells probably compose the UII-like extra-urophyseal system described earlier.[24] In zebrafish embryos, URP2 gene expression occurs in the floor plate of the neural tube.[26]

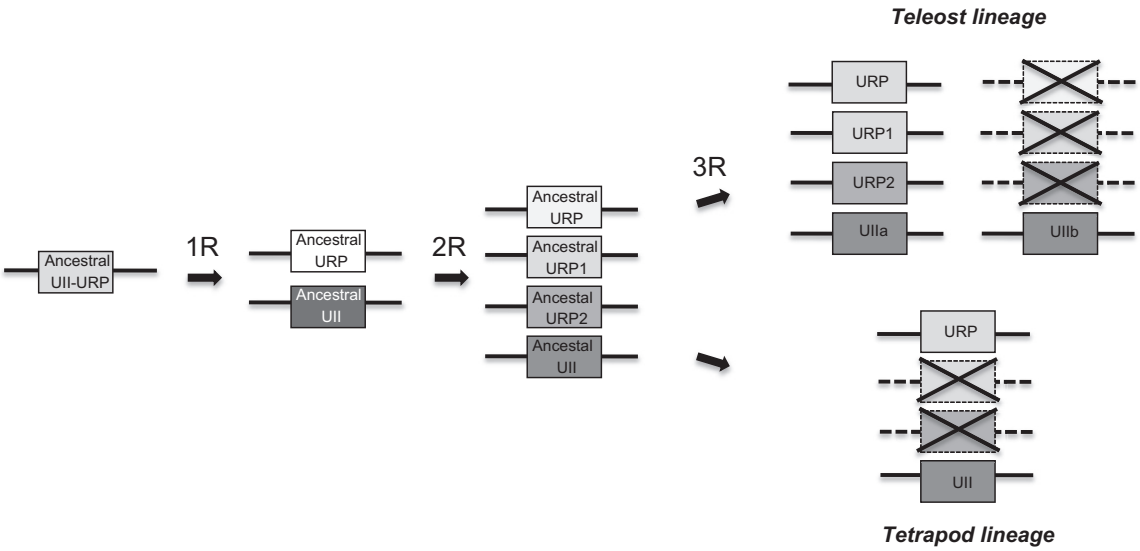

FIGURE 3 A proposed evolutionary scheme for the UII/URP family in vertebrates. R: rounds of whole genome duplications. Crossed-out boxes represent lost genes.

RECEPTORS AND SIGNALING CASCADES

The UT Receptor

The orphan G protein-coupled receptor GPR14, initially characterized by a homology based approach, was subsequently identified by reversed pharmacology as the UII receptor and then renamed UT receptor.[1] This receptor exhibits the highest sequence identity with somatostatin (27%) and opioid (25-26%) receptors. In human, the UT receptor comprises 389 amino acids and is encoded by an intronless gene located on chromosome 17q25.3. The UT receptor belongs to the class A family of GPCRs, characterized by a short N-terminus, an Asp residue in TMD2, a D/ERY motif at the junction of TMD3 and the second intracellular loop, a NPxxY motif in TMD7, and potential Ser/Thr phosphorylation sites in the cytoplasmic tail. UT also exhibits putative N-glycosylation sites in the N-terminal extracellular domain and two Cys residues in the first and second extracellular loops (ECL). Substitution of the Asp residue in TMD2 alters the capacity of receptor transition to an active state, while this modification or mutations in the ERY motif in TMD3 markedly reduce PLC activation.[25] Photolabeling studies with photoprobes have shown that a pair of methionine residues (Met^{184}/Met^{185}) of TMD4 in the rat UT receptor interacts with the Phe residue present in the cyclic region of UII. In addition, the N-terminal domain of UII ligands seems to be in close proximity to a Met residue (Met^{288}) in ECL3 of UT. Within TMDs, an Asp residue in TMD3 could be involved in an ionic interaction with the Lys residue in the cyclic domain of UII while, in TMD6 and TMD7, specific residues may participate in the formation of the binding pocket of the UT receptor.[25]

The UT receptor undergoes internalization via clathrin-coated pits through an arrestin-independent, dynamin-dependent mechanism. A cluster of Ser residues (potential kinase phosphorylation sites) located within the cytoplasmic tail of the UT receptor is crucial for its ability to be internalized efficiently. The existence of caveolin-binding sites in rat UT also suggests a caveolin-dependent endocytotic pathway. In addition to internalization, UT can be regulated by desensitization through an arrestin-dependent mechanism since UT colocalizes with arrestin-1 and -2 in endocytotic vesicles and with arrestin-3 at the plasma membrane. The UT receptor recycles quantitatively within 30 min and the continuous externalization of the UT receptor provides the basis for repetitive and lasting UII-mediated effects.[25]

Signaling Cascades

The biological effects of UII are mediated through activation of a number of transduction pathways. In many cell types and cell lines, including macrophages, endothelial cells, smooth muscle cells, skeletal muscle preparations, cardiomyocytes, and astrocytes, the main transduction mechanism associated with UT is the activation of the $G_{\alpha q/11}$ subtype of heterotrimeric G proteins coupled to phospholipase C (PLC)-IP3-dependent intracellular calcium mobilization.[19,29] However, $G_{\alpha i/0}$ coupling has also been reported in native astrocytes and UT-transfected cell lines.[19,35] UT may also be coupled to $G_{\alpha 12/13}$ since UII activates the small GTPase RhoA and its downsteam effector Rho-kinase, a pathway usually, but not exclusively, associated with $G_{\alpha 12/13}$.[17] One of the most documented downstream signaling pathways of

FIGURE 4 Alignment of UII and URP sequences identified so far. The number of amino acids (AA) of each peptide is indicated. * indicates that this sequence is conserved in all mammals or all teleosts.

UT, generally associated with cell proliferation, involves the members of the MAPK family (ERK1/2 and to a lesser extent p38) through Gαq/PLC/PKC or Gi/0.[17,27,35] As shown for many GPCRs, a network of interconnected transduction mechanisms occurs in different cell types, which are coupled to diverse cellular responses (proliferation, apoptosis, migration, hypertrophic growth).[17,27] In neural cells, notably motoneurons, UT is coupled to Ca^{2+} influx and neurotransmitter release via both the PKA and the PLC-IP3 pathways[3] while, in astrocytes, activation of UT triggers a Gαq-PLC-InsP3-Ca^{2+} cascade and a Gi/o-PI3 K-PTX-sensitive pathway, the latter being induced by UII, not URP.[19] Alternately, in a number of cell types (cardiomyocytes, renal and smooth muscle cells), UT can activate these pathways indirectly via the transactivation of epidermal growth factor receptor upstream of the MAPK pathway.[17,32]

Distribution of the UT Receptor

In peripheral organs, the highest concentrations of UT receptor mRNA are mainly found in the heart (ventricular myocardium) and vascular tissues (endothelial and smooth muscle).[1,13] UT receptor transcripts are also found in a number of organs including kidney, lung, liver, adipose tissue, skeletal muscle, in the gastrointestinal and genitourinary tracts (stomach, esophagus, small intestine, colon, bladder, ovary, testis, prostate), and endocrine glands (pituitary, thyroid, pancreas, adrenal gland).[1,13] In the CNS, UT receptor mRNA is widely expressed in the cortex, septum, nucleus accubens, striatum, hypothalamus, the pyramidal cell layer and the dentate gyrus of the hippocampus, amygdala, several tegmental nuclei, cerebellum, pons, medulla oblongata, spinal cord and dorsal root ganglia.[1,13,20] UII- and

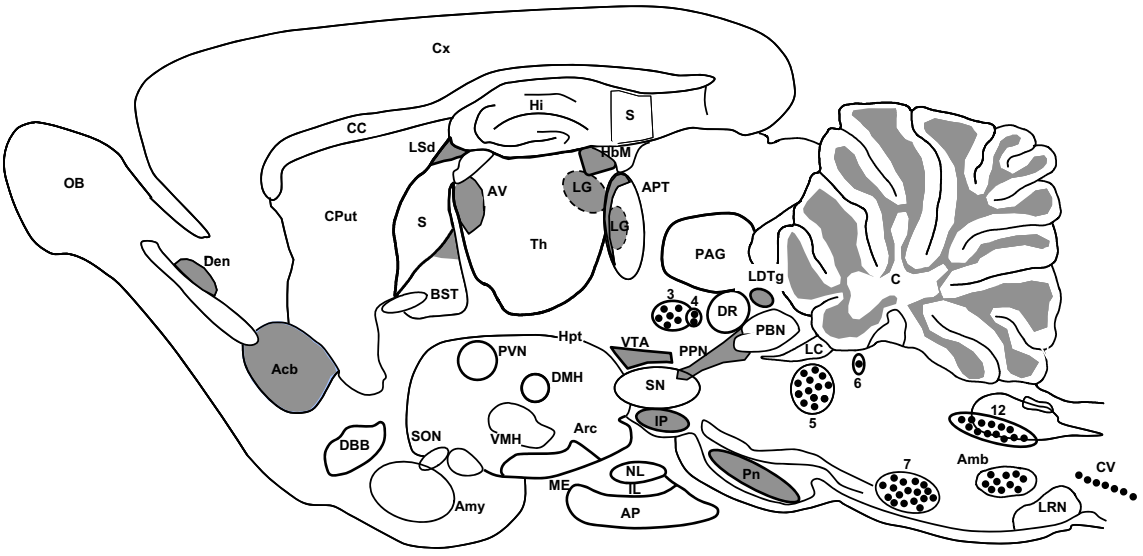

FIGURE 5 Schematic drawing showing the distribution of UII neurons and [^{125}I]UII binding sites in the rat central nervous system.

URP-binding sites totally overlap, but are more restricted than UT mRNA expression pattern.[20] They are found in the lateral septum, accumbens nucleus, dorsal endopiriform nucleus, various amydaloid nuclei, medial preoptic nucleus, anteroventral thalamus, medial habenula, anterior pretectal nucleus, ventral tegmental area, interpeduncular nucleus, parasubiculum, pontine nuclei, some tegmental nuclei, geniculate nuclei and cerebellar cortex.[20]

Structure–Activity Relationships

The cyclic region that is common to UII and URPs (Fig. 4) plays a pivotal role for the biological activity of these peptides on native and recombinant UII receptors.[22,33] $UII_{(4–11)}$ is the minimal sequence required for full biological activity and, in fact, URP which comprises a single Ala upstream of the cycle is as efficient as UII to bind and activate UT.[13,30] Disruption of the disulfide bridge or point-substitution of individual amino acids within the cyclic region by Ala or D-isomers markedly reduces the potency of UII and URP. The triad Phe^6, Lys^8 and Tyr^9 is essential to retain full biological activity. Punctual modifications of these residues generate analogs with agonistic and antagonistic properties.[22,32] The N-terminus, which is reduced to a single Ala in URP, is not necessary for the biological activity, and some substitutions in one of these amino acids increase the stability of the analogs. By contrast, the presence of a hydrophobic residue (Val or Ile) at the C-terminal extremity of UII and URP contributes to the biological potency. Determination of the solution structure of UII and URP by NMR spectroscopy has shown that the cyclic region adopts a highly ordered compact conformation while the N-terminal segment of UII is disordered. In both UII and URP, the side chains of the Phe, Trp and Tyr residues of the cyclic region are oriented on the same side of the peptides suggesting that they may all be involved in docking with the binding pocket of the UII receptor.[22]

BIOLOGICAL ACTIONS WITHIN THE CENTRAL NERVOUS SYSTEM

Central Regulation of Cardiovascular Functions

The genes encoding the UT receptor as well as the UII and URP precursors are all expressed in brainstem nuclei associated with cardiac function and in hypothalamic nuclei such as the paraventricular nucleus,[13,20] which is implicated in the control of corticotropin (ACTH) secretion. As a matter of fact, a number of studies have shown that UII modulates hemodynamics and cardiac function at the CNS level. Studies in conscious sheep and rat have shown that icv UII stimulates the sympatho-adrenal and pituitary-adrenal pathways resulting in epinephrine, but not norepinephrine, release.[34] These effects are accompanied by an increase in blood pressure and heart rate, and similar effects were reported after microinjections of UII into the paraventricular nucleus and the arcuate nucleus in anesthetized rats.[23]

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

In fish, at very low doses, UII administered icv increases heart rate without modifying blood pressure, while a higher dose of UII provokes hypertension and takycardia.[21] The chronotropic and inotropic actions of centrally administered UII are blocked by propanolol in sheep and in rat indicating that they are mediated through cardiac β-adrenoreceptors. Furthermore, the observation that the pressor and chronotropic actions of icv-injected UII are attenuated by ganglion blockade indicates that these responses are mediated in part through activation of the sympathetic nervous system.[34] Collectively, these observations show that the inotropic and chronotropic actions of centrally-administered UII in conscious sheep and rat result from stimulation of cardiac β-adrenoreceptors via raised circulating levels of epinephrine and increased cardiac sympathetic nerve activity. Supporting this view, activation of neural activity has been detected in the central amygdala, the paraventricular nucleus, and the nucleus of the solitary tract, after icv UII administration in rat. URP may be directly involved in adrenal sympathetic outflow regulation since its mRNA is highly expressed in neurons that are intermingled with TH-immunoreactive A1/C1 cells in the rostral ventrolateral medulla.[13] Altogether, these observations indicate that central administration of UII/URP causes site- and dose-dependent cardiovascular responses in both fish and mammals.

Neuroendocrine Actions

The regulation of pituitary-sympathoadrenal medullary and pituitary adrenal cortex pathways (see above) are not the unique neurosecretory functions of UII.[34] Indeed, icv administration of UII provokes an increase in plasma prolactin and thyroid-stimulating hormone (TSH) in rat.[16] The stimulatory effect of UII on prolactin, TSH, and ACTH release is probably mediated through activation of thyrotropin-releasing hormone (TRH) and corticotropin-releasing hormone (CRH) neurons that are both located in the paraventricular nucleus[20] (see chapters on TRH and CRH in this section of the book).

Behavioral Responses

Consistent with the widespread distribution of GPR14 mRNA and UII binding sites in the CNS, central administration of UII elicits a number of behavioral effects in rodents.[11] A number of studies have shown that UII is implicated in various mood and sleep processes. Thus, icv injection of UII induces anxiogenic and depressant-like effects in mouse[11] and increases neural activity in rat periaqueductal gray, a midbrain region implicated in anxiety control. In addition, local administration of UII into the pedunculopontine nucleus modulates paradoxical sleep through direct activation of brainstem cholinergic neurons by UT receptors present in the mesopontine tegmental area.[18]

Motor Functions

The expression of the mRNA encoding the UII and URP precursors and the UT receptor in motoneurons of the brainstem and spinal cord indicates that UII/URP may act as autocrine modulators of motoneuron activity.[1,5,8–10,13,20,30] Consistent with this notion, the UT receptor is expressed on a subset of cholinergic nerve terminals in part originating from the recurrent motoneuron axon collaterals in mouse spinal cord.[4] In addition, dissociated rat motoneurons are equipped with functional UT receptors coupled to calcium mobilization.[15] Other results support a role of the UII/URP system as co-transmitter at cholinergic motoneuron terminals, capable of regulating transmitter release and contributing to the excitatory transmission. Thus, UII is present at the neuromuscular junction, in synaptophysin-containing vesicles[13] and retrograde labeling has shown that UII-containing neurons actually innervate muscle.[14] Next, UII stimulates acetylcholine release at the frog neuromuscular junction and in rat and mouse synaptosomes obtained from the spinal cord.[3,4] Finally, UT receptor mRNA is expressed in skeletal muscle and functional UT receptors occur in human skeletal muscle cell lines[12,13] suggesting a post-synaptic regulation of neurotransmitter release. Of note, UII/URP expression may be subject to sexual dimorphic regulation in motoneurons since the androgen receptor is co-localized with UII and URP mRNA in motoneurons, and castration down-regulates the expression of the two genes.[24]

In the brain, icv UII/URP injection increases locomotion in mouse, rat and fish.[11,16,21] High density of UII binding sites has been found in regions of the human and rat brain (cortex, accumbens nucleus, pontine nuclei, cerebellum) which are involved in motor control.[20] Noteworthy, serotoninergic and dopaminergic systems are not altered in these structures following icv UII injection in rat, although they are modulated by other neuropeptides, orexins for instance.

In conclusion, UII exerts an excitatory effect in some cases, since it modulates cardiovascular tone through activation of the sympathetic system and controls REM-on state and acetylcholine release from cholinergic brainstem neurons and motoneurons, respectively. By contrast, UII induces a decrease in neuronal excitability associated to a potentiation of $GABA_A$ receptor-mediated Cl^- current, in neurons of aplysia abdominal ganglion and CA1 area of rat hippocampus.

PHYSIOLOGICAL AND PATHOPHYSIOLOGICAL SIGNIFICANCE

UII was first described as the most potent vasoconstrictor ever discovered, being ~10-fold more potent then endothelin-1,[1] although the magnitude of its effect is highly

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

dependent on the species and tissue source of the vessel. In physiological conditions, the UT receptor is present both on smooth muscle and endothelial cells,[1] so that the vascular effect of UII is a balance between vasoconstriction and vasodilation resulting from the release from endothelial cells of nitric oxide, prostaglandins, and endothelium-derived hyperpolarizing factors. The urotensinergic system is thought to participate in the basal vascular tone through the prolonged effect of UII, its pseudo-irreversible binding properties, and the slow dissociation rate of UII at UT.[12] The concentrations of UII in plasma, urine and/or cerebrospinal fluid are increased and the UT receptor is upregulated in many diseases, including essential hypertension, chronic heart failure, atherosclerosis, renal failure, renal dysfunction, portal hypertension/cirrhosis, and diabetes mellitus.[32] Therefore, the urotensinergic system may not contribute to the regulation of organ function in healthy states, but most probably play a significant role in disease states.[27,32]

The upregulation of the urotensinergic system has many physiopathological consequences. In cardiovascular diseases for instance, UII participates to the formation of atherosclerotic plaques and the development of hypertension in several manners: vasoconstriction resulting from endothelial dysfunction and impaired vasodilation, stimulation of acyl-coenzyme A:cholesterol acyltransferase-1 (ACAT-1) activity in macrophages, foam cell infiltration, and smooth muscle cell proliferation.[17,32] In myocardial ischemia and congenital heart failure, the effects of the urotensinergic system on cardiac remodeling and function are still controversial. Patients with significantly elevated plasma UII concentrations display improved outcomes post-myocardial infarction. It has been suggested that UII may play a cardioprotective role in cardiac remodeling, via transactivation of the EGF receptor. By contrast, in animal models of cardiovascular diseases, administration of UT antagonists improves both hemodynamics and cardiac remodeling suggesting the implication of the UT receptor in the development of the disease state.[32] In support of this latter hypothesis, the urotensinergic system has been shown to impair heart function through fibrosis and cardiomyocyte hypertrophy.

The kidney, together with the heart, is one of the major sources of UT, UII, and URP, the expression being highest in the medulla than in the cortex. UT is found in renal tubular cells and collecting ducts, as well as in glomerular arterioles, but the exact roles of UII in tubular reabsorption and secretion of water and electrolytes remain to be clarified. Several studies have reported that UII and URP binding at UT in renal tubules causes a decrease of glomerular filtration rate, urine volume and urinary sodium excretion.[32] The concentrations of UII are increased in biopsies from patients with diabetic nephropathy, in urine of patients with renal tubular disease, and in the plasma of patients with chronic renal failure. The UT antagonist palosuran is effective in diabetic nephropathy, reducing albuminuria in a small number of patients. Furthermore, in patients with moderate-to-severe chronic kidney disease, plasma UII is an inverse predictor of death and fatal cardiovascular events.[32]

UII participates to the metabolic syndrome, via its inhibitory effect on insulin release by pancreatic beta cells and its stimulatory effect on circulating levels of inflammatory cytokines (IL-6), resulting in insulin resistance, atherogenesis and hypertrophy.[27,32] Elevated plasma UII concentrations have been observed in patients with diabetes. Further, association of polymorphisms in the UII gene with type 2 diabetes has been reported in Chinese and Japanese subjects. Hence, UT antagonism may have a beneficial effect on patients with type II diabetes. However, antagonism of the UII system does not influence insulin secretion or sensitivity or daily blood glucose levels in diet-treated patients with type 2 diabetes. By contrast, in a rat model of type 2 diabetes. glycaemia, serum cholesterol, triglycerides, HbA1c, insulin concentrations, renal blood flow, and renal damage are improved.[32]

Although numerous studies have addressed the effects of the urotensinergic system at the periphery, the actions of UII and URP at the central level in pathophysiological states remain poorly documented. UII/URP and UT mRNAs are largely expressed in different brain regions and cell types, including neurons, glial cells and neuromicrovascular endothelial cells.[6,8–10,13,19] In a rat model of cerebral ischemia, icv-injected UII induces a sustained hyperemia through vasodilation and, as a consequence, exacerbates ischemic brain lesion.[6] Injection of UII in the striatum also increases the lesion size in a model of NMDA-induced brain injury.[6] Similar UII concentrations are found in the cerebrospinal fluid and in the serum, indicating that this neuropeptide may be also involved in the maintenance of pial vascular tone. Paradoxically, while numerous *in vitro* results suggest a role of UII and URP in the regulation of neuromuscular function, no results are yet available concerning the possible involvement of the urotensinergic system in neuromuscular disorders.

In hopes of a new therapy for cardiovascular, metabolic and renal diseases, several peptidic and nonpeptide antagonists of the UT receptor have been designed by the combination of biochemical and computational methods.[22,32] However no potent and safe antagonists that could be used in human have been yet developed.

Chapter 128

VIP

Sandrine Passemard, Catalina Abad Rabat, Pierre Gressens and Vincent Lelièvre

ABSTRACT

The vasoactive intestinal neuropeptide VIP is widely expressed throughout the whole body and highly conserved in evolution. Interacting with high affinity receptors, namely, VPAC1 and VPAC2, it plays important roles in regulating peripheral and central functions. This chapter aims to recapitulate some of its most prominent actions in the adult and developing nervous system. In particular, we highlight its regulatory function on cortical development that was recently deciphered at a molecular level, its action in the control of the rhythmic activity of the endogenous brain clocks, and its pivotal role in the expanding field of neuroimmunology. In line with these biological actions, we also point out its striking potentials in pathological conditions including its neuroprotective capability in numerous brain injury models.

INTRODUCTION

Isolated 40 years and 20 years ago, respectively, the related neuropeptides VIP (vasoactive intestinal peptide) and PACAP (pituitary adenylate cyclase activating polypeptide) not only share 68% identity at the amino acid level, common receptors and signaling pathways, but also overlap in patterns of expression and functions. This makes it difficult to comprehensively depict the role of VIP in the brain without referring to PACAP actions. Nevertheless, in this chapter, we attempt to review the most recent results on VIP actions in the brain that highlight previous puzzling findings and also illustrate the potentials of VIP as a diagnostic, preventive or even therapeutic drug in human brain diseases.

STRUCTURE OF THE mRNA/GENE

Fifteen years after its original discovery, the human VIP gene was finally cloned and assigned to chromosome 6q25. Later, orthologs were identified in rats and mice and mapped on chromosome 1p11 and 10, respectively. Just like many other neuropeptides, the VIP gene encodes for a prepropeptide of 170 amino acids.[14] Posttranslational processing finally generates two bioactive peptides encoded on adjacent exons, the 28aa VIP and the 27aa peptide histidine isoleucine and peptide histidine methionine (i.e. PHI/PHM) that solely differ between rodents and humans by their ultimate residue (I vs. M). However, two alternative forms have been observed, namely, peptide histidine valine (PHV42) and PHI-Glu. The 170 amino acid prepro-VIP is initially cut by a signal peptidase in the endoplasmic reticulum to yield the 148 amino acid proVIP. ProVIP is further cleaved by prohormone convertases to VIP-GKR (proVIP125-155) and PHM-GKR (proVIP81-110). These intermediate products are subsequently cleaved by carboxypeptidase-B-like enzymes into VIP-G and PHM-G. The G-forms can then be finalized by PAM enzymes in VIP and PHM, harboring an amidated C-terminus. Conformational analysis of VIP has shown an initial N-terminus sequence made of a β-turn tandem of four amino acid units, followed by two helical segments at residues 7–15 and 19–27 that are connected by an undefined hinge. The three-dimensional structure of VIP confirms the helical segment that is shared between members of the VIP/glucagon family including PACAP27 with minor conformational differences. This may contribute to the selectivity of the peptides for their receptors. Such a hypothesis was confirmed[6] by showing that among the whole VIP sequence the specific domain generated from the α-helix up to the C-terminus interacts with the N-terminal binding domain of the human VPAC1, one of the VIP Receptors.

It is worth noting that the VIP gene has been also identified in numerous lower species, thereby proving its high phylogenetic conversation in sequence and structure.[4] In addition, the PACAP gene structure and processing are very similar: one preproPACAP generating both PRP and PACAP bioactive peptides encoded on similar exons (4 and 5) than PHI/PHM and VIP. The actual hypothesis is that they are derived from a common PACAP-like ancestral gene that duplicated some millions years ago. Other alternative mechanisms including exon skipping or deletion may participate in the full biopic of the VIP/PACAP gene superfamily. There is no evidence of alternative splicing for the mammalian VIP transcript.

Finally phylogenetic studies of the VIP/PACAP gene family have also revealed a very intriguing twist in their

respective functions (see the receptor sections). Studies of PACAP genes in reptiles reveal that the gila monster expresses a novel peptide family member named exendin. These peptides that exist as four variants of 35–39 amino acids named exendin-1 (helospectin), exendin-2 (helodermin), exendin-3, and exendin-4 are found exclusively in the salivary gland of this venomous lizard native to the southwestern United States and northwestern Mexican deserts. Structurally, exendin-2 is related to human PACAP with 53% sequence identity and exendin-4 to human GLP-1 with a similar identity, although Exendin-2 differentially interacts with the VIP and secretin receptors resulting in an increase in cAMP in rats. However, extensive studies suggest that exendins do not have mammalian homologs.

Expression of the VIP gene is regulated by many factors, including cAMP and PKC. Indeed, promoter studies have revealed that the VIP gene upstream sequences contains three TATAAA boxes, AP2 consensus sites, a 17 bp cAMP-responsive element (CRE) within 100 bases from the start site,[4] and a 180 bp cytokine-responsive area (CyRE) controlled by the ciliary neurotrophic factor (CNTF)/leukemia inhibitory factor (LIF). This element can also bind Smad-containing complexes in response to TGFβ alone or in combination with CNTF in neuroblastoma cells. Estrogen or thyroid hormone can act directly within the pituitary to regulate VIP gene expression in an opposite manner. During embryonic brain development, the neurogenic transcription factor Nurr1 regulates VIP mRNA and protein levels, by transactivating the VIP promoter through Nurr1-responsive cis elements. Loss of heterozygosity in nurr1 reduces VIP transcription and alters the survival of these VIP-producing dopaminergic cells. Dexamethasone studies have also revealed a glucocorticoid response element in the VIP promoter sequence. When a CAT reporter gene is fused to 5.2 kb of the upstream sequence of the human VIP gene, the truncated promoter fails to produce a proper CAT pattern in mutant mice with normal expression in the intestine, but no brain localization. Similarly, a 16.5 kb portion of the mouse VIP promoter fused to beta-galactosidase shows the same partial pattern in adult mice. However, in neonates and embryos, beta-galactosidase staining perfectly matches the original VIP localization in cranial cholinergic and superior cervical ganglia but not in sensory ganglia. These and other results indicate that the multiple transcriptional elements controlling VIP expression are all required for proper *in vivo* patterning.

DISTRIBUTION OF THE mRNA/PEPTIDE

After the initial discovery of VIP, numerous studies have investigated the distribution of this neuropeptide in a large variety of species throughout their whole development.[13] Keeping in mind that VIP can be synthesized and secreted by neurons and also neuroendocrine and immune cells, we focus our review on the central and peripheral nervous system. In the adult brain, VIP is highly expressed in the cerebral cortex, amygdala hippocampus, suprachiasmatic nucleus, and hypothalamus, structures that also express PACAP. In the cerebral cortex, the diversity of cortical GABAergic interneurons is critical to its function. Recent results suggest the existence of three types of regulatory neurons based on the expression of either parvalbumin or somatostatin or again, the ionotropic serotonin 5HT3a receptor known to include the VIPergic neuron subpopulation. In addition, VIP immunoreactivity has been shown in preganglionic sympathetic neurons located in the intermediate zone of the spinal cord and in local nerve fibers in the rat and monkey. These neurons project to parasympathetic ganglia that exhibit VIP-immunoreactive nerve fibers in many vertebrates. In sympathetic ganglia, VIP expression peaks during early development in birds and rodents (from E9 to E14.5) then dramatically decreases later on. VIP immunoreactivity is also observed in large lumbosacral postganglionic neurons and colocalized with catecholamine and CGRP, while it is also codetected with dopamine-β-hydroxylase and NPYin thoracic postganglionic neurons in pig. In mouse embryos, VIP expression detected as early as E10 suggests the possibility of paracrine/autocrine actions during cerebral development to further sustain the placental production of VIP.[27]

RECEPTORS AND SIGNALING CASCADES

Years before the successful cloning of VIP receptors achieved in 1991 from HT29 human adenocarcinoma cell lines, pharmacological studies had already revealed VIP receptors coupling to adenylate cyclase by interacting with GTP binding proteins to stimulate intracellular signaling cascades. In addition, radioactively labeled (iodinated) VIP was generated to develop pharmacological assays that revealed the presence of high affinity binding sites for VIP in a variety of cell types.[13] In parallel, a complete characterization of the pharmacological properties of these VIP binding sites was progressively achieved along with the development of suitable ligands including helodermin and other natural analogs of VIP. In parallel, multiple artificial nonselective "VIP receptor" ligands were created and reported. Most of them were either modified truncated or chimeric VIP peptides, whereas some were proven VIP antagonists. The concept of distinct VIP receptor subtypes was finally accepted to explain how these peptides could show differential affinity with VIP binding sites and exert a wide range potency on cAMP production. Finally, the molecular cloning of three different receptors, the PAC1 receptor that corresponds to PACAP-preferring binding sites and two VIP-preferring receptors namely VPAC1 and

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

VPAC2 was achieved. Expression of the cDNA encoding for VPAC1 and VPAC2 in cells confirms their differential pharmacological profiles. In addition, later studies also suspected and/or revealed additional VIP receptors. For instance, type-C natriuretic peptide receptor (NPRC) exhibits high affinities for VIP analogs when overexpressed in Xenopus oocytes.[23] Similarly, PHI/PHM-preferring VIP receptors detected in liver and neuroblastoma cells by biochemical and functional studies were finally cloned in fish.

The VIP-preferring VPAC1 and VPAC2 receptors belongs to the group B GPCR family and are characterized by an N-terminal domain of >120 amino acids that contains a hydrophobic sequence and a cysteine-enriched putative binding domain, a seven transmembrane domain (7TM) region and a long C-terminal segment involved in signal transduction.[13] Numerous structure-function studies have been performed to identify both ligand recognition domain and key motifs necessary for proper signal transduction. Indeed, ligand binding involves both hydrophobic core and N-terminus and extracellular loops of VPACs to initiate physical/conformational changes that permit recruitment of different classes of heterotrimeric G-proteins including the α_s subunit. Directed mutagenesis revealed the role of Tyr239 and Leu240 residues in VPAC1 sequence to circumvent the lack of a G-protein binding E/DRY motif, whereas others proposed that the missing E/DRY motif could be recreated in VPAC1 by three nonadjacent residues Arg174, Glu236, and Tyr239 located in the cytoplasmic end of TM2 and in the distal part of TM3. All in all, studies agreed on the active participation of two specific Tyr residues in TM1, one Lys in TM2 and one Asn in TM3 in VPACs activation.[22] Additional information on VPAC activation was provided by receptor variants. Existence of such variants was proposed as early as 1993 when the group of Gressens revealed the presence of VIP receptors that show no affinity for PACAP to mediated VIP action on mouse brain growth[18] or on neuroprotection against ibotenate-induced lesions.[17] Later, a VPAC2 variant originating from a deletion of exon 11 or 12 was detected in murine thymus and spleen resulting in a weaker coupling to signaling pathways. Finally, in the mononuclear SUPT1 cell line, a larger deletion of 88 aa spanning the TM6-7 region was also detected and associated with a reduced coupling to AC. Moreover, interactions with accessory proteins such as Receptor activity-modifying proteins (RAMPs) can strongly interact with VPAC1 to enhance VIP-induced inositol phosphate hydrolysis without affecting the cAMP pathway.

As already mentioned, the canonical transduction in VPACs requires a coupling with Gαs subunit leading to the activation of adenylate cyclase and subsequent cAMP production. Accumulation of intracellular cAMP may lead to the activation of the protein kinase A that may modulate the ERK (extracellular-signal-regulated kinase) signaling pathway to control cell proliferation and differentiation in cancer cell lines. VIP-induced PKA activation is also responsible for most of the anti-inflammatory activity of VIP by regulating several signaling pathways and transcription factors. VIP receptors are also able to activate PLC in a partly pertussis-toxin-sensitive manner that seems to differ between VPAC1 and VPAC2. Additional couplings may also elicit alternative transduction cascades including phospholipase D and phosphatidylinositol 3-kinase. In the rat pineal gland, VIP stimulates cGMP formation through activation of nitric oxide synthase, nitric oxide (NO) production and activation of cytosolic guanylate cyclase. Ultimately, activation by VIP agonists also initiates the process of receptor desensitization. VPAC1 and VPAC2 are rapidly phosphorylated after agonist exposure. This process starts with phosphorylation of the receptors on Ser/Thr residues in intracellular loops and C-terminus by receptor-activated-dependent kinases (GRKs). GRK-mediated phosphorylation of the receptors initiated a direct interaction with β-arrestins before recruiting the clathrin-dependent endocytic machinery necessary for receptor internalization. VPAC1 and VPAC2 are both rapidly internalized after agonist exposure but differ in their trafficking pattern. After internalization, VPAC1 is not recycled back to the cell surface within a couple of hours, while VPAC2 has already returned.

The receptor distribution has been extensively studied in central and peripheral tissues from numerous species.[30] VPAC1 and VPAC2 transcripts have a completely different and apparently complementary distribution in the rat CNS. Thus, VPAC1-R mRNA is expressed mainly in the cerebral cortex, the hippocampus, and also in deep cerebellar nuclei, thalamus, hypothalamus, and brainstem, whereas VPAC2-R mRNA is detected in the cerebral cortex, hippocampal formation, amygdalar (central) regions, deep cerebellar nuclei, hypothalamus, thalamus and in the pontine nucleus of the brainstem. The distribution of VPAC2-R overlaps with that of VPAC1-R mostly in the hippocampus, playing a key role in adult neurogenesis and memory in a coordinated manner.[35] In the olfactory bulb, VPAC1-R and VPAC2-R mRNAs are differentially distributed, that is, VPAC1-R mRNA is present in the external plexiform layer, whereas VPAC2-R mRNA is expressed in the internal granular layer. In the cerebral cortex, VPAC1-R mRNA is abundant in layers III and V, whereas VPAC2-R mRNA is exclusively localized in layer VI. Both VPAC1-R and VPAC2-R mRNAs are present in astrocytes, whereas VPACs had been identified in neuronal progenitors and preoligodendrocytes undergoing differentiation. In addition, VPACs have also been found in numerous brain tumors, including neuroblastoma and glioma. VPACs have been extensively studied in these pathological tissues and shown to modulate their proliferation and differentiation. They have also been used as prognosis marker or imaging targets for early detection or metastatic development, when overexpressed.[13]

BIOLOGICAL ACTION WITHIN THE BRAIN (AND PITUITARY) AND PATHOPHYSIOLOGICAL IMPLICATIONS

Based on the wide distribution of VIP and its potential receptors, biological actions of this neuropeptide have been reported in almost all tissues. Indeed, VIP acting as an hormone, a transmitter or a neuromodulator, or again as a tropic factor, exert important roles on metabolism and homeostasis in general that were confirmed by phenotypic analysis of several lines of transgenic mice, including tissue-specific overexpressing animals and complete knockouts.[13] Original transgenic mice expressing the human VIP gene in pancreatic beta cells exhibited a significant reduction in circulation glucose concentration and remained insensitive to glucose intolerance after partial pancreatectomy, suggesting potential values for VIP and related peptides in diabetes treatment. Conversely, the mouse line harboring a chimeric VIP-diptheria toxin transgene produces 20% less cerebral VIP and exhibits cognitive deficits, whereas VPAC2-expressing transgenic mice exhibits impaired rhythmic activity in SCN. However, the first complete VIP-KO mouse line generated in 2003 exhibited a complete loss of both VIP and PHI neuropeptides without compensatory phenomena at ligand (PACAP) or receptor levels. Animals proven viable and fertile suffered from complex behavioral deficits and critical chronobiological symptoms that will be further discussed in the next sections. They also exhibited peripheral deficits in intestinal, immune, and testicular functions.

Three different PAC1-deficient mice have been generated. Numerous *in vivo* studies were performed to evidence the PACAP action on pancreatic and gastric secretion, hippocampus and memory function, light-induced circadian rhythm synchronization, social and psychomotor behavior and also on nociception and sensory system. When animals lack both VIP and PACAP, animal growth and life expectancy are dramatically reduced.[26]

More specifically, VIP may act as an autocrine/paracrine trophic factor on immune and neural cells, leading to important concepts of VIP as a neuromodulator of brain activity in adult and developing brain and also as a neuroimmunomodulator in pathological conditions including brain injury and infection/inflammation situations. These particular actions of VIP are summarized below in greater detail.

VIP Effects on Early Brain Development

VIP regulates growth and embryonic development during the neural tube closure period and the early stages of neurogenesis. Treatment of E9 whole culture mouse embryos with VIP shows a dramatic increase in growth and development over a 4-h period in a dose-dependent manner.[18] PACAP has no effect on embryonic growth during this narrow window of time. VIP receptors are expressed as early as E9 at the floor plate of neural tube, whereas VIP itself is not expressed in embryonic telencephalon before E11–E12.[32] Before E12, VIP comes from T lymphocytes of the maternal decidua where VIP RNA is expressed from E6 to E12 (peak at E8).[29] VIP crosses the placenta, reaches the embryo, and binds to VIP receptors in neural tube or telencephalon.[21] Gressens and coworkers showed that VIP blockade during early neurogenesis using a VIP antagonist (VA), intraperitoneally injected twice a day to the pregnant mice from E9 to E11, leads to microcephaly.[19] They showed how VIP is crucial for cortical development and dissected the VIP signaling pathway in this model.[27] VIP blockade induces a reduction of 20% of cortical thickness, when observed at P5, that affects both upper and lower layers and mimics the phenotype of MCPH patients (autosomal recessive microcephaly, defined by a reduction in brain weight without cortical cytoarchitecture defects causing developmental delay in affected patients). This thinner cortex is the result of a decrease in proliferation of neural progenitors at the ventricular zone at E11.5 by increasing the cell cycle length, accelerating cell cycle exit and promoting early differentiation of cortical progenitors. They showed that VIP blockade disrupts Mcph1 signaling because VA downregulates expression of Mcph1 at both gene and protein levels, as well as its targets, Chk1, a key check point of the cell cycle, and Brca1, in the telencephalon of treated embryos (Fig. 1). *In vitro* silencing of either Mcph1 or Chk1 in neurospheres mimics VA-induced inhibition of cell proliferation, and this inhibition of VIP on neural stem cell progenitors is mediated by VPAC1 receptors coupled with a cAMP/PKA signaling pathway. Taken together, these experiments show that the VIP/Mcph1/Chk1 pathway is the key to normal cortical development and that environmental factors, including maternal ones, such as VIP, can influence neural progenitors proliferation and thereby the size of the brain.

Behavioral consequences of VIP blockade (E9–E11) on neonatal mice are a developmental delay. Pups exhibit retardation in the appearance of 5 (such as eye opening and several motor reflexes) of the 10 developmental milestones, modeling some mental retardation features observed in human MCPH.[33] In adult stages, some other developmental disorders and severe behavioral disorders appear. Adult mice that had been treated by VA between E8 and E10 exhibit anxiety-like behavior and deficits in social behavior such as autism. The developmental delays and social behavior deficits seen in mice treated by VA during embryonic stages are similar to that obtained with $VIP^{-/-}$ mice.[24] But more interestingly, developmental deficit and social behavior disorders are determined by the VIP genotype of the mother, not the genotype of the offspring, because heterozygous offspring of VIP null mother were equally retarded

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

in development. These experiments show that deficiency of maternal VIP during neurogenesis contributes greatly to the developmental delay and social behavior deficit in the offspring of VIP-deficient mothers and that expression of VIP by E12 in those offspring with one VIP gene does not ameliorate the developmental deficiency.[24] In conclusion, maternal VIP production influences (1) final brain size by regulating neural progenitor proliferation through Mcph1/Chk1 pathway and (2) the achievement of developmental milestones in offspring and normal social behavior in adult stage.

Immunomodulatory Effects

Immune cells patrol the CNS as a mechanism of defense against infections, and microglia and astrocytes have the ability to produce cytokines in response to insults. However, chronic inflammation of the brain is a key feature in certain autoimmune diseases such as multiple sclerosis (MS), and it has been suggested that aberrant immune responses may perpetuate damage in the brain of Alzheimer's and Parkinson's disease patients as well. Nevertheless, the immune system seems to be a double-edged sword, because in certain circumstances immune cells can secrete neuroprotective molecules that improve axon regeneration and tissue healing. Immunomodulatory therapies that block harmful immune responses and promote beneficial effects of immune cells may be the most promising approaches to ameliorate MS and other neurodegenerative diseases. Extensive evidence reviewed in Refs. 1, 11, 28, and summarized below and in Fig. 2 demonstrates that VIP exhibits such properties.

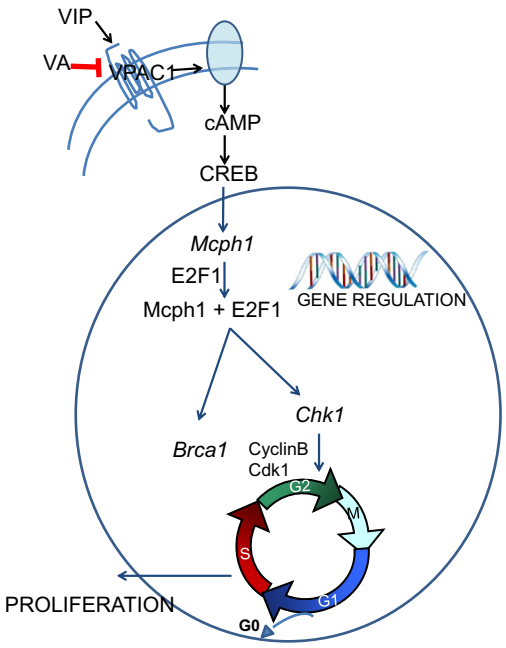

FIGURE 1 Current hypothesis depicting how VIP can induce mouse neural stem cell progenitor proliferation through VPAC1–PKA–Mcph1–Chk1 signaling pathway. VIP proliferative effects are mediated by VPAC1 coupled to the cAMPc–PKA pathway, and this action is blocked by VA. PKA can phosphorylate CREB that potentially binds to one of the 3 cAMP-responsive element sequences on *Mcph1* gene. VIP blockade induces a decrease of *Mcph1* gene expression. *Mcph1* in turn regulates *Chk1* and *Brca1*, two key check points of the cell cycle, through its interaction with E2F1 on the promoter of both genes. VIP blockade then induces a decrease of neural stem cell proliferation through VPAC1–cAMP–PKA–Mcph1–Chk1 signaling pathway. See color plate 36.

The first studies suggesting a link between the neuropeptide VIP and the immune system revealed its presence within the innervation of immune organs and in immune cells. Moreover, VIP receptors are found in the surface of immune cells with a different pattern depending on their activation status: Although in basal conditions macrophages express VPAC1 and PAC1 and lymphocytes express only VPAC1, VPAC2 is expressed after the activation of these cells with stimuli of different nature. VIP modulates different aspects of immune cell physiology, including migration, proliferation, and cytokine secretion. Early studies revealed that VIP exerts strong anti-inflammatory actions *in vitro*. For example, studies using murine peritoneal macrophages show that VIP inhibits the lipopolysaccharide (LPS)-induced production of the proinflammatory cytokines TNFα, IL-6, and IL-12 while stimulating the expression of the anti-inflammatory cytokine IL-10. In addition, VIP may also impede the amplification of the inflammatory response through its inhibitory action on chemokine production, as it reduced the expression of chemokines such as RANTES, KC, MIP-1α, MIP-1β, and MCP-1 in macrophages stimulated with LPS. Moreover, VIP decreased the production of free radicals in macrophages stimulated with LPS at least in part by reducing the expression of inducible nitric oxide synthase (iNOS), and it suppressed cyclooxygenase 2 (COX2) expression in macrophages, microglia, and dendritic cells. Similarly, and relevant to CNS pathogenesis, VIP reduced the LPS-induced production of proinflammatory cytokines, chemokines and other proinflammatory mediators by cultured primary microglia. VIP may inhibit inflammation by acting downstream of toll like receptors (TLRs) and/or other proinflammatory pathways: VIP reduces in naive macrophages the expression of TLR4, the receptor for LPS. Evidence suggests that most of the immunomodulatory effects of VIP are mediated by the inhibition of NF-kB and/or MEKK1/MEK4/JNK pathways, and the induction of cAMP, protein kinase A and CREB phosphorylation.[11] In contrast, this peptide reduces IFNγ signaling in macrophages and microglia by inhibiting Jak1/2-STAT1 phosphorylation.

Most of the anti-inflammatory effects of VIP are believed to be mediated through the VPAC1 receptor, and partially by VPAC2, except IL-6 inhibition, which at least in some contexts depends mainly on the PAC1 receptor. Besides

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

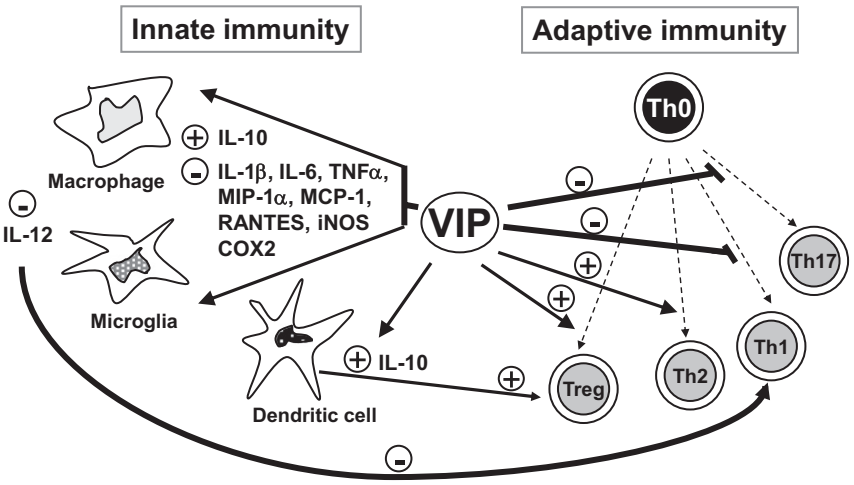

FIGURE 2 VIP modulates the innate and adaptive arms of immunity. VIP exerts its antiinflammatory actions by (1) inhibiting the production of pro-inflammatory cytokines and chemokines from myeloid cells (macrophages and microglia) including IL-1b, IL-6, TNFa, MIP-1a, MCP-1, and RANTES among others, as well as iNOS and COX-2 but stimulating the production of IL-10; (2) inducing a tolerogenic dendritic cell phenotype producing high amounts of IL-10; 3) switching the lymphocyte immune cell response from Th1/Th17 to Th2/Treg, by several mechanisms, including the inhibition of IL-12 production from antigen presenting cells.

its effects on the innate immune system, VIP exhibits important actions on lymphocyte biology and other aspects of adaptive immunity. One of the best known actions of VIP is the ability to potentiate Th2 at the expense of Th1 responses.[11] Although several mechanisms seem to be involved, the modulatory effects of VIP on Th cells are mediated at least partially by its actions on antigen presenting cells (APCs). For example, VIP reduces the production of IL-12, a Th1 promoting cytokine, by macrophages stimulated with LPS. VIP may also selectively modulate Th chemotaxis at the site of antigen presentation by decreasing dendritic cell production of the Th1 chemokine CXCL10, while increasing the Th2 chemokine CCL22. In addition, VIP promotes *in vivo* the generation of memory Th2 cells. Finally, VIP improves Th2 survival at least in part by selectively blocking the expression of granzyme B, FasL, and perforin in these cells. Another mechanism by which VIP may exert its anti-inflammatory action is through the generation of regulatory T cells (Tregs), which has been shown both *in vitro* and *in vivo*.[8] Tregs have been implicated in the resolution phase of inflammation by suppressing effector T cell proliferation and activity. Again, the actions of VIP on dendritic cells may account for their effects on Tregs. Dendritic cells generated from murine bone marrow precursors or human blood monocytes in the presence of VIP were $CD11c^{low}CD45RB^{high}$, secreted high amounts of IL-10 and did not upregulate CD80, CD86, or CD40 after LPS stimulation. These cells were tolerogenic, in the sense that they promoted the production of Tregs *in vitro* and *in vivo*.

The anti-inflammatory effects of VIP have been confirmed *in vivo* in different murine models of disease including LPS-induced endotoxemia, collagen-induced arthritis (CIA), TNBS colitis, and nonobese diabetic (NOD) mice, models for rheumatoid arthritis, Crohn's disease and autoimmune diabetes respectively, reducing the Th1 and inflammatory components that are common to their pathogenesis.[11] Regarding CNS disease, VIP exhibits therapeutic properties in chronic and relapsing-remitting experimental immune encephalomyelitis (EAE) murine models of MS, reducing the clinical symptoms of paralysis, CNS immune cell infiltration and axonal damage while increasing the numbers of oligodendrocytes.[3] MS is believed to be an inflammatory Th1-driven pathology. In the EAE studies, the expression of proinflammatory cytokines in the CNS is significantly reduced in VIP-treated mice while the expression of cytokines generally considered to be anti-inflammatory (IL-10, IL-1Ra, and TGFβ1) is increased after VIP treatment. In addition, the ex vivo analysis of T cell responses suggests that VIP peripheral administration decreases Th1 but favored Th2 responses. The therapeutic action of VIP in EAE is also associated with an induction of Tregs, which may act by blocking the ongoing lymphocytic responses or accelerate the recovery phase of the disease.

Studies in other experimental models of disease highlight a potential therapeutic role for VIP in neuroinflammation. For example, local administration of VIP prevents neurodegeneration induced by intraventricular administration of LPS, reducing microglia activation and TNF-α, IL-1β, and iNOS expression.[10] Likewise, local administration of VIP decreases pathological events occurring after stab wound brain trauma in the periventricular area, including immune cell infiltration, microglia activation, and TNF-α and IL-1β production.[10] VIP administration also decreases microglial activation in the 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

(MPTP) model of Parkinson's disease.[9] This peptide also reverses the detrimental effects of IL-1β on ibotenate-induced lesions of the periventricular white matter.[15] Finally, VIP exerts protection against β-amyloid-induced neurodegeneration by inhibiting microglia activation at multiple levels, suggesting a therapeutic potential against Alzheimer's disease.[12]

The direct *in vivo* administration of VIP or receptor analogs is only one option to take advantage of their therapeutic immunomodulatory potential. Initial studies have suggested that the ability of VIP to induce ex vivo dendritic cells with tolerogenic potential and thus capacity to induce Tregs could be successfully exploited for the treatment of autoimmune and other inflammatory diseases.[1] C57BL/6 mice treated with VIP-generated dendritic cells after the onset of EAE show diminished clinical scores compared with control mice. Cells with the ability to migrate to inflammatory sites and immune organs could be also used as carriers of VIP-encoding vectors, allowing the continuous but local production of VIP. Bone marrow derived dendritic cells transduced with a lentiviral vector encoding human VIP (referred to as LentiVIP) result in VIP-secreting dendritic cells, with tolerogenic phenotypic and functional characteristics (secreting little if any of the proinflammatory cytokines but producing high levels of IL-10).[1] When LentiVIP-Dendritic cells pulsed with myelin peptides are administered intravenously to mice with EAE, a reduced severity of the symptoms is observed. Although the mechanisms explaining the *in vivo* effects of these cells remain to be elucidated, it is possible that LentiVIP-dendritic cells exert double beneficial actions first through the secretion of VIP, which may act do inhibit inflammatory cells, and second through their own tolerogenic potential on Treg production.

Neuroprotective Effects

In vitro neuroprotection

In cell culture, VIP stimulates astrocytic mitoses and to protect, at fentomolar concentrations, neurons against oxidative stress, *N*-methyl-D-aspartate (NMDA) receptor-mediated excitotoxicity, HIV-1 gp120 neurotoxicity, 6-hydroxydopamine neurotoxicity, and beta-amyloid neurotoxicity.[2,3,16] VIP protective effects on neurons seem to be mediated by astrocytes as VIP induces the release of trophic factors (such as brain-derived neurotrophic factor—BDNF—and activity-dependent neuroprotective protein—ADNP-), cytokines and chemokines by astrocytes.[2,3,16]

Perinatal brain neuroprotection

Excitotoxicity is a key molecular mechanism of perinatal brain damage, which is associated with cerebral palsy and long-term cognitive deficits. VIP induces a potent neuroprotection against perinatal excitotoxic white matter damage, that is, mimicking lesions observed in preterm neonates.[20] VIP effects are not mimicked by PACAP-27 or PACAP-38. Interestingly, VIP does not prevent the initial appearance of white matter lesion but promotes a secondary repair with axonal regrowth and/or sprouting. This plasticity mechanism involves the following steps: (1) VIP binds to an atypical VPAC2 receptor expressed on astrocytes and activates a PKC pathway; (2) PKC activation promotes astrocytic survival and astrocytic release of soluble factors, including BDNF; (3) released factors such as BDNF activate MAPK and PKC cascades in neurons; (4) MAPK cascade and, possibly PKC, activation leads to axonal repair and/or sprouting.[27] Stable VIP agonists such as stearyl norleucine VIP (a lipophylic VIP agonist that does not activate adenylate cyclase) and RO-25-1553 (a VPAC2 receptor agonist), mimic VIP effects when given systemically and exhibit a large therapeutic window (up to 12 h after the insult).[27]

Adult brain neuroprotection

Neuroprotective effects of stearyl norleucine VIP have also been observed in an animal model of Alzheimer's disease. Mice deficient in apolipoprotein E (ApoE) exhibit decreased cholinergic activity, retardation in the acquisition of developmental milestones, and learning and memory impairments. Daily injections of stearyl norleucine VIP to ApoE-deficient newborn pups increases cholinergic activity and markedly improves the acquisition of behavioral milestones and improves adult cognitive functions.

Neuromodulator Effects

VIP is coreleased with different neurotransmitters to modulate synaptic activity in numerous brain structures. VIP-dependent neuromodulatory activities have been well studied in two central structures, the suprachiasmatic nucleus and the hippocampus.

It is now well established that the suprachiasmatic nuclei (SCN) of the hypothalamus harbors the main mammalian circadian clock.[31] This structure exhibits an endogenous rhythm (pacemaker) synchronized daily and yearly environmental changes through the photic systems. Light controls sleep and locomotor activity monitored by free wheel-running device in rodents. To date, investigations on the neurochemical basis of clock resetting have focused on the influence of SCN afferents. Photic information is conveyed from the retina directly to the SCN by the monosynaptic retinohypothalamic tract (RHT) releasing both glutamate and PACAP. SCN is subdivided into a "shell" and "core." Neurons contain within the shell include AVP- and somatostatin-positive cells, whereas the core neurons produce gastrin-releasing peptide and VIP. This neuroanatomical system perfectly illustrates the synergistic action of VIP and PACAP neuropeptides. In hamsters, the VIP release from the SCN exhibits a daily peak near midday that is completely obliterated under constant darkness. Glutamatergic agonist also stimulates VIP release, whereas selective

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

serotonin receptor agonist suppresses it. Abrogation of VIP effects, as observed in VIP null mice or VPAC2 KO, results in the loss of endogenous nocturnal activity rhythm when animals are kept in constant darkness. The rhythmic activity in SCN generates and synchronizes many biological rhythms such as hormones (glucocorticoids, melatonin), neuronal connections, body temperature, metabolites (glucose), and paracrine signals shown to subsequently entrain the peripheral clocks present in numerous brain structures (including hippocampus, prefrontal cortex, amygdala, or VTA) and peripheral tissues. This phenomenon is illustrated by VIP-deficient mice that exhibit weak rhythms in the heart rate and body temperature. In addition, alteration in clock genes or in normal modulation of SCN activity are directly associated with neuropsychiatric disorders in human.[25] For instance, dementia patients, suffering from neurodegenerative disease (Alzheimer's disease, AD) or genetic disorder (Huntington disease, HD) often exhibit sleep disruption and other circadian rhythm disturbances. Therefore, it is not very surprising that PHI concentration in cerebral fluid of patients with AD is reduced or that VPAC receptor expression is altered in the SCN of a mouse model of HD.

A similar situation is observed in the hippocampus. Glutamate, the main excitatory neurotransmitter in the CNS activates hippocampus glutamate receptors that are essential for postsynaptic responses and synaptic plasticity. These synaptic events are crucial for both spatial learning and memory.[7] Long-term potentiation (LTP) and long-term depression (LTD) of the excitatory synapses between CA3 and CA1 hippocampal pyramidal neurons are well-characterized signatures of this plasticity-dependent learning and memory and are almost entirely controlled by AMPA and NMDARs receptors. The activation of VPACs increases evoked NMDA currents via the cyclic AMP/PKA pathway, whereas activation of PAC1-R stimulates a PLC signaling pathway to enhance hippocampal NMDA receptor function.[34] Therefore, it is not surprising to observe memory and learning impairment in PACAP-, PAC1-, and VIP-deficient mice. Further, adult neurogenesis that occurs in hippocampus has been extensively studied in relationship with learning and memory function.[5] Abrogation of neurogenesis in dentate gyrus leads to memory impairment, while stimulation of hippocampal neural stem cell (NSC) proliferation enhances learning and memory in aging animals. Adult VPAC2$^{-/-}$ mice exhibited reduced progeny survival and dentate neurogenesis.[35] Indeed VPAC2 receptor activation shifts the fate of self-renewing NSCs toward nestin-positive progenitors, whereas selective VPAC1 receptor activation differentiates these progenitors into granule cells. This synergistic VIP receptor system on adult hippocampal neurogenesis offers an exciting potential use of pharmacological manipulation of this precursor pool for therapeutic application in the treatment of cognitive deficits.

Chapter 129

VP/OT

John F. Morris

ABSTRACT

Vasopressin (VP) and oxytocin (OT) are the two mammalian representatives of an ancient line of brain peptides central to the investigation of neurosecretion and peptide signaling. Their peripheral actions are well understood; recent research has focused on their central actions and role in behavior. Magnocellular neurons that synthesize VP and OT release them from posterior pituitary axons and from their dendrites; their large size and grouping in the supraoptic and paraventricular (PVN) nuclei have made them robust models for peptidergic neurons in general. Smaller parvocellular neurons in the PVN project to the median eminence, brainstem, and spinal cord. Other small VP and OT neurons are sparsely distributed; their receptors are more widely located. Some VP and OT is produced in peripheral tissues. Systemically, VP is involved in fluid balance and vascular and autonomic control; OT in milk ejection and parturition. Centrally, both the peptides are involved in social behavior including stress, aggression, and pair bonding.

DISCOVERY AND HISTORY[21]

The hormonal activities of vasopressin (VP) and oxytocin (OT) were among the first peptide actions to be discovered. Between 1895 and 1915, Oliver and Schäfer showed vasopressor activity in pituitary extracts, which Howell showed came from its neural lobe (NL); similarly, Schäfer showed antidiuretic activity, and von den Velden showed its NL source. Originally, it was believed that these actions resulted from two hormones, hence the interchangeable use of ADH and VP today. Ott and Scott discovered the mammary effects of OT, Gaines distinguished milk ejection from milk secretion, and Dale showed its uterotonic actions. When these actions were discovered, it was believed that the hormones were synthesized in the NL; it was the studies of Ernst and Berta Scharrer and Wolfgang Bargmann that showed synthesis in large hypothalamic neurons giving rise to the whole concept of neurosecretion into the systemic circulation. The structure of the peptides (Fig. 1a) was elucidated by DuVigneaud in 1953. Acher studying neurophysins and Sachs and Takabatake studying precursor processing showed that OT, VP, and the neurophysins were produced from larger precursors. Molecular understanding dawned in 1984 when Ivell and Richter described the two genes; shortly after, the gene defect giving rise to diabetes insipidus in the Brattleboro rat was identified.

The development of radioactively labeled hormones in the 1950s pioneered the study of receptors for the hormones and the VP receptor subtypes were identified (see Jard in Ref. 35); this led on to the elucidation of the activation cascades initiated by the ligand receptors. The development of electrophysiological techniques showed that the substantial release of both VP and OT relied on bursts of action potentials traveling to the NL but that the pattern of electrical activity differed between VP and OT neurons to the extent that this could be used to identify the two types of cell; VP neurons when activated fire in increasingly long bursts separated by quiescent unresponsive gaps (phasic firing), whereas OT neurons fire in synchronized bursts for parturition before milk ejection (Armstrong et al. in Ref. 3). The use of immunocytochemistry and in situ hybridization has shown that not all VP and OT originate from the magnocellular neurons (MCN) in the SON and PVN and project to the NL. Smaller parvocellular neurons (PCN) in the PVN project to the median eminence to control, in particular, corticotrophs in the anterior pituitary. Other small VP and OT neurons are located in other parts of the CNS and project their actions to specific locations. Combining this with receptor localization shows that there is often a significant mismatch so that many of the CNS receptors apparently respond to peptide that reaches it via diffusion through the CSF and extracellular space.[23] Furthermore, although there is little species variation in the distribution of systemic receptors, the same is not true for the CNS and substantial differences in receptor distribution that relate to behavior have been discovered.

Dendrites of MCN secrete VP or OT independently of the axons (Morris and Ludwig in Ref. 18) to act locally and in an autocrine manner on the MCN.[23,24] Because all peptidergic neurons have peptides in their dendrites, dendritic release is presumably the norm. A host of molecular biology techniques are now used to investigate the system. Germ line and increasingly specific and inducible knockouts and

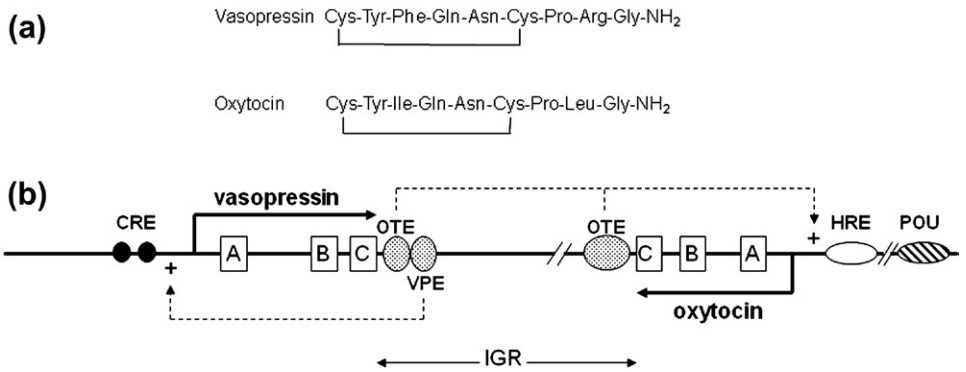

FIGURE 1 (a) Amino acid structure of arginine vasopressin (Mr 1084.38) and oxytocin (Mr 1007.35). In pigs and some marsupials, the Arg in vasopressin is replaced by lysine; the Arg (or Lys) is critical for vasopressin action. Oxytocin has the same structure in all mammals; the Ile is critical for oxytocin action. In birds, reptiles, amphibian, and lungfishes, vasotocin and mesotocin are the VP and OT equivalents; in bony fish, vasotocin and isotocin. (b) VP and OT genes and their regulatory domains (mouse). Enhancers of OT and VP (OTE, VPE) are in a 178-bp segment next to OT exon 3. Cyclic AMP response elements (CRE) are present in the VP promoter; the OT promoter contains a composite hormone response element (HRE) (between −70 and −195) and a POU homeodomain (between −1270 and −1535).

knock-ins have been created for both the peptides and their receptors. Genetic analysis of a large number of humans is gradually revealing not only the wide variety of mutations that occur but also the role of microsatellites and epigenetic silencing in both normal control and disease.

STRUCTURE AND REGULATION OF THE PRECURSOR mRNAs/GENES (FIG. 1)[4,5,21]

The human VP and OT genes (Fig. 1) are on the short arm of chromosome 20 (20p13) (in rats on chromosome 2; mice, chromosome 2; http://www.ncbi.nlm.nih.gov/), tail to tail and transcribed in opposite directions, reflecting evolutionary duplication. The intergene sequence contains a LINE sequence and enhancers for both the OT genes. The close linkage of the genes allows regulatory communication between the two transcription units, but the full extent of controlling sequences remains unclear.

Each gene consists of three exons (~2 kb). Exon A encodes the signal, hormone, a Gly-Lys-Arg cleavage sequence and nine N-terminal amino acids of the hormone-specific neurophysin (NP); exon B encodes the midpart of NP (aa 10–76), which is highly conserved, reflecting its role as a chaperone and hormone binder within large dense-cored vesicles (LDVC). Exon C encodes the remainder of the NP, a single Arg and, for VP only, a 39 aa glycopeptide (GP) the function of which is still unknown. The precursor proteins form homodimers in the rER. Occasional cells containing hybrid VP/OTNP and OT/VPNP mRNAs and proteins have been found and these proteins derived from mutant genes accumulate in the rRER and are not packaged (see Section 7)

Transcription of the genes in MCN is controlled by the activity of the neurons in ways that are still unclear. In both VP and OT neurons, gene transcription and precursor synthesis generally increase with c-fos induction (marker of activation) presumably via the AP-1 site (actions via c-jun and ATF on TPA and cAMP response elements have been less studied). Steroids affect both genes: glucocorticoids act via an inducible GR to stimulate VP synthesis; estrogens stimulate synthesis of OT. Osmotic stimulation doubles the poly(A) tail length on the VP and OT mRNAs to affect their stability. Epigenetic silencing of the genes via methylation is now being studied as an important control; testosterone maintains expression of VP in the BNST in relation to aggressive behavior.[1]

PROCESSING OF THE PRECURSORS (FIG. 2)[4,21]

Transcription of the VP and OT genes yields heteronuclear RNA, which is then spliced to form mRNA, that leaves the nucleus and attaches to free ribosomes. VP mRNA has a long half life (1.9 days). Translation of the signal peptide causes attachment to the rRER, and preprovasopressin and preprooxytocin are translated and translocated into the rER lumen where the signal is cleaved, S–S bonds and folding are established, and proximal glycosylation of the GP moiety of provasopressin occurs, to produce the prohormones. These then pass to the Golgi where terminal glycosylation of cleavage of the GP occurs, and the mature prohormone together with processing enzymes is packaged by the transGolgi into LDCV (the neurophysin moiety is essential for this). As the LDCV are transported into the axons and dendrites, the prohormone is cleaved and the C-terminal glycine of the hormone is amidated. The acidic pH in the LDCV is optimal for the cleavage enzymes and for binding the hormones to their neurophysins. VP neurons express prohormone convertases (PC)

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

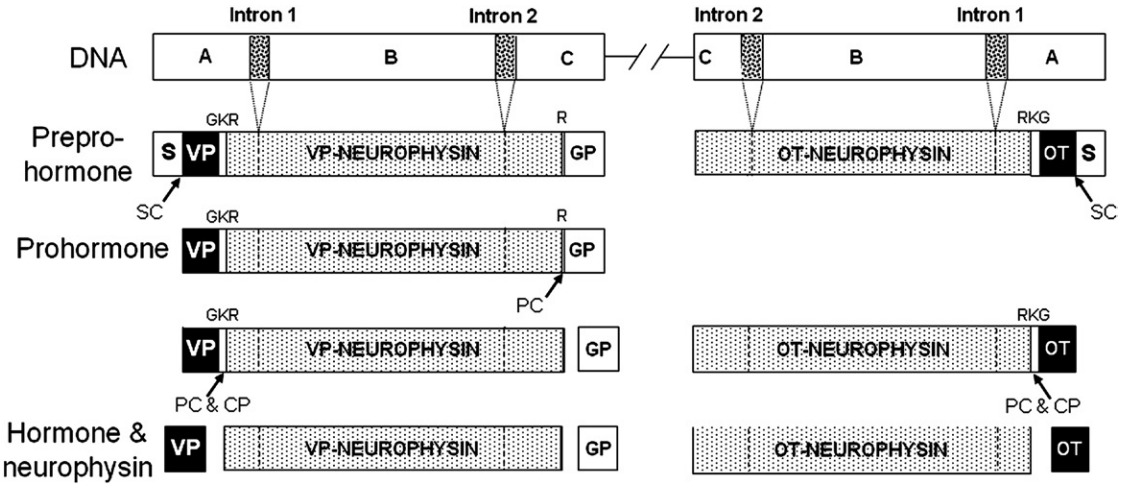

FIGURE 2 Processing of vasopressin (left) and oxytocin (right). The signal-cleaving peptidase (SC) removes the signal peptide from the preprohormone. Prohormone convertases first remove the CP in provasopressin, then cleave between hormone and neurophysin within the large dense-cored vesicles.

1 and 3, but PC5 predominates in OT neurons. The PCs cleave the bond between hormone and neurophysin, carboxypeptidase H/E then trims the remaining C-terminal to reveal glycine, which is amidated by peptidylglycine α-amidating monoxygenase (see Peptide Biosynthesis/Processing section of the book). Both transcription and processing are upregulated in activated neurons.

DISTRIBUTION OF VP AND OT PRODUCING CELLS; SITES OF RELEASE (FIGS. 3 AND 4)[4,5,10,22,25]

Magnocellular neurons:[10,17,24] The SON consists almost entirely of MCN; VP neurons are mostly situated ventrally/caudally, OT neurons dorsally/rostrally. In the PVN OT, neurons are situated more rostrally, VP neurons more caudally. Other scattered MCN are found in the preoptic area, lateral hypothalamic and perifornical areas, in the subcommissural nucleus and nucleus circularis. Most MCN axons project to the NL, but have sparse collateral branches in the hypothalamus; the dendrites of both SON and PVN MCN are located close to the CSF; those from the SON in a plexus on the ventral brain surface, those from the PVN beneath the wall of the third ventricle. Although MCN were believed to produce exclusively VP or OT, most MCN produce small amounts of the other peptides even in unstimulated animals; in lactation, 17% produce large amounts of both peptides. It is now clear that MCN, like many if not all peptide-secreting neurons, also produce and copackage small amounts of many other neuropeptides (including: apelin, CCK, CRH, enkephalin, dynorphin, galanin, nesfatin, PHI, salusin β, secretin, TRH [other chapters in this volume]). The copackaged peptides exert local paracrine and autocrine actions, some of which are known.

In addition to release from their axons, MCN releases OT and VP from their dendrites and somata by calcium-dependent exocytosis. The peptides then act on local and autoreceptors and diffuse via the extracellular fluid and CSF to distant receptors—"volume transmission."[24]

Parvocellular neuroendocrine neurons: In the PVN, parvocellular neurons (PCN) predominate in the medial/caudal part. In medial PVN, CRH neurons coexpress VP when stimulated by stress/adrenalectomy. These CRH/VP neurons project to the median eminence to control pituitary corticotrophs.[28,32]

Other small VP neurons are widely distributed. A population in the shell of the suprachiasmatic nucleus (SChN) rhythmically displays clock gene expression, which is reduced in aging; they project dorsally to the PVN, DMH, POA, and caudally to the retrochiasmatic area and VMH. Other VP neurons are located in the BNST and medial amygdala (involved in aggression/fear); expression is sexually dimorphic (more VP in males); these project to the lateral septum, lateral habenula, locus coeruleus and hypothalamus. In the POA, males have less VP than females do. VP in periglomerular neurons in the olfactory bulb has been linked to social recognition.[30]

Parvocellular OT neurons in the posterior PVN project to the brainstem and spinal cord where OT is involved in erection. Other OT neurons are located in the MBH, median POA, periventricular area, and BNST. In general, OT projections are more widespread than those for VP, being found in the hypothalamus, limbic system, nucleus accumbens, central gray, with large amounts in the olfactory system and insular cortex.

In addition to these CNS sources, VP mRNA has been detected in NL pituicytes, and OT mRNA and peptide in ovarian follicles, corpora lutea, endometrium, testicular interstitial cells, and other peripheral tissues involved in reproductive functions.

RECEPTORS FOR VP AND OT; SIGNALING CASCADES (FIG. 5)[21]

Receptors for VP and OT are all members of the G protein–coupled 7-transmembrane family. As with the hormones, there is a high degree of homology of the receptors and their cis and trans control elements across species[8,11] and about one-quarter of the receptor amino acids are invariant across all VP and OT receptors. Three types of VP receptor (VR) have been identified (AVPR1a, AVPR1b (V3), and AVPR2), but only a single OT receptor (OXTR). The VP receptors are relatively specific for VP ($K_i \cong 1$ nM)

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

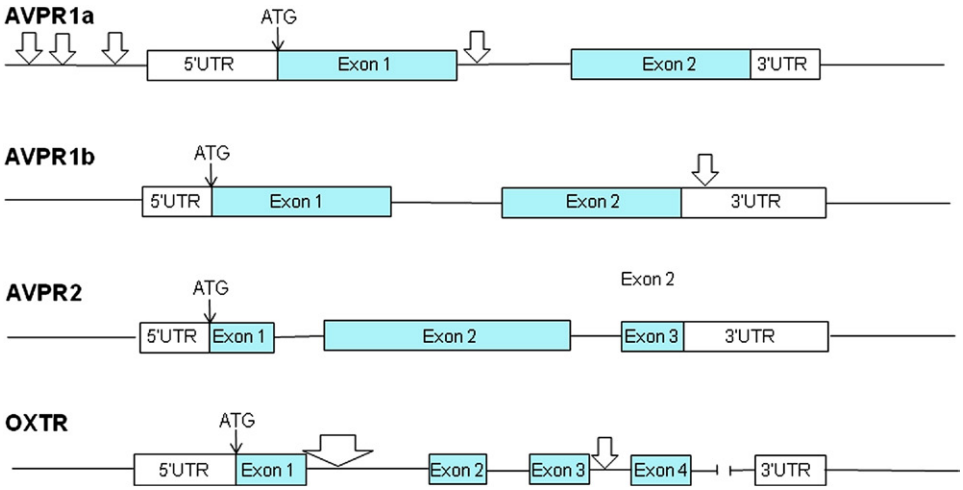

FIGURE 5 Diagrammatic structure (not to scale) of genes for the receptors for VP (AVPR1a, AVPR1b, AVPR2) and OT (OXTR). Block arrows mark the regions where microsatellites in AVPR1 and SNPs in the OXTR have been linked to autism in some studies. The block arrow in AVPR1b marks, a haplotype linked to depression (van West in Ref. 27). For the location of the numerous mutations in AVPR2 linked to nephrogenic DI, see Ref. 2.

compared with OT ($K_i > 64$ nM) whereas the OT receptor is relatively nonspecific (K_i 1 nM for OT, 16 nM for VP). The human AVPR1a is located on chromosome 12 (q14–15), AVPR1b on 1(q32), AVPR2 on the X(q28); they are, respectively, 418, 424, and 371 aa in length. The OXTR is on chromosome 3(p25.3). The genes are unusual among GPCRs in that there is an intron between transmembrane segments 6 and 7 (Fig. 5).[16]

The AVPR1a acts via $G_{q/11}$ to regulate various phospholipases (C, D, A2). It is expressed in liver, vascular smooth muscle, in most peripheral tissues that express VR, and is probably the most common VR in brain, including expression on VP MCN.[15] AVPR1b also acts via $G_{q/11}$ to stimulate PLCs; it was first identified in pituitary corticotrophs but is now known to occur in many brain regions including the VP MCNs, and in kidney, heart, lung, spleen, thymus, uterus, and breast[27] (Jard in Ref. 35). AVPR2 preferentially couples to $G\alpha_s$, stimulating adenylyl cyclase and the cAMP cascade. It is expressed only in the kidney.[2] The OXTR is also coupled via G_q to PLC-β. It is expressed in the myometrium, breast, and many other reproductive structures, including many parts of the brain with reproductive functions.[11,16] OXTR are abundant in parts of the olfactory system (anterior olfactory nucleus and tubercle (dependent on sex-steroids)), BNST, limbic system (ventral hippocampus, amygdala), neostriatum, and spinal cord (dorsal horn).[31]

There is some evidence that VPR expression can be regulated by cortisol, testosterone, and epigenetically, but OXTRs are strongly regulated by estradiol (E_2) (though they do not disappear entirely after gonadectomy) and adrenal steroids.[5] In nonexpressing tissues, OTR is constitutively repressed by hypermethylation.[7] Regulatory elements that control tissue-specific expression are present in the 5′ sequences but not yet fully elucidated.[16] On ligand binding the receptors are rapidly (5–10 min) internalized; AVPR1 but not OXTR or AVPR2 are recycled to the membrane. Homo and heterodimerization of the receptors occurs and control the amount of receptor on the cell surface. A possible direct progesterone effect on OXTR is controversial; the brain is known to produce progesterone derivatives but whether these affect OTR is not known.

BIOLOGICAL ACTIONS[21]

Systemic effects of VP and OT are well known, but evidence for actions of neurophysins and GP is lacking. Systemic VP is the main controller of body water and osmolality via AVPR2 and aquaporin 2 in the distal nephron; it is a more minor player in vascular regulation via AVPR1.[13] Pituitary portal vein VP acts in the adenohypophysis via AVPR1b to facilitate ACTH secretion. VP also acts in the liver, pancreas, adrenals, myometrium, kidney mesangium and medullary vasculature, endothelial cells, and platelets;[10] systemic OT stimulates milk ejection and myometrial contraction at term (when OXTR increases 200-fold); in fetal membranes, OT stimulates prostaglandin production near term. In the pituitary, OT influences the stress axis and, toward the end of gestation, stimulates prolactin release via E2-induced OXTR and is required for the development of the neurovascular interface.[14] In the ovary, OT stimulates follicular steroidogenesis and is luteotropic.[22] In the testis, Leydig cell–produced OT stimulates tubule movement; it also affects the prostate and epididymis where there is little evidence for OXTR. OT is produced and acts in the heart[13] and acts in the pancreas, thymus, adipocytes (where it has insulin-like actions), and adrenal.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

In the CNS, one would expect a good correlation between OT or VP receptors and axonal terminals containing the peptides, but this is often not the case. The peptides act both by axonal secretion at their synaptic targets and also by "volume transmission" after release by axons and dendrites.[23] In the SON and PVN VP inhibits VP neurons, but OT facilitates OT neuronal activity (separation of the respective MCN and bundling of OT dendrites at parturition/lactation apparently compensates for the non-selectivity of OXTR).

The distribution of OXTR and AVPR1a vary markedly.[1,11,27,31] VP and OT and their receptors are located in centers involved in osmotic and cardiovascular regulation (OVLT), median preoptic nucleus, area postrema, dorsal motor nucleus of the vagus. In the SChN and its targets, VP is involved in rhythm generation via AVPR1a and 1b. Both AVP and OT are released by noxious stimuli; in the limbic system, VP reinforces aversion-related learning and memory, whereas OT attenuates it by reducing NMDA receptor activity.

A major emphasis of research on the peptides and their receptors currently focuses on reproductive and related social behaviors such as recognition memory, pair bonding/grooming, care of offspring, maternal and male competitor aggression,[5,8,10,16,19,22,25,27,31] Although many key observations were made in animals (voles, rats, sheep) it is now becoming clear that similar effects occur in humans. Large amounts of OT are released in parturition and lactation and at orgasm. In both males and females, OT is secreted centrally in stress, activates stress-associated grooming, and has anxiolytic properties that reduce stress-activated behaviors, which might impair maternal care and pair bonding. In females, OT influences receptive (lordosis) and seems to be critical for the initiation and development of maternal behavior; in males OT causes erection.

PHYSIOLOGICAL AND PATHOLOGICAL IMPLICATIONS (SEE CHAPTERS IN CARDIOVASCULAR AND RENAL PEPTIDES SECTION OF THE BOOK)

Vasopressin. The obvious pathological conditions related to VP and its receptors are diabetes insipidus (DI) and the syndrome of inappropriate ADH secretion (SIADH) leading to hyponatremia. DI results from a lack of VP action in the kidney. Disruption of the hypothalamic–neurohypophysial system causes "central" (neurohypophyseal) DI. Causes include accidental stalk shearing, tumors, and mutations of the VP gene. In Brattleboro rats, a single base deletion in exon B causes a frameshift that prevents the mRNA being efficiently translated, and no VP is packed in LDCV. Human central DI differs and may be partial or complete. Mutations (>60 are reported) in the human VP gene are autosomal dominant or X-linked recessive; most affect the NP part of the molecule, to cause protein misfolding, dimerization, and aggregation in the rER; rare mutations involve the signal- and hormone-coding regions. Most result in progressive destruction of VP magnocellular neurons.[2]

Mutations in the AVPR2 gene (X-linked, semirecessive) or aquaporin 2 gene (autosomal dominant) cause nephrogenic (renal) DI. More than 200 mutations are known and affect all aspects of receptor function: the most common cause misfolding and retention in the rER; others cause truncation, misfolding that affects interaction with VP or with the $G\alpha_s$.[2] (In nephrogenic *di/di* mice, overactive phosphodiesterase prevents AVPR2 action, but this has not been reported in humans.)

In SIADH, plasma VP is inappropriately high for plasma osmolality. It can be caused by ectopic expression of the VP gene by carcinoma of the breast or lung, by a variety of CNS disorders with no obvious link, and by serotonin reuptake inhibitors, particularly in the elderly. Marked changes in the VP and OT neurons of the PVN and SON also occur in Alzheimer's disease.[17]

In many species, changes in central VP adjust behavior in stressful situations.[9] Overexpression can lead to hyperanxiety, whereas a deficit can reduce anxiety. Polymorphisms in the central receptors seem to reflect anxiety status.[10]

In mice, knockout of OT prevents milk ejection but not parturition. No deletions of the human OT gene have been reported. Studies across vertebrate species suggest that the distribution of central VP and OT receptors is strongly correlated with social behavior, and that deficits in bonding and social interaction which occur in many situations but particularly in autism, may reflect deficits in the function of these receptors. Variation in rat maternal care is heritable and appears to result from estrogen–OT interactions and epigenetic effects on hypothalamic estrogen receptors.[7] OXTR knockout mice do show maternal behavior deficits and autism-like behaviors.[26] Two species of voles, one promiscuous, one monogamous, show marked variation in the distribution of central OT and VP receptors. They show no difference in OT or VP neurons or in the essential structure of the receptors,[5,16] although increasing OT in the nucleus accumbens enhances partner bonding.[19] VPR1a receptor distribution may be controlled by polymorphisms in a complex 5′ DNA microsatellite.[8] Despite the lack of human data on the distribution of VP and OT receptors, there is now growing, if controversial evidence for effects of the peptides on human behavior, and for mutations and polymorphisms in their receptors in autism.[6,8,12,16,25,26,29,32] Variations in the human AVPR1a gene locus are associated with diverse social behavior including partner bonding[33] and the same locus is implicated in autism.[8] Intranasal OT can enhance "trust" between gaming competitors[20] and reduces social anxiety disorder.[16] Reduced plasma OT has been reported in autism, but this and attempts to link autism to specific genetic/epigenetic

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

effects on the receptors remain controversial. That said, there is encouraging evidence that intranasal OT can ameliorate some symptoms of autism.[6,12,16,29,34]

Space considerations preclude consideration of VP and OT agonists and antagonists, but both peptide and nonpeptide varieties are widely used both in research and treatment.

Chapter 130

Adiponectin

Frederik J. Steyn and Chen Chen

ABSTRACT

Adiponectin was isolated, and its molecular structure was identified nearly two decades ago. Although after initial observations it was hoped to characterize adiponectin as a key intermediate that signals from adiposity, recent developments clearly illustrate that the actions of adiponectin extend well beyond that of a simple indicator of adiposity. Significant progress has been made regarding the identification and characterization of adiponectin intermediates, including adiponectin receptors and binding proteins; more work is still needed to clarify the complex role of adiponectin under normal healthy and diseased conditions. This chapter provides a brief overview of the better-demonstrated aspects of adiponectin and established mechanisms underlying well-known functions of adiponectin.

DISCOVERY

Lodish and colleagues first described Adiponectin as a 30-kDA protein similar to complement factor C1q and consequently named it Acrp30 (adipocyte complement–related protein of 30 kDa).[25] Within months of this initial publication, a number of similar observations were reported.[10,18,21] These equally contributed to the identification of this adipokine, and as a result, adiponectin came to be known as Acrp30, AdipoQ, apM, or GBP28. Although the naming of adiponectin may have varied between these early discoveries, all initial observations found that the expression of adiponectin is highly specific to adipose tissue. As such, adiponectin was heralded as a key adipokine that may participate in energy homeostasis and in particular the regulation of adiposity.

THE ADIPONECTIN GENE AND PROTEIN STRUCTURE

The adiponectin gene is located on chromosome 3q27. This gene encodes a 244-amino acid protein composed of an amino-terminal signal peptide, a collagen-like domain at the N-terminus, and a globular domain at the C-terminus (Fig. 1). The globular domain is homologous to proteins such as collagens VIII and X and complement factor C1q[25] and facilitates binding to the adiponectin receptor. The N-terminal of adiponectin is structurally unique, and this collagen-like domain allows for the formation of three distinct multimer complexes of adiponectin. Hydroxylation and glycosylation of the lysine residues within the collagenous domain of adiponectin gives rise to trimers. Adiponectin trimers can associate into hexamers and high-molecular-weight (HMW) adiponectin[30] (Fig. 1). These multimers are the predominant form of circulating adiponectin and typical measures of plasma adiponectin range from 2 to 20 μg/ml[1]; however, some observations record adiponectin concentrations of up to 30 μg/ml.[7] In serum, a second version of adiponectin exists as a proteolytic fraction corresponding to the globular domain known as globular adiponectin (gAdiponectin).[8] It is believed that proteolytic cleavage of adiponectin multimers to give rise to gAdiponectin is modulated by leukocyte elastase secreted from activated monocytes and/or neutrophils.[29] Compared with full-length adiponectin multimers, gAdiponectin circulates in very small quantities (<1% total adiponectin). Although still under investigation, many observations confirm that the different multimeric forms of adiponectin may target tissues differentially.[13] For example, HMW adiponectin may be more active in the liver, whereas trimers and hexamers may act on a wider range of tissues. Tissue-specific interaction may occur in response to differential expression of adiponectin receptor subtypes, as well as local interactions with binding proteins and downstream modulators of adiponectin action.

PRODUCTION OF ADIPONECTIN

The production and release of adiponectin into circulation are not well understood. Although predominantly isolated from adipose tissue,[10,18,25] observations confirm the expression of adiponectin in many tissues including the pituitary gland, liver, diencephalon, skeletal muscle, ovary, spleen, and the kidney.[17] In human tissue, adiponectin is further expressed in bone marrow cells, osteoblasts, fetal cells, myocytes, cardiomyocytes, and epithelial cells of the salivary glands.[22] The functional significance of adiponectin expression outside of adipose tissue still remains unknown, whereas isolated

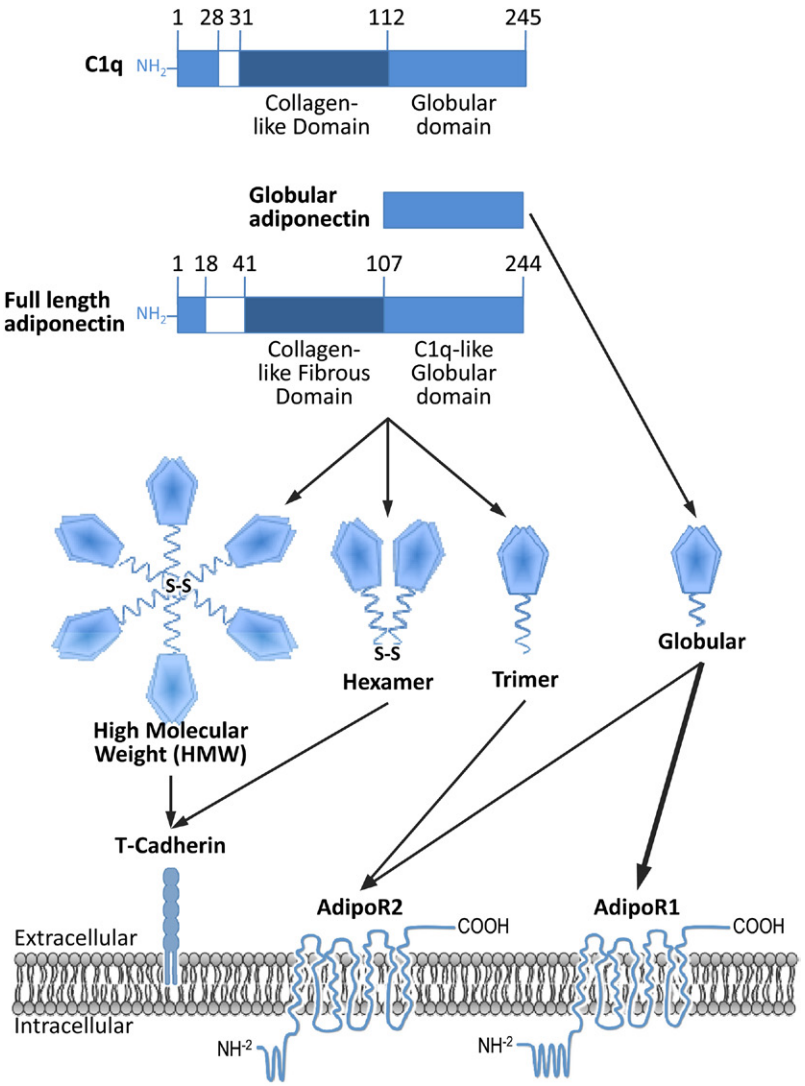

FIGURE 1 Adiponectin is a 244-amino acid protein homologous to complement factor C1q. In the circulation, adiponectin exists in globular form and as trimers, hexamers, and high-molecular-weight (HMW) adiponectin. The actions of adiponectin are mediated via binding to one of three receptors, Adiponectin receptor subtype 1 (AdipoR1), adiponectin receptor subtype 2 (AdipoR2), and T-cadherin. Globular and trimetric adiponectin interacts with AdipoR1 and AdipoR2, whereas HMW and adiponectin hexamers are believed to predominantly interact with T-cadherin.

expression in distinct cell populations suggests a possible autocrine/paracrine role.

Circulating concentrations of adiponectin may vary significantly between individuals. This reflects a large number of potential factors that may influence adiponectin production, release, and metabolism. Adiponectin concentrations in females tend to be elevated compared with that of males. Similarly, adiponectin concentrations may vary depending on nutritional and disease states.[6] Generally, unlike other adipocyte-derived hormones such as leptin, the amount of adiponectin in circulation is inversely correlated with adiposity and conditions associated with insulin resistance including cardiovascular diseases, hypertension, and metabolic syndrome.[13]

ADIPONECTIN RECEPTORS

Adiponectin signals through three distinct receptors. Of these, adiponectin receptor 1 (AdipoR1) and adiponectin receptor 2 (AdipoR2) are seven-transmembrane domain receptors. These receptors are structurally and functionally distinct from G protein-coupled receptors (GPCRs) in that the locations of their external carboxy terminus and intracellular amino terminus are reversed.[32] AdipoR1 and R2 belong to the progestin and AdipoQ receptor (PAQR) family of receptors.[28] Currently, the PAQR family consists of 11 proteins grouped into three classes based on sequence similarities. Class I is widely expressed in eukaryotes and includes AdipoR1 (PAQR1) and AdipoR2 (PAQR2). Class

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

II proteins include nonclassical receptors for progestin including mPRα (PARQ7), while members for Class III receptors (PAQR10 &11) are currently orphan receptors.[28]

Structurally, AdipoR1 and AdipoR2 share 67% protein sequence homology. The N-terminal amino acid sequence for AdipoR1 and AdipoR2 is specific for each receptor, meaning that the remainder of these proteins are highly homologous (80% homology).[13] Structural homology between species (humans and mice) is highly conserved (95% for AdipoR1 and 97% for AdipoR2). In addition to AdipoR1 and AdipoR2, adiponectin may also signal via T-cadherin.[11] This putative adiponectin receptor is a unique cadherin molecule that lacks transmembrane and cytoplasmic domains and is bound to the cell surface via a glycosylphosphatidylinositol anchor.[28] Although T-cadherin may lack an intracellular domain, and thus may not directly induce intracellular signaling, it may still mediate intracellular signaling by competing with AdipoR1 and R2 receptors. Consequently, some debate exists to suggest that T-cadherin may not necessarily exist as a functional adiponectin receptor but rather that T-cadherin acts as a functional adiponectin binding protein.[3]

Binding affinity for adiponectin trimers and gAdiponectin vary significantly between adiponectin receptors. AdipoR1 has a high binding affinity for gAdiponectin, whereas AdipoR2 will bind full-length and gAdiponectin without significant preference.[32] T-cadherin may bind hexameric or HMW forms of adiponectin with very low or no affinity for globular or trimeric forms of adiponectin (Fig. 1).

AdipoR1 and AdipoR2 are universally expressed; however, abundance of expression varies significantly among tissues. AdipoR1 is expressed predominantly in skeletal muscle, whereas AdipoR2 is expressed within skeletal muscle and liver. As with AdipoR1 and AdipoR2, T-cadherin is ubiquitously expressed; however, an abundance of expression is observed in the cardiovascular system with high levels of expression predominating in the heart, aortic, carotid, and iliac arteries and the arteries of the kidney.[14] Distribution of AdipoR1 and R2 expression within various tissues is summarized in Table 1.

ADIPONECTIN SIGNALING

Details regarding the activation of specific signaling cascades by adiponectin are still emerging. Knockout studies reveal that although both AdipoR1 and AdipoR2 are involved in energy metabolism, opposing effects are observed after deletion of either receptor. Deletion of AdipoR1 results in an obese phenotype associated with glucose intolerance and decreased energy expenditure. By contrast, deletion of AdipoR2 results in a lean phenotype associated with resistance to dietary induced obesity and increased energy expenditure.[2] Given the largely universal expression of adiponectin receptors, differential functions may therefore arise from distinct activation of intracellular signaling pathways. Indeed, observations suggest that these receptors act via distinct signaling cascades wherein AdipoR1 signals predominantly via AMP-kinase (AMPK) phosphorylation, whereas AdipoR2 actions are predominantly mediated via PPARα activation.[4]

APPL1, an Adaptor protein containing a Pleckstrin homology domain, a Phosphotyrosine domain, and a Leucine zipper motif, was recently identified as an adiponectin receptor binding protein. Current observations principally focus on potential binding interactions between AdipoR1 and APPL1. The N-terminal amino acids (4–142) of AdipoR1 interact with APPL1 to form an AdipoR1/APPL1 complex.[19] Formation of this complex is enhanced after adiponectin treatment, whereas APPL1 is abundantly expressed in mouse skeletal muscle, c2c12 myotubes and to some degree in hepatocytes.[19] It is therefore probable that the action of adiponectin in modulating glucose sensing within the muscle may occur via this adaptor/binding protein. Interestingly, APPL2 (an isoform of APPL1 that shares 54% protein homology) binds to adiponectin receptors.[20] Unlike APPL1, however, APPL2 seems to inhibit AdipoR1 dependent signaling and may form heterodimers with APPL1. Consequently, APPL2 may inhibit or downregulate AdipoR1 mediated APPL1 signaling by competing with APPL1 binding to the AdipoR and by preventing APPL1 binding through the formation of APPL1/APPL2 complexes. Interactions between adiponectin receptors and binding proteins contribute significantly toward adiponectin signaling and future clarification of these interactions will provide significant insights regarding adiponectin actions.

ADIPONECTIN AND ENERGY HOMEOSTASIS

Adipose tissue, liver, and muscle act in concert to regulate energy homeostasis. Given the predominant expression of adiponectin in adipose tissue and the abundant expression of adiponectin receptors in liver and muscle tissue, it is not surprising that the actions of adiponectin within these tissues, and regarding energy homeostasis are well studied. Here, adiponectin may serve as a key adipokine that modulated muscle and liver metabolism relative to adiposity.

Within the liver, adiponectin modulates insulin sensitivity and fatty acid flux by decreasing gluconeogenesis and free fatty acid flux into the liver, and by increasing fatty acid oxidation. In addition to these metabolic effects, adiponectin has antifibrotic actions in the liver and downregulates the expression of aldehyde oxidase, transforming growth factor and connective tissue growth factor. Furthermore, adiponectin has anti-inflammatory actions within the liver and suppresses proinflammatory cytokines

while stimulating anti-inflammatory cytokines (Reviewed in Ref. 3). Given these metabolic, antifibrotic and anti-inflammatory actions of adiponectin, a reduction in circulating concentrations of adiponectin may contribute to the development of nonalcoholic fatty liver (NAL) and nonalcoholic steatohepatitis (NAS). Although some contention remains, current opinion is that a reduction in circulating levels of adiponectin is associated with the development of nonalcoholic fatty liver disease (NAFLD). One should be careful when interpreting these observations, however, as a meta-analysis of clinical observations reveals that reduced adiponectin may contribute to the progression of NAL to NAS; however, whether an association with reduced circulating adiponectin and the development of NAFLD still remains unclear.[23] Interestingly, adiponectin prevents the development of NAFLD in ob/ob mice.[31] This effect is partly explained by improved hepatic fatty acid oxidation and a reduction in fatty acid synthesis. Therefore, although it remains unclear whether hypoadiponectinemia may contribute to the development of NAFLD, effective treatment strategies to recover liver function may include treatment with adiponectin.

As with the liver, adiponectin may target muscle tissue to regulate energy metabolism. Acting through AMPK, p38 MAPK, and PPARα, adiponectin improves lipid metabolism in muscle resulting in increased glucose use and fatty acid oxidation. In this way, adiponectin may directly contribute to glucose metabolism and improved insulin sensitivity.[3] Although many observations still focus on the potential effects of circulating adiponectin, other observations, including the work of Liu et al. clearly illustrate the functional significance of locally produced adiponectin in improving glucose uptake by muscle.[16] Liu et al. found that an increase in adiponectin message and protein within L6 muscle cells after treatment with rosiglitazone (an antidiabetic drug) is associated with an increase in insulin-induced glucose uptake.[16] Similarly, treatment with rosiglitazone in dietary induced obese mice not only corrects the expression for muscle adiponectin message and protein (HMW) but this also improves whole-body insulin sensitivity. These observations illustrate the metabolic potential of locally produced adiponectin.

The expression of adiponectin receptors within the skeletal muscle is inversely associated with insulin. Consequently, an alteration in insulin levels associated with fasting/feeding or hypoinsulinemia or hyperinsulinemia will greatly influence adiponectin sensitivity. For example, undernourishment during early development results in enhanced insulin sensitivity and fatty acid oxidation. This is associated with an increase in circulating adiponectin and the expression of AdipoR1 in skeletal muscle.[24] Although Prior and colleagues hypothesized that this increase in adiponectin and AdipoR expression in muscle may play a protective role to ensure balanced energy homeostasis after early and prolonged calorie restriction, further clarification of the role in adiponectin in improving insulin sensitivity within muscle is warranted.

ADIPONECTIN AND OBESITY

The paradoxical decrease in circulating levels of adiponectin with increased adiposity was first observed by Arita et al. in 1999.[1] They found that adiponectin is abundantly present in the plasma of nonobese subjects (ranging from 1.9 to 17.0 mg/ml). However, circulating concentrations of adiponectin decrease significantly (to <4 mg/ml on average) in obese subjects. Moreover, Arita et al. reported a negative correlation between plasma adiponectin levels and BMI in both men and women.[1] Follow-up studies reconfirmed these initial observations, and extended measures to suggest that adiponectin concentrations are determined by intraabdominal fat mass, and that additional independent effects depend on age and sex.[5] The reduction in adiponectin associated with obesity recovers after weight loss, and although this may suggest that excess adiposity directly contributes to the suppression of adiponectin, specific factors that directly contribute to decreased adiponectin in obesity remain unclear. Proposed mechanisms include a reduction in insulin-stimulated adiponectin secretion (as a consequence of insulin insensitivity), and direct suppression by TNF-α and IL-6.

It remains unclear whether suppressed levels of adiponectin are a cause or consequence of obesity. Furthermore, the negative consequences regarding altered adiponectin secretion in obesity remain unclear. Evidence implicating adiponectin in insulin-sensitizing and adiponectin's anti-inflammatory and antiatherogenic properties suggest that reduced adiponectin levels after weight gain may contribute to the development of many pathologies associated with the metabolic syndrome. Indeed, elevated concentrations of circulating adiponectin are inversely correlated with insulin resistance, the development of type-2-diabetes, dyslipidemia, and cardiovascular disease. Measures of circulating adiponectin, and in particular HMW adiponectin, may provide a suitable alternative to assess patients with metabolic syndrome-related disorders.[9]

CONCLUSIONS

Since its discovery nearly two decades ago, significant progress has been made regarding the characterization and physiological role of adiponectin. Continued efforts to elucidate signaling mechanisms in many tissues, including the liver, muscle, and adipose tissue will further clarify the physiological role of this adipokine. Although current observations suggest that altered adiponectin secretion is a

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

key factor that contributes to the onset of pathologies associated with excessive weight gain and obesity (including the development of insulin insensitivity), significant work is still needed to determine whether altered secretion of adiponectin is simply a by-product of obesity, or whether this directly contributes to obesity-associated pathologies. Given the abundant expression of adiponectin receptors throughout the body, additional observations investigating the impact of metabolic disorders on adiponectin secretion and actions may identify additional roles for adiponectin in contributing to normal physiology and the impact of altered adiponectin secretion on developing pathology. Consequently, the physiological role adiponectin in healthy physiology will become better defined. These observations are necessary if we are to understand the physiological functions of adiponectin as an antiatherogenic, anti-inflammatory, and antidiabetic adipokine, and the role of adiponectin in contributing to the development or treatment of cancer and NAFLD.

Chapter 131

Adrenomedullin Peptides

Josune García-Sanmartín, Ignacio M. Larráyoz, Laura Ochoa-Callejero and Alfredo Martínez

ABSTRACT

Adrenomedullin (AM) is a 52-amino acid regulatory peptide that is expressed in many organs of the body, including the endocrine glands. Pituitary, adrenals, pancreas, gonads, and some other endocrine organs produce AM and its related peptides (PAMP and AM-2) and have the receptors and/or binding sites for these molecules, suggesting the existence of autocrine and paracrine loops within these organs. This family of peptides influences the secretion of several hormones such as ACTH, aldosterone, corticosterone, catecholamines, insulin, progesterone, and testosterone. The gland architecture is also relevant in understanding local regulation: where is the peptide expressed, what is the direction of blood flow inside the gland, and where are the receptors and binding proteins located with respect to the peptide secretion site. New tools are being developed that may be very helpful in the near future to better understand the local regulation of endocrine physiology through AM and related peptides.

INTRODUCTION

Most peptide hormones are secreted by particular cells and travel through the organism till they find their specific membrane receptors to elicit physiological actions. Depending on how far the receptors are from the secretory cell, classically, we talk about endocrine, paracrine, or autocrine modes of action. Adrenomedullin (AM) and proadrenomedullin N-terminal 20-peptide (PAMP) are not an exception to this rule, and numerous examples can be found where these peptides act at different distances from their point of origin.[12] Nevertheless, at some point in the history of AM, several authors have expressed their doubts on the true endocrine nature of AM. These opinions were based on the extremely low levels of the peptide that were found in the blood stream (between 2 and 20 pmol/liter in humans), which were not enough to activate the AM receptors (discussed elsewhere in this book) with dissociation constants of about 2–3 nM. It was the discovery of a tremendously abundant binding protein in the plasma that recovered the status of AM as a potential endocrine factor. This binding protein, identified as complement factor H,[25] circulates in the blood at extremely high concentrations (~500 μg/ml), has at least 2 different binding sites for AM, and prevents bound AM from being quantified in radioimmunoassays. Therefore, all the studies in which AM levels have been quantified in the past represent gross underestimations of the actual AM values. Unfortunately, a reliable method for quantifying total AM is not yet available. Moreover, the most physiologically relevant pool of AM could be the one that is bound to factor H rather than the free peptide, because the binding protein protects the peptide from protease degradation but does not interfere with the binding of the peptide to its receptor.[25]

But, unlike most peptides, AM and PAMP also have intracellular properties. These peptide hormones bind to the cytoskeleton (Fig. 1), either to the tubulin dimer itself (PAMP) or to microtubule-associated proteins (AM). In the case of PAMP, the binding to the microtubules results in a delayed polymerization of tubulin, thus producing a more plastic cytoskeleton. When the gene that codes for both AM and PAMP is downregulated through siRNA or gene targeting, the cytoskeleton acquires a hyperpolymerized state, and the cells show defects on cell cycle regulation and motility capabilities.[27] Interestingly, this association with the cytoskeleton seems to occur predominantly in nonendocrine cells, such as neurons or epithelial cells. By contrast, in classical endocrine cells, AM and PAMP are located in the secretory granules.[21] Hopefully, after the recent publication of the three-dimensional structures of PAMP and AM,[24] it will be possible to investigate the interactions of the peptides with the components of the cytoskeleton.

Another protein, named AM-2 or intermedin, displays a high homology to AM but is coded by a different gene. Although most of its actions seem to be homologous to those of AM, there are areas where differences have been described.[32]

Regardless, all authors agree on the great potential of AM-related peptides in local regulation. In this chapter, the physiological regulation of the main endocrine organs by these peptides is reviewed.

PITUITARY

AM, PAMP, and AM-2 are expressed in all components of the hypothalamic–pituitary–adrenal (HPA) axis.[32] Immunohistochemical studies have shown a diffuse staining in all cells of the anterior pituitary for both AM and AM-2, whereas PAMP was restricted to the FSH-expressing gonadotrophs. This lack of overlapping colocalization between AM and PAMP, two peptides produced by the same prohormone, has been observed in several locations and may be explained by an alternative splicing mechanism. Immunohistochemical results were confirmed by RIA quantification and gene expression studies, which showed higher levels of AM in the pituitary than in the brain.

Several studies have looked into the functional roles of AM-related peptides in pituitary physiology. The addition of AM to dispersed cells of the anterior pituitary results in a dose-dependent decrease in the secretion of ACTH and an increase on prolactin and GH.[9,29] AM-2 presents a different pattern than AM on the regulation of pituitary hormone secretion. On the one hand, AM-2 increases prolactin secretion as does AM but, on the other hand, it increases ACTH and decreases GH in clear contrast with AM.[32] For the effects of PAMP, we find two studies with opposite results; the first one found that PAMP reduced ACTH secretion,[29] whereas the second report found an increase of this hormone after injection of PAMP in the rat.[14] Perhaps this discrepancy may be explained due to the different approaches of both teams; the first group was working on dispersed pituitary cells in culture, whereas the second was using the complete animal, so all the regulatory elements, external to the pituitary, were in place.

No formal studies on AM receptors in the pituitary are available, although binding sites have been reported. Interestingly, however, female mice lacking one allele for the AM receptor component RAMP2 exhibit enlarged pituitaries and hyperprolactinemia,[8] suggesting important roles for this receptor in pituitary physiology.

The HPA axis is involved in the regulation of the stress response, and AM-related peptides seem to be part of this system, as well. Several situations of experimental and clinical stress induce an increase of the expression of these peptides and, conversely, the deletion of the AM gene resulted in an excessive stress response,[4] suggesting that AM is part of a defensive mechanism against stress.

ADRENALS

AM was initially isolated from a pheochromocytoma, a tumor of the adrenal medulla. The peptide and its mRNA have been found in both compartments of the adrenals, with higher expression in the medulla. In the cortex, AM is highly expressed by the zona glomerulosa and, at lower levels, by the zona fasciculata and reticularis (Fig. 2). A similar distribution has been reported for AM-2.[23] These peptides are costored with catecholamines in the secretory granules of chromaffin cells and are cosecreted with them on activation of these cells.

Binding sites for AM and PAMP have been found throughout the adrenals, and the components of the AM receptors share a common distribution with that of the ligands, suggesting the existence of autocrine and/or paracrine mechanisms in the regulation of the effects mediated by such peptides. Two types of functional effects mediated by peptides of the AM family have been studied in the adrenals: regulation of the secretion of adrenal hormones and growth effects during experimental regeneration of the gland.

The main hormone secreted by the zona glomerulosa is aldosterone, and there are contradictory reports on whether AM and PAMP induce or inhibit aldosterone secretion in the adrenal cortex. In support of an inhibitory function, AM has been shown to decrease the induction of aldosterone secretion elicited by angiotensin II, KCl, and ACTH.[28] PAMP has also been described as an inhibitor of aldosterone secretion, being more potent than AM. This view is also supported by more recent studies using antisense approaches.[26] On the other hand, there are several reports of a stimulating role for both AM and PAMP.[7] This controversy was difficult to reconcile until we realized that different methods were used in these studies. When isolated cells are used, they contain the receptors, but they lack all other environmental cues such as local paracrine effects, which are present in perfusion studies or in *in vivo* models. For instance, in dispersed cell preparations, if there is a mixture of cortical and medullary cells, AM can induce catecholamine release from the chromaffin cells which, in turn, can enhance aldosterone secretion from cells belonging to the zona glomerulosa. All these studies coincide in pointing to AM and PAMP as important autocrine and/or paracrine players in the regulation of aldosterone.

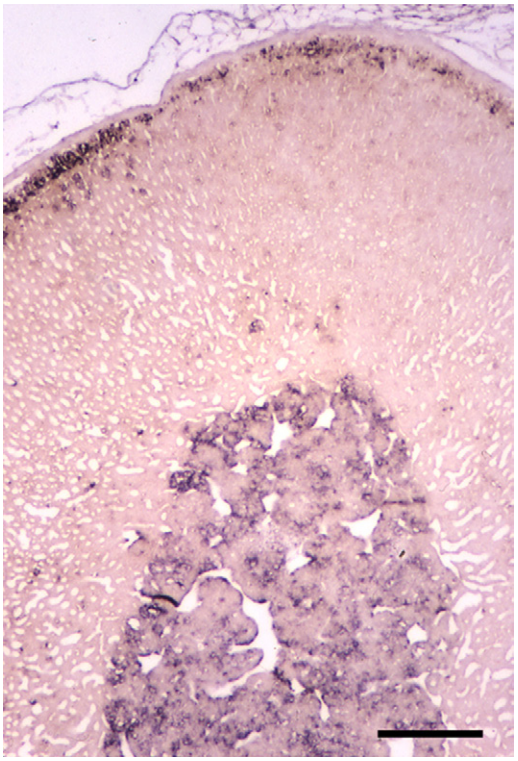

FIGURE 2 Distribution of proadrenomedullin mRNA in a section of rat adrenal gland by in situ hybridization. Proadrenomedullin expression is highest in the medulla and in the zona glomerulosa of the cortex. Bar = 150 μm. See color plate 38.

In the adrenal medulla, AM increases catecholamine release by stimulating Na^+/Ca^{2+} exchange in the membrane of the chromaffin cells whereas PAMP has the reverse effect.[22] Because both AM and PAMP are cosecreted with catecholamines from the chromaffin cells, PAMP would exert an autocrine feedback mechanism on chromaffin cell secretion, whereas AM would tend to multiply the initial secretory stimulus. Nevertheless, AM has been shown to reduce tyrosine hydroxylase activity,[35] so, in the long run, AM may be also part of the negative feedback loop. No studies are as yet available for the effects of AM-2 on the secretion regulation of adrenal hormones.

Enucleation of the adrenal gland provides a good model to study organ regeneration and cell proliferation *in vivo*. During regeneration of the medulla, it has been shown that the levels of AM and its receptor components, especially RAMP2, experiment a marked increase. In this context, AM increases proliferation and reduces apoptosis,[26] in a similar manner to its functions in tumor cells (which are discussed in the Cancer/Anticancer section of this book).

ENDOCRINE PANCREAS

AM has been found in the endocrine pancreas of all vertebrates, from fish all the way to humans. In lower vertebrates, AM colocalizes with all pancreatic hormones in a complex pattern, but in birds and mammals, the cells expressing high levels of AM are exclusively the F cells, which also produce pancreatic polypeptide in the periphery of the islets of Langerhans.[21] This phylogenetic variation is recapitulated during ontogenesis. In early embryos, when the pancreatic bud is being formed, AM expression is already present and colocalizes with all other pancreatic hormones. As the organ matures, AM colocalization pattern is progressively restricted until it reaches its final location just in the F cells.[18]

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

The AM receptor and binding protein, complement factor H, are expressed by the β-cells that synthesize insulin in the center of the islet.[20] This architecture and the fact that blood flow in the islet goes from the periphery to the center suggests a clear anatomical model for local regulation of pancreatic physiology through AM. Indeed, AM has been shown to reduce insulin secretion when applied to isolated islets. Even more impressive is the observation that the application of a monoclonal antibody against AM to isolated islets increased insulin secretion fivefold, demonstrating that AM exerts a tonic inhibition on insulin secretion under normal conditions.[21] This was later confirmed on isolated β-cells in culture.[30] This physiological effect of AM was also shown *in vivo*. Injection of AM in rats increased circulating glucose levels whereas the monoclonal antibody reduced these levels.[19]

As expected from the close relationship that exists between β-cell function and metabolic diseases such as diabetes, obesity, or metabolic syndrome, important variations of AM levels have been reported in such patients. The levels of circulating AM are always higher in patients than in normal controls, and patients with symptoms of advanced disease such as retinopathy, microvascular, or renal complications present even higher levels than do patients without these complications.[1] Based on these observations, some authors have proposed that increasing AM levels are just a consequence of endothelial degeneration, something that occurs late in the natural history of diabetes and other metabolic conditions. Nevertheless, analysis of two populations of patients with a very recent onset of diabetes revealed the existence of two subsets of patients, depending on their AM levels. All diabetic patients had a higher concentration of AM than normal controls did, but some of the diabetic patients exhibited an exceedingly high concentration of AM. In these patients, preexisting excessive AM may have triggered the onset of the disease.[19]

Type-2 diabetes is characterized by a secretory defect at the islet of Langerhans and also by desensitization of peripheral tissues to insulin action. AM seems to play a role at both ends. On the one hand, an excess of AM reduces insulin secretion at the islet level. On the other hand, it has been shown that mice haploinsufficient for AM have increased insulin resistance when compared with that of normal controls.[31]

AM is also involved in adipogenesis. AM delays adipocyte differentiation and insulin reduces AM expression in these cells. Furthermore, in obese patients, AM plasma levels are negatively correlated with insulin levels and always elevated when compared with that of lean controls,[6] suggesting that AM may play an important role in the relationship between diabetes, obesity, and other metabolic conditions.

No information is available on the effects of either PAMP or AM-2 on pancreatic physiology.

DIFFUSE ENDOCRINE SYSTEM OF THE GUT

The diffuse endocrine system consists of a variety of individual cells with secretory endocrine morphology that appear scattered among other epithelial cells throughout the digestive tract. These cells act as chemo and mechanoreceptors of the conditions occurring in the gut and release their secretory peptides to neighboring cells to regulate digestive physiology (Fig. 3). Both AM and PAMP have been found in the secretory granules of a subset of these cells, colocalizing with serotonin and gastrin. The number of PAMP-positive cells in the gut, including the stomach and the small and large intestines, seems to be higher than the number of AM-immunoreactive cells.

The levels of AM increase in pathological situations such as gastric ulcers, microbial infection, colitis or even after chronic starvation,[15] suggesting that AM may constitute in the gut, as it does in other organs, a protective system that maintains homeostasis.

Studying the function of the diffuse endocrine system has always been complex given the dispersion of the cells that constitute the system and the paracrine mechanism of action. This is particularly complicated when we realize that there is another source of AM and PAMP in the gut, namely the parasympathetic nervous system which innervates the smooth muscle layers, the blood vessels, and even the epithelium. Nevertheless, several functions have been ascribed to AM and PAMP that relate to digestive physiology. In most cases, these actions can be better understood from a local perspective rather than involving a bona fide endocrine mechanism. For instance, AM increases somatostatin secretion in the stomach and, probably as a direct consequence, decreases histamine and acid secretion. Both AM and PAMP influence the intestinal absorption of sugars. In addition, AM stabilizes epithelial barrier function in the gut,[34] thus contributing to the well-known protective effect of AM

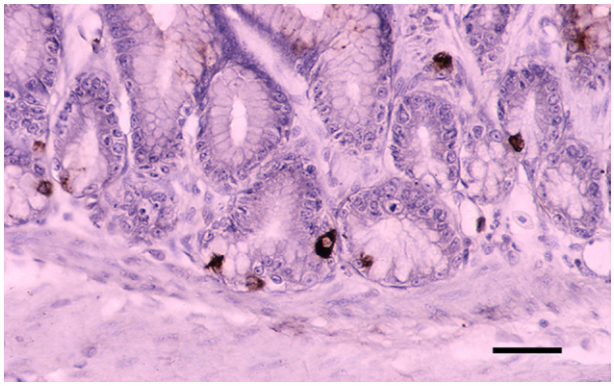

FIGURE 3 Paraffin section of the stomach of the lizard *Anolis sagrei*, stained for PAMP. Note the numerous PAMP-positive cells belonging to the diffuse endocrine system located in the deep portion of the gastric glands. Hematoxylin was used to provide nuclear counterstaining (blue). This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

against stomach ulcers, colitis, and other inflammatory conditions of the gut. Interestingly, some of these effects may be mediated by the impact of AM on the regulation of the hypoxia inducible factor (HIF) system.[13]

OTHER ENDOCRINE ORGANS

AM and its receptor components have been found in the ovary, mainly in the granulosa and thecal layers of the follicles and in the corpora lutea. In the follicles, treatment with AM increases estradiol production but does not affect follicular growth or ovulation rate. In the corpora lutea, AM affects progesterone production in a pregnancy-stage dependent manner, being inhibitory at early and late pregnancy but stimulatory at midpregnancy. Therefore, AM may contribute to the high levels of progesterone that are produced at mid gestation by the corpora lutea.[11] Plasma AM levels change during the human menstrual cycle in a profile similar to the one displayed by luteinizing hormone. AM concentrations inside the follicular fluid correlate negatively with the success of *in vitro* fertilization techniques.[17]

The testis is another organ where AM and its receptors are produced, and they play an important autocrine/paracrine role in the physiology of the organ. AM and the receptor components can be mainly located in Leydig and Sertoli cells. The levels of AM in the seminal plasma are 8- to 9-fold higher than in circulating plasma and correlate with sperm motility.[16] AM has a clear autocrine effect on Leydig cell steroidogenesis by reducing testosterone production.[3] In the Sertoli cells, AM increases inhibin B production, thus having a direct effect on regulating spermatogenesis.[2] In addition, AM levels in the rat testis increase with age.

AM is also present in the thyroid, in both the follicular epithelium and the C-cells, colocalizing with calcitonin (Fig. 4). No specific action has been reported for AM in this gland, but the peptide fragment PAMP(12–20) decreases thyroid-stimulating hormone (TSH) levels and epithelium/colloid ratio in the rat thyroid gland.[5] AM and PAMP levels are increased in animal models and in patients with hyperthyroidism,[33] but the implications of these peptides in the pathophysiology of this disease are not yet clear. AM is also elevated in patients with hyperparathyroidism, where it is mainly produced by the chief cells, although the peptide is not expressed at all by the normal gland.[10]

CONCLUSIONS

AM and PAMP are expressed by many endocrine organs and constitute important regulators of local physiology in these places. To study local functions of these peptides, it may be helpful to use genetically modified mouse models. It is well known that the systemic elimination of either the gene coding for AM/PAMP or for the different components of the AM receptor result in embryo lethality,[8] hence the need for conditional constructs. "Floxed" models are already available for AM,[4] but they have not been specifically targeted to endocrine organs yet. Hopefully, in the near future, these conditional models may help in unraveling the local contributions of AM-related peptides with more detail.

Chapter 132

Ghrelin

Marcos C. Carreira, Ana B. Crujeiras and Felipe F. Casanueva

ABSTRACT

Ghrelin, the endogenous ligand of the growth hormone (GH) secretagog (GHS) receptor (GHS-R), is a 28 amino acid peptide originally isolated from the stomach with GH-releasing and appetite-inducing activities. During the years after its discovery, ghrelin and its receptor have also been detected in other organs, including hypothalamus, pituitary, thyroid, parathyroid, pancreas, adrenal glands, placenta, male and female gonads, and almost every other normal human tissue studied. In addition, it is present in neuroendocrine, pituitary, pancreatic, and thyroid tumors. Thus, ghrelin is involved in many processes, and its endocrine, paracrine, and autocrine effects play an important role in physiological and pathophysiological functions.

INTRODUCTION

Ghrelin is a ubiquitously expressed hormone, which since it was discovered has been proposed as a much-needed therapeutic option for several diseases. This is because of its endocrine, cardiovascular, immunological, reproductive, and behavioral effects that have been described based on the expression of ghrelin and its receptor in a wide variety of tissues.[6,23,32]

This hormone was originally discovered as a strong GH-releasing activity mediated by the activation of GH secretagog receptor type 1a (GHS-R1a). The human GHS-R1a is a G protein-coupled receptor of seven transmembrane domains and 366 amino acids, which transduce information provided by ghrelin.[23] This receptor is mainly expressed in central neuroendocrine tissues. However, a widespread pattern of GHS-R1a expression is observed in a variety of peripheral tissues including the thyroid gland, pancreas, spleen, myocardium, adrenal gland, testis, ovaries, and stomach.[20] The peripheral distribution suggests that ghrelin is involved in functions in addition to the regulation of GH release and energy homeostasis.[20] Moreover, according to the role of ghrelin in regulating proliferation in some tumors, GHSR-1a is expressed in a wide variety of cancers including neuroendocrine cancers, breast carcinomas, prostate cancer cell lines, neoplastic thyroid tissue, and ovarian tumors.[6,23,32]

After the binding of ghrelin, GHS-R1a acts through the G α11 subunit of G protein to activate PLC resulting in the hydrolysis of membrane-bound phosphatidylinositol biphosphate (PIP2) to generate inositol triphosphate (IP3) and diacylglycerol (DAG). Intracellular calcium concentration increases result from the release from IP3-responsive cytoplasmatic storage pools and inflow of Ca^{2+} through the activation of L-type calcium channels (Fig. 1). It has been proposed that GHRH interacts directly with GHS-R1a and modifies the ghrelin-associated intracellular signaling pathway. This interaction may represents a new form of regulation, which could plays a role in the physiology of GH regulation and appetite control.[5]

Ghrelin is derived from the ghrelin gene, which produces three peptides by a posttranslational mechanism (Fig. 2). The ghrelin mature molecule, a 28 amino acid residue peptide, is obtained from the proteolytic cleavage of preproghrelin and exists in two major molecular forms, acylated ghrelin and unacylated ghrelin. The acylation, catalyzed by the ghrelin O-acyltransferase (GOAT)[19,34] occurs on the third residue (Ser) and is essential for its functional activity through GHS-R1a.[19] Ghrelin seems to be the sole substrate for GOAT. Expression of GOAT is limited to the major ghrelin-secreting tissues as gastrointestinal tract, intestine, testis, and pancreas.[19,34]

Unacylated ghrelin (UAG) was initially believed to be nonfunctional but has subsequently been proven to exert biological activities, some of which are similar to ghrelin and others divergent. Both ghrelin and unacylated ghrelin exert functions in cells and tissues that do not express the GHS-R1a receptor involving the existence of an unidentified receptor.[23,32]

The third ghrelin gene product is obestatin (OB), a 23 amino acid amidated peptide derived from the preproghrelin gene.[35] See the obestatin chapter in the Gastrointestinal Peptides section of this book. It was originally believed that obestatin binds to the G protein-associated receptor GPR 39 and postulated as a physiological opponent of ghrelin inhibiting food intake.[35] However, currently, the effects of this peptide on food intake remain unclear. In addition, obestatin is able to produce several biological functions

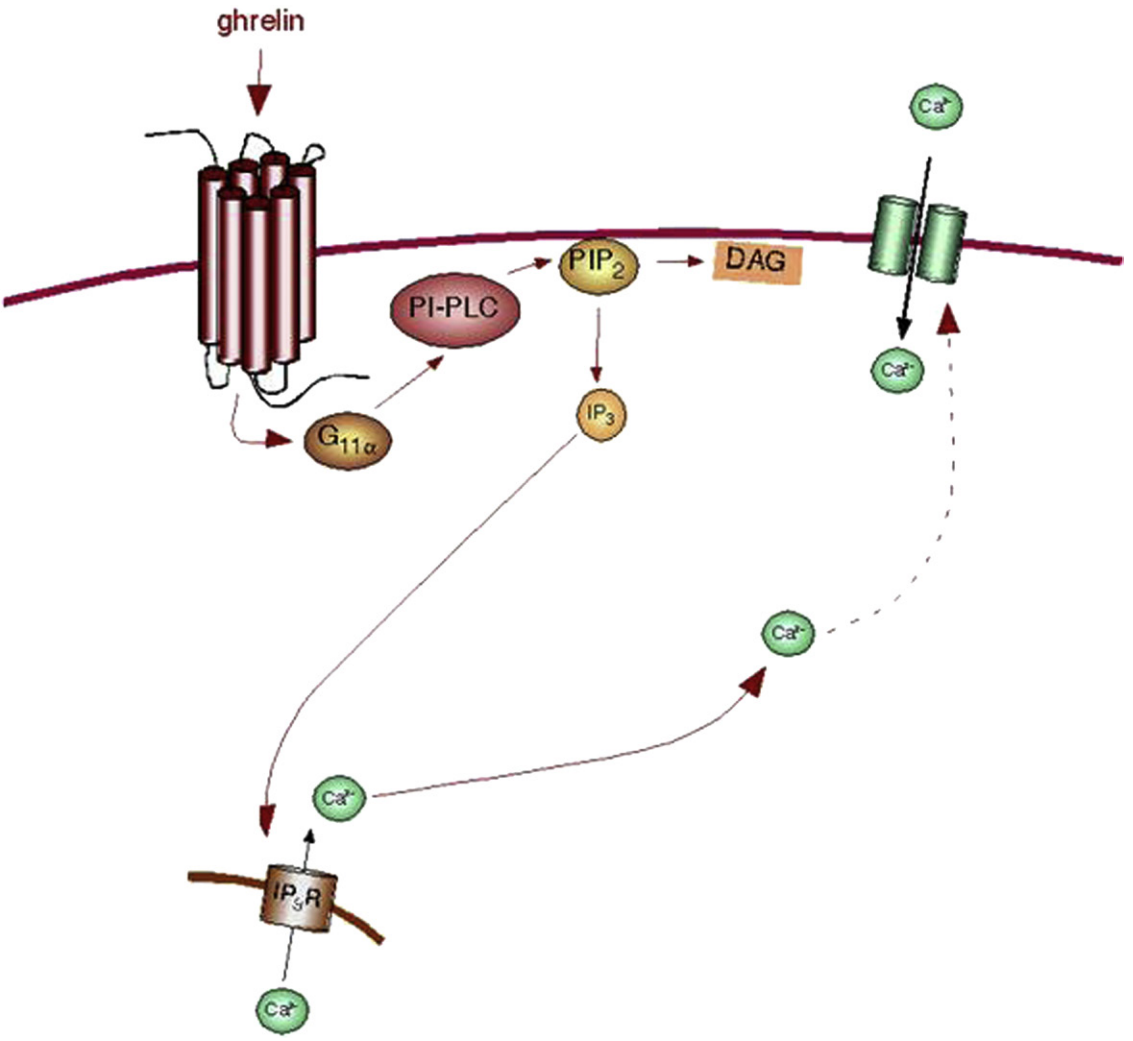

FIGURE 1 Proposed model of the signal transduction pathway activated by the GHS-R1a receptor to elicit intracellular calcium peak.

at the central level such as improving memory, anxiolytic effects, and activation of cortical neurons, and it also has peripheral effects. At the cellular level, obestatin stimulates GH release from rat tumor somatotroph cells[25] and regulates adipocyte metabolism and adipogenesis.[18]

Ghrelin is predominantly produced and secreted by the stomach and in lower amounts in bowel, kidney, pancreas, lung, immune system, placenta, tested, thyroid, hypothalamus, and pitutitary.[23,32]

It was primarily postulated that the main function of ghrelin is to regulate appetite and energy homeostasis by an endocrine or a paracrine signal directly at the stomach level and to activate specific neuronal circuits situated in the hypothalamus although the activation of the afferent vagal nervous system has been proposed.[23,32] However, the coexpression of ghrelin and the functional ghrelin receptor shows that ghrelin has direct effects on several organs and is involved in many more processes than was initially postulated. In this context, this chapter reports the direct effect of ghrelin, and some effects of desacyl ghrelin and obestatin on different endocrine organs at physiological and pathophysiological levels.

GHRELIN SYSTEM IN THE PITUITARY

In addition to the probable hypothalamic effects of ghrelin, this peptide is synthesized locally within the pituitary gland where ghrelin immunostaining is colocalized to prolactin, GH, and TSH secreting cells but not to ACTH or gonadotroph-secreting cells. Thus, within the pituitary gland, ghrelin may influence the release of GH in an autocrine or paracrine manner. GH secretion is pulsatile and, classically, it was believed to be controlled by GHRH and somatostatin, but several studies suggested that other factors play a

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

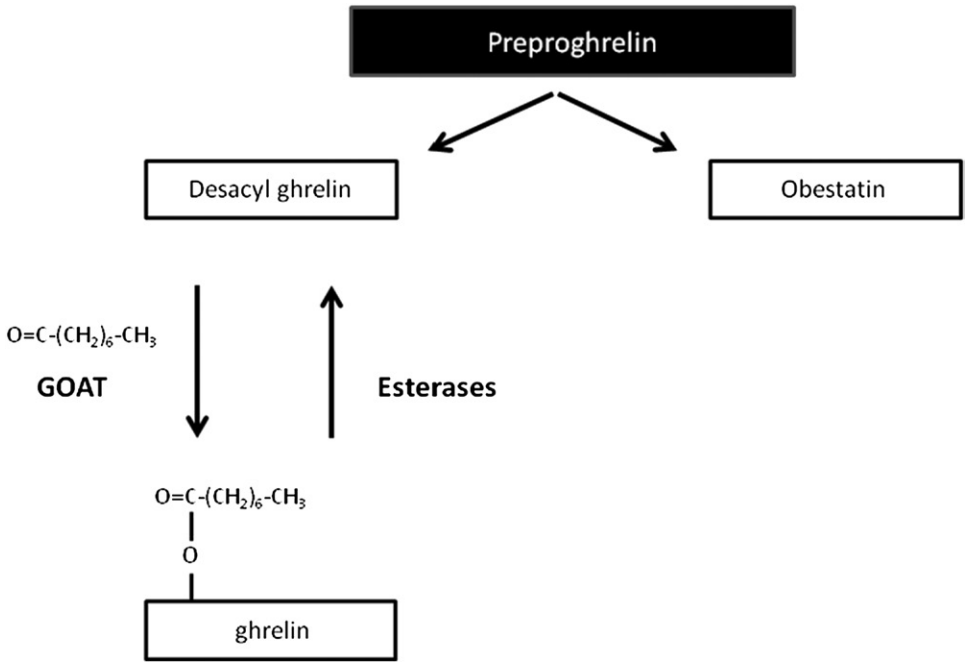

FIGURE 2 Production of the three ghrelin gene products.

role in the regulation of GH release from the pituitary. In accordance with the identification of ghrelin as the endogenous ligand for the GH hormone secretagogue receptor, the initial studies with exogenous synthetic GH secretagogs and ghrelin have shown a strong and dose-dependent GH releasing effect, but the physiological role of ghrelin in the regulation of GH release is still uncertain.

It has been proposed that ghrelin releases GH by a dual mechanism involving the hypothalamus and the pituitary. The effect of ghrelin *in vivo* is stronger than the *in vitro* effect, and it is dependent on the presence of GHRH. In addition, ghrelin shows an additive or a synergistic effect on GHRH stimulated GH release and prevents the cyclic refractoriness to GHRH. The ghrelin effect is markedly reduced, but not totally abolished, in animals with a lesion of the pituitary stalk, suggesting that the most important action of ghrelin to release GH occurs at the hypothalamic level.[6,23,32]

At the hypothalamic level, ghrelin acts via GHRH-secreting neurons because immunization against GHRH or treatment with GHRH antagonists reduces its stimulatory effect on GH secretion. *In vivo* studies have shown an increase release of GHRH in portal blood of the pituitary after synthetic secretagogue administration. In the lit/lit mouse, which has nonfunctional pituitary GHRH receptors, GHS has no effect on GH release. In humans with GHRH receptor mutations, a very small but significant GH response is observed.[23,32] Peripheral or central administration of ghrelin stimulates hypothalamic GHS-R1a and the pituitary receptor directly to release GH. In contrast, some results indicate that peripheral ghrelin stimulates GH release and feeding via a vagus nerve-mediated abdominal action.[8]

The expression of ghrelin in the pituitary in male and female rats is higher during ontogeny and decreases during development in females, whereas in males, there is no variation during development. This pattern of expression is contrary to that observed in the stomach where ghrelin expression occurs in the fetus and increases after birth in an age-dependent manner.[23,32] Ghrelin is expressed in somatotrophs, lactotrophs, and thyrotrophs. Given that GHS-R1a is also expressed in the pituitary, the possibility exists that locally produced ghrelin in the pituitary may have paracrine or autocrine effects on pituitary function. In fact, under experimental conditions in which hypothalamic GHRH expression is increased (GH or glucocorticoid deficiency, hypothyroidism), pituitary ghrelin levels are also increased.[23,32] Consistent with this correlation, pituitary ghrelin expression levels are decreased in conditions in which hypothalamic GHRH expression is decreased, indicating a physiological role of GHRH in stimulating pituitary ghrelin expression.[23,32] Another source of ghrelin is the hypothalamus, although it is not clear that ghrelin-produced neurons project to GHRH and somatostatin neurons. In addition, GHS-R antisense transgenic animals have much less GHS-R expression but maintain typical pulsatile GH secretion and IGF-1 levels.[23,32] Moreover, a direct interaction occurs between the GHRH-R and the GHS-R in the pituitary somatotroph.[7]

Based on its strong and reproducible GH-releasing effect, particularly when combined with GHRH, ghrelin

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

can be used as a diagnostic tool in suspected GH deficiency. Ghrelin when administrated together with GHRH exerts a synergistic action on GH secretion. This combination is the most potent GH releaser.[6,23,32] Clinical studies have demonstrated that ghrelin–GHRH administration may be considered a test of GH reserve in humans because the GH response elicited is not altered by gender, age, or adiposity. This test is able to discriminate between healthy subjects and patients with GH deficiency. In this condition, the somatotroph response to ghrelin is reduced, whereas the lactotroph and corticotroph response is fully preserved.[6,23,32] These results suggest that ghrelin may represent a reliable test to evaluate the maximal secretory capacity although they do not support the idea that impaired ghrelin response is the major cause of GH deficiency.

Moreover, it has been proposed that ghrelin rejuvenates the GH/IGF-1 axis with possible clinical applications for the treatment of aging. Chronic administration of ghrelin is able to increase the low GH levels associated with aging.[23,32]

In addition to its regulatory role on GH secretion, *in vivo* ghrelin induces a significant secretion of prolactin and ACTH/cortisol without significantly altering the release of LH, FSH, and TSH.[23,32]

The mechanisms of adrenocorticotropin regulation by ghrelin may include hypothalamic involvement through the release of CRH, arginine vasopressin, and NPY and/or gamma-aminobutyric acid (GABA).[23,32]

It is possible that ghrelin exerts other effects on somatotroph cell function independently of GH release. Ghrelin influences the expression of the transcription factor Pit-1 through a sequence that contains two cAMP response element.[6,23,32]

Both ghrelin and GHS-R1a receptor, as well as the isoform GHS-R1b obtained by alternative splicing, are expressed in normal human pituitaries and adenomas.[6,23,32] Ghrelin mRNA is expressed at relatively low levels in corticotroph adenomas and relatively high levels in somatotroph adenomas in comparison with normal pituitaries as this expression pattern correlates with the expression of Pit-1.[23,32] GHS-R is expressed in somatotrophinomas, prolactinomas, thyrotropinomas, and some corticotroph adenomas.[24] The presence of ghrelin and GHS-R in pituitary adenomas indicates that adenoma-produced ghrelin may contribute to the development of adenoma cells through an autocrine/paracrine mechanism.

GHRELIN SYSTEM AND THYROID GLAND

Hormones of the hypothalamus-pituitary-thyroid (HPT) axis are involved in energy homeostasis and body weight as well as in the maintaining of body temperature. This axis stimulates the metabolic rate of tissues such as the heart, bone, liver, adipose tissue, and muscle, increasing thermogenesis as well as energy expenditure. As is well known, hyperthyroidism is associated with weight loss and increased body temperature, whereas hypothyroidism is associated with weight gain and lower temperature.

Ghrelin is present in human thyroid tissue. Fetal, but not adult thyrocytes, present significant amounts of ghrelin suggesting that follicular cells are an additional source of ghrelin during thyroid development.[6,23,32]

Ghrelin binding sites have however been detected in the human thyroid, and ghrelin enhances *in vitro* TSH-mediated proliferation of rat thyrocytes and diminished cell proliferation in human thyroid carcinoma cells. It has been suggested that ghrelin affects the HPT axis in humans by direct action over the thyroid by increasing the levels of free thyroxine and decreasing TSH concentrations in plasma.[6,23,32]

The intracerebroventricular administration of ghrelin reduces the size of pituitary TSH-producing cells and TSH plasma concentrations, resulting in less active thyroid follicles and reduced plasma thyroxine (T4) concentrations. Hyperthyroidism is also associated with decreased ghrelin levels and becomes normalized by antithyroid treatment. In addition, ghrelin levels in hypothyroidism are similar to those of healthy subjects, although in animal models ghrelin is increased.

It has been suggested that ghrelin plays an important role in the generation and development of thyroid tumors. It is expressed in malignant epithelial carcinomas, but not in benign cases, suggesting the involvement of ghrelin in the development of thyroid epithelial carcinomas. Both follicular and papillary carcinomas show intense levels of ghrelin expression.[6,23,32] The high proportion of adenomas containing high levels of ghrelin suggests that neoplastic transformation involves the expression or reexpression of ghrelin. No apparent differences in ghrelin expression were observed in thyroid tumors despite tumor grade and differentiation, indicating that ghrelin does not play an important role in tumor progression. Interestingly, high concentrations of ghrelin has antiproliferative properties in thyroid carcinoma cell lines, suggesting that an autocrine mechanism is involved in control of the growth of follicular tumors.[6,23,32]

GHRELIN SYSTEM IN THE PARATHYROID GLAND

Rat and human parathyroid glands present an intense and diffuse cytoplasmic distribution of immunoreactivity for ghrelin.[24] Given the antiproliferative actions of ghrelin in the thyroid and different thyroid cell lines, it is possible that ghrelin could also be involved in the inhibition of the proliferation of parathyroid in both normal and tumor cells. However, specific binding of the radiolabeled synthetic secretagogue hexarelin to membranes from the parathyroid gland is negligible.[27] The parathyroid adenomas are diffusely positive for ghrelin.[24] Ghrelin expression in the

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

parathyroid gland indicates the existence of an additional source of ghrelin in this gland involved in autocrine regulation of parathyroid cell function.

GHRELIN SYSTEM IN THE TESTIS AND OVARY

Evidence suggests that ghrelin and its functional receptor are expressed in mammalian testis and ovaries, where ghrelin may have specific regulatory actions. Thus, ghrelin may participate in the regulation of gonadotropin secretion, and it may influence the timing of puberty.[12] In addition, it has been shown that ghrelin has direct gonadal effects since the expression of ghrelin and the functional ghrelin receptor have been reported in the reproductive system including follicular, luteal, surface epithelial, and interstitial hilus cells in the ovary, as well as in leydig and sertoli cells in the testis.[2,12]

Physiological Functions of Ghrelin in Female Gonads

In addition to the recognized regulatory hormones, several reports have described that the control of the ovary is also exerted by ghrelin. This assumption was shown by the expression of ghrelin and its functional receptor in animal models and the human ovary.[12]

Ghrelin is found in ovarian hilus interstitial cells as well as young and mature *corpora lutea*, whereas ghrelin is not detected in ovarian follicles at any developmental stage.[14] Assessment of relative mRNA levels of ghrelin through the different stages of the estrous cycle has shown that ghrelin mRNA levels vary significantly depending on the phase of the cycle. The lowest expression levels occur in the luteal phase and the highest when the *corporea lutea* enter the functional phase, while remaining lower during *corporea lutea* formation and regression.[4] Further substantiation is provided by immunohistochemical analyses, which show intense and specific ghrelin immunoreactivity in the cytoplasm of steroidogenic luteal cells.[4]

Similarly, ovarian expression of GHS-R1a protein shows a wider pattern of tissue distribution, with detectable specific signals in oocytes as well as somatic follicular cells, luteal cells from young, mature, old, and regressing *corporea lutea*, interstitial hilus cells, and fallopian tube epithelium.[15] Therefore, the presence of both components (ligand and receptor) of the ghrelin-signaling system within the ovary opens up the possibility of a potential regulatory role of ghrelin in ovarian function.[12] In this regard, the recent assessment of the biological actions of ghrelin in the human ovary by an *in vitro* model showed that ghrelin is able to significantly inhibit, in a dose-dependent manner, estradiol (E2) and progesterone (P4) production by granulosa-lutein cells by acting through GHS-R1a.[33] Such a mechanism could contribute to the suppression of the reproductive axis in situations of negative energy balance, such as starvation, which is characterized by low blood gonadotropins and E2 levels and high ghrelin concentrations. However, ghrelin does not inhibit, but rather promotes, the function of chicken, rabbit, and porcine ovarian cells in cultures. In these cells, ghrelin directly promotes ovarian cell proliferation (measured by an increase in the proliferation-related peptides PCNA, cyclin B1, and MAPK/ERK1,2), inhibits their apoptosis (measured by a decrease in the apoptosis-related substances bax, p53, and caspase 3), and stimulates the release of ovarian derived hormones (progesterone, testosterone, estradiol, IGF-1, prostaglandin, and others).[29] Therefore, the role of ghrelin in controlling ovarian secretory activity requires further study.

Despite the proliferative actions of ghrelin on the ovarian, analysis of metaplastic lesions and tumors of the ovary shows that the pattern of expression and cellular distribution of the GHS-R1a is similar to that of normal and neoplastic ovaries, but malignant tumors that derive from the ovarian surface epithelium show weak or no GHS-R1a immunoreactivity.[24]

Physiological Functions of Ghrelin in Male Gonads

The testis is a complex endocrine organ in which different cell types interplay to ensure male fertility under the control of an array of extragonadal and intragonadal hormones and growth factors. Current results suggest that ghrelin participates in such a regulatory network.[30]

Within the testis, expression of ghrelin has been observed in mature Leydig cells of both rats and humans. In addition, expression of the functional ghrelin receptor, the GHS-R type 1a, is seen in Sertoli and Leydig cells. In contrast, expression of GHS-R1a in the seminiferous tubules strongly suggests that the seminiferous epithelium may be a target for ghrelin action that directly regulates seminiferous tubule functions.[30]

These results pertaining to the rat testis as a model *in vitro* show that ghrelin is able to significantly inhibit, in a dose-dependent manner, human choriogonadotropin (hCG)-and cAMP-stimulated testosterone secretion.[12] This inhibitory effect on testosterone secretion is associated with a significant decrease in hCG-stimulated expression of genes related to the steroidogenic route, suggesting that ghrelin may participate in the autolimitation of testicular secretion of testosterone in responses to gonodotropic stimulation.[30] In addition, in *in vivo* models, ghrelin is able to inhibit the proliferative rate of immature leydig cells during puberty by inhibiting the expression of the gene encoding stem cell factor, a Sertoli cell product involved in the germ cell development and survival factor for the spermatogenic

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

cells.[3] Reinforcing these effects, shown by acute intratesticular administration of ghrelin, the chronic treatment of ghrelin induces a significant decrease in the number of the different spermatogenic cell types except for spermatogonia, a decrease in the thickness of the germinal epithelium of the seminiferous tubules, as well as an intracellularly reduction in the size and number of mitochondrial while increasing vacuolated areas within the matrix of the cells.[22]

Overall, these results confirm that ghrelin has antiproliferative effects on different testicular cell types and is a negative modulator of male reproductive system in situations of negative energy balance, such as starvation, where limited resources are allocated to major physiological processes.[12,22]

At the pathophysiogical level, ghrelin expression is conserved in Leydig cell tumors and is linked to the degree of cell differentiation.[13,24] Therefore, this peptide is suggested as a novel regulator of testicular development and operates as marker of Leydig cell differentiation, both during normal development and in tumor transformation.[13,24]

GHRELIN SYSTEM IN THE PANCREATIC ISLETS

Pancreatic islets consist of four major endocrine cell types that produce the hormones necessary for maintaining appropriate levels of circulating glucose. The α-cells synthesize glucagon, β-cells synthesize insulin, Δ-cells synthesize somatostatin, and pancreatic polypeptide (PP) cells synthesize PP. A few years ago, a fifth mammalian islet cell type, the ghrelin-producing epsilon cell, was described. Besides these novel islet cells, multiple experimental systems have also shown ghrelin-immunoreactivity in α-cells and β-cells.[10] In regards to the ghrelin receptors in pancreatic islets, messenger RNAs (mRNAs) encoding GHS-R are expressed in the pancreas of rats and humans as well as in β-cell lines, and double immunohistochemistry shows GHS-R-like immunoreactivity mainly colocalized extensively with glucagon-pancreatic islets. Moreover, rodent studies show that the expression of pancreatic ghrelin changes dramatically during fetal development and that ε-cells are the major source of ghrelin during fetal life rather than the fetal stomach.[16]

Besides the expression pattern of ghrelin in the pancreatic islets mentioned above, radioimmunoassays comparing the concentration of ghrelin in the pancreatic vein with that in the pancreatic artery rats show ghrelin release from pancreatic islets.[10] However, the regulation of ghrelin release from the pancreas as compared with that from the stomach remains to be clarified.[10]

Little is known about the role of ghrelin within the pancreas, but it seems that ghrelin could play a paracrine/autocrine role in the regulation of β-cell survival and function. In this context, ghrelin has recently been reported to promote proliferation and cell growth and also to inhibit apoptosis of pancreatic β-cell and human islets. This suggests that one function of ghrelin in the developing pancreas could be to promote cell growth and maturation locally.[16] Study of the effect of ghrelin on pancreatomized rats showed an increase in the regenerative capacity of the remaining pancreas after pancreatectomy.[21]

Ghrelin also exerts inhibitory effects on the expression and production of inflammatory cytokines and attenuates the development of acute pancreatitis in rats by blocking the inflammatory signal transduction pathways.[11] Moreover, pharmacological, immunological, and genetic blockade of ghrelin or ghrelin action in pancreatic islets markedly enhances glucose-induced insulin release, suggesting an insulinostatic function of islet-derived ghrelin.[10] *In vitro*, ghrelin inhibits glucose-stimulated insulin secretion in a dose-dependent manner from culture pancreas, isolated pancreatic islets, and immortalized β-cells lines, suggesting that it acts directly on β-cells to achieve this effect. In this regard, the infusion of acyl-ghrelin, the bioactive endogenous ligand of the GHSR-1a, reduces glucose-stimulated insulin secretion and glucose disappearance in healthy humans after an intravenous glucose tolerance test (IVGTT), suggesting that endogenous ghrelin has a role in physiologic insulin secretion, and that ghrelin antagonists could improve β-cells function.[31] However, a significant inverse correlation of ε-cell mass with body mass index (BMI), consistent with reports of an inverse correlation between plasma ghrelin and BMI, leads to speculation that the loss of ε-cells mass associated with increase in BMI could produce increased insulin secretion and also an enhanced susceptibility to apoptosis and inflammation damage in pancreatic islets.[1] Moreover, a preventive action of ghrelin was reported on the development of diabetes in streptozotocin-treated newborn rats via enhanced regeneration of β-cells[17] and the ghrelin-induced increase in the regeneration of pancreatic exocrine and endocrine cells after pancreatectomy, together with high proliferative rate of islet cells, resulted in decreased plasma glucose concentration as compared with the group treated with a ghrelin antagonist.[21]

In regard to the role of ghrelin on α-cell function, increased glucagon secretion by ghrelin has been seen *in vitro*, but the effect of ghrelin on its release is less impressive *in vivo*, with levels unchanged or mildly increased after ghrelin administration. In fact, no relevant change in glucagon level is seen with pharmacologic doses of ghrelin during fasting or IVGTT in healthy humans.[31]

Acylated ghrelin, unacylated ghrelin, and obestatin may prevent pancreatic β-cell death and improve β-cell function after treatment with cytokines, which are the major causes of β-cell

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

destruction in diabetes. UAG and OB improve glucose metabolism and preserve islet cell mass in streptozotocin-treated newborn rats, suggesting therapeutic potential in medical conditions associated with impaired beta-cell function.[17]

Coexpression of ghrelin and its receptor have also been seen in pancreatic adenocarcinoma and endocrine pancreatic tumors. This hormone increases proliferation of a pancreatic adenocarcinoma expressing the ghrelin receptor. However, few patients with pancreatic tumors have high concentrations of circulating ghrelin, and no correlation has been found between the expression of ghrelin and its receptor and malignant features. Therefore, the clinical influence of ghrelin production from pancreatic tumors remains unknown.[24]

Combining all the results, pancreatic secreted ghrelin seems to play a role in early islet biology and in β-cell survival and function. Further studies are necessary to delineate mechanisms by which endogenous ghrelin may affect islet function, maturation during fetal life, and pancreas reorganization in adulthood.

GHRELIN SYSTEM IN THE ADRENAL GLAND

The adrenal gland has two distinct structures, the adrenal cortex and the medulla, both of which produce hormones. The human adrenal cortex consists of the *zona glomerulosa* (ZG), which produces aldosterone, the *zona fasciculata* (ZF) responsible for cortisol production and secretion, and the *zona reticularis*, which is essential for adrenal androgen production. The adrenal medulla is the core of the adrenal gland and is surrounded by the adrenal cortex. The chromaffin cells of the medulla, named for their characteristic brown staining with chromic acid salts, are the body's main source of the circulating catecholamines, epinephrine and norepinephrine.

The function of adrenal gland is regulated by the hypothalamus–pituitary–adrenal axis, in which ghrelin plays an important role by the stimulating effect on CRH, ACTH, and cortisol secretion. Besides the indirect effect of ghrelin on adrenal gland, this peptide seems to have a direct effect on adrenal gland. The presence of ghrelin binding sites and the expression of preproghrelin and ghrelin receptors GHS-R1a and GHS-R1b at the mRNA and protein levels in both the cortex and medulla have been shown.[28] However, the direct effect of ghrelin on the secretory activity of this gland is under discussion, while a potent effect of the peptide on raising proliferative activity and decreasing apoptotic deletion rate of adrenocortical cells is established. In cultured human ZG cells, ghrelin does not significantly affect either basal or agonist-stimulated aldosterone secretion but exerts proliferative and antiapoptotic effects via MAPK.[9] As in humans, ghrelin does not affect corticosteroidogenesis in rat adrenocortical cells or adrenal slices.[9] In contrast, ghrelin can potently stimulate corticosterone secretion in cultured cells.[28] This study was performed in freshly isolated and cultured rat adrenocortical cells where the prolonged exposure to ghrelin resulted in a potent effect, comparable to ACTH, stimulating the effect of ghrelin on corticosterone secretion. This steroidogenic, ACTH-like effect of ghrelin on cultured cells was accompanied by a notable increase in the expression of P450scc, a cholesterol side chain cleavage (CYP11A1), the gene-coding synthesis of a key regulatory protein involved in corticosteroidogenesis.[28] The action of ghrelin on adrenocortical cells seems to have been performed with the acylated ghrelin form as shown by the presence of GOAT mRNAs. The concomitant expression of preproghrelin and GOAT genes in adrenal ZG suggests that newly synthesized ghrelin peptide may be rapidly octanoylated into an active form in glomerulosa cells.[28]

With respect to the role and localization of ghrelin in the medulla, the ghrelin precursor, proghrelin and mature ghrelin expression have been found in the adrenal medulla, as in the stomach, showing that ghrelin is synthesized by the adrenal medulla in both humans and rats.[26] Therefore, ghrelin synthesized in the adrenal medulla could be involved in the autocrine/paracrine regulation of chromaffin cell secretion. Indeed, ghrelin stimulates dopamine secretion from rat pheochromocytoma PC 12 cells.[26] However, further studies are needed to clarify the direct role of ghrelin on the regulation of catecholamines release.

GPR39, the putative obestatin receptor (GPR39v1 and GPR39v2) whose mRNAs levels are similar in adrenocortical zones and adrenal medulla, is present in all compartments of the rat adrenal gland and cultured adrenocortical cells.[28] However, the role of obestatin in the regulation of adrenocortical cell growth and function remains unknown.

CONCLUDING REMARKS

Ghrelin is secreted from the stomach into the circulation, but it is also synthesized in many endocrine and nonendocrine tissues suggesting a possible dual role as autocrine/paracrine and/or endocrine factor (Fig. 3). Moreover, ghrelin provides information from the periphery and from within the brain's interconnecting hormonal axis and produces an integrative response on the endocrine control of the organism. In addition, the characteristic acyl modification is necessary for some functions but not for others. The production of obestatin from a common precursor messenger RNA with a complex gene structure and transcription regulation as well as the probable existence of new nondescribed receptors increase the challenge of understanding

Chapter 133

Leptin

Krzysztof W. Nowak, Przemyslaw Kaczmarek, Tatiana Wojciechowicz and Mathias Z. Strowski

ABSTRACT

Adipocytes are the major source of leptin production, and plasma leptin concentrations directly correlate with the amount of total body fat. Leptin fulfills a variety of pivotal physiological functions as a signaling molecule between peripheral organs and the central nervous system, regulating numerous endocrine functions relevant for the maintenance of energy expenditure, appetite regulation, body weight control, and the function of endocrine organs. This review focuses on the description of the expression of leptin and leptin receptors and delineation of the major endocrine activities of leptin in regulating various functions of the endocrine pancreas, hypothalamus–pituitary–thyroid axis, reproductive organs, and the hypothalamus–pituitary–adrenal gland axis. In addition, well-known, less understood novel aspects, as well as controversies regarding the roles of leptin and its receptors in the pathophysiology of metabolic disorders are summarized and discussed.

INTRODUCTION

Leptin (Greek *leptos* meaning thin) was discovered in 1994 at the Rockefeller University by Jeffrey M. Friedman and coworkers during the study of leptin-deficient *ob/ob* mice. Leptin, also termed ob protein, is a hormone consisting of 167 amino acids (16 kDa) encoded by the *ob* gene. Strong leptin expression was reported in the adipocytes of white adipose tissue. In addition, leptin is also produced in much lower quantities by brown adipose tissue, placenta (syncytiotrophoblasts), ovaries, skeletal muscle, the lower part of fundic glands of the stomach, mammary epithelial cells, bone marrow, pituitary, and liver. Plasma concentrations of leptin are directly proportional to the total amount of fat in the body, suggesting that leptin plays a role in the pathophysiology of obesity.[22]

Six splice variants of leptin receptors (Ob-Ra–Ob-Rf, or LepRa–LepRf) are known, which are encoded by a single gene, Ob-R or LEPR. The "short forms" of the leptin receptor are widely expressed in many tissues, whereas the "long form" (OB-Rb, containing a longer cytoplasmic domain) is highly expressed in the CNS. Ob-Rb is a type 1 cytokine receptor, which stimulates the JAK/STAT3 pathway and PI3K,[22] possibly explaining the regulation of inflammatory processes by leptin.

Because endocrine glands highly express leptin and its receptors, this chapter focuses on the distribution and actions of leptin on the tissues of peripheral endocrine system (Fig. 1).

REGULATION OF PANCREATIC B-CELL FUNCTIONS BY LEPTIN

Leptin regulates whole body metabolism and controls the energy homeostasis. In this context, regulation of various functions of the endocrine pancreas by leptin is of important physiological relevance. Leptin receptors are expressed in pancreatic islets. In physiological concentrations, leptin decreases insulin secretion from B-cells in healthy lean and leptin-deficient *ob/ob* mice.[9,18] By contrast, leptin fails to affect the secretion of insulin from islets derived from *db/db* mice.[9] *db/db* mice fail to express functional leptin receptors, which explains the incapability of leptin to influence insulin secretion from pancreatic islets isolated from these animals.[9]

Leptin inhibits glucose-stimulated insulin secretion via cAMP/PKA and phospholipase C/protein kinase C pathways. By contrast, at low glucose levels, leptin fails to influence insulin secretion.[28] These *in vitro* observations are in agreement with the results of *in vivo* studies showing that leptin decreases plasma insulin levels only in fed, but not in fasted mice.[18]

The mechanism regulating glucose-stimulated insulin release encompasses depolarization of B-cells, as a consequence of closure of ATP-sensitive potassium channels. Hyperpolarization of cell membranes resulting from the opening of these channels by the leptin-dependent decrease in intracellular Ca^{2+} is one of the additional possible mechanisms of leptin action.[17] Furthermore, leptin decreases insulin biosynthesis by reducing proinsulin mRNA expression in rodent B-cells.[30] The suppression of insulin biosynthesis is presumably independent on the K_{ATP} channels activation because diazoxide, the K_{ATP} channel opener, has no effect on leptin-dependent suppression of insulin biosynthesis.[30]

Several studies shown that leptin displays insulinotrophic activity, by prolonging B-cell survival and protecting B-cells from apoptotic cell death. Zucker diabetic fatty rats have a full length but dysfunctional leptin receptor resulting from a mutation. In comparison with Zucker fatty or lean rats, Zucker fatty rats with type 2 diabetes mellitus have markedly lower B-cell mass, which results primarily from the increased rate of B-cell death.[27] Increased triglyceride accumulation in B-cells in type 1 and type 2 diabetes mellitus accelerates B-cell death. Leptin can decrease lipid content in B-cells by accelerating the intracellular fatty acid oxidation.[31] Noteworthy, leptin decreases insulin-stimulated glucose transport, lipogenesis and protein synthesis in isolated rat adipocytes.[24] One of the possible mechanisms by which leptin affects the anabolic activities of insulin is the attenuation of insulin binding, as reported in isolated hepatocytes.[26] Thus, leptin influences B-cell functions by controlling the secretion, and biosynthesis of insulin. In addition, leptin modulates the anabolic activities of insulin. These activities of leptin are relevant in the context of regulation of glucose homeostasis.

ROLE OF LEPTIN IN REGULATING THYROID FUNCTIONS

The hypothalamus–pituitary–thyroid (HPT) axis plays a significant role in controlling energy expenditure and whole body metabolism. Therefore, the modulation of HPT axis by peripheral signals of energy deposition has a pivotal relevance for the maintenance of metabolic homeostasis.

Leptin stimulates thyroid functions by increasing thyrotropin-releasing hormone (TRH) secretion.[19] Leptin also increases the growth of the thyroid gland tissue and stimulates the secretion of thyroid hormones (TH).[19,25] In the hypothalamus, leptin induces STAT 3 phosphorylation of Ob-Rb via Y1138 in nuclei of TRH neurons.[15] This observation suggests that STAT 3 is critical in mediating the effects of leptin on preproTRH gene expression. Indeed, stimulation of preproTRH gene expression by leptin via the STAT 3 response element, which is located in the preproTRH promoter, was confirmed by the use of heterologous expression system (transfected 293T cells).[13] In addition, STAT 3 mediates the transcriptional activity of leptin *in vivo*.[12] Moreover, systemic leptin administration into fasting animals not only

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

increases preproTRH mRNA in the PVN but also fully restores thyroid hormone levels and TRH to normal or even higher levels.[19]

Animal studies have shown that prolonged fasting is accompanied by the fall of circulating leptin, and that fasting lowers circulating T3 and T4 levels at low or normal TSH levels are restored to normal after leptin injections.[19] Leptin administration in hyperthyroid rats is followed by an increase in serum TSH concentrations.

Rat thyroid gland expresses the long form of leptin receptor (Ob-Rb) mRNA. Furthermore, Ob-Rb-like immunoreactivity is found in membranes of the thyroid epithelial cells and in C-cells of the gland.[25] These findings suggest that leptin can directly act on the thyroid gland.

Acute leptin administration into animals does not affect thyroid ^{125}I uptake; however, serum TSH, T3, and T4 concentrations are increased. In contrast, no changes in serum TSH and TSH secretion *in vitro* were observed in leptin-treated hypothyroid rats.[6] Furthermore, chronic continuous leptin infusion in rats lowers plasma concentrations of TSH, while those of thyroid hormones (free T3 and total T4) are raised.[25] Contrary to the *in vivo* results, *in vitro* studies on rat FRTL-5 cells show that leptin reduces iodine uptake.[16]

Apart from influencing the HPT-thyroid axis, leptin modulates the monodeiodinases in various tissues, depending on the energetic status.[12] Thus, leptin controls energy expenditure at the level of TH secretion and TH synthesis by acting on the HPT-TH axis and by controlling the conversion of TH in numerous extrathyroidal tissues.

LEPTIN AND THE REPRODUCTIVE SYSTEM

Leptin Expression in Reproductive System

Leptin is expressed in the reproductive tissues in rodents and humans, including ovary, placenta, and also in the fetus. On the cellular level, leptin is expressed in murine trophoblastic cells and in human trophoblastic placental cell lines JAR and JEG-3. *In situ* hybridization and immunohistochemistry reveal leptin-immunoreactivity in murine fetus including cartilage and bone, brain, heart, liver, and hair follicles.[22] Within the ovaries leptin is expressed in steroid-producing cells including granulosa, thecal, and luteal cells as well as in interstitial cells of rodents, and in both healthy women and patients with polycystic ovary syndrome (PCOS).[22]

Ob-Rs Expression in Reproductive Tissues

Six Ob-Rs isoforms are known, which are differentially expressed in numerous mammalian peripherial tissues, including heart, liver kidneys, lungs, small intestine, placenta, pancreas, adrenal gland, ovaries, testes, and adipose tissue. Within the ovarian follicles, functional Ob-Rb isoform is detected in steroidogenic granulosa (GC) and theca cells of many examined mammalian species.[22] Moreover, after ovulation, luteal cells occur, which also express leptin receptor.

The expression of the long Ob-Rb and short Ob-Ra isoforms vary throughout the rat estrous cycle. Low expression of both isoforms reported in proestrus and diestrus II rather than in estrus and diestrus I could result from changes of plasma concentrations of steroids and leptin as well as from responses to the changing environment of the ovary.[7] *In situ* hybridization reveals leptin receptor expression in spermatic and Leydig cells in murine testis.[4] In mouse testis germ cells, the Ob-R immunoreactivity shows stage- and age-dependent variability, suggesting that the leptin system may play a role in regulating the proliferation and differentiation of germ cells.[8]

Leptin Function in Ovaries and Testis

The majority of studies show that leptin inhibits ovarian steroidogenesis. *In vitro*, leptin directly suppresses IGF-1-, TGF-beta-, and glucocorticoid–stimulated secretion of steroids from GC.[3] Downregulation of Ob-Rb expression in ovarian cells with the consecutive restriction of its binding sites during the estrous cycle may represent a compensatory mechanism to attenuate the inhibition of steroidogenesis by leptin.

In contrast to studies in isolated GC or TC cells, Gregoraszczuk et al. showed differential effects of leptin on estradiol secretion in whole follicles of different sizes obtained through the porcine estrus cycle.[11] Leptin fails to alter estradiol secretion from small- and moderate-sized follicles. However, in cultured large, preovulatory follicles leptin inhibits basal, GH- and IGF-1 stimulated estradiol secretion, and increases progesterone secretion. These results suggest that leptin may promote the luteinization process.

Numerous reports indicate that leptin participates in controlling the growth and maturation of ovarian follicles and acts as a proliferative factor.[1] In healthy women and patients with PCOS leptin levels in follicular fluids serve as a predictor of successful pregnancy.[21] Leptin can cross the murine blood–testis barrier[2] and has the ability to modulate the paracrine network that controls testicular steroidogenesis.[4,34] In primary cultured rat Leydig cells and the Leydig tumor cell line (MLTC-1), leptin inhibits LH-[4] and hCG-stimulated[34] testosterone secretion.

Leptin Controls Fertility and Puberty

Genetically obese ob/ob mice of both, male and female sexes, are infertile. The infertility is reversible upon administration of exogenous leptin,[5] which restores ovulation,

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

pregnancy, parturition, and lactation. Leptin induces an early puberty in healthy mice, indicating that leptin acts as a signal initiating the onset of puberty.

Role of Leptin in Pregnancy

During pregnancy, hyperleptinemia occurring in the second and third trimesters is not associated with physiological changes of food intake or energy expenditure.[23]

Because leptin is expressed in placenta and in many fetal tissues, it was hypothesized that leptin may act as a growth factor and serve as a messenger controlling energy status between mother and a fetus. In the placenta, leptin probably acts as an auto- and/or paracrine manner because syncytiotrophoblasts express leptin receptor.[29]

REGULATION OF ADRENAL GLANDS BY LEPTIN

The interactions of peptides regulating food intake, and especially leptin with the hypothalamus–pituitary–adrenal (HPA) axis are of great physiological relevance because glucocorticoids hormones are known to be involved in the control of energy homeostasis and adipogenesis. In addition, a strong correlation between serum concentrations of cortisol and leptin is well documented. Several reports clearly show that leptin modulates the functions of both the HPA axis and the systemic symphatic/adrenomedullary (SS/AM) system.[20] This part focuses on reviewing the interaction of leptin with the adrenal gland.

Localization of Leptin in Adrenal Glands

In contrast to the remaining members of HPA axis (hypothalamus and pituitary) ob mRNA is not expressed in adrenal glands, neither in adrenocortical nor medullary cells. Therefore, paracrine or autocrine mechanisms of leptin's action on the adrenal glands are unlikely.[20] Remarkably, adrenal glands are naturally surrounded by adipose tissue and presumably exposed to high local concentrations of leptin. In addition, some evidence suggests that leptin is expressed in intra-adrenal mast cells.[20]

Localization Ob-R Protein in Adrenal Glands

Leptin receptors (Ob-Rs) are also present in the adrenal glands of humans, rats, pigs, and cows, suggesting a direct regulation of cortex and medullary adrenal tissues functions by leptin.[20] Real-time PCR studies show the expression of Ob-Ra, Ob-Rb, Ob-Rc, Ob-Re, and Ob-Rf in both adrenal cortex and medulla.[20] Except for Ob-Re, the level of expression of all ObR isoforms is significantly higher in the medulla.[20]

Role of Leptin in Regulating Adrenal Cortex Functions

Growing evidence from *in vivo* studies collectively shows that leptin inhibits the HPA axis activity in humans, monkeys, sheep, mice, and rats (for detailed review see Ref. 20). It should be noted that the net effects of leptin reported in *in vivo* studies represent the sum of complex direct or indirect interactions of leptin with central and peripheral organs. In light of the rather scarce data available to date, the mechanisms of a direct interaction of leptin with the receptors of adrenocorticals cells remain not well understood. The initial studies performed by Malendowicz et al.[20] reveal that leptin upregulates basal but not ACTH-stimulated steroid secretion in dispersed rat adrenocorticals cell cultures. On the contrary, Bornstein and colleagues reported that leptin inhibits both basal and ACTH-stimulated steroid release from cultured human and bovine primary adrenocorticals cells, and the NCI-H295 cell line.[10] In addition to the regulation of steroid secretion, leptin has antiproliferative activity by suppressing the growth of the adrenal cortex in the rats.[20] More recently, the mechanism of leptin-dependent inhibition of ACTH controlled adrenal steroidogenesis was proposed.[14] The mechanism encompasses modulation of ACTH-regulated JAK2-PI3K/Akt-PDE3-cAMP pathways with the consecutive downregulation of the expression of steroidogenic genes.[14]

Role of Leptin in Regulating the Functions of the Adrenal Medulla

There are few studies available that assess the functional interaction between leptin and adrenal catecholamines. Most of the studies were performed in cultured cells, showing that leptin stimulates the synthesis and secretion of catecholamines.[33] The mechanism of action encompasses the activation of the voltage-gated Ca^{2+} L- and N-type channels.[32]

Role of Leptin in Pathophysiological Conditions

Leptin has been reported to dampen the HPA-axis responses (ACTH and/or corticosteroids) to various stressors with the exception of cold stress.[20] However, mechanisms underlying this regulation remain unclear.

Several studies (extensively reviewed in Ref. 20) suggested that leptin may play a role in the pathophysiology of adrenal tumorigenesis by affecting the growth, proliferation, and secretion processes. However, the results of the studies are ambiguous.

In obesity, the ability of leptin to decrease food intake is impaired. Obese individuals frequently develop central leptin resistance. It has been proposed that the attenuated

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

leptin sensitivity in the adrenal medulla could contribute to the higher catecholamine production previously observed after neonatal hyperleptinemia. Later, it was shown that neonatal hyperleptinemia leads to medullary adrenal hypertrophy and high catecholamine production.[35] These effects do not seem to result from a direct action of leptin on the medulla because the leptin signaling pathways are down-regulated in this tissue, and leptin treatment in adulthood has limited effects.[35]

CONCLUSIONS

The discovery of leptin about 2 decades ago allowed a better understanding of the regulation of crucial physiological processes including food intake, body weight control, and maintenance of energy homeostasis. Because leptin was one of the first adipokines described in fat cells, the discovery led to a better understanding of the adipose tissue compartment serving not only as a simple storage of excessive energy as lipids, but also playing a considerable role as "endocrine active tissue" that influences numerous physiological functions in the peripheral and central nervous system. Because of its well-documented impact on the endocrine pancreatic B-cells, leptin can control glucose homeostasis and play a role in the pathophysiology of type 2 diabetes mellitus, at least in animal models of this disease. Resulting from its interaction with organs such as the pituitary, regulation of the HPA axis activity, and modulation of the fate of pituitary hormones in peripheral tissues, leptin plays a considerable role in regulating energy expenditure and obesity. Importantly, leptin serves as a "messenger molecule" between peripheral organs (most importantly fat cells) and the central nervous system, which is of crucial relevance as a feedback mechanism for the control and maintenance of metabolic homeostasis. Lastly, leptin regulates the function of ovaries and testes and plays an important role in controlling fertility and puberty. Although the wide range of pleiotropic endocrine activities of leptin is well known, the role of this adipokine in the context of neoplastic (see the Leptin chapter in the Cancer/Anticancer section of this book) and hormonal disorders, with the resulting concomitant potential introduction into therapy remains to be established.

Chapter 134

ANP

Jolanta Gutkowska

ABSTRACT

Atrial natriuretic peptide (ANP) was the first member of the natriuretic peptide (NP) family isolated from heart tissue, and since its discovery, other members of this family, including BNP, CNP, urodilatin, and DNP were isolated from the brain, kidney cells, and snake venom. The physiological actions of NPs are mediated by two guanylyl cylase (GC) receptors, known as A- and B-type, and a third receptor called "clearance" C receptor, whose main role was initially believed to internalize and degrade NPs. However, recent results suggest that the C receptor may mediate physiological actions of NPs. Activation of GC receptors leads to the increase in cGMP and subsequent intracellular events. NPs were originally associated with cardiovascular homeostasis, but their presence and the distribution of their cognate receptors in a various organs suggest a much broader range of functions. Indeed, NPs have antiproliferative, antifibrotic, anti-inflammatory, insulin-like functions, and are involved in the regulation of bone growth. NPs are essential for the growth and maturation of ovarian follicles and act as regulators of various functions at the level of several glands.

DISCOVERY

The existence in the heart of a hormone regulating blood volume was predicted long ago before its discovery. Pioneering studies by Gauer and Henry[13] advanced the concept that volume regulation is an integral part of an overall cardiovascular system. The search for a natriuretic hormone was stimulated by the experiments of de Wardener et al.[7] who observed a potent natriuretic effect in renal artery-clamped dogs, which could not be explained by a change in aldosterone levels or in glomerular filtration rate, which remained constant under these experimental conditions. With the advent of electron microscopy, discovery and characterization of specific atrial granules, presumably of a secretory nature, gave new direction to the search for a natriuretic hormone. Atrial granularity was shown to depend on both the hydromineral status of the body and intact adrenal function. The relevance of these observations was confirmed by de Bold et al.[5] who performed landmark experiments and reported that, in anesthetized rats, injection of rat atrial tissue extract caused rapid but short duration diuresis and natriuresis.

The discovery of the cardiac hormone, ANP, was considered a major breakthrough in the search for natriuretic hormones.

STRUCTURE OF THE PRECURSOR mRNA GENE

ANP was originally purified from the rat heart, and cDNA clones encoding the ANP precursor were isolated from atrial cDNA libraries. In the adult heart, ANP gene is expressed predominantly in the atria where ANP mRNA represents 1–3% of total mRNA.

ANP is the first member of the NP family, which consists of four other peptides: BNP and CNP, both isolated from the porcine brain.[31] The BNP and CNP genes seem to each synthesize only one peptide hormone, BNP-32 and CNP-22, from their respective biosynthetic precursors, i.e., (prepro) $BNP_{1–108}$ and (prepro) $CNP_{1–103}$. The fourth peptide of this family, a 32-amino acid peptide known as urodilatin is a product of alternative processing of proANP in kidney cells and found in urine. The recently discovered dendroaspis-type natriuretic peptide (DNP) is a 38-amino acid peptide isolated from the venom of the *Dendroaspis angusticeps* snake, which has a structural and functional similarity to other NPs. Like ANP and BNP, DNP activates the GC-A receptor resulting in natriuretic and diuretic effects. A DNP-like peptide has been reported to be present in human plasma and heart and is elevated in human congestive heart failure.

All NPs have structural homology in the 17-amino acid ring formed by a disulfide bond between cysteine residues at positions 105 and 121 in humans. The biological activity of the peptides depends on the integrity of the ring structure (Fig. 1). The ANP structure is highly conserved during evolution, and there is a difference of only one amino acid between human and rat ANP. Methionine in human ANP replaces isoleucine in rats in position 110.[23] The gene encoding proANP consists of three coding exon sequences separated by two intron sequences (Fig. 2).

All NPs are synthesized by different genes and stored in the form of prohormones: ANP (126 amino acids), BNP

(108 amino acids), CNP (126 amino acids) in secretory granules. However, the DNP prohormone gene structure is still unknown in humans. The ANP gene is present not only in the animal kingdom but also in plants. The pro-ANP gene is located on the distal short arm of chromosome 1 in band 1P36 in humans and on chromosome 4 in mice.

The availability of ANP-specific antibodies allowed the development of immunocytochemical and radioimmunoassay analyses for ANP. Further developments in molecular biology led to the mapping of ANP-expressing tissue. With these tools, ANP has also been detected in several extraatrial tissues,[16] including brain, lungs, endocrine, and exocrine glands where it exerts physiological paracrine or autocrine effects. ANP is highly expressed in various regions of the brain, particularly in the rostral diencephalon, and the ability of NPs to interact with the secretion of hypothalamic neuroendocrine systems regulating, and various hypothalamic releasing and inhibiting hormones has been established.[27] Furthermore, ANP is synthesized and secreted by rat adrenal chromaffin cells and is detected in peripheral ganglia, superior cervical nodosa, and in the cell bodies of superior celiac mesenteric ganglia.[16]

ANP prohormone is present in the blood vessels, namely, in inferior and superior vena cavae, extrapulmonary and intrapulmonary veins and in the smaller vasculature of the lungs, from which ANP is released as a 28-amino acid peptide. The digestive system and gastrointestinal tract contain NPs with functions well established, as mentioned later in this chapter. Linkage between ANP and the immune system has been supported by the demonstration of ANP in thymus and lymphoid tissues.[33] Other tissues, such as the thyroid, male and female reproductive organs, and liver contain NPs, and in some of them, a physiological role of NPs has been postulated.

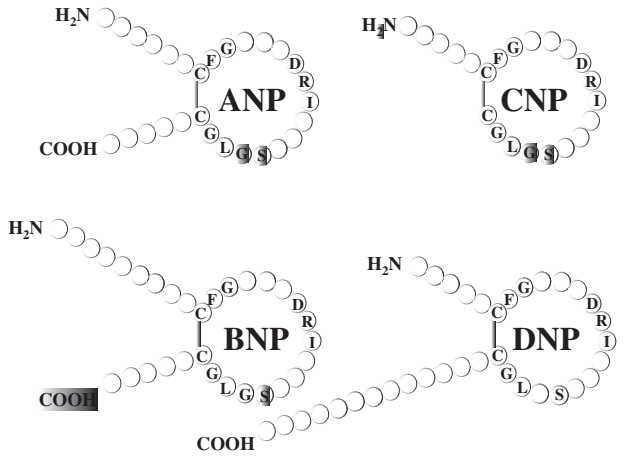

FIGURE 1 Primary structure of the NP family. Each peptide consists of a highly conserved 17 aa ring created by a disulfide bond which is required for receptor binding. Marked residues in the circles denote aa that are conserved between peptides.

PROCESSING

Since the discovery of ANP, enormous progress has been made in identifying the structural and functional properties of this peptide. The human ANP precursor peptide gene encodes a 151-amino acid preprohormone, a molecule that contains a 25-amino acid signal peptide sequence. The signal peptide is cleaved during the transport of the peptide across the endoplasmic membrane reticulum producing a prohormone $ANP_{(1–126)}$. The final proteolytic cleavage of $ANP_{(1–126)}$ to the major, biologically active peptide $ANP_{(99–126)}$ takes place during or just after the release of the peptide by exocytosis in secretory vesicles, which are transferred to the plasma membrane after increases in levels of cytoplasmic calcium. Several groups have purified biologically active ANP peptides of different lengths from rat atrial homogenates. These other "related" peptides are most probably artefacts of proteolytic digestion during purification. Several enzymes have been shown to convert $proANP_{(1–126)}$ to $ANP_{(99–126)}$, such as carboxypeptidases, kallikrein, trypsin, thrombin, corine, and others, but those of physiological relevance have not yet been established.[23]

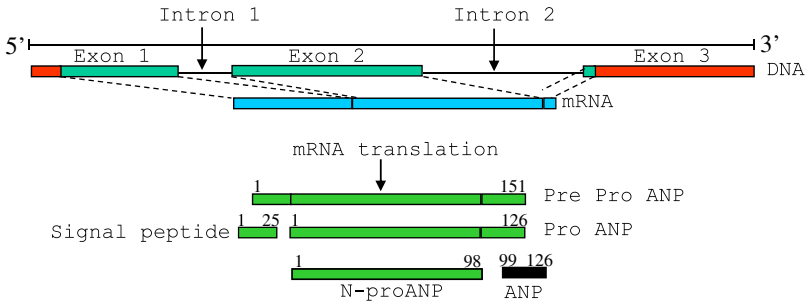

FIGURE 2 Structure of the ANP gene. ANP is synthesized as a prepropeptide from mRNA originating from three exons of ANP gene. Prepropeptide and its derivative ANP propeptide are stored in the cells. Proteolytic cleavage of the propeptide sequences results in the formation of mature (low molecular mass) $ANP_{99–126}$ and N-terminal $N\text{-}proANP_{1–98}$.

RELEASE OF NPs

ANP release is controlled by many neural and hormonal factors, but the principal stimulus controlling ANP synthesis and release is atrial and ventricular wall stretch, resulting from volume expansion. Angiotensin II, endothelin, glucocorticoids, norepinephrine, oxytocin, arginine–vasopressin, morphine, and other factors, acting via hemodynamic stress or by direct effects on cardiac cells, have been shown to stimulate ANP release.[23]

RECEPTORS AND SIGNALING CASCADE

Molecular cloning techniques revealed the existence of three NP receptors, two, membrane GCs with tyrosine-like kinase domain GC-A and GC-B and C or "clearance" receptors, which exhibit distinct structural features and are widely distributed and display different affinities to the members of the NP family. ANP and BNP bind with higher affinity to GC-A and GC-B, whereas CNP binds to GC-B. All NPs bind with a relatively similar affinity to a third, very abundant C receptor whose role as originally believed was to internalize and degrade NPs (Fig. 3). However, recent results revealed that the GC-C receptor is a G protein-coupled receptor with an intracellular domain coupled to adenylyl cyclase inhibition through an inhibitory guanine nucleotide regulatory protein and/or to phospholipase C.[2] Therefore, the C receptor may mediate the biological actions of NPs by the inhibition of cAMP or stimulation of phosphoinositide hydrolysis. In the intestine and kidney, the activation of GC-C by intestinal peptide uroguanylin induces diuretic and natriuretic activity, providing an endocrine link between the intestines and kidney to modulate renal function in response to oral salt load.[17] The GC receptors belong to a family of seven isoforms of transmembrane enzymes, which convert guanosine triphosphate into cyclic 3′.5′ guanosine monophosphate (cGMP). The activation of intracellular cGMP subsequently modulates the activity of regulatory proteins such as cGMP-regulated phosphodiesterases, ion channels, and cGMP-dependent protein kinases types I and II. These proteins, which are differentially expressed in various cell types, modify the cellular functions of cGMP. There is considerable homology between guanylyl cyclase-containing receptors and between the species for particular receptors.

BIOLOGICAL ACTIVITIES OF NPs

Although ANP was found to be a potent diuretic and natriuretic substance, ANP and other peptides of this family are now recognized as hormones with a wide spectrum of central and peripheral, autocrine/paracrine actions, including cell

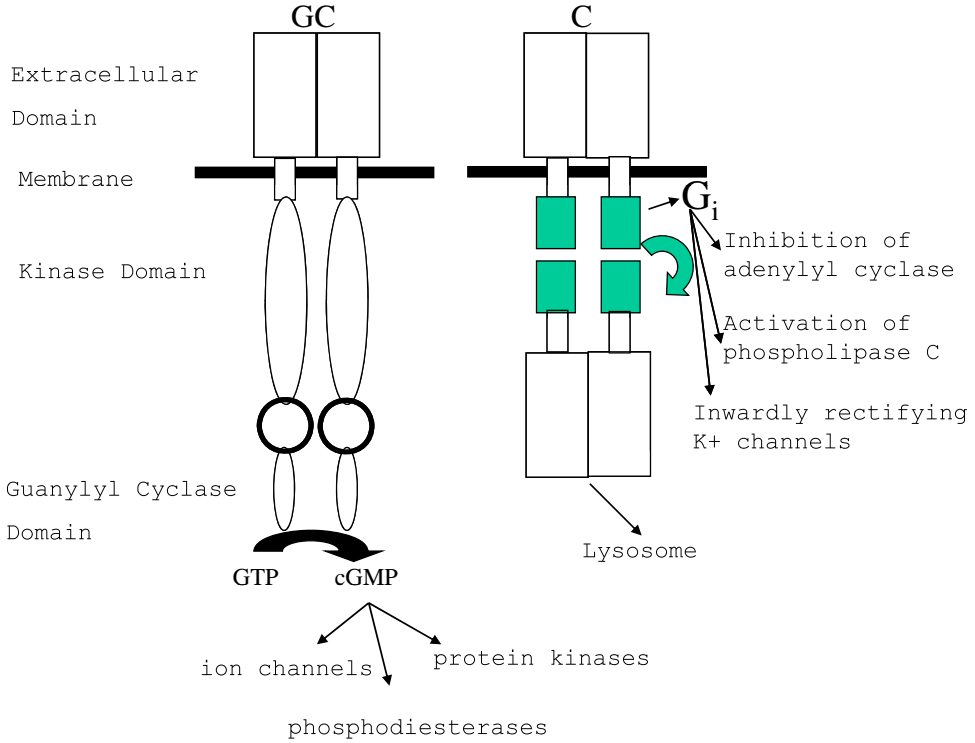

FIGURE 3 Natriuretic peptide receptor subtypes and their signaling pathways. GC-A, GC-B are particulate GC receptor producing cGMP. Receptor-C internalizes bound NPs and subjects them to lysosomal degradation. Receptor-C can also lead to G protein-coupled inhibition of adenylyl cyclase, activation of phospholipase C and G protein-gated inwardly rectifying K+ channels.

proliferation and differentiation in various tissues, regulation of reproductive function, and bone formation.

Heart

Several studies have established that ANP, by activating the GC-A/cGMP pathway, regulates blood pressure and the cardiorenal axis through its ability to antagonize the renin–angiotensin–aldosterone system and sympathetic nervous systems, or through its direct vasodilatory and natriuretic responses, modulating endothelial permeability and fluid shift from vascular beds into the lymphatic system.

NPs exert several and important autocrine and paracrine actions within the heart and coronary circulation. All NPs have effects on cardiac contractility, considered as being negatively inotropic, although conflicting results have been reported. NPs are involved in the regulation of coronary blood flow, cardiomyocyte growth, inhibition of cardiac fibroblast proliferation, and extracellular matrix secretion. Robust cardioprotective and anti-ischemic effects as well as a vasorelaxant influence in the coronary circulation have been documented.[17] Most of these diverse physiological actions within the heart are mediated by cGMP.[4]

The generation of animal models with deletion or overexpression of genes has given a new insight into the molecular physiology and diverse biological functions of NPs and their receptors. The first GC-A and ANP knockout mice showed that this hormonal system is not only essential for the maintenance of blood pressure and volume homeostasis but also has local growth-mediated functions. Mice lacking the GC-A receptor present marked cardiac hypertrophy and fibrosis, disproportionate to their increase in blood pressure, and chronic antihypertensive treatment of these animals normalizes blood pressure without a marked effect on cardiac hypertrophy.[20] The targeted deletion of the BNP gene has indicated that BNP may act as a local antifibrotic factor and may be involved in the mechanism that inhibits the development of cardiac hypertrophy and fibrosis.[17] Further studies with deletion of CNP, BNP, or GC-B receptor showed that these natriuretic peptides are in fact unlikely regulators of volume and sodium excretion, but exert autocrine and paracrine effects mediated by cGMP on cellular proliferation and differentiation in the different tissues, in particular vasculature, bones, and fibroblasts.[17]

Endocrine and Exocrine Pancreas

All NPs and their receptors are expressed in the pancreas and gastrointestinal tract.[26] Rat pancreatic islet α and β cells, and insulinoma cells (INS-1E) express GC-A receptor, whereas C receptors are only expressed in pancreatic α cells.

The close link between ANP and diabetes mellitus has been shown.[18] Acute hyperglycemia in the type 1 diabetic patient is associated with increased ANP mRNA and plasma ANP levels.[18] Although the short-term effect of ANP on insulin secretion is controversial, recent studies have shown that long-term exposure of isolated islets to ANP inhibits glucose-stimulated insulin secretion and ATP generation.[35] Furthermore, ANP activation of GC-A receptor in pancreatic β cells and in the glucose-responsive insulinoma (INS-1E) cell line, results in growth involving SER-THR kinase AKT/PKB, FoxO1a pathways, and cyclin D2-mediated by activation of phosphatydylinositol 3`kinase (PI3K). Insulin secretion in response to other secretagogues is also markedly inhibited by ANP. ANP significantly increased the level of islet-activated hormone-sensitive lipase and the expression of uncoupling protein-2 and peroxisome proliferator-activated receptors γ and α. Interestingly, although islet GC-A receptor expression was reduced by 60% after 7 days in culture with ANP, cGMP levels remained similar to control islet levels.[35] Finally, the GC-A knockout mice showed glucose-stimulated islet insulin secretion, supporting the concept of inhibition of insulin secretion by ANP.[22]

Gastrointestinal Tract

All three NP receptors have also been shown in isolated acini from rat pancreas,[25] and ANP is present in acinar and centroacinar cells and in nerve fibers in the pancreas of porcine and other species. Both CNP and ANP stimulate amylase release secretion from isolated pig pancreatic segments. Because of the close association between peptide localization in nerve fibers with pancreatic secretory cells, it has been suggested that nerve fibers release ANP, which subsequently stimulates protein and amylase secretion.[1] ANP exerts a direct stimulatory action on the pancreatic secretion of acinar fluid and protein, through C receptors coupled to the phosphoinositide pathway,[26] independent of nitric oxide or parasympathetic activity. ANP has an inhibitory effect on glucagon secretion by a mechanism that involves cGMP inhibition of calcium uptake, likely via C receptors.

Several findings support the participation of ANP in the modulation of gastrointestinal physiology and digestive exocrine glands. All NPs and their receptors are expressed in the human liver.[34] ANP and CNP administered centrally or peripherally decrease spontaneous and sodium dechlorocholate-evoked bile secretion and modify the bile composition by a direct effect, independent of the autonomic nervous system.[26] Some results suggest that the inhibitory response of bile secretion to ANP and CNP occurs by a calcium-dependent mechanism.

ANP has been localized in enterochromaffin cells in gastric antrum and GC-A and C receptors are present in antral mucosa, and ANP has been shown to be involved in the regulation of gastric acid secretion. Intracerebroventricularly administered ANP increases gastric secretion in rat

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

through the vagal-dependent mechanism. However, intravenous injection of ANP has biphasic effect on gastric secretion. Although a low dose enhances vagal-stimulated gastric secretion, high dose decreases it, indicating also paracrine/autocrine action and supporting the involvement of the peptidergic pathway.[24]

The effect of ANP and all NP receptors have been described in exocrine glands related to water and salt homeostasis including the submaxillary and parotid glands. ANP has been localized in both acinar and parotid duct cells. Several studies have shown that ANP plays a regulatory role on gland function such as enhancement of the salivary amylase secretion and on electrolyte composition of the saliva. Although ANP has no effect on salivation per se, it enhances salivation stimulated by various sialogogic agonists. The ANP effect on amylase secretion is mediated by the increase in intracellular calcium level linked to phosphoinositide metabolism within acinar and the ductal cells.[24]

Taken together, these observations clearly indicate an important neuromodulatory role of NPs in the control of digestive functions and may contribute to the development of new strategies for the diagnosis, treatment, and prevention of digestive diseases.

Pituitary Gland

NPs are specifically involved in the regulation of the hypothalamic–pituitary–adrenal axis. ANP immunoreactivity was detected in both anterior and posterior lobes of the pituitary gland. However, ANP synthesis occurs only in the anterior pituitary by detection of prohormone. ANP is a hypothalamic neurohormone that regulates blood pressure and volume by direct effects on blood vessels and kidney and indirectly by inhibiting the secretion of arginine vasopressin (AVP), renin, and aldosterone. In various species, ANP inhibits AVP and oxytocin release in response to osmotic stimuli or after hemorrhage and reduces plasma AVP in euhydration and dehydration.[15]

Recent evidence indicates that CNP has emerged as an important neuroendocrine regulator.[11] Although the highest tissue concentration of CNP is found in anterior pituitary, comparative studies of gene expression in mouse pituitary localized the CNP mRNA specifically in gonadotrophs. Furthermore, gonadotroph-derived cells αT3-1 secrete the mature form of CNP. The accumulation of cGMP in primary cell culture of pituitary gland and in the pituitary cell lines with characteristics of gonadotrophs (αT3-1), lactotrophs (GH3), corticotrophs (AtT-20), and folliculo-stellate cells (TtT-GF) is higher after administration of CNP than ANP or BNP. This indicates that the cGMP in the pituitary gland is predominantly stimulated by the CNP-specific, GC-B receptor.[11]

ANP probably plays an important inhibitory part in the neural control of adrenocorticotrophic hormone (ACTH) release.[10] ANP is a potent inhibitor of basal ACTH secretion, and secretion induced by hemorrhage, central angiotensin II administration, or stress. The latter may be mediated, at least partly, by suppression of AVP release from the neural lobe. One important aspect of the hypothalamic and pituitary action of NPs is their ability to interrupt the mechanism controlling the release of CRH, the hypothalamic releasing hormone involved in the peripheral stress hormone secretion. ANP, BNP, and CNP inhibit CRH-evoked ACTH secretion in mice hemipituitary preparations, with CNP being the most effective.[14] NPs also significantly reduce pituitary pro-opiomelanocortin mRNA expression. ANP can act directly on the pituitary to stimulate luteinizing hormone and follicle-stimulating hormone release, and to inhibit prolactin release, although the effects of ANP on release of these hormones are yet to be confirmed. ANP does not influence the release of thyrotropin and prolactin from dispersed anterior pituitary cells; nevertheless, central administration of high doses of ANP can cause a significant inhibition of prolactin, suggesting that it has no direct influence on lactotroph cells in inhibiting prolactin secretion but may activate the hypothalamic–dopaminergic system.[19] On the other hand, endogenous ANP plays a pathophysiological role in augmenting prolactin release during stress, either by inhibiting the release of prolactin-inhibiting factors or, alternatively, by enhancing the release of prolactin-releasing factors.[12] Intracerebroventricular injection of ANP increases plasma growth hormone levels in both conscious and urethane-anesthetized rats.

Adrenal Glands

Human and rat adrenal medulla is a site of synthesis of NPs and their three receptors. Adrenal chromaffin cells are endocrine cells embryologically derived from neural crest and biochemical analysis of bovine chromaffin cell extracts revealed the presence of mature form of ANP and its precursor indicating local synthesis. Several lines of evidence have shown the presence of NP receptors in adrenal chromaffin cells of various species, suggesting that these peptides secreted from adrenal medulla regulate chromaffin function in an autocrine manner. In the adrenal medulla, NPs participate in the inhibitory control of release and increase in catecholamine uptake. In tissue slices obtained from humans with pheochromocytoma, a tumor derived from the adrenal medulla, the basal secretion of cathecholamines is inhibited by ANP, suggesting that NPs could play a role in the pathology of adrenocortical neoplasms and pheochromocytomas.[21]

NPs are known to inhibit basal and angiotension-II-stimulated aldosterone secretion through an increase of

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

intracellular cGMP and inhibition of T-type calcium channels.[28] NPs also inhibit the growth of cells in zona glomerulosa. The role of ANP in the regulation of aldosterone, which plays a central part in the control of blood pressure, has been suggested in the development of hypertension in offspring from food-restricted mothers. An elevated plasma aldosterone level is associated with decreased plasma ANP and an increased density of adrenal C receptors, which could explain, at least in part, the observed increase in arterial blood pressure.[28] The adrenomedullary synthesis of ANP is increased in patients with primary aldosteronism, and ANP mRNA is upregulated in the adrenal medulla and cortex of DOCA-salt treated rats, confirming the role of ANP in regulating both aldosterone release and blood pressure.

Adipose Tissue

Stress-related chronic stimulation of hypothalamic–pituitary–adrenal axis and increased glucocorticoid exposure are important pathophysiological factors in the development of obesity. It has been recently hypothesized that NPs, which mediate endocrine and behavioral responses to stress, could also be involved in the pathophysiology of obesity. Several lines of research have shown that obese patients have lower plasma levels of NPs than lean patients do, even though obesity is associated with an increased risk of cardiovascular disease such as heart failure and hypertension, which are paradoxically accompanied by increased NPs. Therefore, it could be hypothesized that reduced peripheral NPs could lead to reduced lipolysis and excessive weight gain, which would contribute to the development of obesity.[3]

Until recently, ß-adrenergic agonists were considered as main hormones controlling lipolysis in human adipocytes, but results now indicate that part of lipid mobilization could result from the direct effect of NPs both in situ in human adipose tissue and *in vitro* in human fat cells.[30] ANP and BNP stimulate lipolysis with the greater potency than CNP in human isolated fat cells, and this effect is accompanied by cGMP accumulation. The activation of cGMP-dependent protein kinase may be a key mechanism of action of NPs in human adipocytes. Understanding the potential mechanism of the association between adiposity and NP status could allow the development of new therapeutic strategies.

Thyroid and Parathyroid Glands

The entire NP system is present in the thyroid gland, and some results point to a functional role of NPs in the regulation of thyroid hormone secretion. Plasma concentrations of ANP are decreased in patients with hypothyroidism, whereas in hyperthyroidism, a two-fold increase in circulating plasma ANP is observed in comparison with normal healthy subjects. Thyroxine treatment of hypothyroid patients normalizes ANP circulating levels. ANP infusion in humans decreases plasma triiodothyronine and T_4 levels, resulting in a reciprocal increase in TSH secretion, indicating that the ANP action occurs directly in the thyroid not via the pituitary or hypothalamus; otherwise, TSH levels would decrease in the circulation if the inhibitory effects occurred at hypothalamic or pituitary sites.[32]

In terms of thyroglobulin production, ANP suppresses production in cultured human thyroid cells, and this is correlated with a reduction of cAMP, indicating that the effect is mediated by C receptors. The role of GC receptors is supported by another study where ANP and CNP altered the morphology of human thyroid cells by increasing cells of the retracted phenotype.[29] The upregulation of the ANP gene expression by thyroid hormones together with the observation that T_4 increases plasma ANP in patients with hypothyroidism indicates the clinical relevance of NPs in the thyroid gland.

The functional interaction between parathyroid hormone (PTH) and NPs have been observed in modulating cyclic nucleotides and cell proliferation in chondrocytes and osteoblasts, indicating a possible role of ANP on calcium and phosphate metabolism The direct action of ANP on the release of endothelin from cultured rat parathyroid cells has been shown, indicating the presence of NP receptors in the cells. The identical circadian rhythms of NPs and PTH together with the evidence that PTH may release ANP let to conclusion that some of the effects of PTH may be mediated by NPs. Some evidence suggested the possible interactions of ANP in the PTH (1–84) regulation of blood pressure and volume homeostasis in healthy subjects. Volume depletion by bolus injection of ANP was associated with the decrease of PTH (1–84) in healthy subjects but not in patients with liver cirrhosis or nephrotic syndrome; however, the clinical relevance is yet to be shown.[6]

Reproductive Organs

Although all NPs are highly expressed in male and female reproductive organs, and stimulate the release of gonadotropin factors from the pituitary gland, there is strong evidence that CNP acts as a local paracrine or autocrine regulator in female reproduction, pregnancy, and fetal development. CNP also plays a distinct role in male reproduction.[19]

In rodent ovaries and uteri, both CNP and GC-B show estrus cycle-dependent gene expression, with maximal expression at proestrus.[8] The modulation of follicular atresia in follicles at preantral to antral transition has been postulated. During pregnancy, the synthesis of CNP shows an organ-specific expression in maternal reproductive tissues with the highest concentration occurring in the placenta. The highest expression of CNP mRNA in the placenta would indicate a defined biological function of this peptide in gestation, possibly to antagonize overactive vasoconstrictive systems. Higher CNP levels have been found in the fetal

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

rather than in the maternal circulation, suggesting the need for and ability of the fetus to synthesize de novo CNP and ANP. Pathological pregnancies, such as intrauterine growth retardation or preeclampsia, present differential regulation of CNP synthesis. When compared with normal pregnancy, CNP decreases in the placenta with an increase in the myometrium, indicating CNP organ-specific function in these pathologies. Because maternal plasma levels do not correlate with those alterations, it can be suggested that the CNP/GC-B/cGMP system acts locally in an autocrine/paracrine fashion exhibiting organ-specific effects. Interestingly, the offspring of CNP-deficient mice show dwarfism resulting from impaired endochondral ossification. Neonatal mice show growth retardation and high mortality, although surviving animals are fertile. Transgenic mice overexpressing CNP also show bone malformation suggesting that the main function of CNP in fetus is the regulation of bone growth by the chondrocyte proliferation and cartilage matrix production.

NPs stimulate testosterone production by Leydig cells. In humans, acute α-hANP injection significantly increases testosterone concentrations in the spermatic vein but not in peripheral blood. The role of NPs in the early phase of fetal testicular steroidogenesis has been postulated before the onset of pituitary luteinizing hormone secretion.[9] Furthermore, the paracrine action, particularly of CNP, includes relaxation of seminiferous tubules necessary to regulate sperm transport and testicular blood supply.

Support for ANP function in the maintenance of serum testosterone and testicular steroidogenesis is provided by a study in Leydig cells isolated from GC-A –/– and transgenic mice. ANP had no effect on testosterone production in GC-A –/– mice. However, Leydig cells isolated from animals having extra copies of GC-A gene showed increased steroidogenesis.

CNP and GC-B receptors are expressed in the testis[19] and in porcine seminal plasma. CNP regulates testicular function, such as testosterone release, modulation of spermatozoa mobility, and testicular cell germ development. The possible involvement of CNP in penile erection has also been hypothesized, because CNP activates GC-B receptors and increases production of cGMP localized on the cavernosal membrane. The specific relevance of cGMP system for the reproductive functions has recently been shown by the successful use of sildenafil, an inhibitor of cGMP-specific phosphodiesterase type-5, for the treatment of erectile dysfunction. Because NPs are involved in multiple local functions in testis, it may be speculated that NPs via cGMP- mediated processes might influence the *potentia coeundi* within the penis and *potential generandi* at different levels within the testis.[19]

PATHOPHYSIOLOGICAL IMPLICATIONS

In patients with congestive heart failure, plasma concentrations of ANP and BNP and their N-terminal fragments of prohormones are elevated because the cardiac hormonal system is activated by volume overload and pressure. NPs have a beneficial, compensatory action in heart failure by inducing vasodilatation, natriuresis, and inhibition of the sympathetic nervous and renin–angiotensin–aldosterone systems. Furthermore, with their well-documented autocrine/paracrine effects within the heart, such as regulation of coronary blood flow, proliferative responses contributing to vascular remodeling, and cardioprotection, NP therapy could greatly benefit the patient with cardiovascular disease. These diverse actions may have a significant counterregulatory role to the various neuroendocrine mechanisms activated in cardiovascular diseases.

Although the effects of NPs have been reported in various glands in several experiments, the intracellular signal transduction pathways remain to be identified in the organ in which the effects have been observed. The elucidation of these regulatory mechanisms would allow us to understand the importance of autocrine/paracrine regulation by the NPs in physiology and in pathophysiological states. During the past decades, great progress has been seen in our understanding of cGMP regulation of many endocrine functions. However, the question still remains whether the most important role in cGMP generation occurs by the action of natriuretic peptides or nitric oxide. Ultimately, an understanding of autocrine/paracrine actions of NPs may lead to their therapeutic application in various pathologies.

Chapter 135

Neuromedins U/S

Ludwik K. Malendowicz, Marcin Rucinski and Agnieszka Ziolkowska

ABSTRACT

Neuromedin U (NMU) and neuromedin S (NMS) are structurally related and highly conserved neuropeptides that act via two receptors designated NMUR1 and NMUR2. NMUR1 is expressed predominantly in the periphery, whereas NMUR2 is expressed in the central nervous system. NMU and NMS share a C-terminal pentapeptide and bind to the same receptors. Therefore, it is believed that both the peptides have similar putative physiological actions. A growing body of evidence suggests that NMU and NMS function in the regulation of smooth muscle contractions, central and peripheral energy homeostasis, ion transport, circadian rhythms, stress responses, vasoconstriction, nociception, and bone remodeling. This system has also been implicated in the pathogenesis of septic shock, mast cell-mediated inflammation, and cancer. This chapter focuses on the expression and function of NMU and NMS in the endocrine system. Progress in molecular biology techniques provided new information on this subject, allowing a better understanding of the role played by both the neuromedins in the endocrine system.

INTRODUCTION

In 2000, neuromedin U (NMU), a multifunctional neuropeptide originally isolated from porcine spinal cord, was identified as an endogenous ligand for the orphan receptors FM-3/GPR66 and FM-4/TGR1 Subsequently, these receptors were named NMUR1 and NMUR2, respectively. NMUR1 is expressed predominantly in the periphery while NMUR2 is highly expressed in specific regions of the central nervous system.[1,8,24] In 2005, another endogenous ligand for NMUR1 and NMUR2 receptors was identified in the rat. This ligand is highly expressed in the suprachiasmatic nucleus of the hypothalamus, and therefore, it was designated as neuromedin S (NMS).[25] In various species, numerous NMU molecular forms have been identified and their amino acid sequences extend from 8 (NMU8) to 38 (NMU38) aa.[24] NMS, however, is a 36-amino-acid neuropeptide, which shares the amidated C-terminal pentapeptide with NMU. Interestingly, NMS analogs—NMS17 and NMS33—have also been identified. Despite these similarities, the human NMU and NMS genes have been mapped to different chromosomes. Thus, NMS is not a splice variant of NMU. NMUR2 has a greater affinity for NMS than NMU and in the rat NMS mRNA has a more limited distribution than NMU.[25] Experimental results suggest that NMS exerts more potent activity than NMU in the central nervous system but both peptides exert similar activity in peripheral tissues and *in vitro*.

Controversy exists over the presence of endogenous NMU and NMS in the general circulation. The manufacturers' manuals for various kits contain data on the neuropeptide concentration in plasma (human NMU – 0.1–5 ng/mL; NMS – 0.2–0.9 ng/mL) and comparable figures are shown in clinical studies.[18] However, experimental results suggest that neither endogenous NMU nor NMS are circulating, at least in the rat. Further, the t1/2 of NMU is shorter than 5 min. These findings suggest that NMU and NMS may function in an endocrine manner, but they also may exert paracrine or autocrine effects on target cells.

Both NMU and NMS contract smooth muscle, increase blood pressure, stimulate pain, modify intestinal ion transport, and regulate feeding and circadian rhythms. In recent years, the interest in neuromedins U and S significantly increased because of the discovery of their involvement in the regulation of energy homeostasis.[10,12,13,19,26,27] Further, both neuromedins are involved in the regulation of neuroendocrine axes and may modulate the growth and secretory activity of endocrine glands.[1,22,24]

This chapter focuses on the expression and function of NMU and NMS in the endocrine system. Progress in molecular biology techniques provided new information on this subject, allowing better understanding of the role played by both the neuromedins in the endocrine system.

Elements of the NMU/NMS and NMUR1 and NMUR2 system are present at both mRNA and protein levels in the hypothalamus and all classic endocrine glands. Examples of results for NMU/NMS and NMUR1 and NMUR2 mRNA expression in the rat are shown in Figures 1 and 2.

HYPOTHALAMUS

The earliest studies indicated a high level of NMU-like immunoreactivity in the rat, mouse, and human hypothalamus.[4,11] Modern molecular biology techniques have enabled

a more precise localization of NMU to hypothalamic nuclei and cell types. Generally, in the anterior and middle hypothalamus, which are the regions involved in neuroendocrine regulation, NMU is localized in nerve fibers while an intense NMS-like immunoreactivity is present in cell bodies of the suprachiasmatic nucleus.[1,24,25] In the rat hypothalamus, expression of the NMS gene is nearly 3-fold higher than that of the NMU gene.[29] These regions of the hypothalamus are also provided with highly specific NMU-binding sites, which have been identified as NMUR2. Among others, NMUR2 mRNA is expressed within the paraventricular nucleus (NPV) and the wall of the third ventricle (ependymocytes). The presence of NMUR2 receptors in these regions of the brain has also been confirmed by receptor autoradiography.[1,24]

The above-described localization of elements of the NMU/NMS and NMUR2 system in the hypothalamus forms a basis of regulation by NMU and NMS of neuroendocrine function. It is well documented that NMU administered icv enhances expression of c-Fos immunoreactivity or its mRNA in PVN, supraoptic nucleus, arcuate nucleus, and lateral hypothalamic area. Further, in the rat NMU administered icv, subcutaneously or into the NPV increases blood ACTH and glucocorticoid concentrations via the stimulation of CRH release.[15,22,32] Also, NMS administered icv stimulates corticosterone secretion in the rat, and similar changes were observed in steers administered icv with NMU or NMS.[14] These findings suggest that both NMU and NMS activate a main part of the hypothalamic–pituitary–adrenal (HPA) axis.

Several reports suggest the involvement of NMU and NMS in the hypothalamic regulation of gonadotropin release; however, the available results are controversial. In the rat icv, NMU administration inhibited LH and FSH release or had no effect.[8,31] Increased release of LH, however, was observed

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

only after icv, but not after intravenous administration of NMS. NMS (from 1 to 1000 nM) directly stimulated GnRH release from the pig hypothalamic explants. It has also been suggested that NMU administration to the rat slows the onset of puberty.[33]

Both NMUR2 and oxytocin mRNA are coexpressed in the rat NPV. Therefore, it is not unexpected that icv NMU administration stimulates arginine vasopressin and oxytocin release.[32] Of interest is that after icv administration output evoked by NMS is more pronounced than that induced by the equimolar dose of NMU. Rapid NMS-induced oxytocin release may indicate that NMS may mimic the suckling-induced oxytocin release.

The above-described NMU and NMS-induced alterations in functioning of the central part of the neuroendocrine axes suggest that both neuromedins, acting by the activation of different controlling systems of the brain, may indirectly regulate secretion of pituitary hormones. However, evidence is available that they may also exert a direct effect on hypothalamic structures controlling these axes. A direct stimulating effect of NMU on CRH and AVP release from rat medial basal hypothalamic explants *in vivo* was shown by Wren et al.[32] Further, by means of whole cell patch-clamp recordings, Qui et al.[28] observed that NMU selectively depolarized the subpopulation of PVN parvocellular neurons (which are known to secrete, among other peptides, CRH) via enhancement of the hyperpolarization-activated inward current.

PITUITARY GLAND

Soon after the discovery of NMU, RIA and immunohistochemistry showed the presence of NMU-immunoreactive substances in the intermediate and anterior pituitary gland lobes of various species, among them mouse, rat, and human.[4,5,23,30] In the mouse, rat, and human adenohypophysis, NMU immunoreactivity is found in corticotrophs.[2,30] Electron microscopy studies revealed NMU-like immunoreactivity in some thyrotrophs and most corticotrophs of the rat pituitary gland. NMU is colocalized with galanin and ACTH in the same secretory granules.[22]

NMU mRNA is highly expressed in the rat adenohypophysis, while expression of NMUR1 is relatively low and that of NMUR2 practically absent. In contrast to NMU, NMS mRNA expression in adenohypophysis is very low and in rat expression of NMU gene is almost 1000-fold higher when compared with that of the NMS gene.[29] In the pituitary of the pig, on the other hand, relatively high expression of NMS and NMR2 mRNA was reported.[34]

The physiological role of NMU in pituitary gland is unclear. At the protein level, anterior pituitary expression of this neuropeptide is highly regulated by thyroid hormones.[5]

Only scanty results are available on the direct effect of NMU or NMS on the secretory activity of the adenohypophysis. A direct suppressive effect of NMU on LH and FSH release by rat primary pituitary cell cultures was reported.[7] To clarify the role of NMU in the regulation of gonadotropin secretion, examination of gonadal function in NMU-KO mice revealed an early onset of vaginal opening. NMU-KO mice maintain normal concentrations of NMS and therefore the authors suggested that "it is unlikely that NMS is also involved in the regulation of LH and FSH releases from pituitary." In this context, rather unexpected results had been published on the effects of NMS on the release of LH and FSH from isolated pig anterior pituitary cells.[33] In these studies, NMS dose dependently increased LH release from pituitary cells, while none of the NMS doses changed FSH release.

THYROID GLAND

The NMU content of the whole thyroid gland of the rat is relatively low and thyrotoxicosis induced by exogenous T4 fails to alter it while antithyroid drug treatment lowers it.[3] Immunostaining localized NMU to a minor (~5%) population of parafollicular C-cells, while no staining was observed in nerve fibers.

In rat thyroid gland, there is expression of NMU and NMUR1 mRNA although expression of NMUR2 is very low.[8,29] In the rat thyroid gland, expression of NMU gene is almost 1000-fold higher when compared with the expression of NMS gene. Expression of NMS and, unexpectedly, NMUR2 has been found in the pig thyroid.[34] The functional relevance of NMU and NMS in the thyroid gland remains completely unknown. In this regard, only Gartlon et al.[8] reported that in the rat icv, NMU administration did not affect plasma TSH levels.

PANCREATIC ISLETS

Earlier results on the expression of NMU in the pancreas were obtained from the samples of the entire pancreas. However, in isolated rat pancreatic islets, NMU but not NMS mRNA and NMUR1 but not NMUR2 mRNA have been identified.[16,17,29] Further, in pancreatic islets, NMUR1 protein was also identified by Western blotting and immunohistochemistry showed NMUR1-like substances in peripheral cells of the islets.

A functional study revealed that NMU in concentrations from 1 to 100 nmol/L dose dependently reduces insulin output by isolated rat pancreatic islets.[17] Moreover, NMU also lowers insulin secretion from in situ perfused rat pancreas. The insulinostatic effect of NMU on insulin release is accompanied by increased somatostatin (SST) secretion. As is known, SST is a potent inhibitor of insulin secretion and results of subsequent experiments suggest that SST may mediate the NMU-dependent inhibition of insulin secretion. It should be emphasized that the direct, NMU-evoked and SST-mediated reduction of insulin secretion is in accord with the anorexigenic action of NMU.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

ADRENAL GLAND

Involvement of NMU in the regulation of adrenal cortex growth and function was recognized soon after the identification of this neuropeptide.[22] In view of these findings, the NMU/NMS system in the adrenal has also been studied recently by means of molecular biology techniques. Very low expression of NMU gene in the rat adrenal has been reported by several groups. The human adrenal gland contains both NMUR1 and NMUR2 receptors. Detailed studies on the rat adrenal gland reveals very low expression of NMU and NMS genes at the mRNA level.[29] In immature rat adrenal, NMUR1 is expressed at both mRNA and protein levels, while the signal from NMUR2 is absent. NMUR1 mRNA is present in all adrenocortical zones and in the medulla.[35] Moreover, the presence of NMUR2 mRNA in isolated zona glomerulosa and fasciculata/reticularis cells eliminates the possibility that the expression results from the presence in the assayed specimens of non-parenchymal components of the gland. In contrast to rats, expression of NMS, and (again unexpectedly) NMUR2, has been described in the pig adrenal.[34]

Earlier results on the interrelationship between NMU and HPA axis have been reviewed.[22] Apart from the above-mentioned central CRH-mediated action of NMU on the HPA axis, NMU also directly affects adrenocortical function. As shown by our group, NMU8 has no effect on basal and ACTH-stimulated corticosterone secretion by isolated inner zone adrenocortical cells. This neuropeptide, however, stimulates corticosterone output by adrenal slices, an effect shown only at an NMU concentration of 10^{-8} M. Detailed analysis of the NMU8 action on the rat adrenal slices reveals that at all concentrations tested (10^{-8}–10^{-6} M) NMU8 increases basal pregnenolone and total post-pregnenolone steroid output by gland slices containing both cortex and medulla.[20,21] However, NMU8 is able to stimulate corticosterone secretion only at the lowest concentration. At a higher concentration, the NMU8-stimulating effect is masked by the strong enhancement of 18-hydroxylation. This effect of NMU8 is not observed in adrenocortical autotransplants, which are deprived of chromaffin cells and which display a normal secretory response to ACTH. These results suggest that at the adrenal level NMU8 affects the steroid secretion indirectly by acting on the medullary chromaffin cells, which in turn may paracrinally stimulate the adrenal cortex. It has been suggested that the medullary mediator of NMU8 action on the adrenal cortex may specifically activate 18-hydroxylation and aldosterone synthase activity. Recent results also show a direct stimulating effect of NMU on proliferative activity of immature rat inner adrenocortical cells in primary culture.[35]

As mentioned in the "Hypothalamus" paragraph, growing evidence indicates that the NMU/NMS system plays an integral role in mediating the stress response.[9] In view of the available results, it seems legitimate to suggest that NMU/NMS integration of the stress response is mediated at both a central level (CRH pathway) and at the level of the adrenal cortex.

TESTIS

Rat testes contain NMU mRNA, a finding that is in accordance with earlier results on the presence of NMU-like immunoreactive substances in this tissue.[4,24] Further, in testes expression of NMS was reported by Mori et al.[25] In the rat testis, expression of the NMS gene is almost three-fold higher than that of NMU.[29] There is expression of NMUR1 and NMUR2 in human and rat testis. Unfortunately, no results are available on the cytological localization of the genes in the gonads.

The role of NMU/NMS in the testes remains puzzling. To our knowledge, no results are available either on the presence of particular elements of the MU/NMS system in the spermatogenic or endocrine compartments of the testis or on its function.

OVARY

The presence of NMU-like immunoreactive substances in rat ovaries was reported by Domin et al.,[5] and NMU mRNA was also found. Moreover, in rat ovary, NMS mRNA has been identified.[29] Initially, in the rat ovary, only NMUR2 mRNA was found but subsequent studies revealed the expression of both NMUR1 and NMUR2 genes. In addition to the rat, there is NMS and NMUR2 mRNA in the pig ovary.[33,34] In this species, expression levels of NMS and NMUR2 genes are dependent on the stage of the estrous cycle. Gene expression is the highest in diestrus and lowest in proestrus.

As in the case of testis, no results are available on the presence of particular elements of NMU/NMS system in ovarian compartments. However, NMS at a concentration of 10, but not 1, 100, or 1000 nM was found to stimulate estradiol output from cultured ovarian granulosa cells of the puberal pig.[33] Moreover, in ovarian tumor cell lines, NMU gene is overexpressed when compared with ovarian surface epithelial cell lines.[6]

CONCLUSIONS

The physiologic role of the NMU/NMS system is not fully recognized yet. The available experimental results indicate that neuromedin U and S may exert both endocrine and/or paracrine/autocrine effects on target cells.

Discovery of the anorexigenic action of NMU/NMS triggered great interest in this field and there are new findings on their physiological role. Well documented is the role of NMU/NMS in central and peripheral energy homeostasis regulation and, in this regard, CRH stimulation and direct

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

insulinostatic effects of both neuropeptides. Further, a direct effect of these neuropeptides on the secretory activity of the rat adrenal cortex may also contribute to their anorexigenic action.

Growing evidence indicates that the NMU/NMS system plays an integral role in mediating the stress response, not only through the CRH pathway. This response may also be mediated by neuromedins' action on vasopressin release and via their direct action on the adrenal gland.

Recent results also suggest involvement of NMU/NMS in the regulation of the reproductive system. Scarce experimental results suggest that NMU/NMS indirectly and directly stimulate GnRH release at the hypothalamic level. Moreover, NMU/NMS directly affects FSH secretion from the adenohypophysis and estradiol output from ovarian granulosa cells. Further, NMU affects puberty onset in the mouse.

It has also been suggested that NMU exerts a tumorigenic action that may be involved in cancers such as that of the pancreas. However, results on NMU overexpression are only available for ovarian and pancreatic cancer ductal cells. In this context, the role of NMU expression in pituitary corticotrophs of the normal human gland and ACTH secreting tumors remains to be elucidated.

Chapter 136

Neuropeptide B/W

Fumiko Takenoya, Haruaki Kageyama, Ki Sung Kang and Seiji Shioda

ABSTRACT

Neuropeptides B and W (NPB/NPW) have been identified as endogenous ligands of the G protein-coupled receptors NPBWR1 and NPBWR2, which belong to the orphan G protein-coupled receptor (GPCR) family. NPB/NPW is expressed widely in brain including the hypothalamus, pituitary, and adrenal gland, suggesting that NPB/NPW may have a role in the modulation of neuroendocrine functions. Moreover, intracerebroventricular infusion of NPW suppresses food intake and body weight and increases both heat production and body temperature, suggesting that NPW functions as an endogenous catabolic signaling molecule. Moreover, the expression of NPB/NPW and NPBWR1 mRNA is detected in the periaqueductal gray and amygdala where opioid receptors exist, suggesting that NPB/NPW may be related to pain function. Thus, NPB and NPW play very important physiological functions. In this chapter, we describe the neuroendocrine function of NPB/W and its role in regulating feeding behavior, energy homeostasis, and inflammatory pain.

INTRODUCTION

GPCRs compose the largest family of cell-surface mediators of signal transduction. Therefore, the continued discovery of genes encoding GPCRs has provided an extensive reserve of potential therapeutic targets. Both NPBWR1 and NPBWR2 belong to the GPCR family, the members of which are characterized by their seven transmembrane domains. These two GPCRs were identified by cloning opioid–somatostatin-like receptor genes from human genomic DNA.[21] NPBWR1 is expressed in the brain and peripheral organs of both human beings and rodents but is not expressed in rodents. NPBWR1 mRNA is expressed in the hypothalamus such as the arcuate nucleus (ARC), ventromedial hypothalamus (VMH), paraventricular nucleus (PVN), and dorsomedial nuclei, which are believed to be involved in the regulation of feeding and energy balance. NPBWR1 is most abundantly expressed in the central amygdaloid nucleus (CeA) and bed nucleus of the stria terminalis (BST), suggesting that NPBWR1 may be involved in the regulation of stress, emotion, fear, and anxiety.[13,27] NPBWR1 and NPBWR2 mRNAs are also localized in the pituitary and adrenal glands, suggesting that the peptides may influence the neuroendocrine response to stress via the hypothalamic–pituitary–adrenal (HPA) axis.[16] Moreover, NPBWR1 mRNA is expressed in the spinal cord and thus may be involved in pain regulation.

Between 2002 and 2003, neuropeptide B (NPB) and neuropeptide W (NPW) were identified by several research groups as the ligands for two orphan GPCRs, NPBWR1 and NPBWR2.[2,7,26,30] Both NPB and NPW consist of two forms, 23 and 29, 23 and 30 amino acids in length, respectively. Subsequently, several immunohistochemical studies have shown that NPBs/NPWs are expressed widely in brain including the PVN, midbrain, and in tissues such as the pituitary and adrenal, suggesting that NPBs/NPWs have roles in modulating neuroendocrine functions.[6,13,24,26,28–30]

NEUROENDOCRINE FUNCTION OF NPB/NPW

Immunohistochemical studies have reported that NPBWR1 is expressed in the PVN, supraoptic nucleus (SO), ARC, suprachiasmatic nucleus (SCh), pituitary gland, and adrenal medulla in the human, mouse, and rat.[2,14,21,30] Moreover, NPW23-immunoreactive cells are detected in the PVN, mainly in the parvocellular subdivisions, SO, accessory neurosecretory nuclei, dorsal and lateral hypothalamic areas, perifornical region, ARC, and anterior and posterior pituitary. These observations may indicate that NPBs/NPWs interact with neuroendocrine systems that control hormone release from the anterior pituitary gland. In addition, restraint stress induces c-Fos expression in several brain regions, including hypothalamic and amygdaloid nuclei,[3] where NPW-like immunoreactive (-LI) neurons are abundantly distributed. Moreover, c-Fos expression in the PVN is significantly increased by intracerebroventricular (icv) infusions of NPW in the mouse. This suggests that NPW seems to respond to stress and to release pituitary hormones directly through NPWBR1 on the HPA axis.[20,26] However, NPB and NPW are not reported to influence the release of other anterior pituitary hormones. These neuroendocrine

effects of NPB/NPW are not mediated directly through NPWBR1 but may be mediated indirectly through control of the release of the hypothalamic hormone corticotropin-releasing factor (CRH).[2,23]

NPB/NPW is colocalized with urocortin, a stress-related neuropeptide of the CRH family, in the Edinger–Westphal nucleus (EW). Tanaka et al.[30] have reported, with icv infusion of NPB, the anorexic effect of NPB is enhanced by pretreatment with CRH, which also has anorexic effects. Infusion of these two peptides almost completely suppresses food intake. These results suggest that NPB markedly enhances the anorexic effect of CRH. In addition, NPB-mediated release of corticosterone can be attributed to the release of CRH, as passive immunization using anti-CRH serum results in a significant attenuation of NPB release of corticosterone.[23] In addition, others have reported that NPB increases prolactin secretion but decreases growth hormone.[23]

Infusion of NPW23 stimulates prolactin release in the rat.[26] An *in vitro* study has reported that NPW23, in log molar concentrations ranging from 1.0 pM to 100 nM, significantly alters prolactin, growth hormone, and ACTH release from dispersed anterior pituitary cells harvested from male rats.[1] In *in vivo* studies, 1.0 nM NPW23 stimulates an approximately 2-fold increase in plasma prolactin levels, which attain significance at 60 min.[1] After icv infusion of 3.0 nM NPW23, plasma prolactin concentrations increase to levels 5- to 7-fold higher than those of controls. In addition, icv infusion of NPW23 (1.0 nM) results in a significant, 2-fold elevation in plasma corticosterone concentrations at 10 min after injection.[1] Increase of both prolactin and corticosterone plasma concentrations suggest a role for NPW in the hypothalamic response to stress. However, plasma growth hormone concentrations are inhibited by icv. infusion of NPW23. These findings suggest that NPW is the endogenous ligand for both GPR7 and GPR8 and acts as a mediator of the central control of neuroendocrine function.[1,26] Moreover, Taylor et al.[3] have reported that icv infusion of NPW activates the HPA axis, as shown by increased plasma corticosterone concentrations in conscious rats without stimulating the release of oxytocin (OXT) or vasopressin (AVP) in the peripheral circulation or altering blood pressure or heart rate. Additionally, icv infusion of a CRH antagonist does not significantly reduce corticosterone concentrations. However, pretreatment with a CRH antagonist significantly reduces the capacity of centrally administered NPW to increase corticosterone concentrations.[31] These observations suggest an action of NPW in the parvocellular subdivision of the PVN. Moreover, Taylor et al.,[31] using electrophysiological studies with whole cell patch recording of hypothalamic slice preparations, have shown that NPW depolarizes and increases the spike frequency of the majority of the identified putative neuroendocrine PVN neurons. Furthermore, the response of PVN neurons to NPW in the presence of TTX confirms the postsynaptic actions of NPW on these neuroendocrine cells.[31] Therefore, it is suggested that endogenous NPW may play a physiologically relevant role in the neuroendocrine response to stress in the brain. In addition, Nimi et al.[20] have examined the effect of immobilization stress and cold exposure stress on NPW neurons in the rat hypothalamus. They have found that a double immunostaining for both NPW and c-Fos is significantly increased in response to these stresses. Immobilization stress increases parasympathetic outflow, and cold stress is primarily considered to increase sympathetic outflow, suggesting that NPW may participate in the regulation of both the sympathetic and parasympathetic branches of the autonomic nervous system.

In the PVN, AVP neurons are known to regulate endocrine and autonomic stress responses into hormonal outputs.[32] Kawasaki et al.[11] showed that icv NPW30 significantly increased plasma concentrations of AVP and OXT 5 15 min later. The icv infusion of NPW significantly increases Fos-positive neurons in the SO and parvocellular and magnocellular divisions of the PVN. Moreover, dual detection of Fos-LI and OXT-/AVP-LI in the SO and PVN shows that both AVP-LI cells and OXT-LI cells exhibit nuclear Fos-LI in the SO and PVN after icv infusion of NPW30.[11] These results suggest that in the SO and PVN, NPW may stimulate the secretion of AVP and OXT in magnocellular neurosecretory neurons.

By using a cell patch clamp recording on the somatostatin neurons in the hypothalamic ARC, Price et al.[22] showed that NPW administration in the ARC results in the depolarization of most of the somatostatin neurons, suggesting a direct effect of NPW on the excitability of somatostatin neurons in the ARC. Therefore, the influence of NPW to suppress growth hormone release is caused by the activation of somatostatin neurons in the ARC. We summarize the neuroendocrine function of NPB/W in Fig. 1.

ENDOCRINE FUNCTION OF NPB/W

Hochol et al.[8] have shown that NPW increases ACTH-stimulated aldosterone secretion but does not affect either basal or ACTH-stimulated corticosterone production by dispersed zona fasciculata/reticularis cells. Moreover, bolus intraperitoneal injections of NPB or NPW enhance the plasma concentrations of parathyroid hormone, corticosterone, and testosterone as determined by radioimmunoassay. Furthermore, NPB increases the blood concentration of thyroxine, and NPW raises ACTH and estradiol levels in the rat, suggesting that NPB and NPW play a role in the autocrine–paracrine functional regulation of the endocrine system.[9] In addition, there is an ACTH-independent extraadrenal effect, because NPB and NPW stimulate adrenal glucocorticoid secretion *in vivo* but not mineralocorticoid secretion. In addition, NPW stimulates aldosterone secretion *in vitro* by enhancing the release of medullary catecholamines and subsequently activating beta-adrenoreceptors.[9]

RT-PCR analysis of peripheral tissues has identified NPB mRNA gene expression in the human kidney, uterus, ovary, testis, and placenta. High levels of NPB mRNA have been detected by Northern blot analysis in the rat stomach, spinal cord, testis, liver, and kidney.[1,30] Moreover, we have studied NPW expression in the rat adrenal gland, Total RNA was prepared from the hypothalamus, pituitary, and adrenal. RT-PCR analysis revealed the expression of NPW mRNA in these tissues, whereas in situ hybridization histochemistry showed the presence of NPW mRNA in the adrenal medulla. Immunohistochemical examination of tissue sections of the adrenal gland showed that NPW-LI is expressed only in the medulla but not in the cortex.[25] Moreover, we have shown that NPW-LI is colocalized with norepinephrine, but not epinephrine, in the adrenal chromaffin cells. NPW may play an important role in the regulation of the endocrine system response to stress, not only via the activation of the HPA axis but also via the paracrine pathway from the medulla to the cortex in the adrenal gland.[25]

In addition, NPW-containing cells have been identified by both light and electron microscopy in peripheral tissues such as the gastric antral glands in the rat, mouse, and human being. A double-immunolabeling study showed that NPW is present in the antral gastrin (G)-containing cells. NPW-positive cells accounted for 90% of chromagranin A-LI and 85% of gastrin-LI endocrine cells in rat gastric glands.[19] These results suggest an additional role for NPW in the regulation of gastric function. In the ontogenetic study of the rat stomach, NPW gene expression was initially detected at embryonic day 14 (E14) and gradually increased during development until postnatal day 1 (P1). Thereafter, the NPW mRNA level increased again from the weaning period (P21) through until adulthood. NPW-LI cells in the P1 antral stomach gradually increase during maturation throughout development.[19]

Furthermore, Mondal et al.[18] have reported that the levels of NPW in stomach antral cells significantly decrease after 15-h fasting but increase after refeeding. From these observations, feeding regulation by NPW may be affected through peripheral tissues including the stomach. NPW has also been shown to increase insulin release from isolated pancreatic islet cells in the presence of high concentrations of glucose. Fura-2 microfluorometry experiments with rat single β-cells show a concentration-dependent increase of NPW in cytosolic Ca^{2+} concentration ($[Ca^{2+}]_i$) at high glucose levels, which is abolished under external Ca^{2+}-free conditions and in the presence of an L-type Ca^{2+} channel blocker. Double immunohistochemical analysis shows that NPW-LI is present in pancreatic islets and is colocalized with insulin-LI in B cells, but not glucagon-LI A cells or somatostatin-LI D cells.[5] These results suggest that NPW serves as a local modulator of glucose-induced insulin release in rat islet cells.

REGULATION OF FEEDING AND ENERGY METABOLISM BY NPW

With reference to the hypothalamic nuclei, it is well known that the LH is a feeding regulation center, the VMH is a center for satiety, and the ARC is an integrated center for feeding regulation and energy homeostasis. NPBW1 mRNA is detected in the VMH, the dorsal medial hypothalamic nucleus (DMH), the PVH, and the ARC, which regulate feeding behavior and metabolic disorders. Moreover, several studies have shown the presence of NPW mRNA and NPW neurons in the hypothalamus, in particular the hypothalamic nuclei related to feeding regulation. NPBWR1 knockout mice are hyperphagic and show decreased energy expenditure, suggesting that NPW may act as a modulator of feeding and could modulate feeding behavior. Initial studies indicated that icv infusion of NPW in male rats increases food intake for the first 2 h in the light phase.[26] Similarly, Levine et al.[15] reported an orexigenic action of NPW by showing that administration of NPW into the PVN and LH results in hyperphagia. From these results, NPW was initially considered to be an acute orexigenic peptide.[26]

Our immunohistochemical studies show the colocalization of NPW with other feeding-regulating peptides such as orexigenic and anorexigenic peptides in the rat hypothalamus. NPW-containing nerve fibers and orexin- or melanin-concentrating hormone (MCH)-containing neuronal cell bodies and nerve fibers have been identified in the LH in rat.[28] Moreover, Levine et al.,[15] using a dual immunostaining method, showed that c-Fos-LI is upregulated in orexin-containing neurons in the perifornical region of the LH after icv infusion of NPW. Orexin is recognized as a peptide that promotes food intake and plays a role in the control of sleep and wakefulness. These findings strongly suggest that the effect of NPW on food intake and wakefulness may be mediated via the activation of the orexin pathway.

By contrast, an orexigenic action of NPW in the dark phase in response to continuous icv infusion was reported by Mondal et al.,[17] who showed that this treatment decreases food intake in the rat for 48 h. In addition, the icv infusion of anti-NPW IgG stimulates food intake, suggesting that NPW plays a role as a food intake inhibitory peptide.[17] The action of NPW differs in its effect on feeding action depending on whether animals are maintained in a light phase or dark phase. NPBWR1 is localized in the SCh,[14,27] and we have observed NPW-IL fibers in this area,[29] suggesting that NPW may modulate circadian rhythms.

We have identified NPW-LI cell bodies in the VMH, which is known as a center for satiety. Leptin acts on neurons in the VMH, where its receptors are abundantly expressed, and reduces food intake. Moreover, Date et al.,[4] reported that NPW-LI neurons and leptin receptors are colocalized in the VMH, and that NPW expression is significantly upregulated in ob/ob (leptin-deficient) and db/db (leptin receptor–deficient) mice. Therefore, NPW may play important roles in feeding and energy metabolism, functioning as a substitute for leptin. Moreover, NPW reduces food intake via the melanocortin-4-receptor signaling pathway. Thus, NPW may activate POMC-containing neurons and inhibit NPY-containing neurons to control feeding regulation in the ARC (Fig. 2).[4]

Mondal et al.[17] have also reported that they did not detect enhanced locomotor activity when NPW is administered to rats, but they observed increased O_2 consumption and CO_2 production while showing an increase in body temperature compared with the administration of vehicle alone. This effect, independent of locomotor activity, may result from protein and triacylglycerol catabolism induced by corticosterone. Interestingly, Mondal et al.[17] have found that the levels of NPW isolated from rat stomach antral cells are decreased in fasted animals and increased in animals that had been refed. By contrast, female NPBWR1-/- mice do not display hyperphagic activity compared with wild-type mice.[10] Dun et al.[6] have reported that differences between male and female rats exist with respect to the distribution

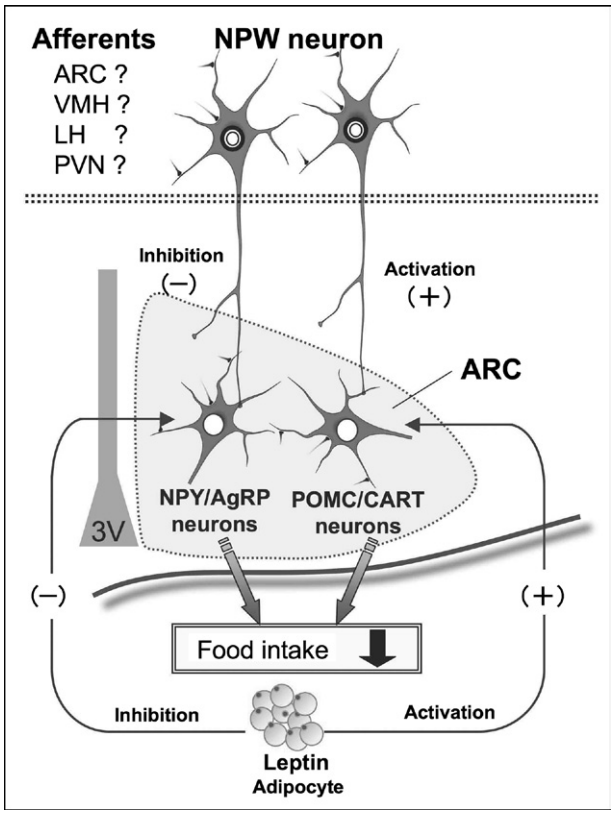

FIGURE 2 Schematic illustration based on the findings of morphological and physiological studies of appetite regulation in the hypothalamus by NPW neurons and feeding-related peptides. The plus or minus indicates stimulatory (+) or inhibitory (−) effects, respectively. FIGURE 3 Multiple pharmacological effects of NPB/NPW. The plus or minus indicates stimulatory (+) or inhibitory (−). A solid line shows the action of NPW, and a dashed line shows the action of NPB.

of NPW. Further studies to elucidate sex differences of the action of NPW are required.

We have hypothesized that NPW may have several actions related to feeding regulation, including not only the regulation of food intake but also salivary secretion, chewing, and tongue movements. Consistent with the observation that the LH, amygdala, and BST are implicated in the regulation of feeding and taste, NPW is also expressed in these areas. In particular, nerve fibers in the LH project to premotoneurons in the NST and LPB. These premotor neurons are well known to innervate the salivary glands and tongue. On the other hand, Tanaka et al.[30] have reported that icv infusion of NPB causes acute effects on feeding behavior in mice; however, the long-term effect significantly reduces feeding behavior. Moreover, in the light phase, injection of NPB has no significant effect on feeding action.[30] By contrast, in the dark phase, icv infusion of NPB (3 nM) increases feeding activity for approximately 2 h. Moreover, a high dose (10 nM) of NPB reduces food intake. In addition, coadministration of NPB and CRH shows a completely inhibitory effect compared with that seen when NPB or CRH are administered separately. Urocortin, a CRH family member, is well known to be observed in the EW nucleus where NPB/NPW is localized. Moreover, we have confirmed NPW mRNA expression in the PVH by RT-PCR analysis.[29] Infusion of NPW icv upregulates c-Fos expression in the PVH region; this c-Fos expression is colocalized with CRH-containing neurons and its expression is decreased by spontaneous locomotor activity, which is considered to be a form of stress relief; spontaneous exercise results in the resumption of the anorexigenic effect of NPW (unpublished data). Therefore, NPB/W may be implicated both in feeding behavior and regulation of the stress response (Fig. 3).

ANTIHYPERALGESIC EFFECT OF NPB/W

NPBWR1 and NPBWR2 belong to the opioid and somatostatin receptor families, though GPR7 receptor binds nonselective opioid ligands with low affinity. In brain, the expression of NPB/NPW and GPR7 mRNA is located in the periaqueductal gray (PAG) and amygdala, which also contain opioid receptors, suggesting that NPB and NPW may be involved in nociception. Tanaka et al.,[30] for example, have used the paw flick test (heat-induced pain) in rat to investigate the participation of NPB in nociception. They found that NPB does not affect the behavioral response against an acute thermal stimulus. However, when the formalin test (chemically induced pain) is used, icv infusion of NPB significantly reduces the duration of licking. Moreover, inflammation induced by carrageenan significantly shortens latency in paw flicking. Later, Yamamoto et al. reported that intrathecal (i.t.) infusion of NPW or NPB decreases the number of agitation behaviors in response to formalin injection into the paw and attenuates the level of mechanical allodynia in rat, but not the level of thermal hyperalgesia induced by paw carrageenan injection in a

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

dose-dependent manner.[33] In addition, antihyperalgesic activity was not affected by the opioid receptor antagonist naloxone, suggesting that the analgesic and anti-allodynia pathways are independent of the activation by opioid peptides.[33] On the other hand, i.t. infusion of NPW23 or NPB does not affect the outcomes of the hot-plate test or mechanical nociceptive test.[33] These results suggest that the effects of NPB result in part from differences of function involving supraspinal regulation of pain. Yamamoto et al.[33] have also observed that NPW participates in pain regulation, but only NPW23 or NPB significantly reduces the expression of c-Fos in the spinal dorsal horn (L4-5) induced by formalin injection into the paw. These results suggest that spinally applied NPW23 and NPB suppress the input of nociceptive information to the spinal dorsal horn, and they produce an analgesic effect in response to inflammatory pain.[33] Kelly et al.,[12] found a significant hyperalgesia to an acute inflammatory stimulus in NPB −/− mice induced by intraperitoneal application of acetic acid.

In addition, a low level of GPR7 receptor expression is observed in normal human and rat nerves and in primary rat Schwann cell cultures. In patients exhibiting inflammatory/immune-mediated neuropathies, increased GPR7 receptor expression is observed in myelin-forming Schwann cells in a manner similar to that seen in an immune-inflammatory animal model. These results suggest that the regulated expression of GPR7 receptor in myelin-forming Schwann cells in inflammatory/immune-mediated neuropathies modulates the effect of pain transmission.[34]

Chapter 137

Orexins

Naima Ahmed, Harman S. Mattu and Harpal S. Randeva

ABSTRACT

Orexins are named after the ancient Greek word *Orexis* meaning hunger or appetite. This was in reference to what was initially believed to be the primary role of Orexins, that is, stimulating feeding. Orexins A and B (hypocretins 1 and 2), the excitatory neuropeptides first discovered in the lateral hypothalamus (LH), regulate feeding, wakefulness, sleep, and energy homeostasis. Previous studies have demonstrated that orexins are produced exclusively in the LH. Recent studies have found orexin peptides and their receptors (OX1R and OX2R) in a wide range of tissues including the intestines, pancreas, adrenal gland, reproductive tract, and adipose tissue. The central orexinergic pathways that originate in the medulla can stimulate the hypothalamic–pituitary–adrenal axis and thus affect sympathetic tone. In the intestines, the receptors are modulated by feeding status and therefore affect insulin secretion and intestinal motility. Therefore, orexins play an important role not only in the CNS but also in the periphery.

OVERVIEW OF THE STRUCTURE OF OREXINS AND ITS RECEPTORS

Orexin, also referred to as hypocretin (Hcrt), was initially discovered in 1998 by two separate independent research groups with the help of orphan receptor technologies and substractive cDNA cloning. The latter involved the analysis of the expression patterns of substracted hypothalamus-enriched cDNAs, which unveiled the original 569-nucleotide clone encoding a 130-amino acid protein residue (prepro-orexin). This putative secretory protein had an apparent signal sequence. Potential maturation and cleavage of this peptide suggested the possibility of two homologous peptides being generated, which shared a weak sequence homology with secretin. These peptides were later named hypocretin-1 and hypocretin-2 because of their hypothalamic localization.[13] The other group, led by Sakurai and colleagues, screened mRNA extracts of rat brain to induce intracellular Ca^{2+} transients in a battery of cells expressing orphan G protein-coupled receptors. Because of their orexigenic effects, the two peptides were named orexin A and orexin B. Orexin B is 28 amino acids in size and was identical to hypocretin 2. Similarly, orexin A, which is 33 amino acids in size, was found to be identical to hypocretin 1.[17]

Apart from the hypothalamus, this peptide is also expressed in various other endocrine gland tissues: pituitary, thyroid, parathyroid, adrenals, testes, ovaries, and the pancreatic islets. The prepro-orexin of mammalians including pigs, dogs, rats, mice, and humans consists of 130–131 amino acids. The human prepro-orexin gene is encoded on chromosome 17. It has two exons, one of which has the full coding region of the finalized peptide. The prepro-orexin gene found in mice consists of a promoter 3.2 kb in size, sufficient enough to direct expression of the genes located downstream of the lateral hypothalamus.[12]

Both orexins A and B can stimulate orexin receptors (OX1R and OX2R). In addition, according to the findings of Sakurai and colleagues, the OX1R shows an affinity that is ten times higher for orexin A than for orexin B, whereas OX2R does not seem to show any preference between the two peptides. The actual cell signaling pathways that become activated remain quite obscure. However, the receptors stimulate Gi, Gs, and Gq proteins.[16] Moreover, an increase in Ca^{2+} is a prevalent response observed in almost all cell lines that have been heterologously expressed.[17]

OX1R seems to act by coupling with adenylyl cyclase regulation via multiple mechanisms.[7] One study involved the production of a recombinant that expressed OX1R in Chinese hamster ovary cells to observe the regulatory pathway of this receptor with respect to adenylyl cyclase. OX1R receptors stimulate adenylyl cyclase through a low potency Gs coupling and a high potency phospholipase C/PKC coupling.[7] After reversing the inhibition by using pertussis toxin, observations suggested the involvement of Gi/o proteins. In addition, orexin B is almost as effective as orexin A in increasing the cAMP levels compared with the increase in Ca^{2+} and phospholipase C activation where orexin A is ten times more potent. Moreover, OX2R seems to be coupled to Gq/11 in addition to the Gi protein when expressed in cell lines. Food deprivation shows a differential effect on the coupling that occurs between orexin receptors and different G proteins.

ADIPOSE TISSUE

Both receptors of orexin play a role in regulating various physiological mechanisms including energy metabolism and body weight. Furthermore, because adipose tissue also plays a role in body weight regulation, the focus was whether components of orexin are also expressed in the adipose tissue. We observed the effect of orexins A and B in human adipose tissue by incubating adipose tissue explants with orexins A and B. This shows an increased expression of PPAR-γ-2, which is known to regulate adipose differentiation.[3] In addition, orexins A and B decrease hormone-sensitive lipase enzyme expression in the omental adipose tissue compartment. Orexin A reduces the release of glycerol indicating that orexin presumably has a role in regulating fat tissue metabolism through the inhibition of lipolysis.[3] Another study involving the treatment of 3T3-L1 cells with low doses of orexin A also shows induction of cell proliferation, whereas orexin B inhibits this action.

GASTROINTESTINAL TRACT

A study conducted in 2003 showed the presence of a subset of neurons in the gastrointestinal tract that has an orexin-like immunoreactivity and is able to express functional receptors that can bind orexin peptides.[10] These also happen to express receptors for leptin. The same study also revealed the role of orexin in increasing GI motility via secretomotor neurons in the submucosal plexus derived from a guinea pig. This combined with the observation that the orexins are present in the lateral hypothalamus and that the lateral hypothalamus has an important role in the control of gut-sensitive neurons in the dorsal vagal complex indicate that orexins might be involved in the central control of the gastrointestinal tract.

Fasting increases the levels of the phosphorylated cAMP response binding protein (pCREB) in orexin immunoreactive neurons.[10] Another study was the first to show the importance of the role of orexin in glucose metabolism and energy homeostasis after using orexin knockout mice.[22] This study showed that orexin deficiency causes age-linked development of impaired glucose tolerance and insulin resistance in both nonobese male mice and mildly obese female mice that are on a normal diet. In the stomach, secretion of gastric acid in response to orexin A occurs in conscious rats, indicating that orexin A might act on the brain to activate acid secretion through the regulation of the vagal system. Moreover, intraperitoneal administration of orexin in rats is ineffective; vagotomy or atropine diminishes the action of central orexin. Nevertheless, some species do express endogenous orexin in their stomach.

HYPOTHALAMIC–PITUITARY–ADRENAL AXIS

Orexin peptides regulate the adrenal glands either directly or indirectly by acting via the HPA axis. A study involving intravenous injection of either peptide has been found to increase the concentration of adrenocorticotropic hormone (ACTH), which is partially modulated by the action of the corticotropic releasing hormone (CRH). Orexins and their receptors were initially found to be expressed in rat and human brains as discussed earlier, and there have been numerous reviews on the presence of mRNA of orexin peptides and receptors in the hypothalamus. However, the orexin peptides are not expressed in the human pituitary gland as no mRNA or protein has been found. Studies conducted in other mammalians have yielded similar results.[8] Interestingly, immunocytochemistry and PCR studies on rat pituitary glands show the expression and distribution of both receptor types for orexin peptides. This has also been observed in both sheep and human studies.[8]

Blanco et al. conducted a study in 2001 focusing on the expression of orexin receptors in the human pituitary, which also showed (in agreement with previous studies in animals) that both the orexin receptors are expressed in the human pituitary gland.[9] In addition, their immunostaining showed that the OX1R is distributed in larger numbers compared with OX2R. Through various other techniques, they also found that the cells that expressed OX1R are somatotrophs, whereas the cells expressing OX2R are largely corticotrophs. Furthermore, they discovered that OX2R is only expressed in the basophil cells of the pars intermedia in the human pituitary.

ADRENAL GLANDS

The initial RT-PCR and immunocytochemistry studies conducted on orexin receptor expression in the rat adrenal gland showed the presence of OX1R and OX2R in the adrenal medulla. Later studies also show the presence of these receptors in the rat adrenal cortex and cortical cells (using RT-PCR, western blotting, and quantitative real time PCR).[19]

In vivo studies (rat) observing the effects of orexin on the adrenal gland show an elevation of plasma concentrations of both ACTH and corticosterone within two hours of a single systemic administration of orexin A, whereas orexin B do not have any stimulatory effect.[19] These findings suggest that orexin A is able to cross the blood–brain barrier relatively quickly, whereas orexin B may be quickly broken down in the circulation, and this confirms direct quantification in 1999 by the highly sensitive multiple time-regression analysis method that orexin A, but not orexin B, rapidly enters brain tissue from blood. Other studies have

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

also shown a direct function of orexins in the adrenal cortex without relying on the HPA axis through a prolonged subcutaneous administration of orexin A and orexin B in rats, leading to increased corticosterone,[2] but not an increase in the ACTH plasma levels. Orexins A and B increase norepinephrine concentrations. High doses of orexin A also increased plasma epinephrine indicating that orexins stimulate the sympathetic outflow and the adrenal medulla.

With regard to cell signaling and coupling of orexin receptors in the adrenal cortex, there have been varying results thus far. The effect of orexin A on the release of glucocorticoid in both rat and human adrenocortical cells are inhibited by adenylyl cyclase or protein kinase A (PKA) inhibitors indicating that the coupling of the involved receptor subtype with Gs increased cAMP production within an hour in the adrenocortical cells. Moreover, local orexin receptors are capable of coupling with Gq, Gi, and Go, which was dependent on the feeding state of the rats.[23] The second messenger studies supported the dose-dependent increase of cAMP and the increase in inositol triphosphate (IP3) after stimulation with orexin A. Furthermore, the human adrenal membranes showed an increase in the labeling of Gq, Gs, and Gi but not Go after the stimulation with orexin A.[2]

Concerning the functional role of orexin in the adrenal glands, one study observed the role of orexins on steroidogenesis in the human adrenocortical NCI H295R cell line.[23] Their findings showed an increase in cortisol secretion and a strong elevation in intracellular Ca^{2+} after the stimulation of the cell line with orexin. Additionally, through the use of quantitative PCR, they studied the steroidogenic enzymes after the stimulation of orexin A. Their findings indicate that mRNA levels of CYP11B1 and CYP11B2 are elevated from the early stages of stimulation with orexin A, whereas HSD3B2 and CYP21 mRNA levels are elevated after a prolonged stimulation. CYP11A and CYP17 levels do not respond to stimulation by orexins. PKC and ERK1/2 are also involved, and there are also high levels of OX2R mRNA compared with those of OX1R in the human adrenals, indicating that OX2R is present in the human and rat adrenal cortices.[23]

Wenzel et al. also confirmed (after comparing the effect of angiotensin II or forskolin on the CYP11B and CYP11B1 expression) that orexin A is low and that the effect of orexin A on the mRNA of HSD3B2 is similar to that of angiotensin II. This study has successfully shown the role of orexin in the differential regulation of the enzymes involved in steroidogenesis and more so in increasing the synthesis of cortisol in the human adrenocortical cell line. Furthermore, the study shows the effect of orexin A on the autoregulatory function of OX2R where the orexins modulate the expression of HSD3B2, which involves PKA and Ca^{2+} signaling pathways and the ERK1/2 kinase activation.[23]

HYPOTHALAMIC–PITUITARY–THYROID AXIS

The paraventricular nucleus (PVN) is one of many sites in the brain, which receive input signals from orexin. The nucleus contains neurons that synthesize the thyrotropin-releasing hormone (TRH). During fasting, the thyroid hormone secretion is reduced and the expression of mRNA prepro-orexin is increased. Therefore, a study led by Kok and colleagues speculated that an orexin neural circuit could regulate the activity of the hypothalamic TRH neurons and hence affect the Hypothalamic–Pituitary–Thyroid (HPT) axis.[11] There are no complete studies on the putative effects of orexins on the HPT axis in animals. An intracerebroventricular or an intravenous administration of orexin A in rats results in decreased concentrations of circulating thyroid-stimulating hormone (TSH). However, numerous other studies have shown that orexin A does not have a significant effect on the pituitary–thyroid axis. However, central administration of orexin A has been shown to increase circulating levels of TSH. Even though the topography of the orexin and thyrotrope neural circuits indicate that orexin input determines the TRH neuroactivity, the characteristics of the signal have been obscure as orexins A and B might have differential effects resulting from their unique chemical structure.

TESTES AND OVARIES

Orexin is involved as one of pleotropic regulators of different biological systems including the reproductive organs. This results from the observations seen in the peripheral expression and functions of orexin and orexin type-1 receptor mRNAs in the testis.[1] The biological mechanisms of orexin and its expression patterns are yet to be studied in male gonads. However, the immunoreactivity of OXA and OXB has been seen. One study took the initiative to analyze orexin A and B immunoreactivity and showed its presence in the rat testis. Moreover, the expression of prepro-orexin mRNA has thus far been found to be expressed in the penis and epididymis but not in the testes. Conversely, in humans, both OX1R and OX2R mRNA are expressed in the testis, the seminal vesicle, penis, and epididymis.[1] Nevertheless, there is no evidence for major reproductive defects in orexin knockout rat models, indicating that orexin might not have a vital role in the control of testicular function. However, regardless of the proven role of orexin in the regulation of food intake from previous studies, the orexin knockout mice that were used are also devoid of the major metabolic phenotype because they exhibit a modest trend to decrease food intake and mild tendency toward obesity.

Orexin receptors OX1R and OX2R are both expressed in the rat ovaries, whereas prepro-orexin was not found

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

to be expressed in this area and differs according to the estrus cycle.[18] This same group also discovered that during proestrus, the expression of orexin receptors increases in the afternoons and evenings. However, this does not occur during other phases of the estrus cycle. After blocking the action or the release of gonadotropin-releasing hormone, Silveyra and colleagues also found that it inhibits the upregulation of expression in the pituitary and the ovaries. However, a similar effect is not observed in the hypothalamus. In addition, an injection of OX1 and OX2 antagonists inhibits the actions of luteinizing hormone and follicle-stimulating hormone as well as ovulation, resulting in the ovaries appearing hyperemic. These studies collectively show that the hormonal environment during the female cycle in the ovaries controls orexin expression. Hence, blocking the signaling pathway in orexin receptors reduces the release of gonadotropin.

PANCREATIC ISLETS

Both orexins A and B are expressed in the pancreas, and the expression varies in different species. For example, Kirchgessner and Liu discovered in 1999 that the rat and guinea-pig pancreas showed receptor OX1R and OX2R immunoreactivity in the β-cell pancreatic islets, nerve bundles, which are involved in blood vessels, and in nerve fibers located in the pancreatic ganglia.[10] Additionally, orexin A is colocalized with insulin in addition to colocalization with somatostatin and glucagon positive cells in humans. However, in rats, orexin A immunoreactivity is seen in β cells and pancreatic polypeptide-containing cells, but this is not observed in human α cell nor in δ cell islets.[4] Another study involving isolated rat islets showed the release of orexin A that is dependent on low glucose concentration. The pathway to this mechanism remains elusive, but the presence of orexin in the pancreas indicates that orexin may be involved in the regulation of pancreatic hormone secretion and the modulation of glucose.[22] The hypothalamic neurons, which are able to sense glucose, have an essential role in activating the adaptive metabolic and behavioral responses. The glucose-excited neurons and the glucose-inhibited neurons are responsible for sensing glucose in the hypothalamus. As the name suggests, the glucose-inhibited neurons decrease the firing rate, whereas the glucose-excited neurons increase it because the glucose levels outside the cells increase within the physiological range in the celebrospinal fluid.[22]

The suprachiasmatic nuclei (SCN) and the PVN are where the circadian clock outputs are initiated in the hypothalamus. The sympathetic and parasympathetic activities are also regulated here. The SCN modulates the daily rhythm in the plasma glucose concentration and is not dependent on feeding activities.[22]

The circadian clock of SCN can be reset via arousal promoting signals from orexin neurons. Reciprocally, the activation of orexin neurons is tightly controlled by the circadian rhythm. After restricting the feeding of orexin knockout mice, the activity and core body temperature rhythms remain, indicating that orexin may not be required for the signal transduction of the food-entrainable oscillator, presumed to be situated in the dorsomedial hypothalamus.[22] Hyperglycemia linked to peripheral insulin resistance suppresses the expression of orexin. Moreover, as this could have otherwise maintained the hypothalamic insulin sensitivity, it leads to a cycle being formed between the peripheral and hypothalamic insulin resistance via the suppression of orexin levels.[22]

ENERGY EXPENDITURE

When comparing the energy expenditure between orexins A and B, the very first study conducted on the correlation between energy expenditure and orexins revealed that not only did orexin increase energy expenditure, but it also showed that orexin B did not increase the metabolic rate as much as orexin A did.[20] The same study also microfused orexin into the third ventricle, resulting in stimulation of the metabolic rate. This stimulation appeared to be higher during the dark cycle when compared with that of the light cycle in mice, indicating that circadian differences of orexin A increase/influence the metabolic rate. Another study found (by using Fos immunoreactivity, which is generally known for providing information on the sites of action of various stimuli) that there is not only an increase in fos immunoreactivity in the orexin neurons but that this increase also coincides with the increase in orexin A-induced metabolic rate in the dark cycle compared with that of the light cycle.[20] ATP and substrate oxidation is required for muscle contraction and other physical activities. Thus, the effects of orexin on physical activities such as locomotion, grooming, and rearing all require muscle contraction, which subsequently results in a calorific cost leading to energy expenditure. To confirm these ideas, one study showed that intra-PVH orexin A increases physical activity and energy expenditure in a dose dependent manner.[20]

Appetite and Food Intake

The lateral hypothalamus is known for regulating metabolism and food intake. This was discovered by studies involving the effect of lesions in the lateral hypothalamus, which leads to reduced food intake and maintenance of the newly achieved reduced weight in obese rats.[14] This fact combined with the expression of mRNA of prepro-orexin in this area of the brain led to studies focusing on the effects of orexin on feeding behavior. Sakurai and colleagues administered orexins centrally, which led to the

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

stimulation of food intake, indicating that orexins play a role in central regulation of feeding.[17] They followed by observing whether this regulation of food intake is modulated by nutritional state and compared the expression of mRNA prepro-orexins in the hypothalamus of both fed and fasting rats. There is an upregulation of mRNA prepro-orexin expression in the fasting rats. This increase in expression is 2.4 times higher compared with that of the nonfasting rats. Moreover, the elevated expression of orexin precursor mRNA surpasses that of the increase observed in NPY mRNA.[16] Another study also found that enhanced orexin receptor-2 signaling prevents diet-induced obesity and improves leptin sensitivity.[5]

PHYSIOLOGICAL IMPLICATIONS

Insulin resistance stemming from impaired glucose metabolism plays a major role in the pathogenesis of type 2 diabetes and occurs during the aging process. In 2008, Tsuneki et al. studied the involvement of orexin on glucose metabolism by using orexin knockout mice.[21] They discovered that orexin has a vital role in maintaining normal insulin sensitivity with advancing age. The male mice with orexin knocked out show an impaired insulin sensitivity and hyperinsulinemia at nine months of age. However, this characteristic is not seen in male mice aged 2–6 months. Curiously, glucose tolerance is not affected in orexin knockout middle-aged males. A plausible reason could be that the insulin resistance is compensated by hyperinsulinemia to maintain glucose tolerance. The orexin knockout female mice also show impaired glucose tolerance and hyperinsulinemia at the same ages as their male counterparts. Interestingly, only the female orexin knockout mice show late-onset mild obesity suggesting that male orexin knockout mice developed age-related insulin resistance without obesity as opposed to insulin resistance combined with other factors related to obesity, which might act synergistically because of impaired glucose tolerance in female orexin knockout mice.[21] The findings collectively suggest that orexin is essential in maintaining hypothalamic insulin signaling. This signaling is probably responsible for preventing the onset of peripheral insulin resistance, which tends to increase with age. This may explain why type 2 diabetes incidence increases in normal weight patients with orexin deficiency.

The orexin/ataxia-3 mice show a late-onset of obesity despite being on a 30% lower food intake during the dark cycle. This pattern of obesity is observed in both male and female mouse models. This finding combined with the observation that orexin is known to increase energy expenditure, provides a plausible explanation as to why these mice gain weight regardless of their diet. Therefore, study of spontaneous motor activity with lower energy expenditure may be attributed to variations therein. Their findings are consistent with the lower energy expenditure in transgenic mice as their spontaneous activity is lower than the wild-type mice. This observation was noted only during the dark period, with no difference observed during the light period.[6] This is an indication of the essential role of orexin-containing neurons in controlling energy homeostasis and wakefulness as well as regulating a susceptible genetic background. Thus, this study and other studies have collectively shown the orexin/ataxin-3 mice model to be an important tool not only for studying the pathophysiology and treatment of narcolepsy but also other neuroendocrinological conditions.

Okumura and Nozu have also proposed that lack of orexin signaling within the brain may possibly trigger the progressive development of functional gastrointestinal disorders (FGID). They also suggested that the increase of orexin signaling by pharmacological manipulation may provide a treatment for FGID.[15]

Peripheral orexin A reduces the rate of gastric emptying in humans. Orexin A significantly insulin plasma concentrations and reduces plasma leptin concentrations. However, orexin A does not have any effect on the plasma concentrations of either glucagon or glucose. Also, appetite does not seem to be affected.[20] Orexin A and orexin receptor-like immunoreactivity are present in the human gut. The physiological implications and mechanisms related to the rate of gastric emptying (which is reduced by orexin A) might reflect a predominant inhibitory tone on gastric emptying while fasting because the gastric acid accumulates to prepare for the next digestive process. Additionally, orexin A plasma concentrations are elevated during fasting, and therefore, the probable pharmacological elevation of orexin A plasma concentrations after eating might reflect the artificial condition that would otherwise have a major effect on appetite ratings. Nevertheless, as these were not affected, it suggests that the peripheral orexin A constitutes its own pool with no interaction with the central orexin A pathways.[20]

CONCLUSIONS

Orexins have various roles and influence many functions including autonomic regulation, endocrine function, food intake, appetite, wakefulness, and sleep. Orexins and their receptors are present in a wide range of organs outside the CNS. These molecules are involved in various physiological mechanisms. Based on the current findings, there is strong evidence supporting their functional roles in the periphery. Moreover, many studies have shown that disturbances in the expression or the levels of orexin peptides can result in pathological disorders such as late-onset obesity, impaired insulin sensitivity, hyperinsulinemia, and disturbances in gut function. Nevertheless, the precise mechanisms through which orexins act are yet to be fully understood.

Chapter 138

PACAP

David Vaudry, Delphine Burel, Ludovic Galas, Hélène Lacaille, Dominique Duterte-Boucher, David Chatenet, Alain Fournier and Hubert Vaudry

ABSTRACT

Pituitary adenylate cyclase-activating polypeptide (PACAP), a peptide of the vasoactive intestinal polypeptide (VIP)-glucagon superfamily, was initially characterized by virtue of its ability to stimulate cAMP formation in cultured rat anterior pituitary cells. Three PACAP receptors have been cloned so far: a PACAP-selective receptor termed PAC1 and two PACAP/VIP-mutual receptors termed VPAC1 and VPAC2. PACAP and its receptors are widely expressed in the brain and in peripheral organs, notably in the hypothalamus and in endocrine glands. Indeed, there is now clear evidence that PACAP exerts neuroendocrine, paracrine, and/or autocrine control of the activity of the pituitary, thyroid, testis, ovary, adrenal medulla, adrenal cortex, and endocrine pancreas. These observations suggest that selective PACAP agonists and antagonists could have therapeutic value for the treatment of various endocrine disorders.

INTRODUCTION

Pituitary adenylate cyclase-activating polypeptide (PACAP) was first isolated from ovine hypothalamic extracts on the basis of its ability to stimulate cAMP formation in cultured rat anterior pituitary cells.[22] Characterization of the peptide revealed that it consists of 38 amino acids and is C-terminally α-amidated. PACAP38 exhibits an internal cleavage site (Gly^{28}-Lys^{29}-Arg^{30}) and can thus generate a 27-amino acid, α-amidated peptide (PACAP27), which is present, in most tissues, at a much lower concentration than PACAP38.[32] PACAP27 exhibits 68% sequence identity with vasoactive intestinal polypeptide (VIP), identifying PACAP as a member of the VIP–glucagon–secretin superfamily. The sequence of PACAP has been remarkably well conserved during evolution from protochordate to mammals, suggesting that the peptide is involved in the regulation of vital biological functions.[32] Knockout of the PACAP gene in zebrafish and mice has shown that PACAP is important for development, reproduction, metabolism, and feeding.[24] Characterization of the PACAP precursor cDNA has revealed the existence of a PACAP-related peptide flanking PACAP on its N-terminal side, whose activity remains unknown. Two types of PACAP binding sites have been characterized: type I binding sites exhibit a high affinity for PACAP and a much lower affinity for VIP, whereas type II binding sites have similar affinity for PACAP and VIP. Molecular cloning of PACAP receptors has shown the existence of three distinct receptor subtypes, the PACAP-specific receptor PAC1, which is coupled to several transduction systems, and the two PACAP/VIP-mutual receptors VPAC1 and VPAC2, which are primarily coupled to adenylyl cyclase. PACAP and its receptors are widely distributed in the brain (see the Chapter on PACAP in the Brain Peptides section of this book) and peripheral organs, notably in endocrine glands including the pituitary, thyroid, gonads, adrenals, and pancreas (Table 1).

EFFECTS ON THE PITUITARY GLAND

Various hypothalamic nuclei, including the paraventricular and arcuate nuclei, contain PACAP-producing neurons that project toward the external zone of the median eminence,[21] and high concentrations of PACAP have been measured in the hypophyseal portal blood, supporting the view that PACAP may act as a hypophysiotrophic neuropeptide. Besides, the occurrence of PACAP has also been detected in a subpopulation of gonadotroph cells[21] indicating that the peptide is expressed within the adenohypophysis and may act as a paracrine and/or autocrine regulator. Indeed, the ability of PACAP to stimulate cAMP formation in anterior pituitary cells provides clear evidence that the peptide controls the activity of the adenohypophysis.[22] The diversity of actions of PACAP on the pituitary has been detailed in previous reviews.[26] Among the different hypophysiotrophic neuropeptides identified so far, the situation of PACAP is rather unique in that functional PACAP receptors are present in all endocrine cell types, and in folliculo-stellate cells of the adenohypophysis. PACAP stimulates the release of growth

hormone, adrenocorticotropic hormone, luteinizing hormone (LH), follicle-stimulating hormone (FSH), and prolactin.[26,32] PACAP is even more potent than "classical" hypothalamic hormones such as gonadotropin-releasing hormone at increasing NOS1 levels in cultured rat anterior pituitary cells,[7] indicating that PACAP exerts important biological functions in these cells. PACAP also enhances the secretion of α-melanocyte-stimulating hormone from cultured rat pars intermedia melanotroph cells. The hypotrophic action of PACAP has been documented in representative species of submammalian vertebrates including fish, amphibians, and birds, indicating that this function has been conserved during evolution. The effects of PACAP on pituitary cells are mediated through activation of adenylyl cyclase, cGMP, phospholipase C (PLC) and/or mobilization of cytosolic calcium (Table 2). PACAP is also released by neuroendocrine tumors and may be involved in their growth regulation. A detailed description of the effects of PACAP on each cell type can be found elsewhere.[32]

EFFECTS ON THE THYROID GLAND

In humans, VPAC1 is the predominant type of PACAP receptors expressed in the thyroid, whereas in mice, thyroid follicular cells primarily express VPAC2.[13] In the human and porcine thyroid, PACAP stimulates cAMP production, which is probably involved in the activation of thyroxin secretion.[4] Further, in PACAP knockout animals, the thyroid axis is altered, leading to a reduction of TRH in the hypothalamus and of deiodinase in brown fat and brain, which could explain the reduction in fat mass in these animal.[1]

EFFECTS OF PACAP ON THE ENDOCRINE TESTIS AND OVARY

The presence of PACAP and its receptors in the testis and ovary strongly suggests that the peptide may operate as a local regulator of gonadal activity.[13,17] The rat testis contains the highest level of PACAP in any peripheral organs.[2]

TABLE 2 Effects of PACAP on Pituitary Cells

Cell type	Second-Messenger Coupling	Hormone Release and/or mRNA Expression
Gonadotrope cells	↑ cAMP, ↑ IP turnover, ↑ $[Ca^{2+}]_i$, ↑ NOS 1	↑/0 LH release,↑/0 FSH release ↑ LH mRNA, 0 FSH mRNA
Somatotrope cells	↑ cAMP, ↑ $[Ca^{2+}]_i$	↑/0 GH release
Lactotrope cells	↑ $[Ca^{2+}]_i$	↑/↓/0 PRL release, ↑/0 PRL mRNA
Corticotrope cells	↑ $[Ca^{2+}]_i$	↑/0 ACTH release
Thyrotrope cells	↑ $[Ca^{2+}]_i$	0 TSH release
Folliculo-stellate cells	↑ cAMP, ↑ $[Ca^{2+}]_i$	↑ IL-6 release
Fibroblasts	↑ cAMP	
Melanotrope cells	↑ cAMP	↑ α-MSH release,↑ BDNF release

↑, stimulatory effect; ↓, inhibitory effect; 0, no effect; ACTH, adrenocorticotrophic hormone; FSH, follicle-stimulating hormone; GH, growth hormone; IL-6, interleukin-6; LH, luteinizing hormone; PRL; prolactin; TSH, thyroid-stimulating hormone.

The concentration of PACAP in the testis is significantly reduced after hypophysectomy and is restored by FSH administration, indicating that testicular expression of the PACAP gene is under the control of pituitary gonadotropins. *In vitro*, PACAP induces a dose-dependent stimulation of testosterone secretion from isolated rat Leydig cells and regulates protein synthesis in spermatocytes and spermatids.[32] In Leydig cells, PACAP acting through PAC1, stimulates both adenylyl cyclase and PLC. The effect of PACAP on Leydig cells may also be mediated *via* another signaling pathway coupled to sodium channels through a pertussis-toxin-sensitive G protein. The effects of PACAP on protein synthesis in spermatocytes and spermatids are both mimicked by dbcAMP. In cultured Sertoli cells, PACAP increases cAMP concentration and stimulates estradiol and inhibin secretion. In the epididymal epithelium, PACAP increases chloride secretion, which is important for sperm activation and storage. The occurrence of PACAP-immunoreactive material in epididymal tubules indicates that PACAP is locally synthesized and thus may act as a paracrine regulator of sperm maturation. The epididymal epithelium-derived PACAP may also stimulate epididymal spermatozoa that have lost PACAP synthesis ability but still possess PACAP binding sites. In human, PACAP dose dependently relaxes norepinephrine- and electrically contracted isolated preparations of corpus cavernosum, suggesting that the peptide may be involved in the induction and maintenance of penile erection. Consistent with this notion, a stearic acid VIP conjugate increases the copulatory activity and penile reflex in testosterone-treated, castrated rats. These results suggest that some PACAP resistant analogs could be useful for the treatment of impotence.

In the rat ovary, most granulosa and cumulus cells from large preovulatory follicles contain both PACAP mRNA and PACAP peptide.[10] Human chorionic gonadotropin (hCG) stimulates the expression of PACAP mRNA and progesterone receptor mRNA.[16] The peak of expression of progesterone receptor mRNA occurs 3 hours after hCG treatment and the peak of PACAP mRNA only after 6 hours, suggesting that progesterone receptor activation is required for PACAP gene expression.[16] Indeed, the progesterone receptor antagonist ZK98299 blocks the effect of hCG on PACAP gene expression.[16] The hCG-evoked stimulation of PACAP gene transcription is abolished by cycloheximide, indicating the requirement of protein synthesis for PACAP mRNA expression.[16] Exposure of cultured granulosa cells to PACAP causes a dose-dependent increase in progesterone production.[9] Reciprocally, immunoneutralization of endogenous PACAP reduces progesterone formation and impairs subsequent luteinization, suggesting that PACAP plays an important role in LH-induced progesterone secretion during the periovulatory period[9] which could, at least in part, explain the reduced fertility observed in PACAP-deficient mice. Incubation of immature rat preovulatory follicles with PACAP or VIP induces a dose-dependent inhibition of follicle apoptosis and reduces FSH-stimulated follicle growth. In luteinized granulosa cells, PACAP seems to be more potent than LH in stimulating cAMP accumulation. In the human female genital tract, PACAP is located in fibers innervating blood vessels and smooth muscle cells of the internal cervical os, suggesting that the peptide could regulate local blood flow and lubrication of the vagina. High concentrations of PACAP are also found throughout the human uteroplacental unit. *In vitro*, PACAP induces relaxation of nonvascular smooth muscle strips from the Fallopian tube and myometrium and stem villous and intramyometrial arteries, indicating that PACAP may regulate the vascular tone in the human female

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

reproductive tract. In placental cells, PACAP enhances cAMP formation, hCG, and interleukin-6 production.

EFFECTS OF PACAP ON THE ADRENAL GLAND

PACAP and its receptors are actively expressed in the adrenal medulla.[32] PACAP exerts a stimulatory action on catecholamine secretion from chromaffin cells,[32] induces the release of brain natriuretic peptide and enkephalins, two regulatory peptides, which are cosequestered with catecholamines in chromaffin granules,[3] and causes a robust increase in VIP mRNA expression in bovine chromaffin cells through a cAMP-dependent, PKA-independent pathway.[11] *In vivo* studies show that PACAP and VIP stimulate catecholamine release in anesthetized dogs through the activation of dihydropyridine-sensitive L-type calcium channels.[8] PACAP-induced catecholamine secretion is significantly enhanced by hypoglycemia, suggesting that PACAP may play a beneficial role in glucose counterregulatory mechanisms in the adrenal medulla during hypoglycemia.[34] The effect of PACAP on catecholamine secretion is mediated through PAC1 and associated with an increase in adenylyl cyclase activity[19] and calcium influx.[23] Incubation of adrenomedullary cells in calcium-free medium or blockage of voltage-operated calcium channels suppresses the PACAP-evoked stimulation of catecholamine secretion, indicating that the effect of PACAP on chromaffin cells is mediated through calcium influx. Concurrently, PACAP increases calcium mobilization from ryanodine/caffeine-sensitive calcium stores. Treatment of chromaffin cells with PACAP activates the expression of tyrosine hydroxylase, dopamine β-hydroxylase, and phenylethanolamine *N*-methyltransferase,[32] and the stimulatory effect of PACAP on tyrosine hydroxylase activity is mediated through the activation of the adenylyl cyclase/PKA signaling cascade.[20] Divergent results have been reported regarding the possible effect of PACAP on multiplication of adrenochromaffin cells: PACAP seems to stimulate proliferation of rat chromaffin cells in primary culture and to inhibit the mitogenic action of nerve growth factor on chromaffin cells. High levels of PACAP and its receptors are expressed in most pheochromocytomas where the peptide could act in an autocrine manner to regulate the secretory activity or the differentiation of tumor cells.[27]

The pheochromocytoma PC12 cell line has been widely used as a model to investigate the neuroendocrine and neurotrophic effects of PACAP. In PC12 cells, PACAP acting through PAC1 inhibits cell proliferation, stimulates neurite outgrowth, and prevents apoptosis.[32] The effect of PACAP on neuritogenesis is mediated through a cAMP/ERK-dependent, PKA-independent mechanism.[25] In PC12 cells, PACAP also stimulates tyrosine hydroxylase and chromogranin A gene expression, and activates the transcription of the transfected neuropeptide Y and proenkephalin A genes.[5] The effect of PACAP on global gene expression has also been investigated in PC12 cells using microarray approaches.[31] Many of the genes or proteins regulated by PACAP are associated with neuritogenesis (ornithine decarboxylase, annexin A2, or EGR1), survival (stathmin), cell growth (growth arrest specific 1 or cyclin B2), cell morphology remodeling (actin, tubulin), vesicle trafficking (synaptotagmin IV), or cell adhesion (Mcma, attractin).[6,25,31]

Intravenous administration of PACAP causes elevation of plasma cortisol levels in dog and calf.[15] PACAP stimulates corticosterone and aldosterone secretion from human, rodent, chicken, and frog adrenal slices.[32] Recent studies highlight the critical role of PACAP along the hypothalamic–pituitary–adrenal axis to mediate a sustained hormone secretion in response to emotional stressors.[30] Exposure of human adrenal slices to the β-adrenoreceptor blocker l-alprenolol totally suppresses the steroidogenic effect of PACAP. Similarly, the action of PACAP on dehydroepiandrosterone and cortisol secretion by the fetal human adrenal gland is suppressed by the β-adrenoreceptor antagonist propranolol. Altogether, these observations indicate that, in most mammalian species, the effect of PACAP on corticosteroid secretion can be ascribed to the stimulatory action of the peptide on catecholamine secretion. In contrast, PACAP stimulates corticosteroid release from dispersed bovine and frog adrenocortical cells. That PACAP enhances cAMP and inositol phosphate formation in bovine glomerulosa cells and calcium mobilization in individual frog adrenocortical cells provides additional evidence for a direct stimulatory effect of the peptide on steroidogenesis in these two species.

EFFECTS OF PACAP ON PANCREATIC ISLETS

In the pancreas, PACAP-immunoreactive fibers innervate both the exocrine acini and the islets of Langerhans, as well as the small arteries of the connective tissue (Table 1). Electrical stimulation of the vagus nerve causes the release of PACAP from the isolated perfused pig pancreas, suggesting that PACAP may control exocrine and/or endocrine pancreatic secretions. PACAP seems to be much more potent than VIP or other regulatory peptides in stimulating pancreatic hormone secretion. *In vivo* administration of PACAP stimulates insulin secretion in mice, calf, dog, and human.[32] Mice with a targeted deletion of the PACAP gene have a more profound insulin-induced hypoglycemia than wild-type animals.[12] The stimulatory effect of PACAP on insulin release has also been documented on perfused rat and pig pancreas and on cultured islet cells. On these cells, PACAP and VIP activate VPAC2 to increase the number of pancreatic β-cells.[28] The role of PACAP in the control of β-cell proliferation has been confirmed in mice overexpressing PACAP in the pancreas under the control of a human

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

insulin promoter.[35] Pancreatic β-cells express cell-surface ectopeptidases capable of degrading PACAP.[14] The amplitude and kinetics of the PACAP-evoked stimulation of insulin release depends on glucose concentration in the incubation medium. PACAP induces a biphasic effect on insulin secretion, that is, a rapid and transient stimulation (acute phase) followed by a rebound of the secretory response (plateau phase).[29] The plateau phase may result from the ability of PACAP to regulate insulin gene expression. The phosphatidylinositol 3-kinase inhibitor wortmannin inhibits the plateau phase but not the acute phase of PACAP-evoked insulin release.[29] Exposure of pancreatic β-cells to PACAP causes calcium influx through L-type calcium channels[33] and the stimulatory effect of PACAP on insulin secretion is abolished by nitrendipine,[18] indicating that activation of voltage-sensitive L-type calcium channels is involved in the insulinotropic effect of PACAP. Paradoxically, the combination of glucose, PACAP and carbachol stimulates insulin release while being unable to elevate intracellular calcium.[18] Incubation of isolated rat islets with specific PACAP antisera inhibits the ability of glucose to stimulate insulin release,[33] suggesting that endogenous PACAP acts as a physiological regulator of pancreatic β-cell activity. PACAP is also a potent stimulator of glucagon secretion. Intravenous injection of PACAP increases plasma glucagon concentration in mouse, dog and human.[32] Likewise, in the perfused rat pancreas, PACAP enhances glucagon secretion. The stimulatory effect of PACAP on insulin and glucagon release is completely abolished by somatostatin. In contrast, the endozepine octadecaneuropeptide (a potent inhibitor of insulin release) has no effect on PACAP-evoked insulin secretion.

Chapter 139

Adiponectin/Resistin

Rexford S. Ahima

ABSTRACT

Adiponectin is synthesized and secreted by adipocytes in rodents and humans, and it enhances insulin sensitivity and fat oxidation. Resistin, however, is produced by adipocytes in rodents and macrophages in humans, and it induces insulin resistance in liver, muscle, and fat. Adiponectin and resistin are both capable of controlling feeding and energy balance. This chapter provides an overview of the central and peripheral effects of adiponectin and resistin on energy homeostasis.

ADIPONECTIN AND ENERGY HOMEOSTASIS

Adiponectin is synthesized almost exclusively by adipocytes, and it circulates as multimeric protein complexes and regulates metabolism in peripheral tissues.[32] Adiponectin lowers serum glucose through the suppression of hepatic glucose production.[33,34] Epidemiological studies have shown that adiponectin is inversely correlated to insulin resistance and other components of the metabolic syndrome.[6,14,32] In rodents, adiponectin deficiency leads to glucose intolerance, insulin resistance, dyslipidemia, and increased susceptibility to vascular injury and atherosclerosis.[17,33,34] Peripheral administration of adiponectin enhances insulin sensitivity and fatty acid oxidation and protects against vascular injury.[17,33,34] The effects of adiponectin on glucose and lipid metabolism are attributed to adiponectin receptors, AdipoR1 and R2, which signal through AMP-activated kinase (AMPK) and peroxisome proliferator-activated receptor α (PPARα) in liver and muscle.[14,32] Adiponectin also acts through IRS-2, STAT3, NFκB, and IL-6 to regulate glucose homeostasis and inflammation.[18,32]

There is a wide distribution of adiponectin receptors in the brains of rodents and humans.[5,10,12] AdipoR1 is widely expressed in rat brain, whereas AdipoR2 expression is limited to the hypothalamus, cortex, and hippocampus.[5,12] Within the arcuate and paraventricular hypothalamic nuclei, AdipoR1 and AdipoR2 are expressed by neurons as well as astrocytes.[5] AdipoR1 and AdipoR2 are colocalized in proopiomelanocortin (POMC) and neuropeptide Y (NPY) neurons in the arcuate nucleus.[5] Intracerebroventricular (icv) injection of adiponectin induces AMP-activated protein kinase (AMPK) phosphorylation in the rat hypothalamus.[5,12] Other studies have shown potent electrophysiological actions of adiponectin in the rat hypothalamus and brainstem.[4,7,8]

Despite the presence of adiponectin receptors in the brain, it is controversial whether adiponectin is transported across the blood–brain barrier.[19,29] Nonetheless, adiponectin is detectable in cerebrospinal fluid (CSF) in rodents and humans,[10,12,13,24] and CSF adiponectin concentration can be increased after intravenous administration of adiponectin in mice.[12,24] Adiponectin concentrations in human CSF is 0.1% of serum concentration and mainly consists of trimeric and low-molecular-mass hexameric complexes.[13] Men have a higher CSF:serum ratio of adiponectin than women have, but it is unknown whether this sex difference affects metabolism.[13]

We first reported that administration of adiponectin in the brain has potent effects on energy expenditure, and glucose and lipid metabolism in mice.[24] Administration of adiponectin icv potently decreases body weight by stimulating energy expenditure.[24] Lepob/ob mice display greater sensitivity to icv adiponectin compared with that of intraperitoneal adiponectin treatment.[24] Adiponectin stimulates thermogenesis and reduces body weight and fat, and serum glucose and lipid levels.[24] Adiponectin increases Fos immunoreactivity in the arcuate and paraventricular nuclei.[24] In contrast to wildtype and Lepob/ob mice, agouti ($A^{y/a}$) mice do not respond to icv adiponectin treatment, suggesting that melanocortin signaling plays a critical role in the CNS action of adiponectin.[24] These results in mice were later corroborated in rats.[21] Chronic icv infusion of adiponectin enhances the signaling of insulin and leptin in the hypothalamus of normal and diabetic rats, and also decreases epididymal fat mass by increasing energy expenditure and fat oxidation.[21] Unlike peripheral adiponectin treatment that enhances insulin action in liver via activation of AMPK, the effects of icv adiponectin on insulin signaling, energy expenditure and fat oxidation are not related to AMPK activation.[21,32]

Masaki et al. compared the CNS and peripheral actions of adiponectin in $A^{y/a}$ mice.[15] They showed that chronic intraperitoneal adiponectin administration reduces body weight and fat, accompanied by increased expression of UCP1 in brown adipose tissue (BAT), UCP2 in white adipose tissue (WAT), and UCP3 mRNA in skeletal muscle.[15] Acute peripheral administration of adiponectin increases sympathetic nervous activity in BAT, rectal temperature, and Fos immunoreactivity in the hypothalamus.[15] In agreement with an earlier report,[24] icv injection of adiponectin has no effect on energy homeostasis in $A^{y/a}$ mice.[15]

Adiponectin icv has opposite effects on food intake in rats.[3,12] Coope et al. reported that icv adiponectin inhibits food intake, and this effect is accompanied by activation of IRS1/2, ERK, Akt, FOXO1, JAK2, and STAT3 in the hypothalamus.[3] AdipoR1 and AdipoR2 are both localized in the arcuate and lateral hypothalamic nuclei; however, inhibition of AdipoR1, and not AdipoR2, prevents the anorexigenic action of icv adiponectin.[3] By contrast, Kubota et al. showed that adiponectin stimulates food intake and decreases energy expenditure.[12] These effects of adiponectin on energy homeostasis require AdipoR1 in the arcuate nucleus and are attenuated by blockade of AMPK activity.[12] Adiponectin knockout mice have reduced AMPK phosphorylation in the arcuate nucleus, associated with reduced food intake and increased energy expenditure, exhibiting resistance to diet-induced obesity.[12] Adiponectin levels in the blood and CSF are elevated during fasting and reduced after refeeding, suggesting that adiponectin serves as a signal from adipose tissue to the brain during energy deficiency.[12]

Ablation of AdipoR1 and AdipoR2 in mice results in different metabolic phenotyes.[2] AdipoR1 knockout mice show increased fat accumulation, associated reductions in spontaneous locomotor activity and energy expenditure, and impaired glucose tolerance.[2] By contrast, AdipoR2 knockout mice are resistant to obesity, and show improved glucose tolerance, and increased spontaneous locomotor activity and energy expenditure.[2] AdipoR1 and AdipoR2 are localized in warm sensitive neurons of the hypothalamic preoptic area (POA).[9] Microinjection of adiponectin in the POA induces hyperthermia, increases oxygen consumption and decreases the respiratory exchange ratio (RER), indicating oxidation of fat.[9] The hyperthermic effect of adiponectin treatment is blunted, while oxygen consumption and fat oxidation are unchanged in AdipoR1 knockout mice. In contrast, the hyperthermic effect of adiponectin treatment is blunted in AdipoR2 knockout mice, but POA adiponectin is able to stimulate fat oxidation.[9] These findings show that adiponectin modulates core body temperature, energy expenditure and fat metabolism via distinct neuronal circuits in the brain.[2,9]

Although the evidence for adiponectin's effects on energy balance is strong, further research is needed to address the controversies surrounding the central versus peripheral responses to different protein forms of adiponectin. The icv route of administration of adiponectin is artificial and may exert different actions in the brain from the true physiological roles of adiponectin. The mechanisms by which adiponectin reaches the CSF from the circulation is crucial. It is still unclear whether a blood-to-brain transport system for adiponectin exists in rodents, humans, and other species. Moreover, the precise signaling pathways in the brain and peripheral organs that mediate the effects of adiponectin on food intake and energy expenditure need to be clarified.

RODENT VERSUS HUMAN RESISTIN

Resistin is a 12.5 kDa cysteine-rich polypeptide that is secreted by rodent adipocytes and suppressed by antidiabetic thiazolidinedione drugs.[27] Resistin belongs to a family of secreted proteins known as resistin-like molecules (RELMs) or found in inflammatory zone (FIZZ) proteins.[27] In rodents, adipose resistin expression is suppressed in obesity while circulating resistin levels are increased.[25] Administration of exogenous resistin or transgenic overexpression of resistin (Retn) induces insulin resistance, whereas blocking resistin activity or ablation of *Retn* improves insulin sensitivity.[1,26,30] Resistin also induces hepatic inflammation and insulin resistance when administered icv in rodents.[16,28]

Although resistin exerts direct actions on adipose, liver, muscle, vascular endothelium, cardiomyocytes, and inflammatory cells, the nature of the resistin receptor and downstream signaling pathways that mediate the actions of resistin are uncertain.[27] Resistin binds to the endotoxin receptor Toll-like receptor 4 (TLR4) and an isoform of decorin. Potential downstream signaling molecules of resistin include AMPK in mouse and rat liver and muscle, and cytokine signaling-3 (SOCS-3) in mouse adipose tissue.[27]

Unlike rodent resistin, human resistin is predominantly expressed in macrophages.[27] The lack of human resistin expression in adipocytes may result from the loss of a genomic binding site for PPARγ that normally controls Retn expression in mouse adipocytes. The expression and secretion of resistin by human macrophages is increased in response to inflammation.[27] Although initial reports on the role of resistin in humans were conflicting, large epidemiologic studies have shown significant correlations of resistin levels with insulin resistance, type 2 diabetes and inflammation.[27] To address the biology of human resistin, the Lazar laboratory generated mice that lack adipocyte-derived mouse resistin but produce human resistin in macrophages.[22] When fed a high-fat diet, the humanized resistin mice rapidly develope white adipose tissue (WAT) inflammation, leading to increased lipolysis and serum free fatty acid levels. Subsequently, diacylglycerol accumulated in muscle, leading to activation of protein kinase C (PKC)-q activity and insulin resistance in muscle and WAT.[30] An

"even more humanized resistin mice" lacking murine resistin but transgenic for a bacterial artificial chromosome containing human resistin (BAC-Retn) has provided new insights into the link between resistin and inflammation.[20] As in humans, lipopolysaccharide (LPS) treatment increased resistin expression and serum resistin levels in BAC-Retn mice.[20] Hypoglycemia induced by acute LPS treatment is attenuated in BAC-Retn mice. Moreover, BAC-Retn mice developed hepatic insulin resistance in response to chronic LPS treatment.[20] These mouse models will be valuable for exploring the connection between resistin and inflammation and the development of insulin resistance and type 2 diabetes.

RESISTIN AND ENERGY HOMEOSTASIS

Several lines of evidence in rodents suggest that resistin is involved in energy homeostasis. Resistin protein levels are reduced during fasting and increased in response to refeeding.[25] Lepob/ob mice lacking resistin develop severe obesity because of a reduction in energy expenditure.[23] In rats, resistin decreases food intake, and this anorexigenic effect is associated with decreased expression of agouti-related peptide and neuropeptide Y, and increased expression of cocaine and amphetamine-regulated transcript within the arcuate nucleus of the hypothalamus.[31] Resistin also increases the phosphorylation of AMPK and its downstream target acetyl-coenzyme A carboxylase (ACC), and decreases the expression of fatty acid synthase in the ventromedial nucleus of the hypothalamus.[31] Chronic icv resistin infusion decreases body weight and fat, and suppresses the expression of lipogenic enzymes in liver and adipose tissue.[31]

Kosari et al. studied the effects of icv resistin on sympathetic nervous activity (SNA) in rats.[11] Acute icv resistin treatment increases lumbar SNA but decreased BAT SNA. However, mean arterial pressure and heart rate, were not affected by resistin. Resistin treatment decreases BAT temperature and core body temperature.[11]

CONCLUSIONS

Adiponectin and resistin levels are altered in obesity and metabolic syndrome. Adiponectin has potent actions in the brain and modulates feeding and energy expenditure via AdipoR1 and AdipoR2. Electrophysiologic and genetic manipulation of AdipoR1 and AdipoR2 reveal distinct actions of adiponectin in the hypothalamus and other regions of the brain. By contrast, there is little known about the role of resistin in energy homeostasis. Although resistin has been detected in human CSF,[10] the blood–brain transport mechanisms are unknown. The resistin receptors and their signaling pathways in the brain, and how these specifically regulate feeding and energy expenditure are also unknown. A better understanding of the effects of adiponectin and resistin on energy balance could provide novel insights on the pathogenesis and treatment of obesity, diabetes, and related disorders.

Chapter 140

Amylin/CGRP

Thomas A. Lutz

ABSTRACT

This chapter focuses on the anorectic action of the pancreatic hormone amylin and the structurally related peptide calcitonin-gene-related peptide (CGRP). Both peptides when given peripherally or centrally produce potent anorectic effects and delay gastric emptying. The anorectic action of CGRP seems to parallel amylin's effect on eating in many aspects; however, in this chapter, more emphasis will be placed on the effects of amylin on eating because amylin's effects may be of physiological relevance, but this is less clear in the case of CGRP. Other effects of CGRP are mentioned in other chapters of this book.

INTRODUCTION

The acute and chronic eating-inhibitory effects of amylin seem to be one important factor in amylin's overall role to control the influx of nutrients into the circulation. Apart from this effect, amylin's action to reduce gastric acid secretion, to limit the rate of gastric emptying, and to diminish pancreatic glucagon and digestive enzyme secretion are other factors serving the same purpose.[12,29] Therefore, by regulating nutrient appearance and the postprandial glucose concentration, amylin seems to be a necessary and complementary factor to insulin in the control of nutrient flux.

Amylin, or islet amyloid polypeptide (IAPP), was first isolated from pancreatic amyloid deposits, which typically occur in human type 2 diabetes mellitus, in feline diabetes mellitus, and in insulinomas in animals and humans. Amylin, however, is also a physiological product of pancreatic B-cells from where it is cosecreted with insulin. It is generally assumed that the pancreatic B-cells constitute the main source for circulating and postprandially released amylin and that the increase in amylin levels in response to eating is the physiological basis for amylin's satiating effect. Accordingly, pancreatectomized cats have very low baseline amylin (and insulin) levels and virtually no postprandial increase in blood amylin levels (unpublished); unfortunately, no measures of eating or meal pattern were determined in these studies.

Eating results in a marked increase in the plasma amylin concentration. This meal-induced increase is rapid and correlates with the size of the pertinent meal. Blood levels of CGRP show only a modest and late increase in response to eating. Therefore, a physiological role for CGRP in satiation seems questionable, at least referring to a hormonal action of circulating CGRP. The source for this increase in circulating CGRP may be by spillover from neuronal cells.

RECEPTORS FOR AMYLIN AND CGRP ACTION

Amylin and CGRP binding sites belong to the family of G-protein-coupled receptors. The functional amylin receptor involves the calcitonin receptor (CT-R) as a core receptor, whose amylin specificity and affinity results from the coexpression of one of several receptor activity modifying proteins (RAMPs).[9,13,24] The CT-R without coexpression of RAMPs represents the classical CT receptor, whereas a typical amylin receptor arises from the interaction of RAMP1 or RAMP3 with the CT-R. A similar principle leads to functional receptors for CGRP; they rely on the coexpression of the calcitonin receptor-like receptor (CL-R) with appropriate RAMPs.

Amylin binding sites are widely distributed in the central nervous system and also occur in high densities in brain areas involved in the control of eating. The area postrema (AP) which seems to mediate amylin's and CGRP's effects on eating, contains all components of functional amylin receptors, as shown by the presence of RAMP1 and RAMP3 mRNA and positive immunostaining for RAMP1, RAMP3, and the CT-R.

Detailed studies of the presence of CL-R protein as part of functional CGRP receptors in the brain and especially in brain areas involved in the control of eating are not available. However, *in situ* hybridization studies have shown that CL-R mRNA is present in the rat brain. Other than in the AP, the physiological relevance of amylin and CGRP binding sites for the anorectic actions of amylin and CGRP remains unknown.

CHARACTERIZATION OF THE EFFECTS OF AMYLIN AND CGRP ON EATING AS SATIATING HORMONE

Amylin shares the typical characteristics of satiating hormones,[12] which are involved in the control of meal size. Amylin is rapidly released during food ingestion, and it dose dependently reduces meal size. Amylin has a rapid onset and brief duration of action, and amylin antagonism increases eating by a specific meal size effect.[14,20]

In contrast to some other satiating hormones such as cholecystokinin (CCK), amylin is also active under conditions of chronic delivery; amylin reduces eating by decreasing average meal size, but it may also reduce meal number by increasing the duration of the intermeal interval. Similarly, amylin increases the latency to eat under certain experimental conditions. Nonetheless, the best characterized function of amylin is its effect to reduce meal size.

Qualitatively, CGRP reduces eating by affecting the same meal pattern parameters as amylin, that is, CGRP reduces meal size after acute and chronic administration and affects the intermeal interval during chronic infusion. Because of the lack of 100% specific antagonists against amylin or CGRP receptors and the lack of studies with specific receptor deficient animals, it remains unclear whether CGRP's effects on eating result from an interaction at amylin receptors or from a specific, amylin independent effect. However, based on its release pattern with an increase of plasma CGRP levels only occurring at least 1 h after meal onset, it seems unlikely that blood-borne CGRP constitutes a physiological satiating agent.[7]

Meal pattern analysis after the injection of amylin or CGRP reveals another potential difference between amylin and CGRP action because CGRP reduces the eating rate in rats, at least at higher doses. This suggests that some aversive or illness-producing effect may at least partly underlie the anorectic action of CGRP, indicating that its action on feeding is not specific. This contrasts with amylin which does not reduce feeding by producing a conditioned taste aversion or by an unspecific effect (e.g., via a reduction in drinking).[12]

The lowest dose of exogenous amylin that produces a significant reduction in feeding yields plasma amylin levels that were about two times higher than the concentrations measured postprandially. Strictly speaking, this means that physiological amylin concentrations that occur at the end of spontaneous meals have not yet been shown to reduce feeding. However, different kinetics of the blood amylin concentration after exogenous amylin delivery rather than endogenous secretion may play a role. Further, under natural feeding conditions many gastrointestinal hormones that individually induce satiation are released at the same time and may interact in a way that may be difficult to mimic in an experimental setting. Overall, we believe that amylin is a physiological control of meal size and that this effect is based on circulating amylin; importantly, several studies have clearly shown that peripherally or centrally delivered amylin antagonists produce an effect opposite to that of amylin, that is, an increase in meal size.[14]

AMYLIN AS AN ADIPOSITY SIGNAL

The role of amylin as a satiating hormone seems to depend on phasic changes in amylin levels, that is, the meal-induced increase in plasma amylin levels. In addition, amylin may also exert a tonic effect on eating, that is, it may play a role in the long-term control of eating or body weight.[10,27]

First, basal levels of amylin also seem to depend on the prevailing body weight and body adiposity, in both rats and humans. High-fat fed, obese rats have higher baseline amylin levels than age matched lean controls: of note; this does not distinguish between a body weight and a diet effect. We also investigated whether changes in body adiposity in single individuals are reflected in changing amylin levels and whether such changes in adiposity and amylin in fact follow the same temporal pattern; rats were rendered overweight by chronic intragastric overfeeding leading to a 30% excess body weight above normal weight rats. To our surprise, basal amylin levels did not change significantly during or after termination of overfeeding. Whether amylin levels may only increase after extended periods of overweight or whether the type of diet used during overfeeding may play a role is currently unknown. It seems clear that further studies are required to define the exact contribution of time, diet, extent of overweight and other potential factors on the obesity related increase in plasma amylin levels.

Second, chronic amylin infusion in rats lowers eating and body weight gain by reducing body adiposity while chronic peripheral or central infusion of amylin antagonists increases body weight with a major effect on body fat mass while sparing lean body mass.[20,23] We showed that chronic third ventricular amylin infusions reduce body weight gain in rats regardless of previous weight manipulations. This means that amylin infused rats, whether temporarily food restricted, overfed or left unmanipulated, eventually reached similar body weight which was consistently lower than in saline infused controls.[27] Hence, the effect of a chronic modulation of amylin signaling is similar to that of leptin or insulin. The relative contribution of amylin versus leptin or insulin to the control of body weight is difficult to judge but it is clear that the lack of leptin in *ob/ob* mice results in a more dramatic obese phenotype than the lack of amylin in amylin-deficient mice.[8,12] However, because obesity-associated leptin resistance prevents leptin from being effective when the effect apparently would be needed most, additional amylin may be a very effective

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

alternative and amylin may play an important modulatory role. Further, even animals with defective leptin and insulin signaling (e.g., the Zucker *fa/fa* rat) keep their body weight relatively stable, even though this occurs at a higher level. Hence, amylin may play some role as an adiposity feedback signal similar to leptin and insulin, at least when the leptin and insulin feedback signaling systems are deficient.

EATING IN KNOCKOUT ANIMALS[16]

Amylin knockout animals have been developed to study the role of amylin in nutrient and bone metabolism.[8] The specific phenotypes of amylin-deficient mice that are not related to amylin's role in the control of eating include a lower bone mass resulting from a higher number of osteoclasts and reduced late phase nociception in the paw formalin test; the latter implies that endogenous amylin increases the perception of chemical pain.

In the same animals, adult body weight does not differ between knockout and wildtype animals in some studies, but amylin knockou*t* mice show a slightly higher rate of body weight gain compared with that of corresponding wildtype controls; the knockout mice grow significantly faster up to about 4 months of age. Eating is slightly though not significantly higher than in control animals.[12]

Interestingly, amylin knockout mice also differ from control animals in their interaction with other factors co ntrolling eating, indicating that endogenous amylin may have a facilitating role for other controls of eating (e.g., CCK;[15] or leptin). Together, these studies suggest a role for endogenous amylin in the overall control of energy balance, most probably by an effect on eating and in interaction with other satiating and adiposity signals.[12]

Eating in amylin receptor knockout animals has not been determined so far. The effect of haplodeletion of amylin and its receptor protein (calcitonin receptor; CT-R) on bone metabolism has been determined in crossbred heterozygous amylin$^{+/-}$ and heterozygous CT-R$^{+/-}$ mice, but neither eating nor body weight were reported.[16]

EATING IN ANIMALS OVEREXPRESSING AMYLIN

To my knowledge, no detailed studies are available on the effect of amylin[16] overexpression on eating or body weight. Rats that were transgenic for the overexpression of human amylin gained weight comparably until 5 months of age but then had a slightly lower body weight than wildtype controls.[4] The authors argued that lower body weight may have been a consequence of energy loss because of the development of glycosuria and diabetes in the transgenic rats, but no detailed data on eating were provided. Hence, reduced eating which in principle would be consistent with the effects of exogenous amylin on eating and body weight cannot be excluded. The rather small difference between transgenic and control animals may have resulted from receptor desensitization or the redundant system controlling body weight. Because the major difference in body weight between amylin knockout and wildtype mice occurs during a certain period of life, the same may also hold true for animals overexpressing amylin. Another article with mice that are transgenic for the overexpression of human amylin also did not report data on eating and body weight.[28]

EATING IN ANIMALS DEFICIENT OF CGRP OR OVEREXPRESSING CGRP

Although no detailed results are available related to the effect of CGRP[16] overexpression on eating or body weight, a later article describes the effect of genetic CGRP deficiency (CGRP knockout) on eating and body weight in mice. CGRP ko mice fed different diets ate slightly but significantly more than control mice of the same diet group; total eating and eating corrected for body weight gain were both increased significantly. This effect on eating in principle is consistent with the effect of exogenous CGRP to reduce energy intake. Surprisingly however, and despite overeating, the ko mice seem to be protected from the development of diet-induced obesity because both their body weight and body adiposity are lower than in wildtype animals. The latter effect may be explained by the increase in core body temperature and energy expenditure in knockout versus wildtype mice.[28]

ENERGY EXPENDITURE AS AFFECTED BY AMYLIN AND CGRP

Many studies have shown that acute (central) and chronic amylin administration increase energy expenditure as assessed by indirect calorimetry (reviewed in Ref. 12; see also Ref. 27). The effect under chronic conditions may in part be secondary to the reduction in adiposity by amylin and hence the relative increase in metabolically more active lean body mass. Acute peripheral injection of an anorectic dose of amylin fails to increase energy expenditure in rats, whereas the long acting amylin agonist salmon calcitonin (sCT) increases it; we therefore believe that this difference may result from the different biological half-life of amylin versus sCT. The central neural targets which may mediate the effect of exogenous amylin on energy expenditure and the underlying mechanisms are not clear.

Given the similar eating-inhibitory effects of amylin and CGRP, the report that CGRP knockout mice have increased rather than decreased energy expenditure is surprising. Whether CGRP replacement would have corrected for this phenotype was not tested.[28]

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

ENERGY METABOLISM IN ANIMALS WITH INCREASED AMYLIN OR CGRP SIGNALING PROPENSITY

Another study has provided an interesting insight into the potential mechanisms of enhanced amylin or CGRP receptor signaling.[30] This study used transgenic mice overexpressing the human RAMP1 gene specifically in the central nervous system; because RAMP1 is a chaperone to the amylin (CT-R) and CGRP (CL-R) receptors, any effect observed in these mice could result from enhanced signaling of amylin, of CGRP or both. Total eating is temporarily reduced in the transgenic mice and eating related to body weight gain is increased. Interestingly, energy expenditure is significantly higher in the transgenic mice, probably explaining the lower body weight and adiposity. Because the effect of exogenous central amylin but not CGRP on body weight gain is markedly enhanced in the transgenic mice, the phenotype of the RAMP1 transgenic mice may mainly result from enhanced brain amylin signaling via the CT-R/RAMP1 receptor complex. This may also explain the apparent paradox between lower body adiposity in these mice, and the effect of the knockout of CGRP in mice that results in a protection from diet-induced obesity.[28]

REGULATION OF AMYLIN AND CGRP SYNTHESIS AND SECRETION IN LEAN AND OBESE INDIVIDUALS

Because of their cosynthesis and colocalization in secretory vesicles, insulin and amylin are normally cosecreted on activation with the appropriate stimuli;[2,3] this typically occurs at a fixed ratio of about 1:10–1:100. Interestingly, divergent secretion of insulin and amylin is possible, but it remains unclear how differential release of insulin and amylin is regulated. Human obesity, various rat models of obesity, diabetes mellitus, pancreatic cancer, and pharmacological intervention (e.g., dexamethasone) may lead to relative overexpression and over-secretion of amylin versus insulin. Clear evidence for a preferential transcription of amylin or increased stability of amylin mRNA under these conditions has not been found so far. It has however been hypothesized that differential regulation of amylin and insulin mRNA production may involve the cAMP and protein kinase A (PKA) pathways and that different transcription factors for insulin and amylin may be involved.

We investigated whether obesity or maintenance on a high-fat diet (HF diet) affect meal induced amylin release in rats. HF fed rats, whether classified as diet-induced obese (DIO) or diet-resistant (DR) exhibit an earlier meal-induced rise in amylin compared with lean chow-fed controls. Further, DR rats have higher amylin:insulin ratios before and after a meal. In principle, these findings are consistent with the demonstration that elevated fatty acids, which can result from the consumption of a diet high in fat, induce enhanced mRNA expression and release of amylin, but not insulin. One important overall conclusion from these experiments in respect to amylin's role in the control of eating and in obesity is that amylin secretion does not seem to be blunted in obesity; it therefore seems unlikely that insufficient release of amylin contributes to overeating in obesity or in individuals on HF diets.

Obese individuals have been reported to have higher CGRP levels than lean controls,[7] but the physiological relevance of this finding is unclear. A direct link between baseline CGRP levels and the degree of adiposity seems unlikely because CGRP does not decrease in response to body weight loss. Plasma concentrations of CGRP increase in response to eating mainly by spillover from sensory nerve endings rather than controlled release from endocrine cells. This is only seen after a high fat, but not after a high carbohydrate meal, and the late increase (>1 h) argues against an effect of CGRP on individual meals. Specific studies directly comparing the meal-induced changes in CGRP secretion and blood concentrations in lean versus obese individuals or in individuals on specific diets have not been reported.

CENTRAL PATHWAYS MEDIATING THE ANORECTIC EFFECTS OF AMYLIN AND CGRP

Experimental evidence supports the idea that the anorectic effect of peripheral amylin is mediated by direct humoral action on the area postrema (AP) in the hindbrain (reviewed in Refs. 12, 17). Amylin binding sites have been described in various CNS locations involved in the control of eating, but behavioral tests with peripheral or local AP infusions, immunohistological, and electrophysiological experiments all indicate that the AP seems to be necessary as primary site of action for peripheral amylin to reduce eating.

Blood-borne amylin has easy access to AP neurons because of the lack of a functional blood–brain barrier in this area; several studies from different laboratories have shown that peripheral amylin's anorectic action is abolished in rats with lesions in the AP. Endogenous blood-borne amylin also seems to act via the AP because an infusion of the amylin antagonist AC 187 into the AP increases eating because of an increase in meal size; further, AC 187 infused into the AP also partly blocks the anorectic effect induced by peripheral amylin injection, providing the best *in vivo* evidence for the importance of the AP in mediating peripheral amylin's anorectic action.

Electrophysiological and immunohistochemical studies indicate that AP neurons are directly and dose dependently stimulated by amylin and that exogenous and endogenous

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

amylin produce a strong expression of the immediate early gene product c-Fos protein as a marker of neuronal activation in AP neurons. Both responses are effectively blocked by AC 187.

PHENOTYPE OF AMYLIN RESPONSIVE NEURONS IN THE AP

Expression of c-Fos protein was used to determine the phenotype of amylin responsive neurons in the AP.[19] We found that about 50% of amylin-activated AP neurons are noradrenergic because they expressed dopamine-beta-hydroxylase (DBH), the enzyme catalyzing noradrenaline (NA) synthesis. These neurons seem to play a specific functional role in amylin's effect on eating because even a partial (~50%) lesion of the NA-containing neurons in the AP is sufficient to block the acute eating effect of peripheral amylin. Further, amylin did not induce a significant c-Fos response in AP neurons in NA-lesioned rats.

INTRACELLULAR SIGNALING PATHWAYS IN AP NEURONS ACTIVATED BY AMYLIN

Despite the widespread use as activation marker, we believe that the amylin-induced c-Fos response in the AP has no functional implications because the kinetics of c-Fos expression and the onset of amylin's anorectic effect are inconsistent.[12,17] We have provided evidence for a functional role of phosphorylation of the extracellular signal regulated kinase (pERK1/2) cascade in amylin's effect; amylin-induced ERK1/2 phosphorylation, and (partial) blockade of this effect-attenuated amylin's feeding response. How this relates functionally to amylin-induced cGMP formation in AP neurons remains to be investigated.

PROJECTIONS OF AP NEURONS IMPLICATED IN AMYLIN'S AND CGRP'S EFFECTS AND HYPOTHALAMIC INVOLVEMENT IN THE ANORECTIC ACTION OF PERIPHERAL AMYLIN.[18,21]

Amylin elicits a strong c-Fos response in AP projection areas, namely, the nucleus of the solitary tract (NTS), the lateral parabrachial nucleus (lPBN), the central nucleus of the amygdala (CeNA), and the bed nucleus of the stria terminalis (BNST). The AP, NTS, and the lPBN form a necessary part of the CNS pathway conveying amylin's anorectic signal to higher brain structures; their activation seems to be secondary to an action of amylin on AP neurons.

Retrograde and anterograde tracer studies confirm reciprocal projections between these amylin-activated areas. We identified dense projections from the amylin-activated neurons in the lPBN and sparse projections from the NTS to the dorsal lateral hypothalamus (dLHA) where amylin reduces fasting induced c-Fos expression; hence, the lPBN may thus mediate the amylin-induced inhibition of the dLHA. This inhibition may be linked to the downregulation of the expression of orexin and melanin-concentrating hormone in the dLHA. Dense efferents are also observed from the lPBN to other hypothalamic areas, namely, to the ventromedial (VMH), dorsomedial, paraventricular (PVN), and arcuate nuclei (ARC). Their functional role is not entirely clear, but see paragraphs on amylin/leptin interactions and the role of the ventromedial hypothalamus.

SITE OF CGRP ACTION

The site of action for CGRP's anorectic action has been investigated in less detail than that of amylin. Similar to amylin, the anorectic action of peripheral CGRP is abolished in rats with an AP lesion. Immunohistochemical and electrophysiological studies have not been performed to the same extent as for amylin, so that it is difficult to integrate these findings into the whole brain network for the physiological control of eating.

FOREBRAIN EFFECTS OF AMYLIN

The role of forebrain amylin[12] receptors is still unclear. It seems probable that these receptors mediate the anorectic action of amylin infused into the third brain ventricle; this effect is very potent and long-lasting, and third ventricular infusion of AC 187 increases eating in rats. The latter is associated with an increase in body weight and the weight of the retroperitoneal fat pads. Nonetheless, the functional relevance of these findings under physiological conditions is not clear, and at present, there is no evidence to suggest that forebrain amylin receptors are involved in the regulation of eating by peripheral amylin.

CNS production of amylin has not been shown unequivocally, except in an interesting study pointing to a potential role of hypothalamic amylin in the modulation of maternal behavior.[6] The physiological relevance of these findings is currently under investigation.

FOREBRAIN EFFECTS OF CGRP

Injection of CGRP into the PVN which contains CGRP binding sites[5] produces a strong anorectic effect, and it increases the concentration of various anorectic neuropeptides in the hypothalamus. However, the physiological relevance of these findings is unclear because very high doses of CGRP had been used, exceeding the EC_{50} for amylin to elicit an anorectic effect after administration into the third

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

brain ventricle by a factor of >200. Further, the PVN content of CGRP was elevated in response to fasting, which is difficult to reconcile with the idea of CGRP acting as an anorectic hormone or neuropeptide. Hence, the role of CGRP as a brain-intrinsic neuropeptide in the control of feeding remains to be investigated.

INTERACTION BETWEEN AMYLIN AND ESTRADIOL

Only few studies have tested the specific anorectic effect of amylin in females.[11,25] Similar to CCK and other satiating hormones, single acute injections of amylin are more effective in ovariectomized rats with physiological estradiol replacement than in rats without replacement. Further, the amylin antagonist AC 187 increases eating more in estradiol replaced ovariectomized animals, pointing to the physiological relevance of the modulating effect of estradiol on amylin action. Surprisingly, the effect is opposite under chronic conditions; in other words, the action of chronic amylin on eating and body weight is stronger in ovariectomized rats lacking estradiol than in control rats or in ovariectomized rats receiving estradiol replacement. Chronic amylin also at least partly restores the metabolic rate that was decreased as a consequence of ovariectomy. Hence, the interaction between amylin and estradiol seems to be complex and these apparently opposing phenomena require intensified study.

SHORT-TERM INTERACTION WITH OTHER HORMONES CONTROLLING INGESTIVE BEHAVIOR

Subthreshold doses of peripheral insulin and amylin reduce eating in rats when coadministered, and central insulin enhances the action of peripheral amylin.[12,22] Further, amylin and CCK also seem to interact in their effect on eating. CCK and amylin synergistically reduce eating; similar synergistic effects have been reported with PYY and for the combination of sCT with the GLP-1 agonist exendin-4 in nonhuman primates.[1] Further, part of the satiating action of CCK seems to be mediated by amylin, because amylin antagonists attenuated CCK's anorectic actions in rats and because the anorectic effect of CCK is almost abolished in amylin knockout mice; the latter effect is restored by amylin. In other words, endogenous amylin seems to modulate the anorectic effect of CCK.

INTERACTION BETWEEN AMYLIN AND LEPTIN

Amylin and leptin[22,26] seem to interact acutely and chronically. Acute central leptin increases the eating-inhibitory effect of peripheral amylin. Further, two-week peripheral infusions of amylin and leptin were performed in leptin resistant DIO rats. Amylin alone reduces eating and leads to a decrease in body weight. Interestingly, rats pair-fed to the amylin group and that received leptin do not lose more weight than amylin-treated rats. However, combined application of exogenous leptin and amylin decreases eating and body weight more than amylin alone, and body fat is lowest after leptin/amylin. Hence, amylin strongly enhances the sensitivity of obese rats to the catabolic effect of leptin, including an increase in energy expenditure. Body fat loss is more in the amylin/leptin-treated rats than in the pair-fed controls; this is consistent with a lower respiratory quotient, indicating preferential fat oxidation. One important point to consider is that the interactions of amylin and leptin on eating and adiposity have mainly been shown under pharmacological, not under physiological conditions.

ROLE OF THE VMH IN THE LEPTIN AND AMYLIN INTERACTION

The interaction[26] between amylin and leptin seems to result from a direct effect of amylin on central leptin signaling, most probably in the VMH and potentially the ARC. Amylin enhances leptin signaling as gauged by increased immunoreactivity of pSTAT3 specifically in the VMH; this effect may be linked to an amylin-induced upregulation of leptin receptor expression and hence direct enhancement of leptin action in VMH neurons. Further, amylin-deficient mice have reduced leptin receptor expression in the mediobasal hypothalamus.

INTERACTION BETWEEN AMYLIN AND METABOLITES

Higher doses of amylin are necessary to inhibit sham feeding than real feeding, which may be because of the lack of cooperative effects between amylin and metabolites (e.g., elevated glucose) under these conditions.[12] Similar to amylin's effect on gastric emptying, amylin's eating-inhibitory effect seems to be reduced in rats with induced hypoglycemia. This is in line with coactivation of AP neurons by physiological concentrations of amylin and glucose. The co-responsiveness of AP neurons to amylin and glucose is similar to that for glucose and CCK; AP neurons may therefore integrate metabolic and hormonal signals that control eating.

PHYSIOLOGICAL AND PATHOPHYSIOLOGICAL IMPLICATIONS

Relatively little is known about the possible role of amylin's effect on feeding under pathophysiological conditions. It has been hypothesized that amylin may contribute to cancer

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

anorexia in certain pancreatic neoplasia, which may be associated with chronically supraphysiological plasma amylin levels.

An altered ratio between amylin and insulin has been supposed to play a role in eating disorders and hence to contribute to abnormal feeding behavior in diabetes mellitus. In other words, the lack of amylin in type 1 diabetes and later stages of type 2 diabetes could result in increased eating or body weight. The clinical experience with the amylin analog pramlintide in the treatment of type 1 and 2 diabetes is consistent with this idea. Individuals treated with pramlintide plus insulin lost body weight while patients treated with insulin alone gained weight. Subsequent trials showed that pramlintide decreases eating and body weight in obese or diabetic patients. Because obesity and chronic hyperamylinemia, which is typically associated with obesity, do not seem to reduce amylin effectiveness, amylin may be a promising and potent approach to treat obese patients. Similar to the results in rats, this effect can be potentiated when amylin is combined with leptin.

Similar results are not available for CGRP. Hence, it is unknown whether CGRP or CGRP analogs produce similar or even more potent effects than amylin in a clinical setting. Given the current availability of data, amylin seems to be a more promising and safer approach than CGRP.

SUMMARY

Both amylin and the structurally related neuropeptide CGRP reduce eating. Amylin may be a physiological control of meal size, but this is less clear for CGRP. The effects of peripheral amylin and CGRP on eating are centrally mediated by the AP in the hindbrain as the most probable primary target area. Chronic exposure to amylin decreases eating and body weight gain. Next to a satiating action, amylin may also constitute an adiposity feedback signal. The anorectic action of amylin is pharmacologically exploited because amylin analogs are under clinical consideration for their effect to reduce eating and body weight in humans; this effect can be potentiated with leptin co-therapy.

Chapter 141

Apolipoprotein (apo) A-IV/apoE

Patrick Tso and Min Liu

ABSTRACT

Although circulating apolipoprotein A-IV (apo A-IV) is mainly produced from the intestine, and apolipoprotein E (apoE) from the liver, both proteins are also synthesized in brain areas involved in the energy homeostasis. Both the proteins have been proposed to physiologically control food intake, and this inhibitory effect is mainly centrally mediated. Intracerebroventricular (icv) administration of apo A-IV or apoE significantly reduces food intake without causing malaise, whereas icv infusion of their antibodies stimulates feeding, implying that these endogenous apolipoproteins tonically inhibit food intake. Both genetically obese (*ob*/*ob*) mice and rats with high-fat-diet-induced obesity have significantly reduced hypothalamic apo A-IV and apoE mRNA levels compared with that of their lean controls. Compelling evidence has thus shown that apo A-IV and apoE exert their potent catabolic influence to regulate energy homeostasis through integration with other central signals.

INTRODUCTION

Apolipoprotein A-IV (apo A-IV), discovered in the late 1970s,[31] is a glycoprotein found in many species; the human form has a molecular weight of 46 kDa. The jejunum is the major site of apo A-IV synthesis, and its synthesis and secretion are associated with chylomicron formation. Once chylomicrons enter the circulation, apo A-IV rapidly dissociates from chylomicron remnants, with the result that the majority of apo A-IV in the circulation exists as free protein, whereas the remainder is associated with circulating high-density lipoproteins. Several studies have provided evidence that apo A-IV plays a role in cholesterol and lipoprotein metabolism, protection against lipoprotein oxidation, and atherosclerosis.[3,4,23] Compelling evidence also supports a primary role for apo A-IV in the control of ingestive behavior.[7,8,16] Although the reduced gastric motility and acid secretion induced by apo A-IV partially contribute to its anorectic effect,[22] compelling evidence suggests that the inhibitory action on food intake is mainly centrally mediated.[17,27,30,32]

Apolipoprotein E (apo E), first described in 1975, is a 299-amino-acid protein with a 34-kDa molecular weight.[33] ApoE is synthesized in several areas of the body, but the liver accounts for the major portion of circulating apoE. When synthesized by the liver as part of very low-density lipoproteins (VLDLs), apoE functions in the transport of triglycerides to the tissues. ApoE is also found in high-density lipoproteins (HDLs) and functions in cholesterol homeostasis. In the CNS, apoE is produced by diverse cell types, including astrocytes and neurons. In the cerebrospinal fluid (CSF), apoE is the most abundant component of HDL-like lipoproteins, which are bound and internalized via receptor-mediated endocytosis by members of the low-density lipoprotein receptor (LDLR) family.[1] Previous studies have shown that apoE plays additional roles in the brain, regulating both neuronal and astrocytic functions, including preventing excitotoxicity, promoting neuron survival and sprouting, protecting neurons against oxidative stress, and regulating innate and adaptive immune responses.[11,14] More recent results indicate that brain apo E is also an important regulator of food intake and body weight in rats.[19,29]

Effects on Food Intake and Body Weight

The role of Apo A-IV in regulating food intake was first proposed by Fujimoto et al.[7] Because chylomicron transport and apo A-IV output in mesenteric lymph increase significantly after a lipid meal, Fujimoto et al. infused mesenteric lymph collected from lymph-fistula rats after lipid administration intravenously (iv) in 24-h fasted rats and observed that those animals eat significantly less, compared with saline controls. By contrast, lymph collected before lipid infusion and lymph collected from a rat fed lipid plus Pluronic L-81 (a potent inhibitor of chylomicron formation) has no such anorectic effect.[7] After specific immunoprecipitation of apo A-IV by a monospecific antibody, chylomicrons and apo A-IV-rich lymph lose their anorectic effect. In 24-h fasted rats, iv infusion of purified apo A-IV, the same amount of apo A-IV as the level in chylous lymph 6–8 h after a lipid meal, suppresses food intake. Fujimoto et al. therefore proposed that apo A-IV is a circulating satiation

signal released by the small intestine in response to fat feeding and probably helps mediate the anorectic effect of fat consumption.[7]

Feeding behavior is influenced by many circulating factors, and chemosensitive monitoring systems for these factors exist both in the CNS and in peripheral organs.[35] To investigate whether the anorectic effect of apo A-IV after lipid feeding is mediated via the CNS, Fujimoto et al. infused different doses of apo A-IV icv and found that apo A-IV inhibits food intake in a dose-dependent manner.[8] Administration of goat antirat apo A-IV serum into the third ventricle of rats results in increased food intake, indicating that apo A-IV may act centrally to control food intake.

It has been reported that targeted absence of apoE yields significantly elevated food intake and body weight in mice fed a diabetogenic diet.[24] Based on that, Shen et al. hypothesized that apoE participates in regulating energy homeostasis. They administered different doses apoE into the third cerebral ventricle of rats, and found that it produces a significant and dose-dependent inhibition of food intake in both ad libitum and 24-h fasted conditions, and the reduction of food intake is not associated with illness.[29] To further determine whether the CNS is the critical site for the anorectic action of apoE, food intake of rats administered iv apoE at doses that are effective centrally does not differ from those receiving vehicle at any time point, implying that icv apoE acts within the CNS to suppress food intake rather than leaking into the blood and acting at peripheral apoE receptors.

To determine whether endogenous apoE signaling influences food intake, Shen et al. administered apoE antiserum icv to *ad libitum* fed rats in the middle of the light phase and observed significantly increased food intake, but icv infusion of preabsorbed apoE serum fails to elicit a feeding response. Further, the anorectic action induced by icv apoE is attenuated by icv-infused apoE antibody.[29] Because food intake is a major determinant of energy balance, Liu et al. hypothesized that chronic icv infusion of apoE would lead to a reduction of body weight. To determine this, rats received a continuous infusion of apoE or vehicle via osmotic minipump, and their food intake, body weight were monitored daily for 10 days. In parallel with the reduction of food intake, there is a significant decrease in body weight in rats by Day 4 of treatment with apoE, compared with that of vehicle controls (Fig. 1). The body weight of pair-fed rats is comparable with that of apoE-treated rats during the entire period of observation, implying that the effect of apoE on body weight is mainly the result of a reduction of food intake.

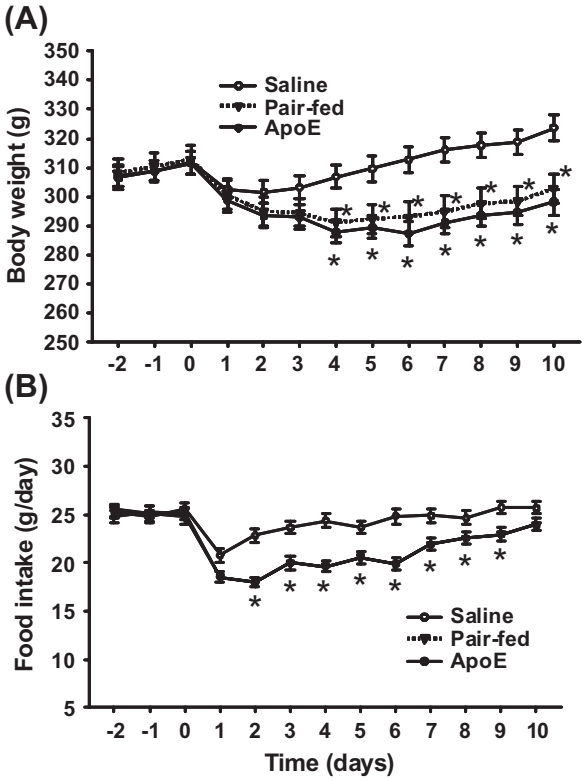

FIGURE 1 Changes in body weight (A) and food intake (B) during chronic central apoE infusion. ApoE (4 μg/day) or saline was infused into the third cerebral ventricle via Alzet osmotic minipump (0.5 μl/h). Data represent the mean ± SEM; $n = 7–8$, $*P < 0.05$ vs. saline controls.

Distribution in Brain Areas Involved in Energy Homeostasis

Liu et al. have provided direct evidence that apo A-IV mRNA and protein are present in the rat hypothalamus.[15] Using immunohistochemical techniques, Shen et al. further characterized the distribution of apo A-IV in brain areas involved in energy homeostasis.[27] Dense apo A-IV staining is detected in the arcuate (ARC) and ventromedial hypothalamic (VMH) nuclei with less staining in cells in the paraventricular (PVN) and dorsomedial (DMN) nuclei. In the brainstem, apo A-IV staining is found in the nucleus of the solitary tract (NTS). Double-staining immunohistochemistry revealed the coexistence of apo A-IV with neuronal nuclei (a neuronal marker), but less with glial fibrillary acidic protein (GFAP, a glial marker), in ARC, suggesting that apo A-IV is largely present in neurons. To ascertain whether the apo A-IV detected in the brain is derived from the circulation, ^{125}I-labeled recombinant rat apo A-IV was injected iv into mice. No increase of radioactive apo A-IV was found in the brain, consistent with a lack of uptake of coinjected ^{99m}Tc-labeled albumin, indicating that circulating apo A-IV is unable to cross the blood–brain barrier.[27]

ApoE is also in the hypothalamus.[28] Shen et al. used immunofluorescence labeling and observed a prominent presence of apoE protein in the ARC and PVN, consistent with its role in the regulation of energy homeostasis. To determine the apoE-producing cell type, Shen et al. investigated the colocalization of apoE with specific cell type

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

markers in the hypothalamus and observed that 87% of the apoE-positive cells are astrocytes, 6% are neurons, 3% are microglial cells, 2% are oligodendrocytes, and 2% are other brain cells.[28]

REGULATION OF APO A-IV AND APOE PRODUCTION

Fasting and Refeeding

Circulating and central apo A-IV levels are influenced by nutritional status.[15] Food-deprived animals have a pronounced decrease in apo A-IV gene expression in the hypothalamus, with a concomitant decrease in the jejunum. Refeeding fasted rats with low-fat chow for 4 h evokes a significant increase of apo A-IV mRNA in jejunum but not in the hypothalamus. However, lipid refeeding to the fasted animals restores apo A-IV mRNA levels in both the hypothalamus and the jejunum. Currently, it is unclear how lipid feeding regulates apo A-IV expression, that is, whether it is a direct or indirect effect. Nonetheless, hypothalamic and intestinal apo A-IV respond similarly to fasting followed by lipid feeding.[15]

Similar responses were observed with rat hypothalamic apoE.[29] Shen et al. measured hypothalamic apoE mRNA levels in rats that were ad libitum fed, 36-h fasted, and 32-h fasted followed by 4-h chow refeeding. The fasted rats had significantly reduced hypothalamic apoE mRNA levels compared with ad libitum fed controls. ApoE mRNA expression was reversed to levels of ad libitum fed rats after 4 h of refeeding.

Chronic High-Fat (HF) Feeding

Weinberg et al. first reported that human plasma apo A-IV levels adapt in response to prolonged consumption of fat.[34] Humans who chronically consume an HF diet initially develop significantly elevated plasma apo A-IV levels that disappear over time. The investigators therefore concluded that intestinal apo A-IV production is autoregulated in response to diets with HF or high-energy density. Kalogeris et al. also examined the effect of daily fat supplementation on intestinal gene expression and protein synthesis and apo A-IV plasma levels.[13] Male rats were administered bolus intragastric injections of either saline or Intralipid for 0, 1, 2, 4, 8, or 16 days. They found plasma apo A-IV to initially increase 40% in rats fed the fat emulsion compared with that in the saline-injected controls. Daily consumption of fat produces a plasma apo A-IV response that rapidly and progressively diminishes, such that, by Day 4, plasma apo A-IV is the same in both the fat- and saline-fed groups. Jejunal mucosal apo A-IV synthesis and mRNA levels also have a time-dependent reduction in response to fat feeding. Both rodent and human results suggest that intestinal apo A-IV synthesis and secretion become less responsive to fat after its chronic consumption.

To further determine whether diet-induced obesity alters apo A-IV gene expression in the intestine and hypothalamus, Liu et al. fed rats a HFD, LFD, or standard chow (CHOW) for 2, 4, 6, 8, or 10 weeks.[18] Rats fed the HFD have significantly greater body weights than rats given the LF and CHOW diets. Intestinal and plasma apo A-IV levels are comparable across dietary groups and time. LF and CHOW rats have comparable hypothalamic apo A-IV mRNA across the course of the experiment. However, HFD rats have a slow and progressive diminution in hypothalamic apo A-IV mRNA over time that becomes significantly lower than that of LFD or CHOW rats by 10 weeks. Intragastric infusion of lipid emulsion to overnight-fasted animals significantly stimulates hypothalamic apo A-IV mRNA in LF and CHOW rats but has no effect in HF rats. These results show that chronic consumption of a HFD significantly reduces apo A-IV mRNA levels and the response of apo A-IV gene expression to dietary lipids in the hypothalamus.[18] This raises the possibility that dysregulation of hypothalamic apo A-IV could contribute to diet-induced obesity.

Similar to the response of apo A-IV gene expression to chronic HFD feeding (10 weeks), diet-induced obesity also alters apoE gene expression in the hypothalamus. Compared with LFD rats, HFD rats have significantly reduced hypothalamic apoE gene expression. Hypothalamic apoE levels of the LFD and pair-fed groups were not statistically different.[29]

Diurnal Rhythm

Fukagawa et al. showed that serum apo A-IV concentration has a circadian rhythm concomitant with the feeding pattern.[9] In 24-h fasted rats, serum apo A-IV maintains a circadian rhythm, being high during the dark. With mesenteric lymph diversion, serum apo A-IV concentration diminishes and the circadian rhythm is abolished. The lymph flow and lymph apo A-IV all exhibit the same circadian rhythm in fasting, with the levels higher in the dark. These circadian rhythms are abolished after bile diversion, indicating that bile is an important determinant of the circadian rhythm of lymph flow and lymph apo A-IV output.

To further understand the roles of central apo A-IV in the management of daily food intake, Liu et al. examined the diurnal patterns of hypothalamic apo A-IV gene and protein expression in freely feeding and food-restricted (food provided 4 h daily) rats.[17] In freely feeding rats, the hypothalamic apo A-IV mRNA and protein levels fluctuate, with highest levels during the light phase, peaking 3 h after lights on, and with a nadir 3 h after lights off. The daily patterns of the fluctuation, however, are altered in food-restricted rats, which have a marked decrease in hypothalamic apo A-IV mRNA and protein levels during the 4-h feeding period of the light phase. Although corticosterone (CORT) secretion temporally coincides with the decreasing phase of apo A-IV

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

in the hypothalamus, depletion of CORT by adrenalectomy significantly decreases, rather than increases, hypothalamic apo A-IV mRNA and protein levels.[17] These results indicate that the diurnal expression of hypothalamic apo A-IV is regulated by factors other than the circulating CORT, for example, the reduced food intake and body weight in adrenalectomized animals. The fact that hypothalamic apo A-IV level and food intake are inversely related during the normal diurnal cycle as well as in the period of restricted feeding suggests that hypothalamic apo A-IV is involved in the regulation of daily food intake.

Different from apo A-IV, hypothalamic apoE mRNA and protein levels fluctuate with peaks occurring during the dark phase and nadirs occurring during the light in freely fed rats.[26] This pattern is altered in food-restricted (4 h food daily) rats, which have a marked increase in hypothalamic apoE mRNA and protein levels during the 4-h feeding period in the light phase. Depletion of CORT by adrenalectomy (ADX) does not significantly influence hypothalamic apoE levels during either period, implying that the circadian pattern of hypothalamic apoE is regulated by factors other than circulating CORT.[26] That hypothalamic apoE and food intake are positively associated during the normal circadian cycle as well as in the period of restricted feeding suggests that hypothalamic apoE is food entrained and probably involved in the physiological regulation of daily food intake.

Leptin

Leptin is a polypeptide synthesized and secreted by adipocytes (see the leptin chapters in Endocrine, Cancer, Ingestive, and Gastrointestinal Peptides sections of the book). Its administration decreases food intake and increases energy expenditure. Doi et al. showed that increased lipid-induced levels of intestinal apo A-IV are significantly attenuated by iv leptin. Apo A-IV immunostaining is reduced by an average of 50% in the jejunum and 35% in the ileum in animals infused iv with leptin.[2] These findings are consistent with those of Morton et al. who observed that leptin reduces apo A-IV mRNA levels 90 min after ingestion of a pure fat meal.[21]

Shen et al. reported that leptin-deficient obese (*ob/ob*) mice have significantly reduced hypothalamic apo A-IV mRNA levels.[30] Intragastric infusion of a lipid emulsion significantly stimulates hypothalamic apo A-IV gene expression in lean controls but not in *ob/ob* mice. Daily ip administration of leptin for 5 days significantly increases hypothalamic apo A-IV mRNA levels of *ob/ob* mice relative to pair-fed controls. In addition, centrally administered leptin raises the reduced apo A-IV gene expression induced by fasting.[30] Using immunohistochemistry, Shen et al. showed that apo A-IV is present in leptin-sensitive phosphorylated signal transducer and activator of transcription-3 (pSTAT3)-positive cells of the ARC. Knockdown of STAT3 expression by small interfering RNA (siRNA) significantly attenuates the stimulatory effect of leptin on apo A-IV protein expression in cultured primary hypothalamic neurons, implying that the hypothalamic apo A-IV is regulated by leptin, and at least partially via the STAT3 signaling pathway. Administration of a subthreshold dose of leptin (1 μg icv) potentiates apo A-IV-induced (subthreshold dose, 0.5 μg) reduction of feeding, indicating the existence of a functional synergistic interaction between leptin and apo A-IV, leading to suppression of food intake.

Consistent with the response of hypothalamic apo A-IV to leptin, Shen et al. showed that apoE mRNA levels in the hypothalamus are also significantly reduced in both genetically obese *ob/ob* mice and HFD-induced obese (leptin resistant) rats, raising the possibility that deficient leptin signaling might be related to the change in apoE gene expression.[29] Leptin or vehicle ip to *ob/ob* or *db/db* mice for 5 days significantly increases hypothalamic apoE mRNA levels in *ob/ob*, but not in pair-fed *ob/ob* or *db/db*, mice.[28] These results indicate that leptin upregulates hypothalamic apoE gene expression and requires an intact leptin receptor, and that this effect is not related to the changes in food intake and body weight. The reduced apoE gene expression caused by fasting, which also results in relatively lower leptin level, is restored by icv leptin. In addition, leptin is significantly less efficacious in apoE KO mice, that is, these animals consume more food and lose less weight after leptin treatment compared with that of wild-type controls.[28] These observations imply that apoE signaling, at least partially, mediates the inhibitory effects of leptin on feeding.

Estrogen

Estrogens have potent suppressive effects on food intake and body weight in many species, including humans. Compelling evidence suggests that the anorectic action of estrogen is through an indirect mechanism by enhancing the strength of other physiological signals that reduce meal size. To determine whether estradiol, the primary form of estrogen, modulates the anorectic effect of apo A-IV, intra-4th-ventricular administration of low doses of apo A-IV was found to reduce food intake to a greater extent in ovariectomized (OVX) rats cyclically treated with estradiol than in vehicle-treated OVX controls, implying that cyclic estradiol replacement increases the satiating potency of apo A-IV. OVX significantly increases food intake and body weight but decreases apo A-IV gene expression in the NTS. All these alterations are reversed by cyclic estradiol treatment. The finding of colocalization of apo A-IV with estrogen receptor-alpha in the NTS suggests that estradiol might act locally in the NTS to upregulate apo A-IV gene expression. Further, OVX apo A-IV knockout mice have a smaller feeding response to estradiol, eating significantly more food and gaining more body weight than OVX wild-type controls

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

during the period of cyclic estradiol replacement. These results indicate that an increased signaling of endogenous apo A-IV may partially mediate estradiol-induced inhibitory effect on feeding.

PERIPHERAL AND NEURAL NETWORKS AND SIGNALING PATHWAYS AFFECTED

Apo A-IV and CCK

Apo A-IV and CCK act both peripherally and centrally to reduce food intake by decreasing meal size. Lo et al. examined the interaction of apo A-IV and CCK-8 in the control of food intake in rats.[20] Ip apo A-IV at 100 μg/kg reduces food intake significantly for 1 h, as do doses of CCK-8 at or >0.125 μg/kg. Doses of apo A-IV (50 μg/kg) or CCK (0.06 μg/kg) alone have no effect on food intake. However, when these subthreshold doses are administered together, the combination produced a significant inhibition of food intake relative to controls, and the duration of the effect is longer than that caused by the administration of either apo A-IV or CCK alone. The satiation effect produced by CCK-8 plus apo A-IV is attenuated by lorglumide, a CCK1 receptor antagonist.[20] Lo et al. therefore concluded that the coadministration of subthreshold doses of the two peptides is highly satiating and works via CCK1 receptor.

Central Melanocortin System

The hypothalamic melanocortin system is important in the homeostatic regulation of body weight. α-Melanocyte-stimulating hormone (α-MSH) derived from proopiomelanocortin (POMC) neurons in the ARC is the primary agonist for melanocortin type 3 and 4 receptors (MC3/4-R) in the brain (see the chapters in the Brain and Ingestive Peptides sections of the book). α-MSH is believed to exert a tonic inhibitory influence over feeding. Agouti-related protein (AgRP) is a peptide produced in non-POMC cells in the ARC and antagonizes MC3/4-R. Consistent with this, AgRP elicits hyperphagia when it is centrally administered.[5] The i3vt administration of metallothionein-II (MT-II), a synthetic MC3/4-R agonist, potently reduces feeding,[6] whereas i3vt administration of SHU9119, a synthetic MC3/4-R antagonist, blocks the anorectic effect of MT-II and elicits feeding when administered alone at higher doses.[12]

Shen et al. showed that apo A-IV is colocalized with POMC in the ARC, and that apo A-IV administration stimulates ARC POMC gene expression, suggesting that the brain apo A-IV system suppresses food intake by stimulating the ARC POMC system.[27] Gotoh et al. showed that icv administration of a subthreshold dose of apo A-IV potentiates icv MT-II-suppression of 30-min feeding in rats.[10] A subthreshold dose of SHU9119 completely attenuates the anorectic effect of icv apo A-IV. Icv apo A-IV also significantly elevates the expression of c-Fos in PVN neurons but not in the ARC or median eminence.[10] These results support a synergistic interaction between apo A-IV and melanocortins that reduces food intake by acting downstream of the ARC.

Shen et al. reported that apoE interacts with the central melanocortin system to control food intake.[29] A subthreshold dose of SHU9119 was administered concomitantly with apoE in rats. Although icv SHU9119 alone does not produce a reliable effect on food intake, apoE significantly reduces food intake 4 h after injection. However, when the two injections are combined, the SHU9119 completely attenuates the anorectic effect of apoE, implying that an interaction occurs between apoE and the melanocortin system with regard to feeding regulation by the brain.[29]

Signaling Pathways

Phosphatidylinositol 3-kinases (PI3Ks) are heterodimeric complexes composed of regulatory and catalytic subunits that recruit lipids as second messengers and control a broad spectrum of cellular functions including survival, growth and metabolism. The PI3 K signaling pathway is important in the regulation of food intake and energy balance by hypothalamic neurons.

Using primary cultured hypothalamic neurons, Shen et al. showed that apoE treatment elicits rapid activation of the PI3 K/Akt signaling cascade.[25] Specifically, apoE induces the phosphorylation of Akt, peaking at 30 min, and the increased phosphorylation of Akt is significantly attenuated after pretreatment with LY294002, an inhibitor of the PI3 K signaling pathway. To determine whether activation of PI3 K by apoE is required for the ability of apoE to reduce food intake, LY294002 was infused into the third-cerebral ventricle before injection of an anorectic dose of apoE. Consistent with previous reports, apoE exerts significant reduction of food intake in the 4-h fasted rats, compared with that of saline. Pretreatment with LY294002 significantly attenuates the potency of exogenous apoE to induce satiation, whereas the same dose of PI3 K inhibitor by itself causes only a slight nonsignificant decrease of food intake. These results indicate that the activation of the PI3 K/Akt pathway is necessary for the acute effects of apoE on food intake.

Receptors

Liu et al. showed that low-density lipoprotein receptor-related protein 1 (LRP1) regulates leptin signaling and energy homeostasis.[19] Conditional deletion of the *Lrp1* gene in the brain results in an obese phenotype characterized by increased food intake, decreased energy consumption, and decreased leptin signaling. LRP1 directly binds to leptin and the leptin receptor complex and is required for leptin receptor phosphorylation

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

and Stat3 activation. Liu et al. further found that deletion of the *Lrp1* gene specifically in the hypothalamus by Cre lentivirus injection is sufficient to trigger accelerated weight gain.[19] These results indicate that LRP1, which is critical for lipid metabolism, also regulates food intake and energy homeostasis in the adult CNS.[19]

To summarize, the control of food intake and energy expenditure is extremely complex and involves many different messengers. Different lines of investigation suggest that disturbances in eating behavior are associated with abnormal hypothalamic neurotransmission and neuropeptide concentrations. Apo A-IV and apoE have been proposed as satiation factors. Both genetically obese (*ob/ob*) mice and rats with HFD-induced obesity have significantly reduced hypothalamic apo A-IV and apoE mRNA levels, suggesting that decreased apo A-IV/apoE may contribute to hyperphagia in these obese animals. Compelling evidence shows that apo A-IV and apoE exert their potent catabolic influence to regulate energy homeostasis through integration with other central signals. A better understanding of the detailed mechanisms underlying apo A-IV and apoE's anorectic actions is needed to develop new therapeutic approaches to obesity.

Chapter 142

Bombesin

Ellen E. Ladenheim

ABSTRACT

Bombesin (BN), a tetradecapeptide originally isolated from anuran skin, belongs to a large family of structurally related amphibian and mammalian peptides. Since their discovery, BN and two mammalian BN-like peptides, gastrin-releasing peptide (GRP), and neuromedin B (NMB) have been shown to exhibit diverse behavioral and physiological actions in a number of species. Receptor subtypes for GRP and NMB and a third receptor subtype, BRS-3, have been identified. BN-like peptides have been shown to suppress food intake after peripheral or central administration and have been proposed as putative satiety signals. Specific agonists and antagonists have been instrumental in determining the individual contributions of BN receptor subtypes to food intake and energy homeostasis. Studies in knockout mice have provided an additional means to evaluate their physiological function. Recent studies have shown that BN-like peptides and receptors participate in long-term effects on food intake and body weight.

BACKGROUND

Bombesin (BN) is a tetradecapeptide isolated in 1970 by Erspamer et al. from the skin of the European frog *Bombina bombina*. It is part of a large family of amphibian and mammalian peptides that are biologically active in mammals (see Bombesin-like Peptides in Amphibian/Skin Peptides section of this book). Since their discovery, BN-like peptides have been shown to affect many gastrointestinal (GI) processes including gastrin release, gastric acid secretion, pancreatic enzyme secretion, gallbladder contraction, and intestinal motor activity. Aside from their well-known effects on gastrointestinal function, BN-like peptides also participate in a number of important neuroregulatory processes such as thermoregulation, glucose homeostasis, circadian rhythms, and food intake.[10]

Although BN itself is not present in mammals, several peptides that are structurally homologous to BN have been detected in mammalian viscera and central nervous system (CNS). These peptides include several forms of gastrin-releasing peptide ($GRP_{1–27}$, $GRP_{1–29}$, and $GRP_{18–27}$, also known as neuromedin C) and several forms of neuromedin B ($NMB_{1–32}$, $NMB_{2–32}$, and $NMB_{23–32}$). Bombesin and GRP share an identical carboxyl terminal heptapeptide sequence, the minimal fragment necessary for their biological activity. NMB contains a portion of these amino acid residues but more closely resembles the amphibian peptides, ranatensin, and litorin.[24]

The distribution of BN/GRP-like immunoreactivity in the gastrointestinal tract is mainly confined to nerve cell bodies in the myenteric ganglia and in nerve fibers of these ganglia. Similarly, NMB-like immunoreactivity is found throughout nerve fibers in the gastrointestinal tract, as well as the pancreas, spinal cord, and pituitary gland. In the CNS, immunohistochemical mapping of GRP and NMB, as well as mRNA studies, have shown distinct and discrete distribution of the two peptides in rat brain. GRP mRNA is highly expressed in the isocortex, hippocampal formation, anterior olfactory nucleus, and several hypothalamic nuclei. NMB mRNA expression is most prominent in the olfactory bulb, dentate gyrus, and dorsal root ganglion.[7]

Because of structural similarities between BN and GRP it was initially believed that GRP was the mammalian counterpart to BN and thus all BN binding sites in the periphery and brain represented GRP receptors. Early work evaluating the effect of BN-like peptides on smooth muscle contraction found that they displayed varying degrees of potency suggesting the existence of multiple receptor subtypes. Subsequent studies by von Schrenck et al.[10] identified and characterized two pharmacologically distinct BN receptor subtypes in pancreatic acinar cells and esophageal muscularis mucosa. BN binding sites in the pancreas displayed a high affinity for GRP and BN and a low affinity for NMB, whereas esophageal BN binding sites had a high affinity for NMB and BN and a low affinity for GRP. Because of these pharmacological characteristics esophageal BN receptors were termed "NMB-preferring" or BB1 and pancreatic BN receptors were termed "GRP-preferring" or BB2. BN has a high and equal affinity for NMB-R and GRP-R, and thus, its activity may be attributed to binding to either or both receptor subtypes. These receptors were later cloned, and an additional mammalian BN receptor subtype, BN receptor subtype-3 (BRS-3 or BB3) was identified through homology screening and found to

share approximately 50% structural identity with GRP-R and NMB-R. Unlike GRP-R and NMB-R, BRS-3 has a low affinity for all naturally occurring BN-like peptides. To date, no endogenous ligand for BRS-3 has been identified and it is termed an "orphan" receptor.[10]

Receptors for BN-like peptides have been identified in a variety of tissues in the periphery and central nervous system. Using an approach similar to that used to characterize peripheral BN receptor subtypes, initial studies evaluated the relative ability of BN, GRP, and NMB to inhibit binding of radioactively labeled BN in rat brain. These studies revealed two distinct binding patterns consistent with those reported in peripheral tissues. Subsequent autoradiographic mapping studies determined that the predominant BN receptor subtype in the rat brain is NMB-R with the highest densities in the anterior olfactory nucleus, nucleus accumbens, and thalamus. The distribution of GRP-R is more limited with the highest densities in several hypothalamic nuclei, basal ganglia and central nucleus of the amygdala.[16] The results of the binding experiments were in general agreement with *in situ* hybridization studies examining expression patterns of GRP-R and NMB-R mRNA. Localization of BRS-3 mRNA was initially reported to be much more limited with the highest expression levels in the arcuate (Arc), dorsomedial (DMH), ventromedial (VMH), and paraventricular (PVN) nuclei of the hypothalamus. A later study using an antibody directed toward BRS-3 found a much wider distribution in the CNS with particularly strong immunoreactivity in the cerebral cortex, hippocampal formation, hypothalamus, and thalamus.[7]

In the periphery, BN binding sites in the stomach were similarly differentiated where the majority of binding was GRP-R. In gastric regions, BN binding sites were localized to the circular muscle layer with the highest density in the gastric fundus. In primates, the highest levels of NMB-R mRNA were detected in the testis and stomach, whereas in rodent peripheral tissue, significant NMB-R expression was found in esophagus, intestine, testis, and uterus.[7] Immunohistochemical evaluation of gastrointestinal BRS-3 distribution demonstrated BRS-3-like immunoreactivity at all levels of the gastrointestinal tract primarily in neurons of the myenteric and submucosal ganglia and in fibers in the longitudinal and circular muscle layers.[29]

In general, the distinct distributions of BN-like peptides and receptors support the view that they function as separate regulatory agents in the periphery and CNS.

PERIPHERAL EFFECTS OF BN-LIKE PEPTIDES ON FOOD INTAKE

A role for BN as a putative satiety signal stems from experiments showing that exogenous administration of BN dose dependently suppresses food intake in a variety of experimental paradigms, and in a number of animal species, including humans. The inhibition of food intake produced by peripherally administered BN is followed by a normal postprandial sequence of behaviors that are characteristic of meal ingestion. The reduction of food intake by BN is not accompanied by behavioral signs of toxicity, such as sickness or malaise, nor are there nonspecific effects on water intake. The decrease in meal size produced by BN is consistent with a behavioral profile that indicates an increase in post-ingestive feedback signaling. Studies in human subjects have demonstrated that intravenous administration of BN reduced intake of a test meal without producing significant side effects.[6]

Although an increase in meal-related plasma BN-like immunoreactivity has been reported, the general consensus is that BN's actions on food intake are mediated through neurocrine or paracrine mechanisms. Supporting this view are studies demonstrating an increase in BN-like immunoreactivity in the antral region of the stomach in response to meal intake, coupled with the localization of BN-like immunoreactivity in gut neurons.[23]

BN has an equal and high affinity for both GRP and NMB receptors. The discovery that BN interacted equally with GRP and NMB receptors presented the possibility that BN was mimicking the actions of GRP and NMB but that both GRP and NMB produced their effects on food intake at distinct receptor populations. A comparison of feeding suppression produced by peripheral administration of BN, $GRP_{1–27}$, $GRP_{18–27}$ and NMB in rats showed that, at intermediate doses, the rank order of potency is $BN > GRP_{1–27} = GRP_{18–27} > NMB$. However, at the lowest and highest doses, BN, $GRP_{1–27}$, and $GRP_{18–27}$ are equivalent. The biphasic nature of the dose response curve for $GRP_{1–27}$ and $GRP_{18–27}$ suggested that these peptides may be interacting with GRP-R at low doses and with both GRP-R and NMB-R at high doses. NMB is consistently less potent than BN in reducing food intake, suggesting that it is interacting only with NMB-R. A more recent study examining the satiety effects of $GRP_{1–29}$ in rats (the predominant form in this species) found equivalent potency to $GRP_{1–27}$. It is believed that the increased potency of BN to reduce food intake, compared with its mammalian counterparts, partially results from a relative resistance to enzymatic degradation. Supporting this idea are studies showing that acetylation of $GRP_{18–27}$, which improves resistance to degradation, increased its ability to reduce feeding, making it equivalent to that of BN.[21]

The notion that the effects of BN on food intake may result from the combined action at both receptor subtypes is also supported by studies showing that peripheral administration of equimolar doses of GRP and NMB reduces food intake and elicits a microstructural licking pattern equivalent to that of BN.[31] Moreover, when a dose of NMB that produces a maximal suppression of food intake is given in combination with a submaximal dose of GRP, the reduction in food intake is significantly enhanced beyond suppression

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

produced by either peptide administered alone.[21] Additional studies show that a specific NMB-R receptor antagonist blocks feeding inhibition by peripherally administered NMB, but not by GRP, suggesting that NMB and GRP reduce food intake by acting at distinct receptor populations.[20] Although several studies found that peripherally administered GRP-R antagonists prevent the suppression of food intake by peripherally administered BN, attempts to increase food intake using GRP-R antagonists, or to block feeding suppression produced by intragastric loads, have been inconsistent.[4,23] The reason for this is unresolved; however, it is possible that the antagonists have limited potency or bioavailability and are unable to access sites that are activated by endogenously released BN-like peptides.

CENTRAL EFFECTS OF BN-LIKE PEPTIDES ON FOOD INTAKE

The presence of BN-like immunoreactivity and BN binding sites in brain regions implicated in controlling food intake suggested that central BN-like peptides may also play a role in satiety. Several early studies showed that BN administered into the lateral cerebral ventricles (LV) in rats produces a potent suppression of food intake.[12] However, the reduction in food intake is accompanied by a decrease in water intake and an increase in grooming and locomotion, suggesting a nonspecific effect of BN on feeding that is dissimilar to the actions of peripherally administered BN.

Subsequently, studies were undertaken to examine the specific brain sites where BN may produce its anorexic effects. Early studies using site specific injections of high doses of BN into various hypothalamic nuclei including the PVN, DMH, VMH, and lateral hypothalamus (LH) significantly reduced food intake, as did injections into extrahypothalamic areas such as the amygdala and periaqueductal gray. However, in all instances, feeding suppression was accompanied by increased grooming activity suggesting that the reduction in food intake may be secondary to competing behaviors.[13] Other experiments using smaller BN doses found that direct injections into the LH and amygdala specifically reduce food intake without producing competing behavioral effects.[6,33]

Initial studies focused primarily on forebrain mediation of BN satiety; however the presence of binding sites for BN-like peptides and BN-like immunoreactive nerve terminals and cell bodies in hindbrain regions known to participate in ingestive control (e.g., nucleus of the solitary tract (NTS)) suggest that this region may be responsive to BN's feeding effects. Several investigators found that injections of BN into the fourth cerebral ventricle (4V), in close proximity to the NTS, are highly effective in reducing food intake in rats[4] The doses required to suppress feeding after 4V administration are up to 100 times lower than those that elicit reduced food intake after LV administration. Further, this action is specific for food and does not produce a conditioned taste aversion or elicit competing behaviors such as grooming and locomotor activity that are associated with injection at other brain sites. Studies evaluating the effect of direct microinjections of BN into the NTS found this brain region to be particularly sensitive for feeding inhibition by BN.[23]

Although several studies have examined the feeding effects of centrally administered BN receptor agonists, a systematic comparison across peptides has not been conducted. It is assumed that the order of potency is BN>GRP>NMB based on studies examining each peptide individually or comparing one peptide against BN using a limited range of doses. Although the majority of BN binding sites in the vicinity of the 4V are NMB-R, studies using specific GRP-R antagonists have identified the contribution of hindbrain GRP-R to the feeding inhibitory actions of BN. Two reports showed that pretreatment with selective GRP-R antagonists facilitates feeding in sated rats, supporting a role for endogenously released GRP in reducing food intake.[5,23] Injections of $GRP_{1–27}$ and $GRP_{18–27}$ into the central amygdala have also been reported to transiently decrease food intake without producing changes in body temperature or stereotypic behaviors.[3]

Relatively little attention has been given to the role of central NMB-R in food intake. Agonist studies have not been particularly informative because central NMB exhibits very poor potency to inhibit feeding. However a role for hindbrain NMB-R in ingestive control was determined in studies using a specific NMB-R antagonist.[19] As shown with GRP-R antagonists, 4V administration of an NMB-R antagonist alone also increases food intake and blocks the effects of centrally administered BN. In addition, 4V administration of GRP-R and NMB-R antisense oligonucleotides prevents the suppression of food intake by centrally administered BN, supporting a role for both receptor subtypes in mediating BN's central feeding effects.[23]

NEURAL PATHWAYS MEDIATING THE EFFECTS OF BN-LIKE PEPTIDES

Several studies have been conducted to determine the site of action and neural substrates underlying the satiety actions of peripheral and central BN-like peptides. Early work evaluating the effect of adrenalectomy, hypophysectomy, vagotomy, and lesions of the ventromedial and dorsomedial hypothalamus reported that none of these surgical manipulations were effective in preventing BN's ability to suppress food intake.[6] By contrast, Stuckey et al. examined the effect of individual or combined lesions of the afferent innervation of the GI tract and found that, while vagotomy alone fails to reduce BN satiety, combined bilateral subdiaphragmatic vagotomy, spinal cord transaction (T6), and dorsal rhizotomy (T1–T6) significantly attenuate the ability of peripheral

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

BN to reduce food intake.[6] A subsequent study found that rhizotomy and spinal cord section, in the absence of vagotomy, also attenuate BN's feeding effects. More recently, it was shown that vagotomy combined with splanchnic afferent and efferent denervation of the gut lessen the effects of GRP1–29 on meal size in rats.[35]

To more clearly define the pathways through which BN-like peptides exert their satiety actions, studies were undertaken to evaluate the effects of capsaicin on the suppression of food intake produced by BN. Capsaicin, a derivative of red pepper, is a neurotoxin that selectively damages a subset of primary sensory fibers that include both vagal and spinal neurons. Adult rats treated systemically with capsaicin exhibit a significant attenuation in the feeding inhibitory response to peripheral BN administration.[18] A subsequent report showed that neonatal capsaicin treatment, which produces a more complete deafferentation, completely abolishes peripheral BN's feeding effects in adult rats without affecting the inhibition of food intake produced by third ventricular (3V) administration.[23] Because of the distinct roles of BN-like peptides to reduce food intake, additional studies were conducted in adult rats treated neonatally with capsaicin to examine whether different neural substrates underlie the feeding suppression by BN, GRP, and NMB.[17] The suppression of food intake by peripheral administration of BN and NMB is abolished or attenuated by capsaicin treatment, whereas the effects of GRP remained intact except at the highest dose. These results suggest that BN-like peptides use distinct neural pathways to reduce feeding.

The presence of gastric BN binding sites and changes in gastrointestinal BN-like immunoreactivity in response to meal intake led to the proposal that BN may produce its effects on food intake through a gastric mechanism, although evidence to support this has been equivocal. In support of a gastric site of action for BN, it was shown that local celiac artery infusions of BN are much more effective in suppressing food intake than either intraperitoneal or superior mesenteric artery infusions.[11] However, another experiment that compared the feeding effects of various doses of BN with the gastric inhibitory effects of BN, concluded that BN's satiety actions are dissociated from its effects on gastric emptying, as is the potency of BN to reduce food intake compared with its relative affinity for gastric receptors.[9] These results suggest that BN's effects on food intake are not mediated by a gastric site or via a gastric inhibitory mechanism. Although BN-like peptides have been shown to excite mechanosensitive gastric branch vagal afferents, electrophysiological studies have determined that this is an indirect action secondary to its stimulation of gastric motor effects, consistent with the lack of BN binding sites in the vagus nerve.

The neuronal pathways through which peripheral and central BN-like peptides exert their effects on food intake have been also been examined by evaluating patterns of c-fos immunoreactivity, a marker of neuronal activation. Peripheral injection of BN induces c-fos in the area postrema (AP), medial NTS, parvocellular PVN, and to a lesser extent in central nucleus of amygdala, parabrachial nucleus, supraoptic, and magnocellular PVN. A comparison between peripheral and central (4V) BN administration found that both routes of administration show strong fos-LI in the PVN. Fos-like immunoreactivity was also detected in the medial NTS, central nucleus of amygdala, and bed nucleus of the stria terminalis, though the regional distribution differs depending on the route of administration. Differences were also found in the AP where peripheral, but not central, administration induced c-fos activation.[1,30]

A more recent study compared the effects systemic administration of different forms of GRP on c-fos activation in the gastrointestinal tract and hindbrain. Myenteric neurons in the stomach and neurons in the area postrema are activated by $GRP_{18–27}$, $GRP_{1–27}$, and $GRP_{1–29}$. In the duodenum, both $GRP_{1–27}$ and $GRP_{1–29}$ increase c-fos activation in the myenteric plexus, whereas only $GRP_{1–29}$ increases fos-LI in the submucosal plexus.[34]

The necessity of central BN-like peptide receptors to the peripheral effects of BN-like peptides has also been examined. Merali et al. (1988) first reported that 3V infusion of BN antisera, or a GRP-R antagonist, blocks the suppression of food intake by peripheral BN administration. Other studies have shown that ablation of the AP/NTS complex or blockade of hindbrain GRP receptors with 4V GRP-R antagonists attenuate the ability of peripherally administered BN or GRP to suppress feeding.[23]

Converging behavioral and anatomical evidence indicates that the NTS is a critical region for the feeding effects of BN. This region receives sensory input from the gastrointestinal tract via vagal and spinal neurons. Within the NTS, BN-ir is located in the medial subnucleus, an area that is associated with nerve terminals that synapse on cell bodies or dendrites of vagal motoneurons. Compelling evidence for the importance of the caudal hindbrain to BN's feeding effects is provided in experiments showing that either peripheral or 4V injections of BN reliably suppress sucrose intake in chronic decerebrate rats, a surgical preparation that severs communication between the hindbrain and forebrain. These results support the idea that local neural circuitry residing in the caudal hindbrain, independent of forebrain systems, is sufficient to mediate the effects of BN-like peptides on ingestive behavior.[4]

Although the necessity of central neural substrates, particularly in the NTS, play a critical role in BN's effects on food intake there are still questions remaining concerning how the signal is transmitted. Whether peripheral administration of BN-like peptides causes a central release of GRP (or NMB) or whether they gain direct access to critical hindbrain receptors has not been fully determined.

CONTRIBUTION OF BN RECEPTOR SUBTYPES TO FOOD INTAKE USING GENETICALLY MODIFIED MICE

The development of mice with targeted deletions for each BN receptor subtype has provided a complementary means to evaluate the individual roles of BN receptor subtypes to ingestive control and other physiological effects of BN-like peptides.[26] The first of these to be developed are mice lacking the GRP-R. In studies to evaluate the overall contribution of GRP-R to food intake, GRP-R KO mice fail to suppress intake after exogenously administered of either BN or GRP, suggesting that GRP-R alone mediates the satiety effect of BN-like peptides in mice. An analysis of 24-h meal patterns reveals that GRP-R KO mice exhibit an increase in meal size consistent with a deficit in satiety signaling, but 24-h food consumption is not different from control mice because of a reduction in the total number of meals consumed. A long-term analysis of body weight found that body weights between GRP-R KO mice and WT controls are comparable in early life although a small but significant elevation in body weight occurs in aged GRP-R KO mice. Additional studies show GRP-R deficient mice display increased night-time locomotor activity, loss of GRP-induced hypothermia, and increased social investigatory behaviors. Metabolic disturbances, including decreased secretion of glucagon-like peptide 1 and abnormalities in insulin release and glucose tolerance, are also present in GRP-R KO mice.

Unlike GRP-R KO mice, previous studies in mice lacking NMB-R (NMB-R KO) found no differences in food intake and body weight between NMB-R KO and WT control mice. However, a subsequent study showed that although female NMB-R KO mice fed a chow diet show no differences in body weight, when presented with a high fat diet they are partially protected against body weight gain and adipose accumulation and exhibit normal glucose tolerance compared with that of WT littermates.[28]

Recent attention has been directed toward the role of BRS-3 in food intake and energy homeostasis. Progress in determining the physiological function of BRS-3 was hindered by the lack of an identifiable natural ligand or a suitable synthetic ligand. To assess the function of BRS-3, Ohki-Hamazaki and colleagues generated mice with a targeted deletion of BRS-3 (BRS-3 KO) and found that they develop obesity accompanied by hypertension, impairment of glucose tolerance, and insulin resistance. In addition, BRS-3 KO mice exhibit reduced metabolic rate, increased feeding efficiency and hyperphagia, and showed alterations in glucose transport.[26]

Additional behavioral and physiological studies were conducted to identify factors contributing to increased food consumption and body weight in BRS-3 KO mice.[15] A primary deficit leading to the obese phenotype of BRS-3 deficient mice is an uncompensated increase in meal size resulting in an overall increase in total food intake. Although the increase in body weight could be overcome by pair-feeding to the caloric intake of WT controls, they still exhibit significantly elevated leptin concentrations and body fat distribution, confirming a metabolic dysregulation in BRS-3 KO mice. Despite the finding that BRS-3 KO mice increase their meal size, they exhibit a normal response to peripherally administered peptides (e.g., cholecystokinin and BN) that participate in meal-related controls of food intake. A study evaluating the effects of centrally administered peptides reported that mice lacking BRS-3 are leptin resistant, hyperresponsive to the orexigenic effects of exogenously administered melanin concentrating hormone (MCH), and have elevated levels of MCH mRNA in the lateral hypothalamus.

Studies have also suggested that hyper-responsiveness to taste stimuli may contribute to overeating in BRS-3 deficient mice particularly when exposed to highly palatable foods.[26] BRS-3 KO mice exhibit a stronger taste preference for saccharin solution and a stronger aversion to quinine solution compared with that of WT littermates. Using a conditioned taste aversion paradigm, BRS-3 KO mice display a stronger aversion to both saccharin and sodium chloride solutions after intraperitoneal lithium chloride administration. A preliminary study reported exaggerated hyperphagia and weight gain in BRS-3 KO mice maintained on a high fat diet, a characteristic that is consistent with other mouse models of obesity.

BN-LIKE PEPTIDES/RECEPTORS AND ENERGY HOMEOSTASIS

Although a major focus for determining a role for GRP and NMB in ingestive control has been to evaluate their function as short-term or meal-related satiety signals there is also evidence to suggest that they interact with energy regulatory pathways and may contribute to long-term energy balance.

Previous studies show that peptides that play a critical role in energy homeostasis work in concert with gastrointestinal signaling peptides to reduce food intake. Leptin, the protein product of the ob gene, is synthesized and released by adipocytes and circulates at levels proportional to body fat. Although many of the hypothalamic signaling pathways involved in leptin's actions have been identified, the specific mechanisms mediating their effects on food intake are not clear. Several studies show that the effect of leptin on food intake is characterized by a reduction in meal size without affecting meal frequency, a behavioral profile shared by satiety peptides. A study evaluating the interaction of leptin with BN found that when a subthreshold dose of leptin administered into the 3V is combined with a peripheral injection of BN, there is a significant potentiation in the reduction of food intake. Consistent with the behavioral results, c-fos activation in the NTS is increased

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

by combined dosages of leptin and BN beyond the individual response to either peptide. These results support the idea that the effects of leptin on food intake may be mediated, in part, by modulating meal-related satiety signals such as BN.[25]

In the brain, the preponderance of GRP and GRP receptors are found in several hypothalamic nuclei that play important roles in energy homeostasis. GRP mRNA is localized in the hypothalamic PVN in a region that receives input from neurons in the Arc. Previous studies have shown that direct bilateral PVN infusion of BN (presumably acting on GRP-R) results in a decrease in food intake and a robust increase in blood glucose, free fatty acids, and corticosterone,[8] suggesting that BN binding sites in the PVN may participate in regulating circulating metabolic fuels and the hypothalamic–pituitary–adrenal (HPA) axis. Other studies show that food ingestion evokes a rapid elevation of GRP levels in various hypothalamic sites, including the PVN and Arc.[23] A follow-up study determined how these changes correlate with release during different phases of ingestion and found that during food consumption there is a substantial decrease in the release of BN-like peptides in the PVN which is then followed by an increase in release during the postprandial phase. These results suggest that the decline in release during the prandial phase is conducive to meal initiation, whereas the elevation in release provides a signal for meal termination.

A more recent study found that challenges that represent different nutritional states alter expression of GRP mRNA expression in the PVN.[14] Food deprivation significantly decreases GRP mRNA expression in the PVN, whereas activation of the melanocortin system with the melanocortin 4 receptor (MC4-R) agonist MTII increases levels of PVN GRP mRNA and prevents the reduction in GRP mRNA induced by fasting. Further, this population of neurons respond to MTII injection, as seen by c-fos activation, and co-expresses MC4-R. These results show that food deprivation and stimulation of the melanocortin system produce opposing changes in GRP gene expression in the PVN, suggesting that GRP-containing neurons in the PVN may be part of the hypothalamic signaling pathway controlling food intake and energy balance.

Electrophysiological studies have evaluated the effects of GRP and NPY on identified Arc NPY cells.[32] The results indicate that nanomolar amounts of both the peptides produce strong direct excitatory effects on NPY neurons, surpassing the actions of other energy regulatory peptides such as ghrelin and orexin. Similar excitation is also seen in Arc POMC neurons. Because these two sets of neuronal populations are generally activated in opposition to one another it is surmised that BN-like peptides may function to initiate broad activation, rather than excitation or inhibition of specific cellular populations in the Arc.

Several studies have also identified NMB as an important contributor to energy balance regulation. NMB and NMB-R are significant regulators of the HPA axis through modulation of thyrotropin secretion.[27] Hoggard et al. have reported that NMB mRNA is present in human and rodent adipose tissue and that the expression levels can be changed through alterations in energy balance and leptin signaling.

Neuromedin B has also been proposed as a strong candidate for gene linking eating behaviors to the susceptibility to obesity in humans.[2] The Quebec Family Study, a large prospective study designed to identify the genetics of obesity and related diseases, found that a missense mutation within exon 2 of the NMB gene was significantly associated with eating behaviors and obesity, resulting in twice as much body fat gain over a six-year period compared with those without the mutation. Subjects that are homozygous for the mutation are twice as likely to exhibit high levels of disinhibition and susceptibility to hunger and to exhibit positive associations for sweet craving.

As mentioned above, the physiological role for BRS-3 has been examined primarily by evaluating the consequences of BRS-3 deletion in genetically engineered mice. A recent advance in studying the role of BRS-3 in energy homeostasis has been the development of specific agonist and antagonist ligands for BRS-3.[22] Experiments using a specific BRS-3 antagonist, show that chronic LV infusion results in increased food intake, body weight, and adiposity. Conversely, acute BRS-3 agonist administration reduces food intake and increases fasting metabolic rate. Chronic delivery is effective in lowering food intake and fat mass in diet-induced obese mice.

Additional studies examined the interaction of BRS-3 activation with other central neural pathways that are important in energy homeostasis.[22] Results obtained in a variety of KO mice (i.e., Npy(−/−), Mc4r(−/−), Cnr1(−/−) and Lepr(db/db)) indicate that BRS-3 agonists are still capable of reducing food intake in these mice and thus activation of BRS-3 seems to be independent of these pathways. BRS-3 also plays a role in body temperature regulation, but this seems to be secondary to its effects on energy metabolism. In general, results from experiments in BRS-3 KO mice and with BRS-3 agonist and antagonist compounds have led to the conclusion that BRS-3 plays a more significant role in long-term or metabolic controls of energy balance than either GRP-R or NMB-R.

Chapter 143

CART

Graham J. Dockray and Guillaume de Lartigue

ABSTRACT

Peptides derived from cocaine and amphetamine-regulated transcript (CARTp) are expressed in central and peripheral neurons associated with ingestive behavior. CART is coexpressed with proopiomelanocortin (POMC) in arcuate nucleus (ARC) neurons that are linked to satiety. Expression is decreased by food withdrawal and stimulated by leptin; intracerebroventricular (icv) administration of CARTp inhibits food intake. Mice null for CART have a tendency toward mild obesity and are prone to diet-induced obesity. However, microinjection of CARTp into some hypothalamic nuclei stimulates food intake and the functional significance of this observation remains unknown. In vagal afferent neurons, CARTp is expressed in a cholecystokinin (CCK)- and leptin-dependent manner and seems to act as an autocrine enhancer of the satiety effect of CCK. Mutations of the *CART* gene are linked to human obesity syndromes. Collectively, the data indicate roles for CARTp at multiple levels in controlling ingestion through mechanisms that are still poorly understood.

INTRODUCTION

Cocaine and amphetamine-regulated transcript (CART) was discovered by differential mRNA display of the striatum from rats treated with cocaine or amphetamine.[12] Soon after, peptide sequences predicted to be derived from CART were identified, CART expression was shown to vary in the arcuate nucleus (ARC) with food deprivation, to be regulated by leptin, and a predicted peptide (CARTp) was shown to inhibit food intake after intracerebroventricular (icv) injection.[20] The main active forms of CARTp correspond to the 55–102 and 62–102 sequences of one of the splice variants first characterized in the rat (the numbering differs for peptides derived from an alternative rat transcript, and from the human transcript). In addition to roles in the control of food intake, there is also growing evidence for a role of CARTp in reward mechanisms and in endocrine functions.[25] We focus here on the evidence for the role of CARTp in controlling ingestive behavior.

EFFECTS ON FEEDING BEHAVIOR

A variety of experimental approaches indicate that exogenous CARTp inhibits food intake. Many different laboratories have reported that exogenous CARTp inhibits food intake when administered by icv injection; set against this, however, a few studies using microinjection of hypothalamic nuclei have reported increased food intake. Intracerebroventricular injection of CARTp 55–102 was first shown to reduce food intake in 24 h fasted rats.[20] Similarly, icv injection of the shorter CARTp fragment 62–102, but not of 55–59, decreases food intake.[21] Inhibition of food intake with icv administration is dose (~0.1–1 nmol) and time (20 min–8 h) dependent. Chronic icv infusion of CARTp 55–102 also inhibits feeding and results in 15% body weight loss in lean rats after 3–5 days.[22] Sustained expression of CART after icv administration of an adeno-associated virus (AAV) CART construct is also associated with reduced food intake and decreased body weight gain in rats on a high-fat diet.[24] Importantly, there is direct evidence supporting a role for CARTp as an endogenous satiety factor from the results of experiments with icv injection of CARTp antibodies, which show increased food intake in rats.[20,21] Moreover, microinjections of CARTp 55–102 into the nucleus accumbens (NAcc) shell decrease food intake,[32] whereas knocking down CART expression by microinjection of short interfering (si)RNAs into the NAcc increases food intake in mice.[15]

In contrast to the evidence for satiety effects of CARTp, direct injection of CARTp into several hypothalamic nuclei has been reported to stimulate food intake in fasted rats. Thus, administration into the ARC, ventromedial nucleus (VMN), paraventricular nucleus (PVN), lateral hypothalamic area (LH), anterior hypothalamic area (AHA), dorsomedial nucleus (DMH), and supraoptic nucleus (SON) all increase food intake.[1] There are differences between nuclei in the time course of the response and sensitivity to CARTp; for example, there is an orexigenic response to 0.04 nmol CARTp 55–102 in the VMN and ARC but only at 0.2 nmol after 4 h in the PVN, LHA, AHA, DMH, and SON.[1] The orexigenic response has a delayed onset (1–2 h for VMN, ARC, and DMN; 2–4 h for the other regions) compared with the relatively rapid onset of the anorexic response to icv injection. Orexigenic responses have also been reported in studies overexpressing CART through delivery of an AAV construct; there is increased food intake and increased weight gain, which are accentuated on a high-fat diet after

Copyright Elsevier 2024

injection of the construct into the rat PVN.[27] Moreover, overexpression of CARTp in the ARC results in increased food consumption and body weight gain in rats[17]. The reasons for the different responses to icv compared with that of local injection remain unclear and further work is needed to determine the precise sites and mechanisms of action of CARTp in different experimental conditions.

Locomotor changes with CARTp administration have been reported in several studies. For example, icv administration is associated with movement related tremor, body flattening, and a change in licking microstructure.[3,20] It seems possible, therefore, that at least some of the effects of CARTp on ingestive behavior, particularly after icv administration, are secondary to behavioral changes influencing locomotion. In addition, it should be noted that icv administration of CARTp 55–102 (1 μg, 0.19 nmol) has been associated with conditioned taste aversion.[2] For these reasons, it is appropriate to be cautious in interpreting the physiological relevance of responses to icv administration.

STUDIES FROM GENETICALLY MODIFIED ORGANISMS

Mice null for CART exhibit a relatively mild phenotype, which is nevertheless consistent with a role in inhibiting food intake. Asnicar et al. reported that CART$^{-/-}$ mice on a C57Bl/6 background exhibit modest increases in food intake and increased adiposity on a high-fat diet, on a normal diet; however, body weight in these mice is similar to wildtype up to 17 weeks.[4] Using a different strain of CART$^{-/-}$ mice, Wierup et al. found increased body weight at 40 weeks on a normal diet, but no difference in food intake, indicating a modest phenotype with late onset.[31]

FUNCTIONAL RESPONSES IN DIFFERENT METABOLIC STATES

Reports of the effects of CARTp on food intake come from studies in both freely feeding animals and previously fasted animals. In specific circumstances, the effects of CARTp have been shown to be dependent on nutritional status. For example, microinjections of CARTp 55–102 into the NAcc shell had a greater inhibitory effect on food intake in freely fed compared with that of 48-h fasted rats.[32] Direct comparison has been made of the effects of CARTp administration icv for 6 days in control rats on normal chow compared with that of obese rats fed a high-fat diet, and the results suggest similar inhibition of food intake.[26]

There is good evidence that the expression of CART in the hypothalamus is strongly influenced by nutritional status. Thus, Kristensen et al. first reported decreased CART mRNA in the ARC of 24- and 48-h fasted rats,[20] and there is also decreased CARTp measured by radioimmunoassay in the hypothalamus of 24-h fasted rats.[29] The abundance of CART mRNA is strongly dependent on leptin stimulation. In Zucker *fa/fa* rats (in which there is mutation of the leptin receptor), there is a profound decrease in CART mRNA in the ARC, and a lesser decrease in the DMH; similarly, in *ob/ob* mice (in which the *leptin* gene is mutated), there are also profound decreases in CART mRNA in the ARC, and modest decreases in the DMH.[20] Because neurons expressing CART also express the leptin receptor (ObR) and because leptin stimulates these neurons (see below), the results suggest that CART abundance in this system is strongly dependent on circulating leptin status.

The expression of CART in peripheral neurons is also dependent on nutrient status. In vagal afferent neurons where CART is coexpressed with the cholecystokinin (CCK)-1 receptor,[6] there is a sharply decreased expression in fasted animals, which is promptly reversed by the administration of exogenous CCK8s, or by refeeding via a mechanism dependent on endogenous CCK.[8] In addition, fasting decreases CARTp concentrations in blood and abolishes its diurnal rhythm.[28] Multiple organs probably contribute to circulating CARTp including the adrenal gland, and a role for glucocorticoids in regulating circulating CART concentrations has been suggested. In general, peripheral administration of CARTp (intraperitoneal, ip) alone has a weak effect on feeding behavior. The response is, however, dependent on previous nutrient availability. Thus, after fasting rats for 15 h, ip CARTp has a small effect in increasing food intake, whereas after 2.5 h, fasting there is a small decrease in food intake. Importantly, however, ip CARTp prolongs and potentiates the satiating effects of ip CCK8s after the short, but not the long, duration of fasting.[9]

NEURAL NETWORKS INVOLVED

The notion that CARTp in hypothalamic neurons is implicated in control of food intake has been grounded in the early observations that (a) CART is expressed in neurons that are strongly associated with control of ingestion, (b) these neurons are stimulated by leptin, (c) CART expression in them changes in response to leptin and food deprivation, (d) there are changes in food intake on administration of exogenous peptide, and (e) there are changes in food intake on inhibiting endogenous CARTp by either siRNA knockdown or antibody administration. However, CARTp in other systems may also play a role in regulating ingestive behavior, including, for example, NAcc, hind brain sites and vagal afferent neurons. Because fourth ventricular injection of CARTp 55–102 reduces the short-term intake of a liquid meal,[2,34] and because plugging the cerebral aqueduct between the third and fourth ventricles blocks the anorectic effect of third ventricular injection of CARTp,[3] it has been proposed that icv CARTp reduces food intake from

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

hind brain sites albeit with questions about the physiological relevance of responses by this route of administration.[2] Even so, the role of CART acting within the brain stem is interesting in the context of observations of the expression and actions CARTp in vagal afferent neurons that terminate the nucleus tractus solitarius (NTS, see below).

Hypothalamus

In the ARC, CART is expressed in neurons that also express proopiomelanocortin (POMC).[13,14] There is a well-defined role for the POMC-derived peptide, α-melanocyte stimulating hormone (αMSH), in inhibiting food intake via actions on melanocortin-(MC)3 and MC4 receptors expressed by target neurons. The POMC/CART-expressing neurons are distinct from those expressing neuropeptide Y (NPY) and agouti-related peptide (AgRP) in the ARC, both of which are associated with stimulation of food intake. There is, however, a dense network of NPY-immunoreactive terminals surrounding CARTp-positive nerve cell bodies.[5] The CART-expressing neurons of the ARC also express ObR, and leptin stimulates expression of c-fos and suppressor of cytokine signaling-3 (SOCS-3) in these neurons, as well as stimulating CART expression, supporting the idea that these cells are a target for direct actions of leptin in the hypothalamus.[13,14]

In the parvicellular PVN, there are strong in situ hybridization signals for CART,[12] and a high density of cells by immunohistochemistry.[19] These neurons seem to coexpress CARTp and thyrotrophin releasing hormone[5,14] and intravenous leptin administration induces c-fos expression in them.[13] Varicosities containing NPY-immunoreactivity form dense pericellular baskets around the CARTp-immunoreactive PVN cell bodies suggesting a functional link between NPY and CARTp in this system.[21] Interestingly, Cota et al. have reported that CARTp in PVN neurons is colocalized with cannabinoid, CB1, receptors, which are linked to orexigenic responses.[7] The results suggest, therefore, that both anorexigenic factors, such as leptin, and orexigenic stimuli, such as NPY and endocannabinoids, may interact to control CART expression, or release, in the PVN.

In both the LHA and DMH, CARTp colocalizes extensively with the orexigenic peptide melanin-concentrating hormone (MCH).[5,14] Intravenous leptin activates many of these neurons, as determined by the expression of c-fos and SOCS-3, and as they also express ObR, it has been suggested that there is direct leptin stimulation of them.[13,14] The CARTp-expressing neurons of the DMH are surrounded by a population of NPY-immunoreactive terminals that may originate from the ARC and consistent with the suggestion that CARTp is downstream of NPY.[5] The CART-expressing neurons of the LHA and DMH neurons also express CB1 receptors, and in $CB1^{-/-}$ mice, there was decreased CART mRNA abundance,[7] which may be relevant in the context of orexigenic responses to CART on local injection into these nuclei and the colocalization of CART with MCH.

Limbic System

In both the shell and the core of the rat NAcc, there is a high density of CARTp-immunoreactivity fibers.[18] Retrograde tracing suggests that many of the CARTp-immunoreactive fibers reflect projections from the ARC as well as ventral striatum and perifornical region.[32] There are, however, some CARTp-immunoreactive cell bodies in the NAcc, and CART mRNA in the NAcc shell was shown to be suppressed after fasting, suggesting that CARTp may be involved in feeding-induced reward and reinforcement pathways.[32] As noted above, microinjection of CARTp into the NAcc decreases food intake in both fed rats and fasted mice,[15,32] while knocking down CART by the use of siRNAs increases food intake in fed mice.[15] Both 5-HT_4 receptors and CB1 receptors regulate CART expression in the NAcc. Stimulation of 5-HT_4 receptors in the NAcc increases CART abundance and decreases food intake. Conversely, reducing CARTp in food-deprived mice by administration of siRNA abolishes the anorectic effects of a 5-HT_4 receptor agonist,[15] suggesting that CARTp is a mediator of 5-HT_4 receptor-induced inhibition of food intake.

Hind Brain and Vagal Afferent Neurons

There is a high density of CARTp-expressing nerve fibers in the commissural and medial parts of the NTS and also the lateral part of the area postrema.[18,35] There are some CARTp-immunoreactive perikarya in the area postrema, but importantly, there are abundant CART-expressing neurons in the nodose ganglia, and the central projections of these neurons contribute to the CARTp-immunoreactive fibers in the NTS.[6,18,35] Although there are projections to the dorsal vagal complex from hypothalamic nuclei including PVN, LHA, and ARC, retrograde tracing experiments suggest the CARTp-expressing neurons in these regions do not make a major contribution to the CARTp-positive fibers in the dorsal vagal complex.[35]

Administration of CARTp, into the fourth ventricle in doses that inhibit food intake (80 pmol) stimulates c-fos expression in NTS neurons;[35] moreover, it is well established that there is an induction of c-fos in NTS neurons after vagal afferent stimulation by CCK or food intake. Interestingly, however, it has been reported that microinjection of CARTp into the NTS has little or no effect on food intake.[35]

Approximately 50% of vagal afferent cell bodies in the nodose ganglia express CART[6] and CARTp,[8,9] and the

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

same neurons also express CCK1 receptors.[6] In retrograde tracing studies, CARTp is present in a higher proportion of nodose neurons projecting to the duodenum compared with the stomach (although it should be noted that the total number of labeled neurons projecting to the stomach is higher than to the duodenum).[35] The CARTp synthesized in cell bodies of vagal afferent neurons is transported to both central (NTS) and peripheral sites.[6,9] These neurons also express the orexigenic peptide MCH. However, the expression of MCH and CART is differentially regulated depending on nutritional status.[8] Thus, in rats fed ad libitum, CARTp expression is high while MCH expression is low in nodose ganglion neurons, while after 24 h fasting, CART expression is reduced and MCH expression is upregulated. This switch in expression is regulated by CCK. Injection of CCK8s in fasted animals is sufficient to upregulate CARTp expression (and decrease MCH expression), while a CCK1 receptor antagonist inhibits feeding-induced CARTp expression. In cultured vagal afferent neurons, CCK8s also induces synthesis and release of CARTp. These effects are potentiated by leptin[10] and inhibited by ghrelin.[8,9]

RECEPTORS AND SIGNALING PATHWAYS

The molecular mechanism of action of CART remains uncertain. Notably, the putative CARTp receptor has not, so far, been characterized although binding studies on cell lines, and on dissociated hypothalamic neurons have been described.[16,25] There is some evidence for actions at a G protein-coupled receptor acting via $G_{i/o}$ although this conclusion must remain provisional until molecular characterization of the receptor. Potential intracellular mediators of CARTp effects include the transcription factor c-fos, the expression of which has been widely used as a marker of cells responding to CARTp.[30] Many of the latter include neuronal systems implicated in control of ingestion. But in addition, other transcriptional mediators of CARTp include the immediate early gene (early growth response-1) EGR-1 and phosphoCREB that are activated in hypothalamic, brain stem, or vagal afferent neurons. In the vagal neurons, there is evidence that EGR-1 and phosphoCREB mediate the effects of CARTp in regulating its own expression and that of Y2 receptors.[9]

INTERACTIONS WITH OTHER SYSTEMS

Many different interactions between CARTp and other systems have been suggested that have implications for the control of energy balance. These include interactions with endocrine control mechanisms, with reward systems and components of the limbic system, and with autonomic mechanisms controlling digestion and energy expenditure. There may also be interactions with other peripheral systems including the pancreatic hormones.[25]

Cholecystokinin and Leptin

In addition to the evidence for leptin control of CART expression already discussed in the context of hypothalamic neurons, there is also evidence of strongly cooperative interactions between CCK and leptin in determining CART expression in vagal afferent neurons. The action of CCK in stimulating CART expression is mediated by the activation of EGR-1, which is achieved by stimulating its translocation from cytoplasm to nucleus; CCK does not seem to increase EGR-1 expression. Leptin strongly potentiates CCK-stimulated nuclear translocation of EGR-1, but it has no effect on its own. Leptin does, however, strongly stimulate EGR-1 expression. Thus, leptin is able to set the level of EGR-1 abundance but not its activity, whereas CCK determines activation but not abundance, and together, they determine CART expression.[10] These actions are also a target for orexigenic peptides such as ghrelin, which inhibits both leptin stimulation of EGR-1 expression and CCK stimulation of EGR-1 nuclear translocation.[10] Acutely, CCK stimulates CARTp release from cultured vagal afferent neurons, and there is a small effect of leptin in increasing this response. Interestingly, inhibition of CART expression in cultured vagal afferent neurons reduces some of the responses to CCK. For example, CCK stimulates both CART and Y2 receptor expression, and both seem to be partially dependent on CARTp secretion. However, CCK also inhibits the expression of CB1 receptors and MCH in vagal afferent neurons, and CART is not implicated in these responses.[9] Thus, CARTp seems to act as an autocrine enhancer of some, but not all, CCK effects on vagal afferent neurons which may underlie its effects on peripheral administration in potentiating CCK inhibition of food intake. The interaction with CCK may also account for the observation that administration of CARTp alone into the NTS has little effect on consumption of a non-CCK releasing meal (sucrose).[34,35]

Endocannabinoids, NPY, and MCH

Both morphological and functional evidence indicates interactions between CARTp and orexigenic factors including NPY, MCH and endocannabinoids. Further work is still required to elucidate these interactions particularly in hypothalamic nuclei implicated in ingestive behavior. Based on present evidence, it seems that the CB1 antagonist rimonabant inhibits food intake in wildtype mice but not in $CART^{-/-}$ mice; moreover, in mice, null for fatty acid amide hydrolase (FAAH), which metabolizes endocannabinoids, there is reduced CARTp in ARC and DMH and treatment

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

of these mice with rimonabant increases CARTp.[23] These results are compatible with the view that expression and release of CART are inhibited by CB1 receptor stimulation, and that suppression of CART is a component of the orexigenic effect of endocannabinoids.

PATHOPHYSIOLOGICAL IMPLICATIONS

There is evidence that mutations in the *CART* gene are associated with obesity. A missense mutation that results in substitution of Leu at position 34 with Phe was reported to cosegregate with obesity over three generations in one family and was not found in a control population. The mutation is adjacent to a pair of lysine residues, which constitute a site of precursor cleavage raising the possibility of impaired posttranslational processing.[11] In keeping with this, the mutation was also associated with decreased circulating concentrations of CARTp, but increased concentrations of partially processed precursor peptide. In the AtT20 cell line, the mutant precursor was missorted and poorly processed consistent with the idea that this mutation leads to deficiency in CARTp via failure to generate the active peptide.[33]

PHYSIOLOGICAL OVERVIEW

Nearly 15 years after the first demonstration that CARTp inhibited food intake, there remain many unanswered questions. The results of studies in mice null for CART and in humans with *CART* gene mutations support the idea of a role in inhibition of food intake. Moreover, the experimental evidence extends these findings by indicating that CARTp may be a satiety factor at multiple levels including peripherally at vagal afferent neurons, and centrally within the brain stem, hypothalamus, and components of the limibic system. In recent years, some of the cellular mechanisms that govern the relationships between CARTp and other well-established satiety signals including CCK and leptin have started to emerge, particularly with respect to vagal afferent neurons. Set against this, however, there remains the problem that putative CARTp receptors are uncharacterized, and so it is difficult to examine cellular mechanisms of action in any detail, or for that matter to examine the consequences of receptor gene deletion or to develop antagonists. The issue is important given the work of some groups raising questions about the physiological relevance of actions of CARTp (notably when given icv) in inhibiting food intake, together with the work of others suggesting orexigenic actions. Moreover, CARTp has possible roles in other systems that might impact directly or indirectly on energy intake and expenditure, including those associated with pain, anxiety, reward, endocrine regulation, cardiovascular and gastrointestinal systems.[25] Further progress using existing laboratory methods should help to elucidate these inter-relationships and resolve seemingly contradictory findings. Nevertheless, the system will inevitably remain incompletely understood until it is possible to explore fully the relevant receptor mechanisms.

Chapter 144

CCK

Claire Barbier de La Serre and Timothy H. Moran

ABSTRACT

Peripheral administration of the brain/gut peptide cholecystokinin (CCK) inhibits food intake. The actions of peripheral CCK in feeding are consistent with a role in satiety. CCK is rapidly released during a meal, exogenous peptide administration terminates an individual meal without long-term effects on food intake, and CCK antagonists or genetic manipulations that alter CCK-1R receptor signaling result in increases in meal size. A necessary role for CCK-induced vagal afferent activation in CCK satiety has been shown. CCK not only activates vagal afferents providing a feedback signal to the dorsal hindbrain but it also plays a major role in altering gene expression of other orexigenic and anorexigenic peptides and receptors in vagal afferent cell bodies in the nodose ganglion.

INTRODUCTION

In their classic 1973 article, Gibbs, Young, and Smith showed the ability of exogenous administration of the brain-gut peptide cholecystokinin (CCK) to inhibit food intake in rats.[15] The pattern of behavioral changes produced by CCK was consistent with the production of satiety. CCK reduced meal size and meal duration and resulted in an earlier appearance of a behavioral sequence of satiety similar to that seen after ingestion of a normal size meal. From these results, Gibbs et al. suggested that exogenously administered CCK was mimicking a physiological hormonal action of the endogenous peptide.[15] These initial reports have stimulated almost 40 years of work in a variety of laboratories aimed at showing a physiological role for CCK in the control of food intake and at understanding the mechanisms underlying the satiety actions of both exogenously administered and endogenously released CCK. The results of these investigations have shown an important role for CCK as a within meal negative feedback satiety signal. The following chapter will detail the current state of our understanding of the role of peripheral CCK in satiety and the mechanisms through which these actions are mediated.

CCK AS A GUT PEPTIDE

CCK is released from I enteroendocrine cells found in the upper small intestine (duodenum and jejunum). Digestion products of lipids and proteins are the most potent elicitors of CCK secretion with carbohydrates inducing a much smaller response.[9] Different receptors, such as GPR93 or PEPT-1 for proteins and GPR120 for fatty acids, are involved in nutrient sensing and nutrient-induced CCK release. Although these receptors mobilize different intracellular signaling pathways, they have a common outcome, an increase in intracellular Ca^{2+} and CCK release.[25] CCK plays a variety of roles in coordinating digestive processes. CCK delays gastric emptying, stimulates gall bladder contraction and pancreatic secretion, and reduces food intake, all of which optimize digestive capacities.

FEEDING INHIBITORY ACTIONS OF PERIPHERAL CCK

Exogenous peripheral administration of CCK results in a dose-related suppression of short-term food intake in a variety of species and under a variety of experimental situations. CCK effectively reduces food intake in birds, rodents, pigs, sheep, nonhuman primates, and humans. CCK affects both solid and liquid food intake and is effective in spontaneous food intake as well as feeding that is stimulated by access to a palatable food source or in response to deprivation. CCK inhibits both real and sham feeding, in which ingested food is swallowed but drains from the stomach through a gastric fistula, demonstrating that CCK is a sufficient stimulus for reducing food intake even in the absence of other postingestive feedback.[16]

CCK primarily affects food intake by reducing meal size. Repeated meal-contingent CCK administration that occurs at meal onset results in a reliable reduction in meal size without an overall change in food intake.[32] That is, in response to the repeated CCK-induced reductions in meal size, rats compensate for the missed calories through increasing their meal frequency. By contrast, when CCK administration is timed to meal termination, there is no effect on the duration of the intermeal interval and no overall changes in the amounts consumed.[33]

Such meal termination actions of CCK are consistent with the dynamics of CCK in circulation. Exogenously

administered CCK is rapidly degraded with estimates of half-life in the circulation in the range of a few minutes. In response to a meal, plasma CCK levels increase rapidly, peaking within a few minutes of meal initiation, and then fall to less elevated levels that are sustained over a longer time period.[19] This rapid release and short duration in circulation suggest a role in the termination of a single meal without actions on the reoccurrence of eating at the next meal.

The satiating action of CCK is characterized by an inhibition of food intake without abnormal or competing behaviors. CCK elicits the normal behavioral sequence of satiety.[1] Rats treated with CCK stop eating sooner but go through the normal sequence of post-prandial behaviors that characterize response to a spontaneous meal—meal termination is accompanied by a period of grooming and exploration followed by resting or sleep. Doses of CCK that inhibit food intake in food deprived rats do not affect water intake in water deprived rats, showing that the actions of CCK are not secondary to an abnormal alteration in oral motor patterns.[15] CCK inhibits food intake at doses that do not produces a conditioned taste aversion and, in fact, at the low end of the effective dose range for food intake, CCK produces a conditioned preference.[26] Results from human experiments in which the subjective sensations of subjects receiving CCK are assessed show significant suppression in food intake in the absence of significant reports of side effects.[18] Such results support the view that the feeding inhibitory actions of exogenous CCK are specific to satiety.

FEEDING INHIBITORY ACTIONS OF ENDOGENOUS CCK

The availability of CCK receptor antagonists provided the ability to critically assess the physiological significance of endogenous CCK in the control of meal size. Assessments of the CCK receptor subtype mediating the actions of exogenous CCK in food intake point to a critical role for CCK-1R receptors. Sulfated CCK-8 inhibits food intake, whereas nonsulfated CCK-8 or shorter CCK fragments do not. As receptor subtype specific CCK antagonists became available a similar pattern of results was found. CCK antagonists with specificity for the CCK-1R receptor subtype increase food intake in a variety of species and across a range of testing paradigms while antagonists with CCK-2R specificity do not.[20] Overall, the results show that the increases in food intake stimulated by CCK-1R antagonists are dose related, and the majority of the effect is secondary to increases in the size of meals.

The importance of CCK acting through CCK-1R for feeding control has also been seen in studies in Otsuka Long Evans Tokushima Fatty (OLETF) rats lacking the CCK-1R and in CCK 1-R receptor knockout mice. OLETF rats arose from a spontaneous mutation in a colony of outbred Long Evans rats that resulted in obesity and diabetes. In examining overall pancreatic function in OLETF rats, it was discovered that they lacked an amylase response to exogenous CCK, leading to the demonstration that OLETF rats have a 6-kb deletion in the gene for CCK-1R that spans the promotor region and the first and second exons resulting in the absence of CCK-1R in these rats.[13] Functional studies in OLETF rats have revealed that they do not reduce food intake in response to CCK administration and examination of their meal pattern showed that they have a satiety deficit.[22] OLETF rats consume meals that are about twice the normal size. In response to this increase in meal size, meal number is decreased but not sufficiently to normalize overall food intake, resulting in about a 40% hyperphagia (Fig. 1).

In contrast to the OLETF rats, CCK-1R knockout mice consume normal amounts of food intake over 24 h and do not become obese. However, CCK-1R receptor knockout mice consume larger meals than that of wildtype mice of the same background strain. The increase is relatively smaller than that seen in OLETF rat and the mice do compensate for the increase such that total food intake is not significantly elevated. Thus, although these two models result in different overall metabolic phenotypes (suggesting that the OLETF rat has further deficits that those involving peripheral CCK satiety signaling), they do both support the view that CCK signaling is important for the normal controls of meal size.

SITES OF ACTION FOR PERIPHERAL CCK IN SATIETY

Peripherally administered CCK induces a variety of changes in gastrointestinal motility and secretion, and some of these actions are direct local effects of the peptide and some depend on the activation of vagal afferent fibers. A role for CCK-induced vagal activation in CCK satiety has been shown in a variety of experimental settings. Total subdiaphragmatic vagotomy completely blocks the ability of CCK to inhibit food intake and vagal deafferentation significantly attenuates the feeding inhibitory effects of CCK.[21,30] The nature of this attenuation is to eliminate the ability of low doses of CCK to affect food intake while reducing the efficacy of higher doses. Surgical removal of the pyloric sphincter also significantly attenuates CCK satiety. CCK-1Rs are expressed in nodose ganglion neurons and transported both peripherally and central to vagal terminal fields.[23] CCK-1Rs are also expressed in circular muscle fibers in the pyloric sphincter.[31] CCK activates vagal afferent fibers and contracts the pyloric sphincter, an action that contributes to CCK's ability to inhibit gastric emptying and secondary to that effect, reduce food intake.[24]

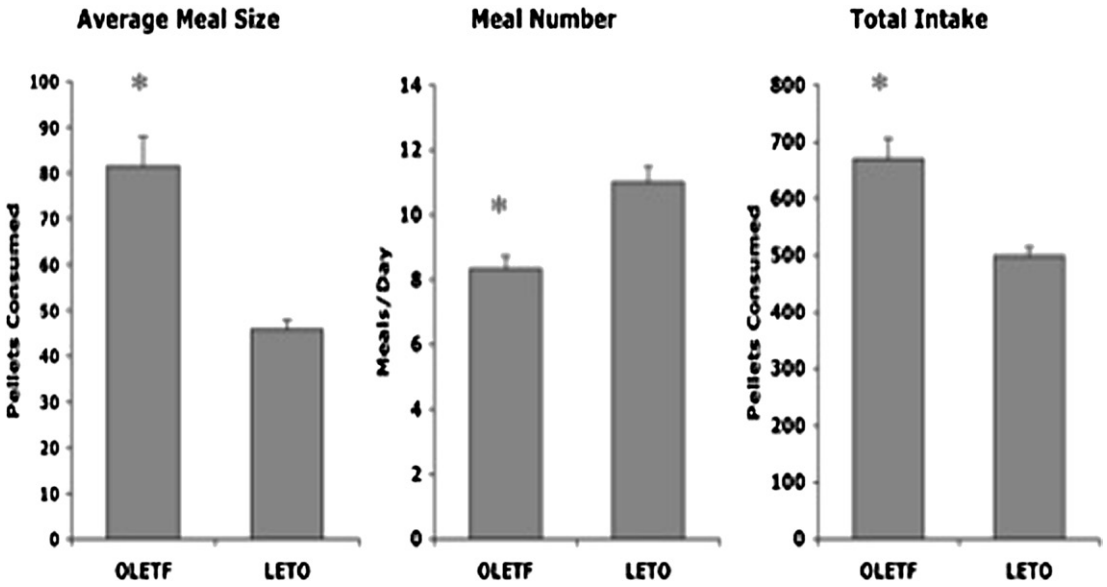

FIGURE 1 Meal patterns in OLETF rats lacking CCK-1 receptors and control LETO rats over a 24-h period. OLETF rats consume much larger spontaneous meals and have a significant reduction in meal number. The reduction in meal number is not sufficient to prevent a significant overall hyperphagia (modified from Ref. 22).

The feeding inhibitory effects of both exogenous and endogenous CCK are predominantly mediated via activation of the CCK-1R on vagal afferents. Vagal afferents nerve terminals are found in the wall of the gastrointestinal tract, in the muscle and mucosa layers. Within the mucosa, terminals are located in the lamina propria close to the basal membrane of I enteroendocrine cells expressing CCK.[2] Local CCK release or exogenous local arterial CCK administration activates vagal afferent CCK-1R, triggering vagal discharge and increase in vagal activity in the form of action potentials. CCK-induced increases in vagal afferent activity are seen in both gastric and duodenal vagal afferents.[27,29] Afferent fibers that respond to CCK are also load sensitive; increases in intraluminal volume also activate these fibers and having been activated by CCK, the identical load produces greater activation (Fig. 2). These interactions provide a basis for synergy between intraluminal load and CCK in inhibiting food intake.

CCK-induced vagal afferent activity results in the modulation of secondary neurons within the nucleus of solitary tract (NTS), the central site of termination of vagal afferents. The feeding inhibitory action of CCK requires the activation of hindbrain NMDA-type glutamate receptors.[34] The phenotypes of the neurons activated by CCK within the NTS include both tyrosine hydroxylase expressing and proopiomelanocortin (POMC) expressing neurons. The necessity of melanocortin signaling in CCK satiety has been shown, as CCK fails to inhibit food intake in mice in lacking MC4R or in mice in which brainstem MC4R are pharmacologically blocked.[12] CCK-induced neural activity at the level of the brainstem is sufficient for mediating CCK satiety, as CCK is effective in decerebrate rats where the hindbrain and forebrain are surgically disconnected.[17] Functional gastrointestinal responses to CCK are mediated via vagal efferents and sympathetic nervous system activation as well as hormonal mechanisms. Neurons in the dorsal motor nucleus (DMV) receive information from the NTS and the midbrain and project back to the GI tract through vagal efferent to modulate gastric functions such as gastric emptying and secretions. Thus, both vagal afferent and efferent probably participate in CCK-induced satiety.[21]

CCK-INDUCED CONTROL OF VAGAL AFFERENT GENE EXPRESSION

In addition to activating vagal afferent fibers, CCK seems to be play a major role in orchestrating gene expression within nodose ganglion neurons and, in this way, modulates vagal afferent sensitivity to a variety of stimuli involved in feeding control. Contrary to long-term regulating signals such as circulating leptin, CCK does not have suppressible tonic activity; thus, the decrease in signaling in a fasted state is not expected to stimulate food intake. However, the absence or presence of food in the gut triggers changes in G-protein-coupled receptors and neurotransmitter expression in vagal afferent neurons that modulate the sensitivity to GI signals. Vagal afferent neurons innervating the stomach and duodenum are found in mid and caudal areas of the nodose ganglion and express receptors for anorexigenic peptides such as CCK, leptin, PYY3–36 and also express receptors for orexigenic signals like orexin, melanin-concentrating hormone (MCH) and cannabinoids receptor.[10] These different receptors are

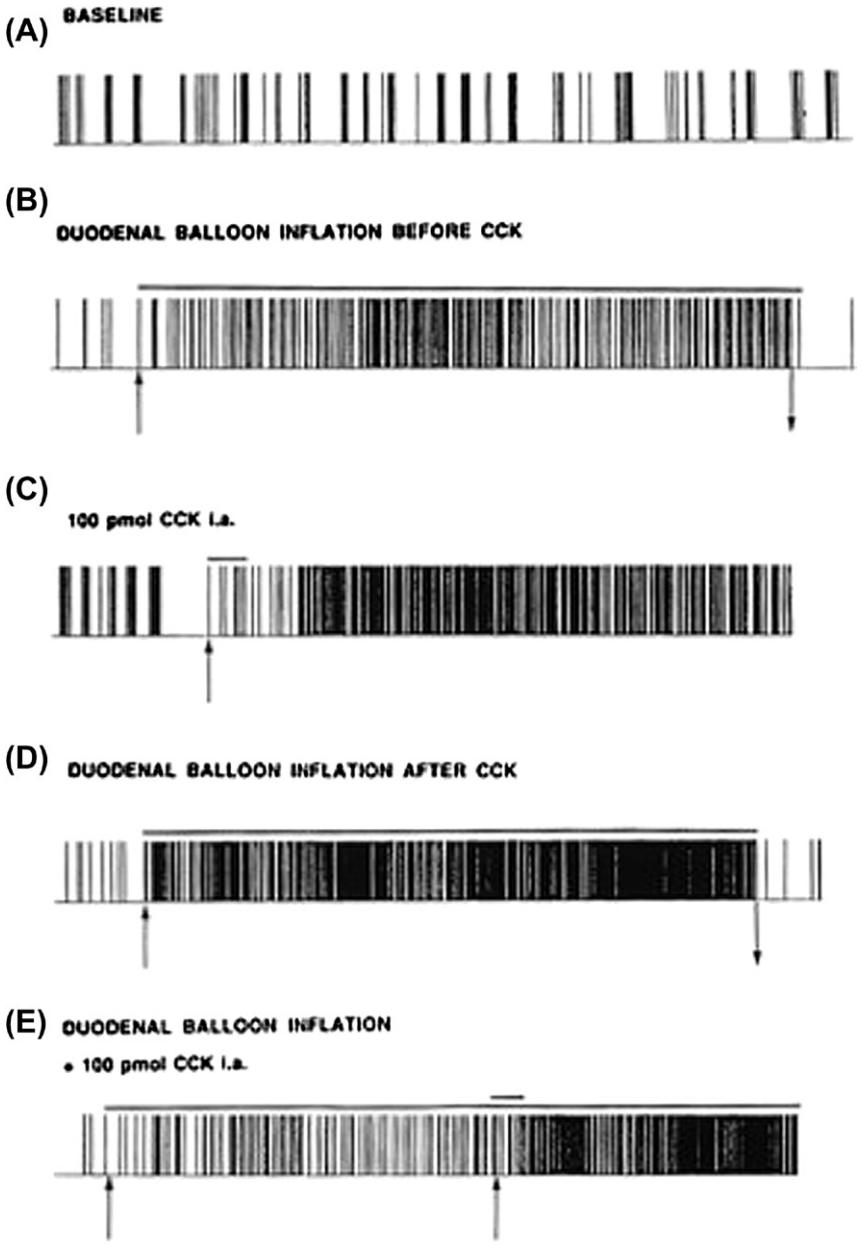

FIGURE 2 Vagal afferent activity in a single fiber innervating the proximal duodenum. (A) Baseline activity. (B) Activity increase in response to intraluminal volume. (C) Activity increase in response to local arterial CCK administration. (D) Activity increase to same intraluminal volume after activation by CCK at a time when activity had returned to baseline levels. E. Increased activity to simultaneous CCK and lintraluminal volume. CCK both activates vagal afferents and sensitizes the afferents to intraluminal volume stimuli.

translocated to the nerve terminals where they can be activated by their respective ligands. In rats, feeding status can influence receptor expression at the mRNA and protein levels through a CCK-dependent pathway. For example, fasting of ≥12 hours in rats leads to an increase in nodose ganglion CB1 receptor expression.[4] CB1 expression decreases 2 h after refeeding and is virtually lost after 5 h. The effect of feeding can be mimicked by exogenous CCK administration and blocked by a CCK-1R antagonist. Likewise, nodose ganglion MCH1R expression increases with fasting and decrease with feeding. Similar to CB1, MCH1R mRNA is undetectable 5 h after refeeding.[5] Administration of CCK has the same effect as feeding on MCH1R expression and feeding-induced decreases in MCH1R occur via a CCK-1R mediated mechanism. Conversely, Y2R expression is decreased 5-fold in vagal afferent neurons of fasted rats compared with that of animals fed ad libitum.[3] In mice, PYY3–36 administration induces fos activation in neurons within the brainstem; this effect is reduced in CCK-1R knockout mice, consistent with a role for CCK in determining Y2R signaling.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Feeding status also influences the expression of neuropeptides in vagal afferent neurons.[10] In rats, expression of the appetite stimulating neuropeptide MCH increases with fasting. Vagal afferent neurons express MCH and MCH1R; the local release of MCH may stimulate MCH1R to promote appetite.[5] This positive feedback loop is terminated with refeeding or CCK injection. By contrast, expression of the peptide cocaine and amphetamine related transcript (CART) in these neurons is associated with a fed state; upregulation of CART is induced by a CCK-dependent pathway.[8] In cultured neurons, treatment with CART stimulates Y2R and CART production but has no effect on CB1, MCHR1 and MCH. Moreover, incubation with CART siRNA abolishes CCK-induced increase in Y2R and CART. CART seems to mediate CCK anorexigenic signaling and to be a part of an autocrine positive feedback loop promoting satiety.

Such results show that anorexigenic and orexigenic factors interact on the same pathways at the level of vagal affertent neurons to modulate satiety signaling, and neurochemical phenotype of these neurons depends on energy intake and encodes the presence or absence of nutrient ingestion over the previous 24- to 48-h period. CCK controls the changes in expression of G-protein-coupled receptors and peptide neurotransmitters, and its effect on orexigenic signal receptors can contribute to its action as a satiety signal. Thus, CCK is not only involved in the acute regulation of meal size, but it can also influence the capacity of vagal afferent neurons to respond to other neurohormonal signals (Fig. 3).

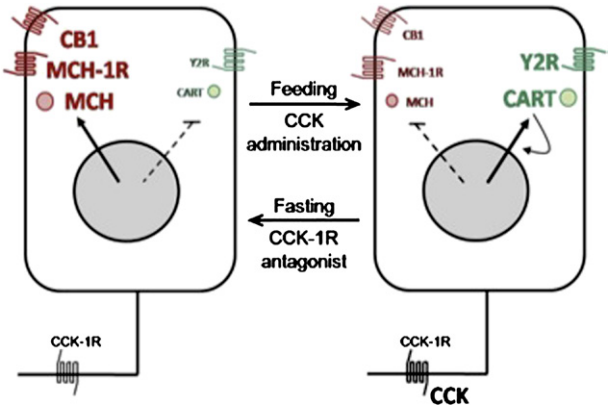

FIGURE 3 In the absence of CCK signaling (fasted or fed in the presence of CCK-1R antagonist), MCH1R, CB1, and MCH expressions are upregulated, whereas CART and Y2R expressions are downregulated. CCK binding to CCK-1R results in an increase in Y2R and CART with CART promoting Y2R and its own synthesis. CCK-1R activation also leads to the downregulation of MCH1R, CB1, and MCH expressions (adapted from Ref. 10).

FUNCTIONAL RESPONSES TO PERIPHERAL CCK IN DIFFERING METABOLIC STATES

The potency and efficacy for peripheral CCK to inhibit food intake depend on the metabolic status. CCK is less effective under conditions of food deprivation than in ad lib feeding, and CCK is less effective in rats during the dark cycle when the majority of feeding occurs. These state-induced changes in the feeding inhibitory efficacy of CCK have been proposed to result from alteration in leptin signaling. Leptin levels are low in response to food deprivation or before nighttime feeding. Leptin affects food intake through a mechanism dependent upon reduction in meal size and some aspects of this action appear to depend on leptin/CCK interactions. Exogenously administered leptin at doses that alone do not affect food intake enhances the ability of CCK to both inhibit feeding and induce neural activation in CCK activated NTS pathways as measured by the presence of the immediate early gene c-Fos or electrophysiolgocial activity.[11,28]

The feeding inhibitory actions of peripheral CCK are also modulated by estrogen.[14] In female rats and mice, the amounts and patterns of food intake vary across the estrous cycle. Food intake is lowest at time points corresponding to high estrogen levels and these decreases are expressed as decreases in meal size. This effect seems to be mediated by altered sensitivity to CCK. In ovariectomized females, CCK is more effective in reducing food intake when females are estrogen primed, and sensitivity to CCK varies across the estrous cycle. Further, CCK antagonists prevent the decreases in food intake that correspond to high estrogen levels.

Chronic consumption of a high-fat (HF) diet also leads to a decreased response to CCK characterized by a reduction in fos activation in NTS neurons after challenge with lipids or CCK and a decrease in CCK-induced anorexia.[6] The presence of fat in the diet seems to lower lipid-induced fos in the NTS independently of caloric density. The pathway by which HF diet alters CCK signaling is unknown. Reduced leptin signaling has been hypothesized to impair CCK action leading to the development of hyperphagia. In rats, leptin signaling is required for normal food intake. Knocking down Ob-r in the hindbrain results in hyperphagia, probably mediated by a reduction in leptin potentiation of CCK signaling. In diet-induced obese rats, vagal leptin signaling is impaired before the appearance of central leptin resistance and coincides with an increase in food intake and weight gained.[7]

Although it is not clear whether the decrease in CCK sensitivity precedes or follows diet-induced hyperphagia, impairment in CCK signaling results in an increase in meal size and alteration in meal patterning eventually leading to an increase in body weight. OLETF rats that have a defect in the CCK-1R gene are hyperphagic and obese. Their increase in daily food intake results from an increase in meal size combined with a lack of a compensatory decrease in meal

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

frequency; when put on an HF diet, they increase their rates of body weight gain compared with control rats. Similarly, HF diet access increases the meal size deficit in CCK-1R$^{-/-}$ mice. Given the importance of CCK in determining the sensitivity to other peripheral signals in vagal afferent neurons, the absence of CCK signaling may lead to an alteration in the expression of receptors and neurotransmitters involved in food intake control promoting orexigenic signaling and contributing to the increased deficits to high-fat feeding in the absence of CCK signaling.

SUMMARY

CCK is an important modulator of food intake at the level of individual meals. Nutrient-induced CCK release is a major controller of meal size. In the absence of CCK signaling, satiety is delayed and larger meals are consumed. CCK satiety signaling is mediated by vagal afferent fibers. CCK activates load sensitive vagal afferent fibers innervating the stomach and proximal intestine resulting in altered neural activity at the level of the brainstem nucleus of the solitary tract. CCK not only alters vagal afferent activity but it also modulates the expression of vagal afferent orexigenic and anorexigenic peptides. These actions can modulate the ability of vagal afferents to respond to a variety of other feedback signals.

Chapter 145

CRH

D. Richard and C. Lopez

ABSTRACT

The corticotropin-releasing hormone (CRH) system is involved in the control of food intake and energy expenditure. CRH and its paralogs urocortins 1, 2, and 3 are known for their hypophagic effects, which are mediated through the CRH receptors 1 and 2 (CRHR1, CRHR2). They are responsible for severe stress-induced anorexia. Additionally, CRH and urocortin 1 are also capable of thermogenic effects exerted on brown adipose tissue (BAT) via the sympathetic nervous system (SNS). The complexity of the brain CRH system renders difficult any precise delineation of this system's action in energy balance regulation. Despite its anorectic and thermogenic potential, the CRH system, when activated, can also be anabolic depending on the receptor and the brain regions involved. The CRH system could be behind anxiety/stress-induced obesity. Indeed, CRH stimulates the secretion of corticosteroids, whose effect on food intake and thermogenesis tends to be obesogenic. Meanwhile, the activation of the CRHR1 in the nucleus accumbens (NAc) stimulates the motivation to ingest palatable food.

INTRODUCTION

Evidence has accumulated throughout the years to suggest the involvement of the brain CRH system in the regulation of energy balance in obesity.[9,12,18,30] CRH and urocortins 1, 2, and 3, via actions mediated by CRHR1 and CRHR2, are capable of producing catabolic effects by reducing food intake and increasing energy expenditure. CRH is responsible for the anorectic effect of stress.[9,30] However, there are results supporting the view that peptides of the CRH familly could be involved in stress-induced obesity either by activating the pituitary–adrenal axis[34] or by influencing the rewarding effects of food.[3]

BRAIN DISTRIBUTION OF CRH, UROCORTINS, AND CRH RECEPTOR

CRH

CRH is a 41-amino-acid peptide expressed in neurons widely distributed throughout the mammalian brain.[23] It is highly synthesized in the paraventricular hypothalamic nucleus (PVH) and is also found in large amounts in extrahypothalamic regions, such as the olfactory bulb, bed nucleus of the stria terminalis (BNST), central nucleus of amygdala (CeA), geniculate nucleus, Barington's nucleus, dorsal vagal complex, and inferior olive. The broad distribution of the CRH neurons conforms to the many expected effects of the peptide including those on the food intake and energy expenditure.[9,12,18,30] The PVH CRH neurons project to the median eminence to stimulate the secretion of the adrenocorticotropic hormone (ACTH), which in turn leads to the adrenal secretion of corticosterone or cortisol. CRH represents the main controller of the basal and stress-induced activation of the pituitary–adrenal axis; CRH-knockout mice exhibit pituitary–adrenal hypoactivity.[25]

Urocortins

Urocortins 1, 2, and 3, which show particularly high selectivities for the CRHR2 receptor, are expressed in restricted areas of the brain.[19,29,35] Urocortin I, a 40-amino-acid peptide, is highly expressed in the Edinger–Westphal nucleus and also found in the supraoptic and hypoglossal nuclei.[35] Urocortin 2, a 38-amino-acid peptide that selectively binds to the CRH_2 receptor with no appreciable affinity for the CRHR1 receptor, is expressed in restricted brain areas, including the magnocellular division of the PVH, the arcuate nucleus (ARC) and the locus coeruleus.[29] Urocortin 3, a 38-amino-acid peptide, which, similar to urocortin 2, selectively binds to the CRHR2, is expressed in discrete brain areas including the BNST, the medial nucleus of amygdala, median preoptic nucleus, and brainstem.[19] None of the urocortin neurons projects to the pituitary gland to physiologically control the pituitary–adrenal axis. Urocortin 1, which binds to both the CRHR1 and CRHR2 receptor with a high affinity, activates the pituitary–adrenal axis and elicits anxiety-like behaviors when injected into the brain ventricles.[24]

CRH Receptors and CRH-Binding Protein

CRHR1, for which CRH (in particular ovine CRH) and urocortin have high affinity, is widely distributed in the brain

with the highest densities of expression observed in cortical, hypothalamic, limbic, and cerebellar regions. Within the PVH, CRHR1 mRNA can only be detected after stressful stimuli.[31] CRHR2, on which urocortins II and III act as selective endogenous ligands, is restrictedly expressed in the olfactory bulb, lateral septum (LS), ventromedial hypothalamic nucleus (VMH), medial and posterior cortical nuclei of the amygdala, mesensephalic raphe nucleus, nucleus of the solitary tract, and area postrema.[20]

In addition to binding to its two receptors, CRH and urocortin also have a noticeable affinity for the CRH-binding protein (CRH-BP), which is widely distributed throughout the brain.[28] In the rat, the protein is expressed in the cortex, amygdale, and hypothalamus. Most brain regions of CRH-BP expression are also sites of CRH synthesis or release, supporting the view that CRH-binding protein could increase the availability of CRH or urocortins for the CRH receptors.

CRH, UROCORTINS, AND ENERGY BALANCE REGULATION

CRH and urocortins are peptides capable of influencing food intake and energy expenditure,[9,12,18,30] the two inescapable components of energy balance regulation. When injected centrally, CRH decreases food intake and increases energy expenditure, whereas the effects of urocortins, especially urocortins 2 and 3, are mainly exerted on food intake. Brain injection of CRH also lowers the body weight threshold at which food-deprived rats start to hoard food in a home cage environment, supporting the idea that CRH could be a germane regulator of energy balance;[5] the body weight threshold at which food-deprived rats start to hoard food represents a surrogate of the body weight set point. Further, the observations (i) that food deprivation decreases brain CRH expression (at least in the PVH)[4] and (ii) that chronically administered CRH[32] and rat/human $CRH_{6–33}$, which dissociates CRH or urocortin from CRH-BP and increases endogenous brain levels of "free" CRH or urocortin, prevent weight gain in obese Zucker rats with little effect in lean animals,[15] speak in favor of a genuine role for peptides of the CRH family in energy balance regulation. However, the exact role of the CRH in energy balance, which is entangled by a complex network of CRH/urocortin neurons and receptors, needs to be fully delineated.

Sites and Mechanisms of the Anorectic and Thermogenic Actions of CRH

Both CRHR1 and CRHR2 could be involved in the effects of CRH and urocortins on food intake and energy expenditure, which complexifies the delineation of the sites and mechanisms whereby peptides of the CRH family exert their effect on the energy balance determinants.[9,12,18,30] Evidence keeps accumulating to emphasize the importance of the CRHR2 in mediating the anorectic effects of CRH and urocortins. CRHR2 agonism would reduce food intake without implicating malaise-like behaviors such as those that could be due to the CRHR1 agonism, which is known to produce interoceptive stress signs associated with anorectic effects.[10] Both urocortins 2 and 3 are capable of anorectic effects when injected centrally, whereas urocortin 2 seems to be more efficient than urocortin 3 in inducing hypophagia when injected in the periphery.[10] The implication of CRHR2 in the control of food intake is also supported by the changes in CRHR2 mRNA levels, which inversely vary with appetite. The expression of the VMH CRHR2 mRNA is decreased in obese, diabetic, and food-deprived rats.[30] It is induced by the intracerebroventricular infusion of leptin.[16] The VMH could represent the main physiological site for the CRHR2 receptor-mediated anorectic effect of the CRH-related peptides. In this regard, this hypothalamic nucleus was demonstrated to be an important site for the anoretic effect of urocortin 3.[7,11] Within the VMH, CRHR2 is expressed on glutamatergic excitatory neurons projecting to the ARC and on which urocortin 3 exerts a stimulating effect triggering proopiomelanocortin (POMC) expression.[7] The LS could also represent a site for the anorectic action of the CRH and CRH-related peptides.[21,26]

The role of CRHR1 in the feeding behavior remains unclear. The observation that urocortin does not elicit an acute anorectic response in CRHR1 ablated mice suggests that CRHR1 plays a role in the anorectic effects of the CRH-related peptides.[30] CRHR1 could mediate the anorectic effects that would be nonspecific and secondary to the anxiety-, fear- and stress-like behaviors (see below).

CRH and urocortin stimulate energy expenditure by increasing BAT thermogenesis.[30] This effect seems to be linked to the stimulation of CRHR1. In fact, the CRHR2 antagonist, antisauvagine-30 proved to be inefficient to block the thermogenic effect of a central injection of urocortin 1.[8] Moreover, the CRHR2 agonism could oppose the stimulating effect of the CRHR1 agonism on BAT thermogenesis; CRHR2-ablated mice exhibit a robust increase in basal BAT thermogenesis linked to an increased basal SNS outflow to BAT.[2] Additionally, CRHR2-mutant mice consume substantially more food when fed a high-fat diet with a reduced feeding efficiency and an increased BAT thermogenic capacity. The idea that the CRHR2 agonism blunts BAT thermogenesis is somewhat in contradiction with the observation that urocortin 3 stimulates ARC POMC neurons when injected in the VMH.[7] The stimulation of those neurons generally leads to the stimulation of SNS-BAT thermogenesis concomitant to a reduction in food intake.

The brain site of the CRHR1-mediated action on BAT thermogenesis is yet to be ascertained. There nonetheless is

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

sound evidence for the existence of a circuit involving the preoptic area (POA), dorsomedial hypothalamic nucleus, and raphe pallidus. It has indeed been suggested that CRH in the POA similar to prostaglandins could activate SNS-mediated BAT thermogenesis.[6] The POA expresses the CRHR1 and also comprises melanocortin-4 receptor neurons connected to BAT.[33] The role of the PVH in mediating the CRH and urocortin thermogenic effect is less certain as controversial effects have emerged from two independent studies.[6,17] That the PVH does not apparently express the CRHR1 except under stress stimulation[30] could explain discrepant sets of results regarding CRHR1 agonism-induced BAT thermogenesis.

A role for the CRH system in the anorectic action of leptin has been suggested. Some investigations have reported that the hypophagic action of a central infusion of leptin be blocked by CRH receptor antagonists.[30] However, it is as yet unclear in those studies if the CRH blockade prevented a leptin-mediated hypophagic action or if it curtails a nonspecific stress-related anorectic effect resulting from an acute central injection of large doses of leptin. Incidentally, leptin is recognized for its antistress effects.[30] CRH has also been suggested to mediate leptin-induced brown fat thermogenesis.[22]

CRH AND STRESS-INDUCED ANOREXIA

The CRH system coordinates a wide range of stress responses and evidence keeps accumulating that CRH is responsible for stress-induced anorexia.[9,30] CRH receptor antagonists block the anorexia associated with stressful conditions known to activate the CRH system, including treadmill running and restraint.[30] CRH antagonism also blocks the hypophagic effect of both estradiol and caffeine.[30] The observation that CRH-knockout mice exhibit indistinguishable anorectic responses to restraint stress suggests that alternative pathways could compensate for the long-term CRH deficiency.[30]

Stress-induced anorexia has long been believed to be solely mediated by the CRHR1.[30] Selective CRHR1 antagonists block the anorexia induced by emotional stress. There are, however, results suggesting that the CRHR2 in the LS and BNST could also be involved.[1,26] Restraint stress has been reported to activate neurons harboring the LS CRHR2.[21]

CRH AND STRESS-INDUCED OBESITY

Paradoxically, the CRH system could also be involved in stress-induced obesity. Stress-induced obesity could, in particular circumstances, prevail over stress-induced anorexia as the stimulation of the pituitary–adrenal axis and that of some brain appetitive behaviors for rewarding foods by CRHR1 agonism might favor obesity development. The metabolic response to stress depends on its severity and duration; severe long-lasting stressful events generally create catabolic responses.[9,30] It also depends on the way individuals respond to or cope with stressful events, which is determined by many factors.

The activation of the pituitary–adrenal axis, which represents the most recognized and studied functions of the CRH system, could *per se* promote obesity. Glucocorticoids ensuing from such activation are indeed anabolic by stimulating fat intake, reducing thermogenesis and promoting abdominal fat deposition.[34] The CRH action at the levels of the pituitary–adrenal is mediated by the CRHR1, whose expression is repressed by CRH and glucocorticoids.[30] In laboratory rodents, increase in corticosteroid levels enhances fat deposition by stimulating food intake and the preference for fat food while likely inhibiting BAT thermogenesis.[30] The activation of the brain CRH system in severe stressful events generally overwhelms the effects of the enhanced secretion of corticosteroids on energy balance; murine and rat studies have clearly emphasized the reducing effect of severe stress on fat deposition (see above).

A parallel way through which stress or the activation of the CRH system might sustain obesity is by increasing the value of or the motivation for palatable sweet/fat food through actions selective to certain brain regions.[3] CRH when microinjected in the NAc[27] have been reported to trigger the motivation for food. This action resembles that CRH (via CRHR1) also has to mediate the motivation for drugs in drug-dependent animals.[14] Increasing the motivation to consume would have the ability to extinguish stress responses associated with, for instance, alcohol, drug, or food withdrawal. Incidentally, ingestion of highly palatable food has been reported to reduce stress in rats.[13] Similarly, the high frequency of food ingestion in fa/fa Zucker rats would also seem to prevent the neurogenic-stress response led to by food deprivation in this the leptin-deficient rat model.[30] Leptin can also be seen as an antistress hormone. In obese mice, leptin downregulates the expression of CRH in the paraventricular hypothalamic nucleus,[30] which is consistent with the apparent ability of leptin to reduce the hypothalamic–pituitary–adrenal axis activity.

CONCLUSIONS

The role of the CRH system in energy balance regulation and obesity is complex. CRH and its paralogs urocortins 1, 2, and 3, through effects mediated by CRHR1 and CRHR2, are capable of hypophagic and thermogenic effects. The CRH system plays a major role in stress-induced anorexia. The sites of the anorectic and thermogenic actions of CRH and urocortins could be the LS, VMH, and the POA

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

(thermogenic action), which express CRHR1 (POA) and CRHR2 (LS and VMH). Growing evidence tends to support a role for the CRHR1 agonism in stress-induced obesity. The pituitary and the NAc CRHR1-mediated potentiation of the "incentive wanting" to eat could be site-specific action of the CRH system to promote obesity and thereby to oppose its (nonetheless predominant) catabolic effects.

Chapter 146

Enterostatin

Charlotte Erlanson-Albertsson

ABSTRACT

Enterostatin is a pentapeptide that specifically suppresses fat intake or high-fat intake as opposed to high-carbohydrate diets. As opposed to most regulatory peptides, enterostatin is formed in the lumen of the intestine and hence is comparable with food-derived peptides. The mechanism for the decreased fat intake is dependent on cholecystokinin pathways, opiate pathways, and melanocortin pathways. Enterostatin also displays metabolic effects, such as inhibition of insulin secretion, lowering of serum cholesterol levels, and enhancement of memory. An enterostatin-deficient mouse has elevated plasma cholesterol levels, pointing to the role of enterostatin in reducing blood lipids. The receptor for enterostatin is the β-subunit of F1-ATPase being localized to the plasma membrane in target cells. Enterostatin and fatty acids cause an increased expression of the receptor on the plasma membrane. Enterostatin may work as a feedback signal in promoting the regulation of fat intake and use of fat as energy substrate.

Peptides are small molecules and can therefore act as regulators in many different ways. Enterostatin is a small peptide comprising five amino acids (Table 1). The structure of this peptide is such that it resembles opiate-like peptides by having two proline residues in positions 2 and 4.[7] Moreover, it is produced in large quantities in the lumen of the intestine, thus being different from most regulatory peptides that are produced in endocrine cells and secreted directly into the blood stream (Fig. 1). Enterostatin instead resembles food-derived peptides that are contained in food proteins and are released during digestion of food proteins, for example, beta-casomorphin, which is formed during the digestion of milk casein (see the Opioid Peptides section of this book). Peptides such as enterostatin may have weak interactions with many different systems, but by virtue of the high concentrations at which these peptides exist, they can influence regulatory systems. In view of these properties, it was perhaps not surprising that the enterostatin knockout mouse displays a high level of stress and elevated levels of blood cholesterol compared with that of their normal littermates (Fig. 2).[19]

Enterostatin is released from pancreatic procolipase during digestion of fat and was first described as a peptide that promotes satiety for fat (Fig. 1). After the initial discovery, many other properties were described, such as the ability to regulate insulin secretion, lower blood cholesterol, improve memory, act antianalgesic, increase thermogenesis, and inhibit angiogenesis. This chapter describes the properties of enterostatin and its suggested mechanism of action. Several reviews have been written on enterostatin, among others.[7]

THE DISCOVERY OF ENTEROSTATIN

The first discovery of enterostatin as a feeding related peptide was in 1988 when during immunization of rabbits with enterostatin the animals lost their appetite. The basis for immunization of rabbits with enterostatin was our observation that all colipase molecules produced by the pancreas were secreted in the form of procolipase molecules. This was strange because colipase is not an enzyme that needs to be protected like other enzymes of the exocrine pancreas such as trypsin or phospholipase. We therefore wondered whether enterostatin was indeed released *in vivo* as we had found *in vitro*. With the knowledge that these rabbits did not want to eat, we started systematic feeding studies in rats and found that enterostatin decreased food intake after intraperitoneal administration.[6] It was very difficult to get this article published, but I was lucky to be invited to write a chapter in the French Journal *Biochimie*, in an issue devoted to professor Pierre Desnuelle, a grand French scientist who died in 1985 and with whom I worked during my postdoctoral scholarship in Marseille in 1972–1973.This was the first publication on the effect of enterostatin, which was then named procolipase activation peptide.[6]

CHEMISTRY OF ENTEROSTATIN AND TISSUE DISTRIBUTION

Enterostatin is a pentapeptide containing two proline residues with an amino acid in between. The structure has been conserved throughout the evolution (Table 1). It is produced through tryptic cleavage of procolipase after secretion into the intestinal lumen (Fig. 1). Enterostatin and its precursor procolipase have been identified in the pancreas, the stomach, and in the central nervous system. By using a specific

TABLE 1 Sequence of Enterostatin from Various Species

Species	Sequence
Human	APGPR
Rat	APGPR
Mouse	APGPR
Rabbit	APGPR
Dog	VPDPR
Chicken	APGPR
Pig	VPDPR
Horse	VPDPR
Hagfish	APGR
Myocco	APDPR
Spermophilus	APDPR
Canfa	VPDPR

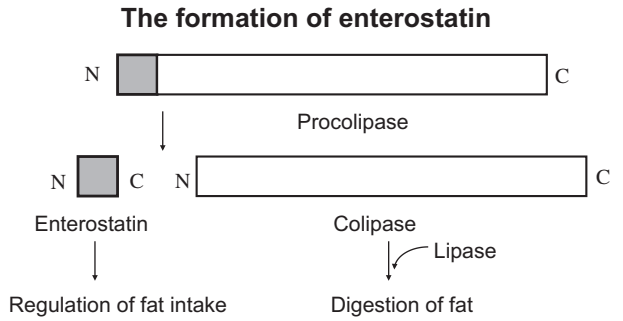

FIGURE 1 Enterostatin is a pentapeptide that is cleaved from the amino terminus of pancreatic procolipase in the intestinal lumen. It is formed in micromolar concentrations representing a high concentration. Although colipase acts as protein cofactor for pancreatic lipase during fat digestion, enterostatin regulates fat intake and fat metabolism in a feedback system.

immune assay, enterostatin was identified in the intestinal content of the rat at a concentration of 1.42×10^{-6} M, which is high for a biologically active peptide. The release of enterostatin into the intestinal content occurs parallel to the release of pancreatic lipase and colipase and is stimulated by CCK.[7] A high-fat diet significantly increases the level of enterostatin in the intestine to 3.86×10^{-6} M already by 24 h after the start of a high-fat diet regimen, indicating a rapid response of enterostatin expression after high-fat feeding.[7]

In the intestinal lumen, enterostatin is degraded within 30 min by epithelial brush border peptidases, mainly eliminating the C-terminal arginine residue. In spite of peptide degradation during normal conditions, intact transepithelial passage of enterostatin occurs in intact form.[7] It was concluded that although immunoreactive enterostatin exhibits a low apparent permeability coefficient in rabbit ileum, the high luminal concentration of enterostatin may be sufficient for the production of biological effects after absorption into the serum.

In the gastrointestinal tract, enterostatin is present also in the gastric mucosa, secreted by chief cells.[7] Cloning of gastric procolipase revealed that this molecule is identical to the pancreatic procolipase. Enterostatin is present in gastric juice, with pepsin and acid being responsible for the cleavage of gastric procolipase into enterostatin and colipase. The role of gastric colipase is unknown but may be important to prepare lipase-catalyzed fat digestion already in the stomach. Enterostatin is also present in endocrine cells in the antral part of the stomach and in the small intestine of the rat.[7] Its immunoreactive cells are more frequently found in the antrum and duodenum and become gradually fewer toward the distal small intestine. In some of the labeled endocrine cells, a coexistence of enterostatin with serotonin was revealed by immunocytochemical double staining, implying that the cells were enterochromaffin cells. Serotonin may be important in the mechanism of action of enterostatin.

Enterostatin has also been identified in the brain in the form of procolipase.[33,27] Procolipase and enterostatin immunoreactivity is seen in PVN, ARC, supraoptic nuclei, amygdala, and dorsal median thalamus.[33] These regions are associated with the regulation of food intake and energy expenditure. Procolipase is seen as dense particles in the cytoplasm, whereas enterostatin immunoreactivity occurs in nerve fibers. This suggests that procolipase is produced and processed in the neuronal cell body, whereas enterostatin is transported down the nerve fiber to be released at the nerve terminal.[33] Because enterostatin is particularly active when injected into the amygdala, the endogenous production of enterostatin in this nucleus suggests that this could be important for the regulation of fat intake. Enterostatin is also present in cells lining the third ventricle, where it may be secreted into the cerebrospinal fluid, as confirmed by Imamura et al.[8]

Hypothalamic procolipase expression is stimulated by a high-fat diet.[27] Because diets rich in fat are energy dense, the stimulation of hypothalamic procolipase seems to be an adequate event to induce satiety and energy balance during fat intake. Fasting overnight causes a 3-fold downregulation of hypothalamic procolipase, which is in agreement with the activity of a satiating agent. There is no expression of classical lipase in the hypothalamus, supporting a specific role of procolipase in the hypothalamus, not related to lipid digestion.[27]

With the immunoreactive method, serum enterostatin has been identified and measured in normal and morbidly obese human subjects.[7] Normal subjects display a biphasic release of enterostatin in the circulation postprandially, whereas morbidly obese patients have a weaker response. The concentration of enterostatin is approximately 10×10^{-9} M, suggesting that enterostatin may be absorbed

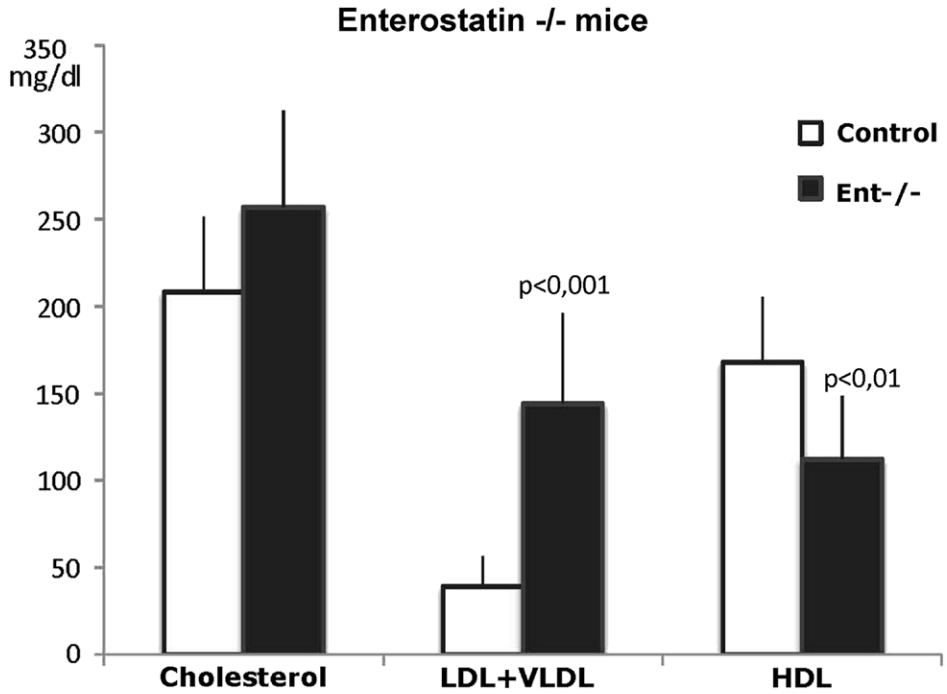

FIGURE 2 Enterostatin affects not only fat intake but also fat metabolism by regulating the use of fat as an energy substrate. The enterostatin-deficient mouse (Ent −/−) displays a normal fat intake but has higher LDL+VLDL blood cholesterol levels and lower HDL cholesterol levels.[19]

through the intestine. At least three different proteins bind enterostatin with a molecular size of 300, 205, and 60 kDa, albumin being one possible binding protein.[32] The presence of enterostatin-binding protein(s) in the circulation retards the uptake of enterostatin into the brain or other local target tissues and may also prevent a rapid degradation.

In rat serum, enterostatin increases postprandially after a meal.[17] The magnitude of response is dependent on the type of meal given. With high-fat and high-fat/high-sucrose meals, the response is greater in magnitude and duration than that after consuming a low-fat meal.[17] Plasma enterostatin concentrations after high-fat feeding are similar to those after intravenous administration of exogenous enterostatin known to inhibit high-fat food intake. Gel chromatography of pooled postprandial plasma extracts from this study followed by high-performance liquid chromatography analysis showed that plasma enterostatin was identical to synthetic enterostatin. Affinity crosslinking of plasma proteins with ^{125}I-enterostatin on sodium dodecyl sulfate-polyacrylamide gel electrophoresis, followed by autoradiography, revealed a single band with a molecular weight of about 66 kDa, indicating the presence of a potential enterostatin-binding protein in plasma.

THE RECEPTOR FOR ENTEROSTATIN

The receptor for enterostatin is the β subunit of F1-ATPase,[2,22] sequenced through MALDI-TOF analysis. By the surface plasmon resonance technique, the binding constant between ligand and receptor is 1.7×10^{-7} M and with an aqueous two-phase system equal to 1.5×10^{-7} M.[3] Because enterostatin occurs at a concentration of 10^{-6} M, for instance, in the intestinal lumen, a binding to the receptor should be possible.

The enterostatin receptor (β-subunit of F1-ATPase) is localized in the plasma membranes of liver cells and in amygdala.[22] It is also present in INS-1 cells, where enterostatin and fatty acids cause an upregulation of the expression of the receptor.[16] The observation that fat components such as fatty acids cause an increased expression of the enterostatin receptor may explain the need to feed animals high-fat diets before they respond to enterostatin.[13] High-fat diets are known to increase the expression of procolipase/enterostatin.[7,26] Thus, high-fat diets cause an increased expression both of enterostatin and its receptor.

The identity and targeting of the F1-ATPase β-subunit in the plasma membrane[22] and not as expected in the mitochondria as part of the ATP synthase complex[2] is not a unique phenomenon of enterostatin action. There are several reports on the presence of the F1-ATPase β-subunit in the plasma membranes of a variety of cell types, including adipocytes, hepatocytes, and various tumor cell lines[5] and the targeting of signals to this protein. In the plasma membrane, the F1-ATPase β-subunit is probably complexed with different subunits than when it is present in the mitochondria. Different functions have been described. The targeting of enterostatin to the F1-ATPase β-subunit in the plasma

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

membrane seems to be a possible mechanism for enterostatin to affect various cellular processes.

The intracellular mechanism once targeted by the enterostatin receptor includes various downstream events. In insulin-producing cells (INS-1 cells), enterostatin targets the F1-ATPase β-subunit with a simultaneous perturbation of ATP production, increase thermogenesis, and reduced insulin secretion.[2] Berger et al[2] suggested that the inhibition of insulin secretion observed in INS-1 cells results from perturbed ATP production and increased thermogenesis, ATP being important to stimulate insulin secretion.

Another intracellular event is an increased activation of AMP-activated kinase (AMPK) as observed during the stimulation of fatty acid oxidation in myocytes by enterostatin. AMP-activated kinase is recognized to have a central role in regulating energy balance during starvation, activating pathways to extract energy from the energy stores of the body, and at the same time inhibiting storage of energy. When activated, AMP-activated kinase leads to increased fatty acid oxidation in the muscle. Enterostatin causes a phosphorylation and subsequent activation of AMP-activated kinase. This is in agreement with the properties of a satiety peptide that not only acts to stop food intake but also acts to recruit energy from energy stores while food intake is suppressed.

Still another intracellular pathway for enterostatin is the activation of cyclic AMP and subsequent activation of MAP kinase ERK pathways.[24] This occurs in GT1–7 murine hypothalamic neuronal cells in culture. In these studies, enterostatin causes a reduced expression of AgRP after 1 hour of incubation.[24] Because AgRP stimulates fat intake, the decreased expression by enterostatin seems a possible explanation for the promotion of satiety for fat (Fig. 3). Initially, enterostatin increased the levels of cAMP, the downstream intracellular event being an activation of the MAP kinase pERK pathway. The activation of the MAP kinase correlates with a decreased expression of AgRP expression. The GT1–7 cells possess the F1-ATPase β-subunit protein, that is, the enterostatin receptor in the plasma membrane, where it is associated with lipid rafts. It was hence suggested that a perturbation of the ATP/ADP occurs by enterostatin, as observed in INS-1 cells,[2] which then increases cAMP concentrations and starts the downstream cell signaling. Thus, the activation of cAMP could initiate both acute events such as the oxidation of energy substrate molecules and more long-term events such as the regulation of hunger/satiety hormone expression.

Another component that is important for the enterostatin response is the presence of CCK-A receptors (Fig. 3). This occurs for the effects of enterostatin on food intake,[12] on memory,[20] and on blood cholesterol.[29] CCK is released by dietary fat reaching the intestine and reduces food intake through a CCK-A receptor. CCK causes a reduction in meal size and is dependent on afferent vagal nerves from the gastrointestinal tract to hypothalamic and extrahypothalamic forebrain regions to reduce food intake in a similar way as enterostatin. The interaction of enterostatin with the CCK-induced signaling is based on studies in the OLEFTA rat, which lacks CCK-A receptors.[12] This rat is unresponsive to enterostatin in contrast to the control LETO rat, where fat intake is reduced by 23% after enterostatin administration. Further support for the involvement of CCK-A receptor is the observation that lorglumide, a receptor antagonist specific for the CCK-A receptor, totally abolishes the enterostatin effect even though there is no binding of enterostatin to the CCK-A receptor, neither peripherally nor centrally. There are therefore several

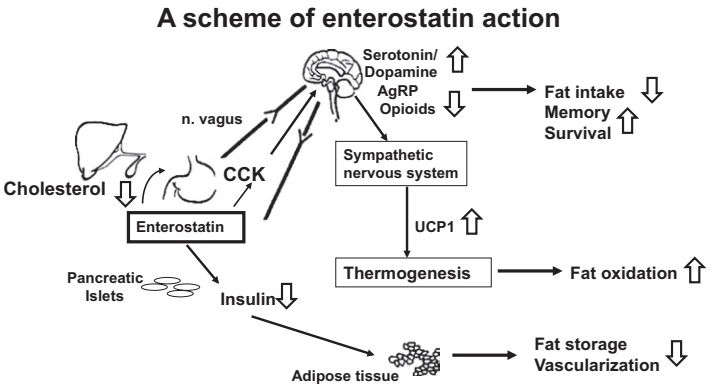

FIGURE 3 Effects of enterostatin: enterostatin is released from the intestine, where it activates CCK-dependent pathways to promote satiety, acting both peripherally to decrease gastric emptying and centrally to release serotonin. In this pathway, the vagal afferent nerves from the intestine to the brain is crucial. Regulation of fat intake by enterostatin further involves the stimulation of dopamine, suppression of AgRP, and suppression of the opioid system. In the islets, enterostatin inhibits insulin secretion, which is important for decreasing fat storage in the adipose tissue. At the same time, enterostatin stimulates thermogenesis through the activation of the sympathetic system and induction of UCP1, important for stimulation of fat oxidation. Low cholesterol levels occur through a CCK-dependent pathway. Enhanced memory by enterostatin is also dependent on CCK-pathways.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

possibilities to explain the enterostatin dependence on the CCK system.

One possible scenario is the influence of enterostatin on CCK-A-receptors present on vagal afferent neurons from the gastrointestinal tract to the brain and higher centers. This is further supported by the observation that vagal afferent neurons are necessary for the mediation of the reduction in fat intake by enterostatin. Another possibility is the release of CCK by enterostatin. The effect of enterostatin to suppress food intake during a longer period than CCK could be explained by a continued release of CCK in response to enterostatin. In the Sprague–Dawley rat, in which procolipase levels were increased through the administration of plant thylakoids,[1] there was also a strong release of CCK suggesting a parallel release between CCK and enterostatin, although the order of release is not known.

MECHANISM OF ENTEROSTATIN IN THE REGULATION OF FOOD INTAKE AND BODY WEIGHT REGULATION

The first experiments showing a specific effect of enterostatin as a regulator of fat intake were performed in Osborne–Mendel rats, rats that are specifically prone to eat fat.[7] In these, there was a dose-dependent reduction in fat intake but not on either protein or carbohydrate intake. In another experimental situation, Sprague–Dawley rats are given a free choice of a low-fat diet (5.2% fat by weight; 14.1% by energy) and a high-fat diet (17.8% fat by weight; 32.8% by energy) in separate containers. After injection of enterostatin into the lateral ventricle, the rats selectively decreased the intake of the high-fat diet by 45% ($p<0.005$), while the intake of the low-fat diet was unaffected compared with that in saline injected controls.[7] It was concluded that the effect of enterostatin to selectively inhibit fat intake is not specific to any special strain of rat. The experiments suggested that enterostatin could act as a feedback signal to regulate the intake of fat (Fig. 3). Dietary fat intake is also reduced after intragastric, intraduodenal, and intraperitoneal administration of enterostatin. The central administration of enterostatin near the celiac artery into the carotid artery likewise gives an immediate effect on feeding at low doses of enterostatin. The most sensitive nuclei to respond to enterostatin response are the PVN and amygdala, where enterostatin decreases meal size and duration.

The response in the gastrointestinal tract is dependent on vagal afferent signaling pathways, whereas the central effect is independent of vagal signaling, suggesting a local transmission of enterostatin signaling close to its production in the brain. By contrast, after intravenous administration of enterostatin a delayed effect on food intake is observed,[18] indicating that the targeting of enterostatin to its receptor protein in this situation is not an immediate process. Enterostatin binds to plasma proteins in the circulating blood, which might influence the response. Whether enterostatin is taken up by the blood–brain barrier to reach brain nuclei[10] after intravenous administration or whether it reaches a peripheral target is not known.

In another type of long-term treatment, rats are given a two-choice diet between high-fat diet and low-fat diet. After adaptation, the animals are chronically infused with enterostatin for 9 days (0.5 μg/h) or artificial cerebrospinal fluid (CSF) into the lateral ventricle of rats. Enterostatin reduces the intake of the high-fat diet with the maximum depression on day 4, without any compensatory increase in low-fat food intake.[7] The body weight of enterostatin-infused rats declines significantly and is associated with a reduction in fat pad and liver weight compared with that of the CSF-infused control rats.[7] Serum triglycerides and insulin are likewise decreased, whereas corticosterone is elevated in enterostatin-infused rats. These studies thus show that enterostatin reduces fat intake in long-term studies and that there is no overeating of the low-fat diet to compensate for the reduced food intake.

The appetite-regulating effect of enterostatin may occur through an involvement of serotonin-dependent pathways. In the presence of a serotonin receptor antagonist (5HT1b), the response of enterostatin is completely abolished.[14] Because enterostatin does not interact directly with a serotonin receptor, the mechanism of action could involve the ability of enterostatin to release serotonin.[9] Serotonin is released by 300% after enterostatin infusion into the lateral hypothalamic area, reaching a maximum 40 min after enterostatin administration. Serotonin may release the satiety hormone melanocyte-stimulating hormone (α-MSH) in the arcuate nucleus to suppress food intake.[11] In melanocortin receptor 4 (MC4R) knockout mice, enterostatin fails to influence satiety. Also the receptor antagonist SHU9119 essentially abolishes the inhibitory effect of enterostatin on food intake, suggesting that the melanocortin pathway is involved in the mechanism of enterostatin in suppressing fat intake.[11] Along the same lines, the long-term effect of enterostatin to reduce appetite for fat could be explained by the ability of enterostatin to decrease the expression of AgRP, a hunger signal specific for fat and interacting with the melanocortin receptor 4 in the amygdala and in the hypothalamus.[11]

There are also studies to suggest that enterostatin promotes the reuptake of dopamine to increase central striatal dopamine in rat.[34] This occurs only after 10 days of high-fat feeding and not after three days of high-fat feeding. High-fat feeding is known to impair the response of dopamine, and hence, enterostatin could act to prevent this downregulation of dopamine in this way promoting satiety for fat

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

intake.[34] Thus, it seems that enterostatin may act to enhance both serotonin and dopamine at different sites in the brain.

The appetite-regulating effect of enterostatin may also occur through an involvement of opioid-dependent pathways. This idea came through because of the similarity in the structure between beta-casomorphin, a digest product of casein with the structure YPFPGPI, and enterostatin with the structure APGPR, both peptides containing proline residues, each bridged by an amino acid. Although beta-casomorphin stimulates fat intake, this effect is inhibited by enterostatin. However, at high doses of enterostatin, there is a stimulation of fat intake, suggesting that the response occurs through two different receptors, one high-affinity receptor and one low-affinity receptor. Beta-casomorphin binds to the F1-ATPase β-subunit, and it was suggested that enterostatin stimulates the binding of beta-casomorphin to the low-affinity receptor by inducing a conformational change in the receptor.[22] The enterostatin response may also occur through the interaction of either the kappa or the mu receptor pathway, although there is no direct binding to these receptors. The kappa-opioid pathway is important for the specific regulation of fat intake, whereas the mu-opioid pathway is more related to basal preferences.

The unusual property of enterostatin is that the main formation of enterostatin occurs in the lumen of the intestine, where food digestion occurs and where other food-derived peptides might form. This property justified experiments in which administration of enterostatin was mixed with food. In one such study, female NMRI mice were fed a high-fat diet with and without enterostatin (116 μg added per gram food) for 25 days, during which body weight and food intake were measured.[25] Food intake and body weight were significantly reduced in the animals receiving enterostatin added to food, showing that the action of enterostatin could really take place through the intestine. In these experiments, brown adipose uncoupling protein expression was measured and found to be elevated in the enterostatin-treated animals. This suggests that the decreased body weight is not only a consequence of a decreased food intake but also an increased diet-induced thermogenesis[25] (Fig. 3). The achievement of energy balance is dependent on the ambient temperature. At a temperature (24 °C), below the isothermal temperature for the mice (27 °C), the animals could increase energy expenditure and stay in energy balance when fed a high-fat diet, whereas at an ambient temperature of 27 °C, the animals failed to increase their expression of uncoupling proteins even during enterostatin treatment and hence became obese during high-fat feeding.[25] For enterostatin to increase energy expenditure, the ambient temperature must be lower than the isothermal temperature.[26]

Whether enterostatin has any importance for human body weight regulation and metabolism is not known. By investigation of the enterostatin precursor gene, procolipase including its promotor, it was found that reduced insulin secretion after an oral glucose test in nondiabetic humans was significantly associated with procolipase gene polymorphism.[31] This observation suggests that the procolipase/enterostatin gene might be a candidate gene for development of type-2 diabetes.[31]

The fact that fatty acid oxidation by enterostatin may be important under extreme conditions has been suggested by mice living in constant darkness.[35] In mice experimentally adapted to living in the dark 24 h a day, an increased expression of the procolipase gene is observed. This is increased not only in the gastrointestinal tract but also in the liver, brain, and adipose tissue, thus also showing ectopic expression.[35] Animals living in the dark must be able to recruit energy from their energy stores. It is concluded that these animals have an enhanced fatty acid oxidation and also a curbed appetite though the action of enterostatin/procolipase being overexpressed. Enterostatin/procolipase may be important in hibernating animals to sustain the burning of fat.

EFFECTS OF ENTEROSTATIN OTHER THAN FEEDING EFFECTS

Enterostatin displays various effects, including lowering of blood cholesterol, reduction of angiogenesis, regulation of protein trafficking, regulation of analgesia, and stimulation of memory (Table 2). Whether these are essential for feeding effects is not known but may be due to an interaction of enterostatin with several hormone systems or receptors, remembering the ability of small molecules to interact both specifically and nonspecifically with various receptors that by virtue of quantity can result in significant effects.

The effect of enterostatin to reduce blood cholesterol seems to be important because enterostatin knockout mice show significantly increased serum cholesterol levels.[19] This reduction in cholesterol levels occurs independent of the food suppressive effect of enterostatin and is dependent on cholecystokinin action.[29] The mechanism may be a stimulation of bile salt excretion into the feces by enterostatin, and after this, a conversion of cholesterol to bile salt resulting in reduced serum cholesterol levels takes place.[28]

Enterostatin also reduces angiogenesis, which may be important in reducing fat tissue[23] (Fig. 3). Adipose tissue is a highly vascularized tissue that has the capacity to expand throughout life. Some studies suggest that blocking of angiogenesis in the adipose tissue can help to induce loss of fat mass. By using angiogenic blockers in obese mice, loss of body fat has been induced. In human obesity, several angiogenic factors are increased in the circulation, including VEGF A, C, and D as well as the inflammatory cytokine interleukin-6 and insulin. In liver cells (Hep G2 cells), enterostatin inhibits angiogenesis through the suppression of angiogenic factors such as VEGF.[23] It is possible therefore

TABLE 2 Properties of Enterostatin

Effects	Reference
Satiety for fat	7
Receptor: Beta-subunit F1-ATPase	2,22
Receptor increased by high-fat diet	15
Reduction of insulin	2
Reduction of serum cholesterol	29,18
Stimulation of fatty oxidation and thermogenesis	4,25
Promotion of memory	20
Promotion of antianalgesia	30
Inhibition of angiogenesis	23
Regulation of protein trafficking	21

that this antiangiogenic effect of enterostatin may contribute to the loss of adipose tissue that is observed after enterostatin administration. The release of fatty acids increases the availability for fatty acids to be oxidized.

Enterostatin can also act as a regulator of protein trafficking.[21] This could explain the inhibition of insulin secretion, where enterostatin causes a downregulation of the proteins needed for insulin sorting, such as dynamin2 (Fig. 3). Hence, enterostatin by virtue of its structure or small size could act as a regulator in many different ways.

Enterostatin has an antianalgesic effect in mice, suggesting that enterostatin acts as an antiopiate[28] (Fig. 3) (see the Antiopioid chapter in the Opioid Peptide section of this book). There is no direct binding of enterostatin to the mu receptor to explain the antianalgesic effect. Instead, this occurs through a CCK-receptor-dependent action, the CCK-receptor antagonist Lorglumide being able to totally abolish the antianalgesic effect of enterostatin.[29] Taken together, a variety of central actions of enterostatin, such as anorexia and antianalgesia seem to be mediated through a CCK-dependent mechanism.

Enterostatin has been reported to stimulate memory in mice after both central and oral administration shown in a step-through-type passive avoidance test.[20] In this, test mice are made to enter a dark room and are subjected to an electric shock. The latency to enter this room is measured with and without enterostatin. The memory-enhancing activity of enterostatin is completely blocked by a CCK-receptor antagonist lorglumide. Because enterostatin does not interact with the CCK receptor, enterostatin may release CCK, which activates the receptor. Several anorexic peptides have been shown to enhance memory, such as CCK, leptin, and CRH (discussed elsewhere in this book); thus, enterostatin is another example of such an activity. Because enterostatin has an effect through oral administration, it is possible that food that releases enterostatin may promote memory.

ACKNOWLEDGMENTS

The author's research on enterostatin and the regulation of fat intake has been possible through grants from the Swedish Medical Research Council (VR), Vinnova, FORMAS, and Crafoord Foundation, to whom the author expresses gratitude.

Chapter 147

Galanin

Jessica R. Barson, Irene Morganstern and Sarah F. Leibowitz

ABSTRACT

Galanin (GAL) plays an important role in stimulating ingestive behavior, acting particularly through the paraventricular nucleus of the hypothalamus (PVN). This peptide exhibits a special relationship with dietary fat and alcohol, stimulating the ingestion of these two substances and being stimulated by them. A large number of signaling molecules interact with GAL, including hormones, neuropeptides, and monoamines, but lipids and inflammatory cytokines show a particularly strong relationship with GAL, possibly mediating the interaction of fat and ethanol with this peptide. Although GAL may have provided an evolutionary advantage by specifically promoting intake of the most energy-efficient macronutrient, fat, it has taken on a nonhomeostatic role in the present-day environment, promoting not only overconsumption of dietary fat but also of the drug alcohol.

INTRODUCTION

Galanin (GAL) is a 29–30 amino acid peptide that is well-conserved among species, including rats and humans.[26] It is widely distributed throughout the brain, including the emotion-regulating amygdala and the feeding-regulating hypothalamus.[4] Within the hypothalamus, GAL is expressed in many neuronal populations, including the paraventricular nucleus (PVN), dorsomedial nucleus, and arcuate nucleus. This peptide is involved in many physiological and psychological processes, including pain, epilepsy, and depression; however, it is also important in ingestive behavior, which is the focus of this review.

EFFECTS OF GALANIN INJECTION ON INGESTIVE BEHAVIOR

The peptide GAL stimulates feeding, primarily through its actions within the hypothalamus. The first study to examine these effects found that acute hypothalamic injection of GAL stimulated food intake in rats.[24] Although this effect is smaller than that seen with the potent orexigenic hypothalamic peptide, neuropeptide Y, it is robust and has since been replicated in multiple studies.[26] This stimulatory effect of GAL on food intake is strongest with injection in the medial parvocellular division of the PVN and sharply diminishes in magnitude as the injection site moves to the lateral PVN and then beyond this nucleus in all directions.[26] Galanin can, however, increase food intake with injection in a limited number of nuclei outside of the hypothalamus, including the central nucleus of the amygdala and, under certain conditions, in the hindbrain nucleus of the solitary tract and the lateral parabrachial nucleus.[4]

The specific orexigenic effects of GAL injection have primarily been examined with the macronutrients and with ethanol. With regard to macronutrients, GAL's effects are most strongly linked to fat. Although injections do not affect the preference for pure fat over carbohydrate, protein, or laboratory chow, the GAL-induced feeding response is stronger and more prolonged in subjects maintained on a high-fat (compared with those on a low-fat) diet and also in strains of rats that naturally prefer fat.[4,26] The intake of fat is reduced by PVN injection of the general GAL antagonists, C7, galantide, and M40 and by repeated PVN injections of antisense oligonucleotides to GAL mRNA, which decrease GAL peptide levels.[26] Chronic injections of GAL cause rats to overeat and eventually become overweight but only if the diet contains at least 30% fat.[26] This special relationship with fat is consistent with the idea that GAL may be involved in the large meal size and overeating that occurs when fat-rich foods are available.

Of other ingested substances examined for their relationship with GAL, alcohol intake shows the most robust stimulation by GAL injection. In rats, injection of GAL into the PVN or adjacent third ventricle enhances the drinking of ethanol at a variety of concentrations, in the dark or light and with or without food concurrently available.[4] The opposite effect occurs with injection of the GAL antagonist M40 into these regions.[4] and peripheral injection of the specific GAL 3 receptor antagonist SNAP 37889 decreases operant responding for ethanol.[2] As with fat, the GAL-induced ethanol drinking response is strongest with injection in the PVN and in fact has not been found to occur with injection in other areas of the hypothalamus or outside of the

hypothalamus.[4] Aside from ethanol and fat, the effect of GAL injection on the ingestion of other substances has only been reported in one study which found operant responding for both sucrose and saccharin to be decreased by the same peripheral GAL 3 receptor antagonist that decreased operant responding for ethanol.[2]

Endogenous GAL also drives fat and ethanol intake. Gene expression and GAL peptide levels are increased in the anterior parvocellular region of the PVN during food deprivation, when the drive for fat intake is exacerbated.[4] In free-feeding rats, hypothalamic GAL reaches peak levels during the middle of the feeding cycle, when the preference for fat naturally rises.[26] Elevated hypothalamic GAL has also been described in strains of rodents, both rats and mice, which have a strong, natural preference for fat, even if they do not have access to a high-fat diet. These include multiple lines of inbred mice, obese Zucker rats, and Brattleboro (di/di) rats.[4] Interestingly, Brattleboro rats drink more ethanol than controls do.[29]

GENETIC MANIPULATION OF GALANIN

Genetic manipulation of GAL in mice has yielded further support for the stimulatory effect of this peptide on fat and ethanol intake and has further confirmed the specificity of this relationship. Mice with deletions of the GAL gene consume less fat both with chronic access and in acute meal tests, and they show a decreased preference for fat compared with that of littermate wild-type controls.[4] Mice missing the GAL 1 receptor also consume less fat than wild-type mice do.[4] By contrast, mice that overexpress GAL consume more of a high-fat diet compared with wild-type controls.[4] Similarly, GAL knockout mice drink less ethanol and show a lower preference for ethanol than wild-type mice do, whereas GAL overexpressors drink more and show a higher preference.[4] These changes in ingestive behavior seem to be specific to dietary fat and ethanol. Neither GAL knockout nor GAL overexpressing mice show differences in sucrose or quinine preference,[4] and GAL knockout mice also show no difference in overall cocaine self-administration.[10] Further, despite substantial evidence that hypothalamic GAL injection stimulates the intake of laboratory chow, GAL knockouts and overexpressors consume chow at the same levels as wild-type mice and consequently have similar body weight when maintained on a low-fat diet.[21] Therefore, studies with genetically manipulated mice suggest that GAL drives ingestive behavior specifically of fat and ethanol.

EFFECTS OF INGESTIVE BEHAVIOR ON GALANIN

In addition to driving fat and ethanol intake, GAL expression and levels are also increased by the intake of these substances, suggesting that GAL exists as part of a nonhomeostatic, positive feedback loop that can promote excessive fat or ethanol intake. With regard to the macronutrients, consumption of a diet high in fat compared with one high in carbohydrates or a balanced, control diet for 1–4 weeks stimulates gene expression and peptide production of GAL in the PVN.[3,4] This is seen particularly in the anterior and middle parvocellular regions of this nucleus, where GAL is positively correlated with the amount of fat consumed.[3,4] Moreover, outbred rats made obese by their diet also have elevated GAL expression in the PVN, although only if the diet contains a sufficient amount of fat rather than carbohydrate.[4] Conversely, pharmacological blockade of fat oxidation reduces the PVN expression of GAL and stimulates PVN gene expression of the GAL 1 receptor.[4] Thus, in addition to stimulating fat ingestion, the intake of dietary fat, through signals arising from fat oxidation, itself stimulates the production of GAL.

These effects of dietary fat intake in adults can also be seen in the offspring of dams that consumed a fat-rich diet during pregnancy. Gene expression and peptide levels of GAL in the PVN are elevated at birth and through adulthood in rats prenatally exposed to a diet high in fat as compared with a carbohydrate-rich or balanced, control diet.[5,11] This effect is probably specific to the macronutrient fat, as it does not occur with prenatal exposure to a high-carbohydrate, low protein diet compared with a balanced diet.[7] The effect of fat seems to occur by stimulating the proliferation and differentiation of developing neurons that ultimately express GAL in the PVN.[11] As expected from animals with higher levels of GAL, these fat-exposed offspring also show a higher preference for fat after puberty.[11] Thus, exposure to fat *in utero* reprograms the brain to express GAL at higher levels over the long term which can then lead animals to ingest excessive amounts of dietary fat.

In addition to fat, the ingestion of ethanol also stimulates GAL expression and levels in the PVN. This occurs in adults with chronic drinking or acute ethanol injection and, like fat, is seen preferentially in the anterior and medial portions of the PVN.[4,12] Ethanol drinking also correlates with hypothalamic gene expression of the GAL 1 receptor.[4] These studies suggest that GAL functions in a positive feedback loop with ethanol, just as it does with fat.

ROLE OF GALANIN RECEPTORS

The peptide GAL can interact with any of three G-protein-coupled receptors, GalR1, GalR2, or GalR3, all of which are expressed within the hypothalamus.[32,33] Although GalR1 and GalR3 are believed to be G_i/G_o-coupled receptors, GalR2 seems to be coupled to a G_q/G_i-mediated pathway.[32,33] The evidence to date suggests that it is the GalR1 that mediates the role of GAL in fat intake, whereas GalR1 or GalR3 may mediate its role in ethanol intake. Mutant mice lacking the GalR1 gene consume fewer calories than

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

wild-type mice when fed a high-fat rather than low-fat diet,[4] and ventricular injection of the specific GalR1 agonist M617 stimulates outbred rats to ingest more high-fat milk.[30] Expression of GalR1 is also higher in the PVN of fat-preferring Brattleboro rats[25] as well as after one week of high-fat compared with balanced diet intake in outbred rats.[3] By contrast, food intake is no different between GalR2 knockout and wild-type mice,[18] and intake of neither high-fat milk nor cookie mash is altered by ventricular injection of any of the several GalR2 agonists.[30] With ethanol intake, GalR1 expression in the hypothalamus correlates with ethanol drinking.[4] In support of the role of the GalR3, peripheral injection of the GalR3 antagonist SNAP 37889 decreases operant responding for ethanol, although it also reduces it for sucrose and saccharin.[2] Although more studies need to be conducted on the role of the GAL receptors in ingestive behavior, the available evidence supports a strong role of GalR1 in fat and possibly ethanol intake and also points to a role for GalR3 in ethanol intake.

EFFECTS OF HORMONES ON GALANIN

The positive feedback loop between fat intake and GAL may be mediated, in part, by reproductive hormones. In female rats, fat ingestion stimulates circulating levels of estrogen and progesterone.[4] In addition, it increases GAL levels not only in the PVN but also in the median eminence, the medial preoptic nucleus just anterior to the PVN and in the nearby anterior pituitary. Notably, in ovariectomized females, GAL expression and levels in the hypothalamus and anterior pituitary are stimulated by injection of estradiol in a dose- and time-dependent manner, and they are stimulated even further by progesterone replacement after estrogen priming.[4] Also, in intact females, GAL peptide levels increase in the anterior parvocellular PVN, median eminence and medial preoptic nucleus during proestrus, a time when estrogen and progesterone levels naturally increase.[4] Notably, the preference for fat also increases in females during proestrus and is found to be greater in female rats with higher GAL than in males.[4] Although the regulation of GAL by estrogen and progesterone has received a great deal of attention, GAL may also be regulated by reproductive hormones in males. Hypothalamic GAL gene expression in castrated male rats is increased by treatment with either estrogen or testosterone.[14]

The relationship between fat intake, sex steroids, and GAL can also be seen in female rats during puberty. Although GAL levels steadily increase in the hypothalamus starting as early as day 15 of gestation, greater levels are not seen in females compared with that of males until puberty.[17] It is during this time (around day 40 in rats) that females begin to show an increase in their preference for fat.[4] In rats examined at different ages before (day 30) and after (days 45 and 60) puberty, this rise in fat intake is associated with a marked increase, from days 30 to 45, in the levels of estradiol and progesterone and also in GAL mRNA or peptide levels, specifically in the PVN and medial preoptic nucleus but not in other hypothalamic areas.[4] This positive relationship between increased fat intake, sex steroids, and GAL across ages is also evident in pubertal rats that naturally prefer fat (>25% of total diet) compared with those consuming little fat (<15%) or rats that reach puberty at an early age (days 30–34) compared with those that are late (days 37–40). These rats with early puberty onset exhibit a strong fat preference 3–4 days before vaginal opening, which is positively related to steroid levels, GAL, fat intake and also with body fat accrual after puberty.[4] These findings suggest that one signal for puberty onset may involve a surge in steroids that stimulate GAL to increase fat intake in females.

INTERACTIONS BETWEEN GALANIN AND OTHER OREXIGENIC TRANSMITTERS

The stimulatory effects of PVN GAL on fat intake may occur through interaction with any of a number of other orexigenic neurochemicals, including neuropeptide Y (NPY), norepinephrine (NE), dopamine (DA), and the opioid peptide enkephalin (ENK). Although NPY is produced in many areas of the brain, it exerts its potent feeding effects predominantly through transcription in the arcuate nucleus and release within the hypothalamus.[26] In contrast to GAL, NPY is more closely linked with carbohydrates rather than fat. Injection of NPY into the PVN stimulates ingestion of a high-carbohydrate diet in preference to a high-fat or high-protein diet,[27] while ingestion of a carbohydrate-rich diet increases levels of NPY specifically in the parvocellular area of the PVN.[23,34] Although GAL has been found to stimulate NPY secretion from primary hypothalamic neurons in culture,[9] inhibitory NPY axons projecting from the arcuate nucleus also surround and make contact with GAL cells in the PVN.[22] These findings imply that GAL stimulates NPY but that NPY in turn inhibits GAL. This negative feedback by NPY suggests that the ingestion of carbohydrates by stimulating NPY may, by inhibition of GAL, causes a reduction in subsequent fat intake. Notably, the same high-carbohydrate meal that stimulates NPY levels in the PVN also reduces GAL in this nucleus.[34] Further, Brattleboro di/di rats, which consume more fat and less carbohydrate and have higher expression of PVN GAL, also have lower NPY levels in the PVN.[6]

With NE, PVN GAL may work in part by stimulating this neurochemical. The injection of NE in the PVN produces a rapid feeding response in satiated rats,[4] which is comparable in magnitude to that induced by GAL.[4] With both GAL and NE, the PVN is the nucleus that yields the strongest effect on feeding, as most other brain areas are generally unresponsive.[4] In addition to GAL coexisting

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

with NE in cells of the PVN, GAL also seems to stimulate NE release. Injection of GAL into the PVN increases levels of NE in this nucleus by nearly 90%, whereas GAL-induced feeding is inhibited by an α_2-noradrenergic receptor antagonist or a compound that inhibits NE synthesis.[4] The stimulatory effect of GAL on food intake may thus be due, in part, to downstream effects on NE release.

Another downstream effect of GAL activity may be an increase in mesolimbic DA levels. The ventral tegmental area, which contains the dopaminergic cell bodies that project to the nucleus accumbens (NAc), expresses all three GAL receptor types, and GAL binding in this area has been demonstrated with autoradiography.[4] Local application of GAL in the ventral tegmental area enhances the accumulation of DA metabolites in the striatum, indicating an increase in the rate of DA synthesis.[4] Importantly, PVN injection of GAL increases extracellular levels of DA in the NAc shell, and it does so only in animals that, on separate test days, show a feeding response to PVN GAL.[4] This DA conveys signals of the incentive-motivational properties of a reward such as a meal high in fat or a drink of ethanol.[4] These results suggest that GAL in the PVN stimulates ingestive behavior, in part, by increasing accumbal DA levels. Interestingly, just as ingestion of a high-fat diet or ethanol stimulates GAL in the PVN, they also increase levels of DA in the NAc shell.[4] Therefore, GAL may stimulate NAc DA release, to enhance not just the consumption of fat and ethanol but also the motivational aspects of their consumption.

Evidence also strongly suggests that GAL stimulates ENK within the hypothalamus. As with GAL, ENK has its strongest feeding effects in the PVN, and the injection of ENK analogs stimulates consumption of a high-fat over a high-carbohydrate diet as well as ingestion of ethanol over food or water.[4] Administration of ENK analogs into the PVN, much like GAL, also increases levels of DA in the NAc shell.[4] Similar to that occurring with NE, injection of GAL just dorsal to the PVN stimulates expression of ENK in this nucleus,[4] which may occur through GalR1-induced inhibition of the many γ-aminobutyric acid-containing neurons in the PVN.[3] Galanin-induced fat intake in particular seems to be driven by its effects on PVN ENK. Not only can fat ingestion induced by GAL injection be blocked by pretreatment with peripheral or central injection of the general opioid antagonist, naloxone, or by a mu-opioid receptor antagonist[4] but also fat intake induces the co-expression of GAL and ENK within the same parvocellular neurons of the PVN.[3] This suggests that, within the hypothalamus, GAL stimulates and may act in concert with PVN ENK.

Outside of the hypothalamus, the relationship between GAL and ENK is less straightforward. In mice lacking the GAL gene, drug reward is decreased[28] while symptoms of withdrawal from the general opioid agonist morphine are increased.[4] In contrast, morphine withdrawal is lessened in GAL overexpressing mice or by centrally administered GAL or the GAL agonist, galnon, in wild-type mice.[4] These differences seem to result from transcriptional changes in mesolimbic regions, including the NAc and amygdala where, for example, morphine increases CREB phosphorylation in GAL knockout but not in wild-type mice.[19] Although GAL outside of the hypothalamus may antagonize the effects of the opioids, it may also simply be acting to replace them.

CLOSE RELATIONSHIP BETWEEN GALANIN AND CIRCULATING LIPIDS

The particular relationship of GAL with fat and ethanol may be mediated in part by circulating lipids, specifically triglylcerides (TG). Fat and ethanol both increase levels of circulating TG when taken acutely or chronically.[4] With fat, this occurs in direct proportion to the amount consumed, with TG levels rising higher and remaining elevated for longer periods after fat-rich meals[4] and with diets higher in saturated compared with unsaturated fat.[3] Behaviorally, there is also a close, positive relationship between fat and ethanol ingestion that, in turn, may be associated with circulating TGs. Rats maintained on a high-fat diet or exhibiting a preference for fat are found to consume more ethanol.[4] Similarly, injection of ethanol preferentially stimulates ingestion of fat relative to carbohydrate.[4] Clinical studies show that fat intake is greater in ethanol drinkers, with bingeing on fat-rich foods associated with high rates of alcohol use disorder and drinkers on a fat-rich diet compared with a carbohydrate-rich diet exhibiting shorter periods of abstinence from ethanol.[4] In support of the idea that TG mediates this relationship, there is evidence that ethanol consumption is stimulated by the lipid emulsion Intralipid, which increases TG levels[4] and is reduced by the fibrate drug, gemfibrozil, which lowers them.[4] In addition, whereas dietary fat and ethanol both elevate TG levels, their consumption together produces a considerably larger increase in TGs than does the ingestion of ethanol with a low-fat diet or of a fat-rich diet without the intake of ethanol.[4]

This interaction between fat, ethanol, and TGs may operate centrally through effects on PVN GAL. In recent studies, GAL in the PVN has been found to be strongly, positively related to circulating levels of TG.[4] This relationship with GAL is robust, seen in different models of dietary obesity and even with acute exposure to a high-fat diet, supporting its independence from changes in body weight and adiposity-related hormones. Further, it is seen with both acute and chronic ingestion of a diet high in saturated, compared with unsaturated fat[3] suggesting that GAL is particularly associated with saturated fatty acids. Injection of Intralipid, which increases TG levels, also stimulates GAL expression in the PVN.[4] Although TGs themselves may not have a direct effect on GAL gene expression, fatty acids from the hydrolysis of TGs can cross the blood

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

brain of barrier to exert central effects. Although not yet examined with GAL, short-chain fatty acids have been shown to regulate gene expression of ENK[4] that, as described above, acts in close relation to GAL. Although fatty acids from TGs may stimulate GAL, this relationship may also work in reverse, with PVN GAL increasing TG levels. Rats and mice that exhibit a preference for fat, compared with those preferring carbohydrate, have higher levels of circulating TGs in addition to elevated GAL in the PVN.[4] Further, transgenic mice that overexpress GAL have a ten-fold increase in circulating TG levels, even when maintained on a low-fat chow diet and not overeating this diet.[4] The relationship between TGs and GAL, just as with fat or ethanol and GAL, may therefore, be bidirectional, forming part of a positive feedback loop that can lead to escalating fat or ethanol intake.

ROLE OF INFLAMMATION IN INCREASED GALANIN

The relationship of GAL with fat and ethanol may also be associated with inflammation, specifically inflammatory cytokines. Levels of interleukin-1 beta (IL-1β), interleukin-6 (IL-6), and tumor necrosis factor-alpha (TNF-α) have been found to increase in the hypothalamus after chronic high-fat feeding[13] or acute ethanol administration.[15] Not only are receptors for these cytokines transcribed within the PVN[8] but the parvocellular PVN, where GAL is most significantly affected by fat and ethanol, is also particularly stimulated by the cytokines.[16] Compellingly, GAL gene expression in cultured cells is stimulated by the application of IL-1β or TNF-α.[1] indicating that cytokines induced by fat or ethanol may directly stimulate GAL transcription. An increase in PVN GAL may be necessary for proper responding to cellular damage induced by fat or ethanol ingestion. The normal neurogenic inflammatory response to injury or TNF-α application to the skin is absent or greatly diminished in GAL knockout compared with wild-type mice.[31] Although still preliminary, this evidence points to a specific role for inflammation and inflammatory cytokines in mediating the stimulation of GAL by dietary fat and ethanol.

CLINICAL SUPPORT

Although far less numerous than the animal studies, several clinical studies have also examined GAL in relation to fat and alcohol, and they generally support the animal work. Consistent with the increase in GAL after fat intake or potentially with its stimulation of fat intake, GAL peptide is elevated in the serum of obese menopausal women, whereas it is reduced in the cerebrospinal fluid of recovered anorexic women.[4] Just as with animals, however, it does not seem to be directly related to body weight *per se*. No allelic differences in the GAL or GalR1 genes have been found in obese children or adolescents compared with healthy underweight young adults, and, perhaps not surprisingly, no association has been detected between obese phenotypes and GalR2.[4] In support of the idea that circulating TG may be related to an increase in GAL, the Rs2187331 allele, which resides in promoter regions of the GAL gene, has recently been associated with increased circulating levels of TG.[4] Emerging evidence also supports a role for GAL in alcohol intake. Single-nucleotide polymorphisms on the GAL and GalR3 genes have been associated with alcoholism in adult men.[4] Intriguingly, a recent study has found that the levels of serum GAL are lowest immediately after ethanol discontinuation in alcohol-dependent patients and are negatively correlated with alcohol craving.[20] Although these results may suggest that alcohol intake can inhibit GAL, they could also indicate that drinking, by potently stimulating GAL release, may in long-time drinkers cause a depletion of GAL stores.

SUMMARY AND CONCLUSIONS

The peptide GAL plays an important role in stimulating ingestive behavior, largely acting through the hypothalamus and particularly through the parvocellular PVN. Injection of GAL into this nucleus stimulates the intake of diets high in fat and also the drinking of ethanol, whereas GAL antagonists inhibit these behaviors. Endogenously, hypothalamic GAL expression and levels increase during fasting and in the middle of the feeding cycle when the preference for fat is higher, and they are also elevated in rats and mice that prefer fat. Genetic knockout of GAL diminishes fat and ethanol intake, while overexpression specifically increases it. In turn, the intake of fat or ethanol, whether acute or chronic, during adulthood or *in utero*, further stimulates PVN GAL, acting through a positive feedback loop than can escalate fat and ethanol intake. These effects seem to occur largely through the GalR1, but the effects with ethanol may also be through the GalR3. A large number of signaling molecules interact with GAL, including hormones, neuropeptides, monoamines, lipids, and cytokines. In females, estrogen and progesterone, which are increased during proestrus and at puberty, stimulate hypothalamic GAL and, in turn, increase fat intake. Galanin stimulates the potently orexigenic NPY but is itself inhibited by it, which may be one mechanism for curtailing the positive feedback between GAL and fat intake. Instead, PVN GAL may work in part by stimulating the release of hypothalamic NE and accumbal DA, which can increase the motivational aspects of fat and ethanol intake. In addition, GAL stimulates the opioid peptide ENK within the PVN and may act in concert with ENK in response to fat intake. The specific relationship of GAL with fat and ethanol suggests that these two ingested substances share a special relationship. Indeed, the intake of one can increase the intake of the other, and this may

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

occur through stimulation of the circulating lipids, TGs. Not only does an increase in TGs lead to higher expression of PVN GAL, but also higher GAL may lead to higher TGs, suggesting that a bidirectional relationship exists between these two molecules. In addition to lipids, inflammatory cytokines may also stimulate PVN GAL. Levels of cytokines are increased in the hypothalamus after high-fat or ethanol exposure, and they have been shown in culture to stimulate GAL expression. Although the majority of this work has been conducted in rats and mice, clinical studies largely support these findings. In an environment with limited food availability, GAL may have provided an evolutionary advantage by promoting the intake of fat, which is the most energy efficient of the macronutrients. In the present-day environment, where fat-rich foods are abundant and alcohol is widely available, GAL has taken on a non-homeostatic role, promoting not only overconsumption of dietary fat but also of the drug alcohol.

Chapter 148

Ghrelin

Omar Al-Massadi, Kristy M. Heppner, Rubén Nogueiras, Diego Pérez-Tilve and Matthias H. Tschöp

ABSTRACT

Ghrelin is the only known circulating hormone with strong orexigenic activity. No other peripheral endocrine agent has comparable effects on hunger and energy balance. Although the first evidence of the contribution of ghrelin to the control of food intake was obtained soon after its discovery, the precise mechanisms whereby ghrelin regulates feeding have remained largely unknown. However, recent reports have begun to provide novel insights into the effects of ghrelin on feeding behavior and their neuroanatomical pathways and molecular mechanisms underlying such effects. Because of this, the current view about the role of ghrelin in the control of food intake is substantially more complex than that initially expected. This chapter summarizes the role of ghrelin in regulating multiple aspects of feeding behavior.

GHRELIN REGULATES FEEDING BEHAVIOR ACROSS SPECIES

Although ghrelin was discovered as the endogenous ligand for an "orphan" G protein-coupled receptor (GPCR) involved in the secretion of growth hormone, the growth hormone (GH) secretagog receptor (GHSR-1a), it was soon shown that, in addition to its effect as a GH secretagog, ghrelin plays a role in the control of energy balance. Thus, the administration of ghrelin, either directly into the brain or in the periphery, induces a solid increase in orexigenic activity that results in body weight gain if the treatment is maintained chronically.[17]

One reason that ghrelin receives substantial recognition as a potentially important coregulator of energy balance is that its genomic sequence and its effect on food intake are well preserved across numerous species.[17] Ghrelin influences feeding-related behavior in several species including non-mammals such as goldfish and chicken,[14] and different species of mammals including species with commercial value for the food industry such as sheep, cattle,[24] and swine.[9] Although ghrelin increases feeding in most of the species tested, intracerebroventricular injection of ghrelin reduces food intake in chicken and Japanese quail. Interestingly, peripheral administration of relatively low doses of ghrelin increases feeding in quail.[14] Altogether, these results suggest that ghrelin contributes to the regulation of feeding behavior by multiple mechanisms and through both central and peripheral sites of action.

The role of ghrelin in the control of feeding behavior relates to more than an actual increase of ingested calories. For example, although Siberian hamsters do not develop a marked increase in food intake after ghrelin administration, they exhibit significantly increased foraging and food hoarding behavior.[3] Another activity intimately associated with feeding behavior regulated by ghrelin is olfaction. The olfactory bulb expresses ghrelin receptors and intracerebroventricular administration of ghrelin decreases odor detection thresholds and increases sniffing frequency in rats. In humans, intravenous infusion of ghrelin enhances sniffing without affecting the pleasantness ratings of odors.[28] Finally, ghrelin is involved in the control of digestive processes such as gut motility and gastric acid secretion that may condition feeding behavior. See the chapter on ghrelin in the Gastrointestinal Peptides section of this book, as well as the Brain, Endocrine, and Cardiovascular Peptides sections.

Importantly, ghrelin administration in clinical studies causes an increase in food intake or hunger sensation in both healthy human volunteers and patients with feeding disorders such as anorexia nervosa.[35] In humans, ghrelin stimulates food intake in both lean and obese subjects, although obese but not lean patients report an increase in the palatability of food after ghrelin infusion.[11] These findings are of substantial importance because there are many known peripherally circulating satiety hormones (e.g. cholecystokinin, PYY, leptin, GLP-1, oxyntomodulin) but only one hunger-inducing hormone.

Ghrelin is still the only known circulating peptide with considerable orexigenic potency. However the specific aspects of feeding behavior that are physiologically regulated by changes in plasma ghrelin levels are still being investigated.

THE GROWTH HORMONE SECRETAGOG RECEPTOR GHSR-1A MEDIATES GHRELIN-INDUCED FOOD INTAKE

Results obtained from a series of studies with the endogenous GHSR-ligand ghrelin are consistent with earlier reports published throughout the previous decade, in which several synthetic ligands of the GHSR-1a were found to increase food intake in rodents. This list includes for example, growth hormone releasing peptide-2 (GHRP-2), ipamorelin, GHRP-6, hexarelin, and several other GHSR-1a ligands.

GHSR-1a-KO mice treated with ghrelin do not experience an increase in food intake when compared with wildtype littermates, indicating that GHSR-1a is the essential mediator of this pathway for this phenomenon.[17] The GHSR-1a expression pattern as identified in rodents includes many brain areas involved in the control of food intake.[17] More evidence for the important role of the GHSR-1a receptor in the control of food intake comes from genetically modified rats that overexpress antisense mRNA against the GHSR-1a under the control of the promoter for tyrosine hydroxylase (TH). These rats lack GHSR-1a selectively in the hypothalamic arcuate nucleus and do not respond to GHS with increased food intake as observed in their wildtype littermates.[17] Overall, these transgenic rats show less food intake and lower body weight as well as fat levels in the first weeks after weaning indicating that the GHSR-1a might have an endogenous role in energy balance regulation.

In addition to the interaction with ghrelin, GHSR-1a activity is modulated by heterodimerization with other GPCRs.[15,23] Hypothalamic neuropeptide Y (NPY)/agouti-related peptide (AgRP) neurons coexpress GHSR-1a and melanocortin-3 receptor (MC3R). The MC3R promotes orexigenic activity acting as an inhibitory autoreceptor on proopiomelanocortin (POMC) neurons.[6] *In vitro* studies confirmed that GHSR-1a heterodimerizes with MC3R in neurons of the arcuate nucleus of the hypothalamus (ARC).[23] Functional studies showed that MC3R ligand (alpha-MSH) binding to MC3R-GHSR-1a heterodimer enhances the downstream signaling of MC3R. By contrast, the heterodimer complex diminishes the basal constitutive activity of GHSR-1a. GHSR-1a also heterodimerizes with the dopamine receptor subtype-2 (DRD2) in hypothalamic neurons.[15] To explore the function of the GHSR-1a-DRD2 heterodimer, wildtype, ghrelin−/−, and ghsr−/− mice were treated with a DRD2 agonist, cabergoline. Interestingly, the anorexigenic effect of cabergoline occurred in both wildtype and ghrelin−/− mice; however, a decrease in food intake was not observed in ghsr−/− mice indicating that GHSR is essential for DRD2-induced anorexia. Further, pharmacological GHSR-1a antagonism blocks dopamine signaling in neurons coexpressing DRD2 and GHSR-1a.[15] Mice pretreated with the GHSR-1a antagonist did not experience a decrease in food intake on administration of cabergoline. Taken together, these studies provide novel insight into GHSR-1a receptor signaling and highlight an important interplay between multiple GPCR signaling pathways. Importantly, they implicate a new approach to modulate GHSR-1a activity, which can ultimately lead to the development of a new generation of pharmacotherapies.

GHRELIN TARGETS THE HYPOTHALAMUS TO REGULATE FEEDING

Although the main source of circulating plasma ghrelin is the stomach, and this peripherally secreted ghrelin can cross the blood–brain barrier to target centers in the brain involved in the control of feeding, there is evidence that ghrelin is produced by neurons in the hypothalamus. Some of these ghrelinergic neurons are located in the ventral–lateral part of the arcuate nucleus[17] and in the interstitial areas among the dorsomedial hypothalamus (DMH), ventromedial hypothalamus (VMH), and the walls of the third ventricle. Ghrelin immunopositive fibers were identified in close proximity to NPY-, POMC-, thyroid hormone releasing hormone (TRH)-, and corticotropin-releasing hormone (CRH)-immunoreactive cells, as well as within nuclei that control food intake such as the lateral hypothalamus (LH) and the paraventricular hypothalamus (PVH). Thus, in addition to the blood-borne ghrelin, hypothalamic ghrelin may contribute to regulatory circuits controlling energy homeostasis.

Two major hypothalamic pathways are targeted by ghrelin to control food intake. Ghrelin action increases the activity of orexigenic NPY/AgRP neurons that control feeding in concerted action with the anorectic POMC/cocaine-activated related transcript (CART) neurons. Ghrelin attenuates the melanocortinergic anorexigenic signals, by increasing the release of the melanocortin receptor inverse agonist, AgRP, and indirectly by decreasing the discharge of alpha-melanocyte stimulating hormone (MSH) from POMC neurons onto melanocortinergic receptor neurons in the PVN. Simultaneously, ghrelin increases the expression of the orexigenic NPY and AgRP in hypothalamic neurons in the arcuate nucleus.[17]

Ghrelin reaches at least a certain number of neurons expressing GHSR-1a that are located in mediobasal parts of the hypothalamic arcuate nucleus that are targeted as well by leptin. Such an action seems to be comodulated by a population of mostly bipolar shaped specifically ghrelin expressing neurons that coinfluence the firing rats of the orexigenic NPY/AgRP neurons and the anorexigenic POMC neurons, both of which are a target for ghrelin. This model is consistent with the effect of ghrelin on energy balance, neuropeptide expression, and neuronal activity and points to a combined

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

role for ghrelin as an afferent nutrient sensor and a central energy balance regulator. Both leptin and ghrelin have been clearly shown to modulate the electrophysiological activity of NPY/AgRP neurons, and leptin reduces the ghrelin-triggered increase in calcium concentration in NPY cells.[16] Although ghrelin induces pacemaker activity in arcuate neurons containing NPY and AgRP, leptin suppresses such activity.[32] Similar opposing action occurs in POMC neurons in which leptin increases the expression of POMC mRNA and the neuronal excitability,[6] whereas ghrelin reduces the activity of the POMC neurons by increasing the inhibitory release of gamma amino butyric acid (GABA) onto these neurons.[7] These opposing neurophysiological effects further support the notion that ghrelin and leptin may be endogenous opponents in the regulation of energy balance.

Binding of ghrelin to NPY/AgRP neurons in the arcuate nucleus induces an increase in firing activity,[17] membrane excitability,[32] and expression of NPY and AgRP. The potency of ghrelin to modulate POMC neurons is weaker than its effect on NPY/AgRP neurons. POMC expression is not changed after intracerebroventricular infusion of ghrelin for 72 h, whereas this treatment raises both NPY and AgRP mRNA levels.[17] Ghrelin receptors are not colocalized on POMC neurons, although ghrelin induces a decrease in POMC neuronal firing rate.[7] However, this effect disappears, or is reversed, by adding a Y1 receptor antagonist and an inhibitor of GABA release, suggesting that the effect on POMC neurons is indirect and mediated via the activation of GABAergic NPY/AgRP neurons. However, the integrity of the melanocortin signaling pathway seems to be essential for ghrelin to exert its effect on food intake and adiposity. Thus, ghrelin loses its orexigenic effect in an obese mouse model with ectopic overexpression of the melanocortin receptors inverse agonist AgRP as well as in MC3R and MC4R-deficient mice.[5]

Although the increase in food intake after central administration of ghrelin can be completely prevented in mice lacking both AgRP and NPY, ghrelin-induced adiposity is not exclusively dependent on NPY, because ghrelin increases fat content of NPY deficient mice identical to its effects in wildtype mice.[30] Ghrelin is also involved in anxiety-like behavior in rodents. In mice, both intracerebroventricular and intraperitoneal administration of ghrelin potently induces anxiogenic activities via mechanisms involving the hypothalamic–pituitary–adrenal axis. In addition, peripherally administered ghrelin significantly increases CRH mRNA expression in the hypothalamus and administration of a CRH receptor antagonist actually inhibits ghrelin-induced anxiogenic effects. These findings suggest that ghrelin may have a role in mediating neuroendocrine and behavioral responses to stressors and may not only directly stimulate hunger and appetite but also indirectly affect energy relevant behavior via effects on anxiety.[2]

GHRELIN TARGETS INTRACELLULAR FUEL-SENSING PATHWAYS IN HYPOTHALAMIC NEURONS TO CONTROL FEEDING

Recent studies have provided evidence of the intracellular mechanisms activated in neurons in response to ghrelin. Interestingly, some of those mechanisms involve the control of intracellular fuel availability through the activity of AMP-activated protein kinase (AMPK). AMPK is a serine/threonine kinase implicated in the regulation of multiple metabolic pathways that acts as an intracellular nutrient sensor of energy and nutrients. AMPK is activated when energy is depleted and induces catabolic processes to generate adenosine triphosphate (ATP) through the oxidation of fatty acids and mitochondrial biogenesis.[21] Thus, ghrelin increases AMPK activity in the VMN, resulting in the decrease of intracellular malonyl coenzyme-A levels. Low malonyl coenzyme-A levels lead to the reduction of the de novo fatty acid synthesis and an increase of carnitine-palmitoyl transferase I (CPT1) activity.[21] Accordingly, ghrelin administration reduces malonyl coenzyme-A and increases CPT1 activity in the hypothalamus.

The increase in mitochondrial activity in hypothalamic neurons resulting from the increased CPT1 activity and concomitant fatty acid beta-oxidation is a key component for ghrelin-induced hyperphagia. Conversely, the impairment of mitochondrial function in hypothalamic neurons leads to the reduction of the ghrelin orexigenic action.[1] The increase in mitochondrial fatty acid beta-oxidation is accompanied by the increase in the production of reactive oxygen species (ROS). Uncoupling proteins (UCPs), located within the inner membrane of the mitochondria, prevent excessive ROS production by reducing the proton gradient across the mitochondrial membrane. Hypothalamic cells involved in the generation of the orexigenic effect of ghrelin, such as the NPY/AgRP neurons in the arcuate nucleus, express the uncoupling protein UCP2. Ghrelin administration increases UCP2 gene expression in the hypothalamus, which is an effect that correlates with the increase in mitochondrial respiration. Consistently, the orexigenic response to the administration of ghrelin is blunted in UCP2-deficient mice.[1]

One of the mechanisms whereby ghrelin activates AMPK in the hypothalamus involves the sirtuin 1 and p53 (Sirt1/p53) pathway.[33] Sirt1 is an NAD+-dependent deacetylase that is activated during negative energy balance by the tumor-suppressor protein p53. Sirt1 is implicated in the central and peripheral metabolic control of lipid metabolism as well as glucose homeostasis in peripheral tissues. The role of Sirt1/p53 in the activation of AMPK induced by ghrelin is evidenced by the suppression of ghrelin-induced AMPK phosphorylation when Sirt1 activity is blocked by the use of either a pharmacological or genetic approach. In addition to

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

the blunted AMPK activity, the suppression of Sirt1 leads as well to decreased orexigenic response induced by ghrelin, which correlates with the blunted increase in the expression of transcription factors such as brain-specific homeobox (BSX), forkhead box 01 (Fox01), and cAMP response element binding protein (CREB), or orexigenic neuropeptides such as NPY and AgRP.

The control of gene expression in NPY/AgRP neurons by ghrelin requires the hypothalamic transcription factor BSX. The pharmacological inhibition of CPT1 blocks ghrelin-induced increase in hypothalamic β-oxidation and impairs the BSX-dependent upregulation of NPY and AgRP expression. Other transcription Fox01 and CREB contribute to the control of the gene expression of these neuropeptides by ghrelin.[18] Altogether, these results suggest that the control of intracellular fuel-sensing mechanisms by ghrelin contributes to the control of the transcriptional activity in hypothalamic neurons involved in the control of energy balance.

Although the hypothalamic arcuate nucleus contributes significantly to the orexigenic effect of ghrelin, the PVN seems to be an important site of ghrelin action as well. Intracerebroventricular administration of either ghrelin or the GHSR-1a agonist GHRP-6 induces c-fos expression in PVN neurons[19] and injection of ghrelin directly in the PVN increases food intake.[17] Interestingly, ghrelin immunoreactive neurons have been detected in the PVN indicating that this nucleus is a source of ghrelin as a neuropeptide.[26] The orexigenic activity of ghrelin in the PVN is mediated, at least in part, by endocannabinoids and this effect can be abolished by systemic pretreatment with the cannabinoid receptor antagonist SR141716.[31] The lateral hypothalamus (LH) may be involved as well in ghrelin-induced hyperphagia via the activation of the orexin pathways. Ghrelin treatment increases c-fos expression in orexin expressing neurons in the LH and the increase of food intake induced by ghrelin can be partially blocked by the coadministration of an antiserum against orexin A.[29] The role of orexin as a mediator of the ghrelin-induced hyperphagia was confirmed in orexin A-deficient mice, which show reduced effectiveness of ghrelin in increasing food intake when compared with wildtype littermates.[29]

GHRELIN TARGETS EXTRA-HYPOTHALAMIC AREAS TO REGULATE FEEDING

Although the role of the hypothalamus mediating the increase on food intake induced by ghrelin has been clearly established, multiple CNS regions contribute to the control of feeding behavior by ghrelin. The brainstem is one of those areas, consistent with its role mediating the feeding response of other afferent signals such as cholecystokinin, GLP-1, and leptin. Thus, the administration of ghrelin into the fourth ventricle or directly on the dorsal vagal complex, results in an hyperphagic response of similar magnitude to the one obtained in the third ventricle, measured as total amounts of ingested food as well as by meal pattern analysis.[12] The administration of ghrelin or GHRP-6 increases the number of c-fos positive cells in nucleus of the brainstem such as the nucleus of the solitary tract (NTS) or the area postrema (AP).[19] This is consistent with the expression pattern of the GHSR-1a, which is localized in neurons of the NTS, the dorsal motor nucleus of the vagus (DMNV), and the rostral ventrolateral medulla (RVLM).[20]

Ghrelin acts in multiple areas of the brain not traditionally associated with the homeostatic control of feeding such as the hippoccampus, dorsal nucleus of the raphe, ventral tegmental area (VTA), nucleus accumbens, amygdala, prefrontal cortex nucleus, and the olfactory bulb. As a result of this, ghrelin regulates multiple aspects associated with feeding behavior such as food reward, stress-induced feeding, incentive motivation, addictive behavior associated with the consumption of high calorie diets, alcohol, or drugs, and with learning and memory responses associated with feeding in both rodents and in humans.[8] Studies in human subjects support the involvement of ghrelin in the control of complex behaviors associated with feeding. Hence, intravenous infusion of ghrelin in humans increases the activity in areas of the brain involved in reward, such as the striatum, amygdala, insula, and orbitofrontal cortex. Moreover, ghrelin administration increases the sniffing intensity and even increases the willingness to spend more money on food instead of nonedible items,[8] which suggests that ghrelin increases the perceived value of food in humans.

GHRELIN TARGETS VISCERAL AFFERENTS TO REGULATE FEEDING

There is experimental evidence that in addition to the humoral distribution, ghrelin may control feeding by acting on vagal afferent nerves. Supporting this, GHSR-1a is expressed in neurons of the nodose ganglia that project to the stomach.[17] Further, some reports have shown that ghrelin has no effect on food intake in human subjects that have undergone surgical procedures involving vagotomy. However, experiments performed in rats have been inconclusive. Therefore, although a report showed that elimination of the gastric vagal afferent signals abolished ghrelin-induced feeding, others reported the lack of a significant role of the vagal afferents in the control of feeding by ghrelin.[4]

PERIPHERAL GHRELIN LEVELS ARE REGULATED BY FEEDING AND NUTRITIONAL STATUS

Ghrelin secretion is clearly regulated by feeding and fasting in many species through multiple mechanisms including

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

hormonal, nutrient, and neural signals. The complex and multifactorial control of ghrelin secretion further supports the notion that ghrelin is a hormone with a strong link to ingestive behavior.

The fluctuations in circulating ghrelin correspond to the measurement of both acyl and des-acyl-ghrelin. Acyl-ghrelin circulates in low concentrations, and this limits the understanding of the mechanisms controlling its secretion. Improvements in the methods of detection of acyl-ghrelin and the discovery and characterization of the enzyme responsible of the acylation of ghrelin have provided new tools to study the factors underlying the control of circulating acyl-ghrelin concentrations.

Ghrelin is acylated by the action of a specific enzyme named ghrelin O-acyltransferase (GOAT) (see the chapter on this enzyme in the Peptide Biosynthesis/Processing section of the book). This specificity is manifested by the observation that mice lacking GOAT are devoid of the acylated form of ghrelin. Like ghrelin, GOAT is regulated by nutritional status. Thus, fasting leads to the decrease of the gene expression of gastric GOAT in mice.[25] Interestingly, although total circulating concentrations of ghrelin increase during fasting, this is a result of an increase in the des-acyl form of ghrelin, whereas circulating acyl-ghrelin is unchanged. This indicates that fasting regulates ghrelin activity by the inhibition of ghrelin acylation, independently of the control of total ghrelin secretion.

GOAT is able to use dietary lipids as a substrate to acylate ghrelin, which was shown when mice were found to have circulating ghrelin acylated with a C7-FA side chain after being fed a diet rich in nonendogenously produced C7-chain FAs.[25] When wildtype mice are fed this diet, they experience an increase in body weight and fat mass. Interestingly, GOAT knockout mice fed the same diet do not gain weight or fat mass; however, the improved body composition does not result from a decreased food intake but most probably is a result of increased energy expenditure in the GOAT knockout mice. Transgenic mice that express human GHRL and human MBOAT4 genes in the liver under the control of the human APOE (encoding apolipoprotein E) promoter have significantly higher acyl-ghrelin levels compared with wildtype control mice when fed a medium-chain triglyceride (MCT)-rich diet. The transgenic mice experience a gain in body weight and adiposity, but this is independent of food intake. In addition to genetically manipulating the GOAT/ghrelin system, the development of a pharmacological inhibitor for GOAT has further facilitated examination of the role of ghrelin acylation in mediating food intake. Treatment with the inhibitor for one month prevents a significant weight gain and adiposity in mice fed an MCT-rich high-fat diet, yet no difference in food intake is observed. The resistance to weight gain observed in wildtype mice treated with the inhibitor is not apparent in ghrelin knockout mice that were subjected to the treatment, confirming that the metabolic improvements are mediated by acyl-ghrelin inhibition. Together, these results show that chronic inhibition of ghrelin acylation results in metabolic improvement that is independent of food intake. Further, specific acyl-ghrelin antagonism may be a novel obesity therapeutic.

Because the fluctuations in both insulin and glucose levels are crucial for the control energy balance, it is obvious to suggest that both insulin and glucose may play a role in the control of circulating ghrelin concentrations. Indeed studies in humans involving hyperinsulinemic euglycemic clamps suggest a determinant role of insulin in the control of ghrelin levels. However, studies in streptozotozin-induced diabetic rats have shown that ghrelin levels can be suppressed after a meal in the absence of insulin,[13] indicating that a calorie-dependent but insulin-independent mechanism may control ghrelin levels in response to ingestive behavior.

The nutrients that contribute to the regulation of ghrelin secretion after a meal do not necessarily act from the lumen of the stomach. Thus, the decrease in plasma ghrelin-induced by the delivery of glucose directly in the stomach of rats is blunted when the pylorus is closed, in contrast to the situation when it is open. Consistent with these findings, the decrease of plasma ghrelin also occurs after the administration of nutrients directly into the duodenum and jejunum.[22] This indicates that nutrients either need to be absorbed distal from the stomach to act on ghrelin secreting cells via circulating blood, or nutrient-sensing mechanisms in the upper intestine may trigger signals that lead to the reduction of plasma ghrelin.

In addition to glucose, aminoacids are very effective in reducing circulating ghrelin concentrations. By contrast, the administration of an isocaloric amount of lipids is less effective reducing ghrelin in comparison with the administration of glucose or amino acids,[22] suggesting that in addition to the calorie load, specific mechanisms involved in the nutrient-sensing contribute to the regulation of ghrelin levels. Some of those mechanisms may involve neural signals. The increase of ghrelin levels in response to fasting requires the integrity of vagal efferents from the CNS, and the intragastric administration of nutrients in vagotomized animals fails to decrease ghrelin levels.[34] These results suggest that a regulatory feedback loop between the gut and the stomach, independent of the CNS, cannot be excluded as a potential mechanism for the regulation of ghrelin levels in response to a meal. In addition to vagal signals, the sympathetic nervous system contributes to the control of ghrelin secretion via beta 1 adrenergic receptor signaling, because the increase in the activity of these receptors leads to the increase in ghrelin levels.

In addition to the regulation of plasma ghrelin concentrations by the caloric changes associated with fasting and

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

feeding, there is a distinctive pattern of secretion that correlates with the time of the meals, with three premeal peaks and a nightly increase in humans. The increase in ghrelin secretion may be under the control of the similar neural mechanisms underlying the nutrient independent increase in insulin secretion observed immediately before a meal, known as the "cephalic phase" of insulin secretion. Thus, when rats are trained to consume their daily calories only during an artificial fixed 4-h meal schedule, circulating ghrelin increases before the expected meal.[10] This suggests that, similarly to insulin, ghrelin secretion may have as well a "cephalic phase." This increase in ghrelin levels before the meal suggests that ghrelin may be involved in processes linked to the initiation of meals. Conversely, the decrease in ghrelin secretion from the stomach can be evoked with "tease" feeding (presentation but not access to food) in rats, suggesting that the decrease in ghrelin secretion after feeding may not require an increase in calorie availability.[27] Interestingly, the decrease in ghrelin secretion can be prevented by surgical or pharmacological disruption of the vagal function. This suggests that signals other than nutrient-sensing dependent mechanisms contribute to the control of ghrelin secretion and highlight the contribution of neural signals in the control of ghrelin secretion by feeding.

Chapter 149

GLP-1

Gustavo Pacheco-López and Wolfgang Langhans

ABSTRACT

Glucagon-like peptide (7–36) amide (GLP-1) is mainly produced by enteroendocrine cells in the small intestine and by a small set of neurons in the hindbrain. Exogenous and endogenous peripheral and central GLP-1 inhibits eating. Peripheral GLP-1 can inhibit eating through a paracrine action on vagal afferents or an endocrine action on the brain. Because of the short biological half-life of GLP-1, the endocrine action may be relevant only after substantial stimulation of GLP-1 release or pharmacological interventions. Although hindbrain circuitries alone can mediate the satiating effect of hindbrain GLP-1 receptor (GLP-1R) stimulation, rostral brain areas may also be involved. Peripheral or central GLP-1R activation can cause conditioned flavor avoidance, but GLP-1's satiating and avoidance effects can be dissociated. Finally, enhanced GLP-1 release contributes to the antiobesity and antidiabetic effects of bariatric surgery. In summary, GLP-1 analogs may be a promising therapeutic option to fight obesity and type-II diabetes.

GENERAL

Glucagon-like-peptide (7–36) amide (GLP-1) results from posttranslational processing of proglucagon in the gut and the brain.[15] Proglucagon is encoded by the proglucagon gene, which has been identified in all mammals and in a variety of other vertebrates, suggesting an early origin in evolution and a prominent role for the encoded peptides. A discreet set of neurons in the nucleus tractus solitarii (NTS)[29] and enteroendocrine L-cells located in the distal jejunum and ileum are the main producers of GLP-1.[15] Dietary carbohydrates and fats potently stimulate peripheral GLP-1 secretion, in part by activating taste and other G-protein-coupled receptors expressed on enteroendocrine cells. These cells can therefore detect the presence of nutrients in the intestinal lumen. In addition, a neural feed-forward loop from the proximal to the distal small intestine may be involved in GLP-1 release.[15] GLP-1 has also been identified in sweet- and umami-taste receptor cells in the oral cavity,[21] suggesting that GLP-1 signaling might also be involved in taste perception. Indirect evidence suggests that eating also triggers the release of brain GLP-1, but interoceptive stress seems to be another potent stimulus.[32] GLP-1 receptors (GLP-1R) are widely distributed in peripheral organs such as the pancreatic islets and the whole gastrointestinal (GI) tract,[15] and in the brain, where they are found in several hindbrain and forebrain sites,[29] including areas that are implicated in the control of food intake and regulation of energy balance such as the area postrema (AP), NTS, hypothalamus, amygdala, and in the mesolimbic reward system.

GLP-1 is probably best known for its potent incretin effect, that is, for the stimulation of glucose-induced insulin release,[15] and for the inhibition of gastric emptying that contributes to the ileal brake mechanism.[15] These and other effects of GLP-1 are discussed in other chapters of this volume. This chapter focuses on the inhibiting effect of GLP-1 on eating.[3,11,21,33]

PERIPHERAL GLP-1

General

Peripheral, systemic administration of native GLP-1 or of potent, long-acting natural or synthetic GLP-1 analogs, such as exendin-4 (Ex-4) or liraglutide, inhibits eating in many species, including humans.[3,11,21,33] Ex-4 is a naturally occurring peptide resistant to rapid enzymatic degradation by dipeptidyl peptidase-4 (DPP-4). The synthetic GLP-1 analog liraglutide also resists enzymatic degradation, and its renal excretion is delayed because it also binds to albumin in plasma. Chronic peripheral administrations of GLP-1 or its analogs reduce body weight and improve glucose metabolism in overweight individuals, suggesting that GLP-1 offers a promising therapeutic option to treat obesity and type-II-diabetes (T2D). GLP-1R activation reduces food intake by primarily decreasing meal size,[23] indicating that GLP-1 enhances satiation. Some studies report an additional effect of GLP-1R activation on the duration of the intermeal interval.[3,33] Interestingly, rats adapted to restricted feeding display an increase in GLP-1 secretion about 90 min before the expected food access. Blocking the effect of this preprandial GLP-1 release by GLP-1R antagonism decreases subsequent food intake, indicating that the preprandial spike

in circulating GLP-1 is anticipatory and facilitates handling of the expected nutrient load.[31] Chronic maintenance on, and even brief exposure to, a high fat (HF) diet reduces the acute eating-inhibitory effect of Ex-4, indicating that HF diet exposure compromises the response to GLP-1R activation. Also, intraperitoneally (ip) injected GLP-1 fails to reduce food intake in leptin receptor-deficient Koletsky rats, whereas leptin enhances the satiating effect of ip GLP-1.[34] These findings indicate that leptin receptor signaling is necessary for, and that leptin enhances, the satiating effect of GLP-1, similar to its synergistic satiating effect with other gastrointestinal satiation signals such as cholecystokinin and gastric distension. Some evidence even indicates that GLP-1 acts as a downstream mediator of leptin's inhibitory effect on eating.[3] Whether the decreased sensitivity of HF diet-fed rats to ip GLP-1 is related to the leptin resistance usually induced by HF feeding awaits further investigation.

Peripheral and central administrations of GLP-1 and GLP-1R agonists have also been shown to inhibit water intake in several species. This raises the question of a possible interaction or even crossdependence between GLP-1's eating- and drinking-inhibitory actions. A more recent study[19] showed, however, that GLP-1, Ex-4, and liraglutide all suppressed water intake after ip administration in both the presence and absence of food, indicating that the antidipsogenic effect of GLP-1R activation is independent of the inhibition of eating.

Site and Mode of Action

The reduction of food intake after ip administration of native GLP-1 or GLP-1R agonists may result in part from a peripheral action because peripheral administration of albumin-conjugated GLP-1 that probably does not cross the blood–brain barrier still reduced food intake. Williams et al. showed that the effect of ip injected GLP-1 could be blocked by ip, but not by intracerebroventricular (icv), administration of the GLP-1R antagonist exendin-9 (Ex-9).[35] We reported that the satiating effect of IP infused GLP-1 depends on intact abdominal vagal afferents.[23] Interestingly, however, GLP-1 infused into the hepatic portal vein reduces food intake in rats after subdiaphragmatic vagal deafferentation (SDA) or sham surgery,[23] although the threshold dose for a reliable reduction of meal size and duration is about ten times higher after ip than after hepatic portal vein infusion. These findings suggest that GLP-1R agonists can inhibit eating through activation of at least two partially separate pathways: intravenously infused GLP-1 presumably through an endocrine action on the brain, and ip administered GLP-1 through a paracrine action on vagal afferents.

Unpublished data from our laboratory (Punjabi et al., in preparation) indicate that GLP-1 infused into the hepatic portal vein or ip at doses that effectively inhibit eating do not generate learned aversive behaviors. Therefore, at least under our experimental conditions, that is, in response to remotely controlled hepatic portal vein or ip administrations, GLP-1 can induce satiation independent of aversion.

Although the satiating effect of ip administered native GLP-1 may be primarily mediated by peripheral, presumably vagal afferent GLP-1Rs,[23] ip injected long-acting GLP-1R agonists, such as Ex-4 and liraglutide, can also recruit central nervous system (CNS) GLP-1Rs. This seems reasonable given these compounds' stability and the observation that Ex-4 can cross the blood–brain barrier.[3] Administration of the GLP-1R antagonist Ex-9 into the third cerebral ventricle attenuates the eating-inhibitory effect of ip Ex-4 or liraglutide, in particular at 6 and 24 h after administration.[16] Moreover, much higher doses of Ex-4 and liraglutide are needed to inhibit eating in SDA rats than in sham-operated control rats. Thus, GLP-1R expressed on abdominal vagal afferents and CNS GLP-1R seems to mediate the inhibition of eating after ip Ex-4 and liraglutide.[16] Most of the CNS GLP-1Rs, however, are located behind the blood–brain barrier, and circulating GLP-1 may not be able to reach them. Orskov et al. (1996) in *Diabetes* addressed this question in a study using radioactively labeled GLP-1 and autoradiography and concluded that only GLP-1R in the area postrema (AP) and subfornical organ (SFO) are accessible to circulating GLP-1. The AP and SFO are circumventricular organs with a very leaky blood–brain barrier. However, intravenous injection of albumin-conjugated GLP-1, which is unable to cross the blood–brain barrier, induced an increased expression of c-Fos in the AP, NTS, rostral ventrolateral medulla, parabrachial nucleus, and hypothalamic paraventricular nucleus (PVN),[3,29] suggesting that some of these areas are indirectly activated after binding of GLP-1 to GLP-1R in the AP and SFO. Quantification of influx by the very sensitive multiple time-regression analysis method, provides evidence that intravenous GLP-1 may enter brain parenchyma by a nonsaturable mechanism. In general, the results are consistent with findings from our group suggesting that AP GLP-1R are involved in mediating the satiating effect of native GLP-1 infused into the hepatic portal vein.[4] Whether circulating GLP-1 recruits hindbrain GLP-1 neurons for its inhibiting effect on eating is presently unknown. If so, it can do so only indirectly because the hindbrain GLP-1 neurons do not express GLP-1Rs.[29]

ENDOGENOUS PERIPHERAL GLP-1

Endogenous intestinal GLP-1 has been implicated in meal termination (i.e., satiation) because (1) the presence of nutrients in the small intestine stimulates the release of intestinal GLP-1, (2) exogenous GLP-1 inhibits eating by primarily reducing meal size (see above) and (3) ip injection of the specific GLP-1R antagonist Ex-9 stimulates eating under some conditions,[35] indicating that satiation can be delayed when

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

endogenous GLP-1 signaling is blocked. After secretion into the blood stream, GLP-1 is rapidly degraded into GLP-1 (9–36) by DPP-4, accounting for the short biological half-life of GLP-1 of <5 min. This may limit GLP-1's potential as an endocrine satiating signal unless GLP-1 acts close to the site of its release (for instance in the hepatic portal vein) or when circulating concentrations are substantially increased.

In addition to a possible endocrine mechanism of action, gut hormones can signal the brain through a paracrine effect on afferent nerves, with the vagus being the most common neural route of peripheral to central signaling. After the secretion from intestinal L-cells GLP-1 diffuses across the basal lamina and enters the lamina propria of the mucosa, where vagal afferents terminate and where the highest concentration of active GLP-1 can be expected before its enzymatic degradation by DPP-4 (Fig. 1). Intestinal lymph reflects the composition of the interstitial fluid of the mucosa fairly well. As a result, the intestinal lymphatic GLP-1 concentration increases substantially in response to intragastric nutrient infusions in anesthetized rats and in response to normal meals in freely moving rats (Arnold et al., 2012, *Am J Physiol*). Peptides administered ip accumulate in the intestinal lymph and, hence, presumably target the vagal afferents terminating in the wall of the small intestine. Administration ip should therefore be a good model to examine the paracrine satiating effect of endogenous GLP-1.[21] In addition to the failure of ip infused GLP-1 to inhibit eating in rats after SDA,[23] other findings indirectly support a role of abdominal vagal afferents in the satiating effect of ip administered, and possibly also endogenous, GLP-1: vagal afferent neurons in the nodose ganglion express the GLP-1 receptor gene, and intravenous administration

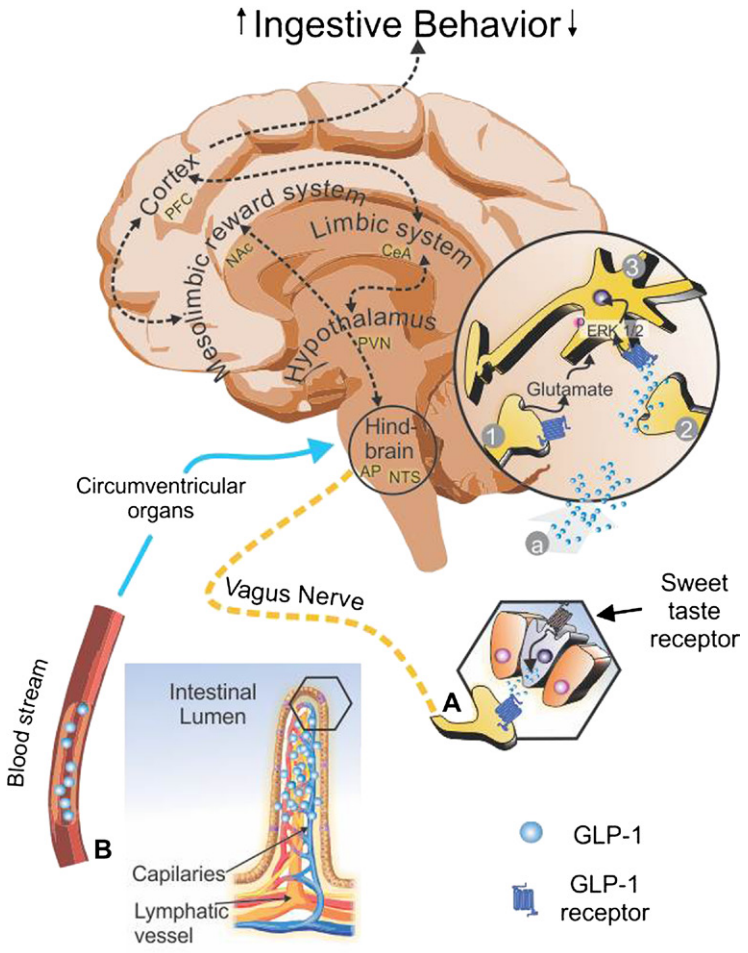

FIGURE 1 Scheme of GLP-1 satiation. Intestinal luminal nutrients trigger GLP-1 release through taste receptor mechanisms present in enteroendocrine L-cells. GLP-1 can inhibit eating (A) through a paracrine action on GLP-1 receptors (GLP-1Rs) on intestinal vagal afferents that connect the gut to the nucleus tractus solitarii (NTS) in the hindbrain; and (B) through an endocrine action on the brain, provided that sufficient GLP-1 escapes inactivation by dipeptidyl peptidase-4 to act through circumventricular organs such as the area postrema (AP) and perhaps elsewhere. (a) Peripheral GLP-1 crossing the blood–brain barrier, (1) pre-synaptic glutamatergic neurotransmission, (2) GLP-1ergic neuromodulation, and (3) post-synaptic activation. Although hindbrain processing of the GLP-1 signal seems to be sufficient to inhibit eating, rostral brain areas such as the hypothalamic paraventricular nucleus (PVN), the nucleus accumbens (NAc) and the central nucleus of the amygdala (CeA) may also be involved. See the text for further details. See color plate 41.

of GLP-1 that produces high physiological plasma concentrations activates ventral gastral vagal afferents in multiunit recordings. Moreover, exenatide, another synthetic GLP-1R agonist, activates duodenal intramural neurons and the dorsal motor nucleus of the vagus.[3,11,21] The food intake reducing effects of GLP-1R activation do not require an intact common hepatic branch of the vagus, suggesting that the abdominal vagal afferent fibers involved do actually originate in the GI tract itself. Interestingly, visceral sensory afferents provide direct glutamatergic input to hindbrain GLP-1 neurons. Endogenous peripheral – and ip adminstered—GLP-1 could therefore, modulate hindbrain GLP-1 neuronal activity through glutamatergic inputs. Whether endogenous peripheral GLP-1 induces satiation through an endocrine or paracrine action is still unresolved, and current research also focuses on this question. Overall, however, these results suggest that GLP-1R activation can inhibit eating through receptor populations in at least two distinct locations, that is, on abdominal, presumably intestinal, vagal afferents and in the brain (Fig. 1).

CENTRAL NERVOUS SYSTEM GLP-1

GLP-1 expressing neurons are located primarily in the NTS.[29] Microinfusions of GLP-1 directly into the cerebral ventricles have long been known to inhibit eating.[26,30] The effect is usually acute and transient, and it could be antagonized by the GLP-1R antagonist Ex-9. Ex-9 alone also stimulates eating in satiated rats, indicating that central GLP-1 is an endogenous short-term control of eating. Repetitive icv GLP-1 or Ex-9 administrations also change body weight,[3] suggesting that central GLP-1 contributes to the regulation of energy homeostasis as well. Results showing that viral-mediated downregulation of proglucagon gene expression in the caudal NTS causes hyperphagia and increased fat accumulation in response to HF diet exposure[2] support this view.

GLP-1Rs are expressed in many areas of the brain. Particularly high GLP-1R densities occur in the hypothalamus and in the brainstem, whereas no GLP-1Rs are found in the cortex and cerebellum. Hindbrain GLP-1 neurons project to the hypothalamic PVN and dorsal medial nucleus, two areas implicated in the control of eating. A projection from NTS GLP-1 neurons to the NAc also seems to be involved in the control of eating,[6] most probably related to the forebrain processing of food reward. GLP-1 icv induces c-Fos expression in the PVN and central nucleus of the amygdala (CeA),[30] suggesting that these areas are involved in the satiating effect of central GLP-1. Consistent with a role of PVN GLP-1Rs in the mediation of the satiating effect of GLP-1, direct intra-PVN injections of GLP-1 reduce food intake without inducing aversion or affecting locomotion.[20]

However, icv administered GLP-1 clearly has aversive effects in other studies.[17,32] The lowest doses that produce a conditioned taste aversion (CTA) and an inhibition of eating were identical. Also, icv GLP-1 and IP injections of lithium chloride (LiCl), a model substance to induce "malaise" and CTA, produce a similar pattern of neuronal activation in the brain. Finally, GLP-1R antagonism blocks the aversive effect of peripherally administered LiCl, suggesting that CNS GLP-1R activation contributes to LiCl-induced CTA.[27] Similar to the results obtained with peripheral GLP-1 administration (see above), the aversive and satiating effects of central GLP-1R activation can be dissociated. Bilateral lesions of the PVN prevent the eating-inhibitory but not the aversive effect of icv GLP-1, whereas bilateral lesions of the CeA produce the opposite results.[32] In another study, lateral and fourth ventricular GLP-1 administrations both reduce food intake, but only lateral ventricular GLP-1 induces an aversion, an effect that could be reproduced by the direct administration of GLP-1 into the CeA.[17] Further, blockade of amygdaloid GLP-1R prevents the CTA in response to ip injections of LiCl, suggesting that amygdaloidal GLP-1R activation contributes to taste aversion learning.[17] More recently, GLP-1 significantly reduced food intake (1, 2, and 24 h posttreatment) but did not induce a CTA after microinjection into the NAc core.[6] All these results indicate that at least partly separate neuroanatomical pathways mediate the satiating and aversive effects of central GLP-1, and that the CeA is involved in GLP-1-induced taste aversion learning. The administration icv of GLP-1 or GLP-1R agonists may therefore activate both pathways. The exact circumstances determining which of the pathways prevail remain to be identified.

In addition to midbrain and forebrain GLP-1Rs hindbrain GLP-1Rs seem to be involved in the control of eating and regulation of energy balance. Hayes et al.[13] showed that peripheral as well as intra-fourth ventricular administration of the GLP-1R agonist Ex-4 reduces glucose solution intake in chronic supracollicular decerebrate rats and sham-operated rats similarly, indicating that hindbrain processing of the signal derived from GLP-1R activation is sufficient for the observed effects. The hindbrain GLP-1R activation increases PKA and MAPK activity and decreases phosphorylation of AMPK in NTS. Further experiments showed that PKA and MAPK signaling contribute to the eating-inhibitory and body weight decreasing effects of Ex-4, suggesting that hindbrain GLP-1R activation decreases food intake and body weight through a coordinated PKA-mediated suppression of AMPK and activation of MAPK.[12] The same group also showed that direct medial NTS injection, but not intrafourth ventricular administration, of the GLP-1R antagonist Ex-9 stimulates eating in rats, and blockade of hindbrain GLP-1R also antagonizes satiation induced by nutrient preload consumption or artificial gastric distension, but not intraduodenal nutrient

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

delivery. These findings implicate activation of hindbrain GLP-1Rs in physiological satiation and suggest that gastric distension, perhaps through a vagal afferent mechanoreceptor signal, activates the hindbrain GLP-1 system. In contrast, intraduodenal nutrient infusions presumably also stimulate intestinal GLP-1 release and, hence, recruit additional pathways that are not antagonized by hindbrain GLP-1R blockade. Nevertheless, these findings are consistent with the idea that nutrient consumption induces satiation via release of both peripheral and central GLP-1, and that both can act on hindbrain GLP-1R to influence eating.[10]

GLP-1 IN OBESITY THERAPY

Roux-en-Y Gastric Bypass (RYGB)

Bariatric surgery, in particular RYGB, efficiently decreases excess body weight and leads to a rapid improvement of insulin sensitivity, with complete remission of T2D in up to 80% of the patients. Most remissions occur almost immediately after surgery and before significant weight loss has taken place. Several reports from studies in humans and laboratory animal models indicate that RYGB substantially increases postprandial circulating GLP-1 and peptide tyrosine–tyrosine (PYY) levels,[22] and that this increase is a major contributor to the obesity and T2D-curbing effects of RYGB. Such findings promote GLP-1 analogs as promising compounds for the pharmacotherapy of T2D and obesity. There are, however, reports that some patients develop mood disorders and that the suicide rate may increase after RYGB.[28] Although patients' well-being apparently tends to improve with exenatide treatment,[7] it is prudent to examine whether psychological problems after RYGB could somehow be related to GLP-1 neurobiology, in particular because some evidence indicates that icv GLP-1 administration increases anxiety in rodents.[8]

GLP-1 and GLP-1 Analogs

Because active, circulating GLP-1 is rapidly degraded by the enzyme DPP-4, pharmacological treatment strategies mainly employ analogs of GLP-1, such as Ex-4 (and exenatide) or liraglutide. Ex-4, a potent and long-acting natural GLP-1R agonist isolated from the saliva of the Gila monster, is a 39-amino acid peptide that shares 53% homology with native GLP-1. Because Ex-4 is not metabolized by DPP-4 it has a much longer plasma half-life than GLP-1.[15] Ex-4 potently reduces food intake, inhibits gastric emptying and improves glucoregulation. Although the strong eating-inhibitory effect of Ex-4 may carry the risk of undesirable side effects such as nausea or general malaise,[1] exenatide, a synthetic Ex-4 (marketed as Byetta) has been approved (FDA, 04-2005) for the treatment of T2D.

The other currently commercially available GLP-1R agonist, liraglutide, is a synthetic GLP-1 analog that shows 97% homology with the native peptide and features an even longer biological half-life than Ex-4. Also liraglutide has been approved as an anti-diabetic drug (FDA, 01-2010). It must be administered only once a day instead of twice daily for Ex-4. Current research aims at the development of other, even more effective GLP-1 agonists that could perhaps be administered only once a week. Despite the obvious therapeutic potential of GLP-1R agonists, some potential risk factors with chronic administration deserve attention. Chronic administration of liraglutide or Ex-4 in laboratory animals was associated with an increased incidence of thyroid cancer and the occurrence of cell lesions, respectively. So far, such effects were not observed in humans, but further studies are required to better judge on the relationship between potential risks and beneficial actions.[18] Another therapeutic option is to enhance intestinal absorption of orally administered GLP-1 by a substance called sodium *N*-[8-(2-hydroxybenzoyl)amino] caprylate (SNAC). SNAC effectively delivers peptides of low oral bioavailability and should produce high intestinal tissue and hepatic portal vein GLP-1 concentrations, hence copying the normal route of delivery after GLP-1 release from enteroendocrine cells into the interstitial fluid of the mucosal lamina propria. A single oral administration of such an SNAC-GLP-1 preparation produced much higher short-term increases in systemic plasma concentrations of active GLP-1 than a meal, decreased food intake and improved glycemic control by enhancing glucose-stimulated insulin release.[24,25] These findings suggest that the SNAC-GLP-1 preparation did in fact produce high local GLP-1 concentrations at the critical splanchnic receptor sites. SNAC preparations of satiating peptides may therefore be another viable option for the pharmacotherapy of T2D and obesity.

DPP-IV Inhibitors

As an alternative to enhancing GLP-1R activation by administering GLP-1 analogs, degradation of the native endogenous peptide can be delayed by inhibiting DPP-4. DPP-4 is a membrane-bound enzyme on capillary endothelia also present in the blood in soluble form. DPP-4 inhibitors such as PF-734200 or sitagliptin decrease prandial increases in circulating glucose mainly by increasing circulating GLP-1 levels.[9] Although DPP-4 inhibitors seem to hold potential for the treatment of T2D, they have scarcely any effect on eating. This is presumably because DPP-4 activates PYY, another eating-inhibitory peptide. The effectiveness of DPP-4 inhibitors for the treatment of obesity is therefore limited. Also, although inhibitor-based therapies are often considered less risky, some side effects such as headache, constipation, diarrhea, etc., have been reported in relation to DPP-4 inhibitor administration.[9,14]

New GLP-1 Co-agonists

GLP-1 may also be promising as part of novel chimeric molecules developed via chemical connection of peptides using polyethylene glycol covalent bonds (i.e., PEGylation). The administration of such a PEGylated peptide combining GLP-1 and pancreatic glucagon agonist activity was shown to normalize adiposity and glucose tolerance in diet-induced obese mice.[5] The reduction of body weight in this study was achieved by a loss of body fat resulting from decreased food intake and increased energy expenditure. Such novel pharmacological "cocktail" approaches to treat obesity and T2D may eventually be possible with custom-tailored combinations of two or more gut-brain peptides in a single molecule. A sound knowledge about the mechanisms underlying the physiological effects of each single peptide is necessary to develop such compounds and to minimize adverse side effects.

CONCLUSIONS AND PERSPECTIVES

This chapter aimed at summarizing and assessing the available evidence for a role of GLP-1 in the control of eating and the underlying mechanisms of its action. Several lines of reasoning implicate both peripheral and CNS GLP-1 in the control of eating. Peripheral GLP-1 stems primarily from enteroendocrine cells in the small intestine; it can inhibit eating through a paracrine and an endocrine action. GLP-1Rs on abdominal, primarily intestinal, vagal afferents most likely mediate the paracrine action, whereas GLP-1Rs in the AP and NTS seem to mediate the endocrine action, which presumably requires significant increases in circulating GLP-1. Because of the short biological half-life of native GLP-1 such increases may occur only when GLP-1 release is substantially stimulated or after pharmacological interventions. Whether peripheral GLP-1 has an additional endocrine satiating effect mediated by GLP-1R on vagal afferents terminating in the wall of the hepatic portal vein remains to be thoroughly examined. A small set of NTS neurons primarily produces central GLP-1. Its inhibitory effect on eating can be mediated solely through hindbrain circuitries, but may also recruit midbrain and forebrain areas such as the PVN, the NAc, and the CeA. It remains to be determined whether or not peripheral GLP-1 ultimately recruits the hindbrain GLP-1 system for its satiating action. The effects of peripheral and central GLP-1R activation on eating may include an aversive component. The satiating and aversive actions of GLP-1 can, however, be dissociated, even with respect to the brain areas involved. Under which conditions one of the two actions prevails, or when they may coexist, needs to be characterized. Strong evidence indicates that endogenous GLP-1 contributes to the striking T2D- and obesity-curbing effects of RYGB. This and the fact that GLP-1 reduces food intake and body weight also in obese individuals spurred substantial interest into the therapeutic potential of GLP-1. Despite some open questions, GLP-1R agonists currently provide promising treatment options.

Chapter 150

Glucagon

Nori Geary

ABSTRACT

Glucagon is a peptide hormone synthesized and secreted by the pancreatic α-cells. The glucagon receptor is a G-protein-coupled, seven-transmembrane domain receptor and is expressed in the liver, pancreatic islets, heart, adipose tissue, and, less abundantly, in other tissues. Glucagon is secreted when blood glucose concentrations decrease, and it rapidly increases hepatic glucose production, through glycogenolysis for the first approximately 3 h and both glycogenolysis and gluconeogenesis thereafter. Glucagon has several effects on lipid metabolism, notably stimulation of hepatic fatty acid oxidation and ketone synthesis. Glucagon is also secreted during stress, such as during exercise, and contributes to the maintenance of metabolic fuel homeostasis in these situations. Glucagon is secreted during most meals, and prandial glucagon secretion contributes to meal-ending satiation. Plasma glucagon concentrations are chronically elevated in diabetes and contribute to its pathophysiological consequences. The therapeutic potential of glucagon in several of the areas mentioned is the focus of current research.

INTRODUCTION

Glucagon research has a long history.[19] In their initial description of the discovery of insulin in 1921, Banting and Best[3] noted that their pancreatic extracts had hyperglycemic and hypoglycemic properties. Only 2 years later, Murlin et al.[22] isolated pancreatic extracts that had only hyperglycemic activity and named the putative active molecule glucagon. Glucagon was isolated to the pancreatic α-cells by Sutherland and de Duve in 1948,[28] the amino acid sequence of glucagon was established by Bromer et al. in 1956,[4] and a radioimmunoassay was developed by Unger et al. in 1959.[29] Consistent with its long history and potent biological effects, glucagon physiology and pathophysiology have been studied extensively in mice, rats, dogs, pigs, nonhuman primates, and, of course, humans. The good correspondence of most results in these diverse animal models with those in humans indicates the high translational utility of animal research on glucagon. Progress in glucagon physiology and pathophysiology through the mid-1990s was reviewed in detail in three volumes of the Handbook of Experimental Pharmacology.[16–18]

GLUCAGON AND THE GLUCAGON RECEPTOR

Posttranslational processing of the glucagon gene product proglucagon, a 160-amino-acid polypeptide, produces a variety of bioactive peptide hormones. This processing is tissue-specific because of the differential expression of the prohormone convertase PC2 (or neuroendocrine convertase 2, NEC2) in the pancreatic α-cells and PC1/3 elsewhere, respectively (see the Peptide Biosynthesis/Processing section of the book). Glucagon, human proglucagon 33–61, is synthesized and released mainly from the pancreatic α-cells and acts almost exclusively on the glucagon receptor, which recognizes glucagon's C-terminal. The exception is that glucagon has pharmacological and perhaps physiological actions on gastrointestinal smooth muscles that are mediated by an unknown receptor that recognizes glucagon's N-terminal. The major residues of glucagon synthesis, that is, proglucagon 1–30 (GRPP, glicentin-related polypeptide), proglucagon 64–69 (intervening peptide-1), and proglucagon 72–158 (MPGF, major proglucagon fragment), seem to be inactive. The glucagon gene and its posttranslational products are highly conserved in the vertebrate lineage. Rat, mouse, and human glucagons are identical.

Intestinal L cells produce glicentin (proglucagon 1–69), which seems to be inactive, as well as glucagon-like peptide-1 (GLP-1; proglucagon 78–107amide), GLP-2 (proglucagon 126–158), and oxytomodulin (proglucagon 33–69), all of which are active. Small amounts of GLP-1 may also result form cleavage of MPGF in the α-cells. As the proglucagon amino acid sequences of these peptides suggest, only oxyntomodulin has structural homology to glucagon and mimics glucagon's bioactivity. Oxyntomodulin, however, stimulates hepatic glucose production about an order of magnitude less potently than does glucagon, presumably because its C-terminal extension interferes with receptor binding. The actions of GLP-1 and GLP-2 are independent of those of glucagon. L cells also produce glucagon in physiologically relevant amounts if the pancreatic α-cells do not, for example, after pancreotomy. Finally, a circumscribed set of neurons in the nucleus tractus solitarius produces GLP-1,

but whether glucagon is produced or acts in the CNS remains controversial.

The human glucagon receptor is a 485-amino-acid protein with a 143-amino-acid extracellular N-terminal. Amino acids 80–142 seem crucial for specific recognition of glucagon, and other sites in the N terminal as well as other extracellular domains seem to determine the receptor conformation that permits binding. The structure of the glucagon receptor, like that of glucagon, is highly conserved. The N-terminal sequence of the glucagon receptor is 97% identical in rats and humans. Glucagon receptors are expressed densely in the liver and also in physiologically relevant numbers in the pancreatic islets, kidney, heart, adipose tissue, gastrointestinal tract, and, possibly, brain. The glucagon receptor is a member of a distinct family of G-protein-coupled seven transmembrane domain receptors, whose activation leads to activation of membrane-bound adenyl cyclase, which increases intracellular cyclic adenosine monophosphate (cAMP) and via cAMP increases inositol 1,4,5-triphsophate (InsP3) or Ca^{2+}. Work on glucagon's intracellular signaling pathway led to Nobel Prizes to Earl Sutherland in 1971, for cAMP signaling, and to Martin Rodbell in 1994, for G-protein-coupled receptor signaling. This remains the canonical glucagon-signaling pathway, although additional mechanisms may contribute in some tissues. For example, some results indicate that some elevation of intracellular InsP3 and Ca^{2+} may occur independent of cAMP in the liver.

Glucagon itself is a prohormone in some target tissues, including liver and heart, where glucagon 19–29, or miniglucagon, is produced by endopeptidases that attack the arginine doublet at positions 17 and 18 of glucagon. Miniglucagon inhibits the hepatic Ca^{2+} pump 2–3 orders of magnitude more potently than glucagon and also is a component of the positive inotropic effect of glucagon in the heart.

GLUCAGON SECRETION

Glucagon is secreted tonically as plasma glucose concentrations decrease during fasting or in hypoglycemia and phasically during sudden-onset hypoglycemia, during meals (except pure carbohydrate meals), and during certain physiological stresses, including exercise. The increase in glucagon secretion produced by decreasing plasma glucose levels is in large part an indirect effect caused by release from a number of inhibitory signals that are tonically active during euglycemia, with some contribution of a direct inhibitory action of glucose.[11,20] The most important of the inhibitory signals that tonically inhibit glucagon secretion are related to local, intra-islet secretions. Falling plasma glucose decreases the secretion of insulin, zinc, and GABA by the pancreatic β-cells. Insulin and zinc act on ATP-sensitive K^+ channels to hyperpolarize the α-cell membrane. GABA, acting via cognate receptors on the α-cell membrane, also produces α-cell hyperpolarization. Decreases in plasma glucose concentratons are also sensed in the ventromedial hypothalamus and other brain sites, leading to increases in sympathetic and parasympathetic neural activity, both of which can stimulate glucagon secretion. Increased epinephrine secretion by the adrenal medulla also participates. The autonomic nervous system is also the main mediator of stress-related and prandial glucagon secretion. Further controls include somatostatin and GLP-1, both of which act on receptors on the α-cell membrane to inhibit glucagon secretion, and various plasma amino acids, which stimulate glucagon secretion (and presumably participate in the increase in glucagon secretion afater ingestion of high-protein meals). Although glucagon secretion is pulsatile, pulsatility has not been shown to affect glucagon's potency *in vivo*.

PHYSIOLOGICAL EFFECTS

Glucagon has a panoply of physiological effects,[13,16–18] a few of which are briefly reviewed here.

Hepatic Glucose Production

Glucagon phasically and tonically stimulates hepatic glucose output.[6,7,11,23,25] The phasic effect results entirely from the stimulation of glycogenolysisis. Over its physiological range of approximately 0–200 ng/L plasma, glucagon has a relatively linear effect on hepatic glucose production, which can vary approximately 10-fold, between 2.5 and 25 μmol/kg/min.[25] The increase in glycogenolysis is mediated by glucagon-stimulated increases in cAMP in the hepatocytes, which activate glycogen phosphorylase and inhibit glycogen synthase. Maximal hepatic glycogenolysis is sustained only for approximately 15 min, however, after which the rate of glycogenolysis decreases to approximately one-third maximal over approximately 3 h. Hepatic gluconeogenesis increases beginning around 3 h after the initial increase in glucagon. This is mediated by slowly developing increases in the activity of pyruvate carboxylase and other gluconeogenic enzymes and by upregulation of several genes. Glycogenolysis and gluconeogenesis seem to contribute quantitatively similar amounts to the tonic stimulation of hepatic glucose production that follows an overnight fast.

Lipid Metabolism

Glucagon and insulin cooperate in the regulation of hepatic ketogenesis. Insulin inhibits adipose tissue lipolysis, thus increasing the supply of nonesterified fatty acids (NEFA) to the liver, which is necessary for ketogenesis. An increase in the liver's capacity for fatty acid oxidation and concomitant decrease in hepatic lipogenesis is also required, which is produced by an increase in the glucagon:insulin ratio.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Ketogenesis results from β-oxidation of fatty acids in the hepatic mitochondria, which is regulated by the activity of carnitine palmitytol transferase I, which catalyzes uptake of fatty acid acyl-CoA into the mitochondria. In turn, malonyl-CoA, the first committed intermediate in the conversion of glucose into fat, acts to negatively regulate carnitine palmitytol transferase I, such that the fall in malonyl-CoA that accompanies the increase in the glucagon:insulin ratio occurring during the transition from the fed to the fasted state directs the flow of fatty acids into ketogenesis.[21] Ketones provide an alternate source of metabolic fuel for otherwise glucose-dependent tissues.

Numerous *in vitro* studies indicate that glucagon acts on glucagon receptors on adipocytes to reduce lipolysis and decrease nonesterified fatty acid release.[13] Attempts to document these phenomena *in vivo*, however, have met with mixed success,[10] probably partly because of the complex interactions between the effects of insulin and glucagon on lipid metabolism.

Glucagon causes the movement of plasma cholesterol and triglycerides into the platelet fraction of the blood. Glucagon also reduces the synthesis of triglycerides and apolipoprotein E in the liver and increases the binding capacity of low-density lipoprotein receptors. In this case as well, the normal physiological relevance of these effects remains unresolved.

Bile Acid Metabolism

A study by Song and Chiang[27] indicates that glucagon down regulates hepatic expression of cholesterol 7-alpha-monooxygenase, the rate-limiting enzyme in bile acid synthesis. This suggests a role for glucagon in the regulation of bile acid metabolism and provides another potential mechanism for its control of plasma cholesterol.

Cardiac Effects

Glucagon stimulates the release of cAMP in the myocardium, thus leading to positive inotropic and chronotropic effects.[30] Because this action does not require a beta-1 adrenoceptor stimulation, glucagon is used to treat overdoes of beta-blockers and other drugs. It may also be used for this purpose in shock, but does not function as effectively as catecholamine treatment in this situation.

Satiation

As mentioned above, glucagon secretion increases during meals, except during very high-carbohydrate meals. The demonstration that antagonizing circulating glucagon during meals increased meal size implicates prandial glucagon secretion in normal meal-ending satiation.[14] This, incidentally, was the first use of an antagonist strategy to identify a normal endocrine control of eating. A subsequent study showed that intravenous infusion of a physiological glucagon dose was sufficient to hasten satiation in normal weight men.[9] The satiating effect of glucagon occurs in the liver or portal vein and is relayed to the brain via vagal afferents.

PATHOPHYSIOLOGY

Diabetes Mellitus

Glucagon has been implicated in the pathophysiologies of both type 1 and type 2 diabetes mellitus (T1DM and T2DM, respectively).[1,2,6,7,12,26] The normal or near-normal fasting plasma glucagon concentrations found in patients with T2DM represent marked hyperglucagonemia relative to the elevated concentrations of plasma glucose and insulin, both of which normally inhibit glucagon secretion, and lead to increased hepatic glucose production. Similarly, carbohydrate ingestion fails to inhibit glucagon secretion after meals, leading to exaggerated prandial glucagonemia and continued hepatic glucose production. The glucagon response to protein ingestion is also exaggerated. Thus, disturbances in glucose-controlled and prandial glucagon secretion are an important component of the pathophysiology of T2DM, and their control may represent a therapeutic option. The mechanisms underlying these disturbances, unfortunately, remain obscure.

Relative hyperglucagonemia has also been implicated in the pathophysiology of T1DM. Lee et al.[15] indicate that this contribution is not merely related to unrestrained glucose production, as described above. These investigators found, as others had reported, that streptozotocin, which is toxic to the pancreatic β-cells and produces a model of T1DM, fails to elicit hyperglycemia in transgenic mice lacking the glucagon receptor. In addition, and very surprisingly, they found that these mice display normal glucose tolerance, suggesting that the lack of glucagon signaling somehow increases the ability of liver and muscle to take up glucose in the absence of insulin. In so far as muscle normally fails to express glucagon receptors, the mechanism must be at least in part indirect. One possibility is that the markedly increased plasma GLP-1 levels in the diabetic, glucagon-receptor knockout mice contribute.

Glucagonoma

Glucagonomas are rare, slow-growing, malignant, glucagon-secreting tumors of the pancreatic islets. Fasting plasma glucagon concentrations are elevated 2- to 200-fold. The commonest presenting sign is necrolytic migratory erythematotic rash. Mild T2DM, weight loss, and anorexia are typical. Metastases occur in the liver, bone, lymph glands, and other tissues. Because glucagonomas are rarely detected early, management is challenging. A combination of dermatologic

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

treatments, tumor-reducing surgery, hepatic artery embolization, and antagonism of the effects of glucagon with somatostatin analogs usually effectively reverses the signs and symptoms of glucagonoma.[8]

THERAPEUTIC USE

Hypoglycemia

The longest-standing therapeutic application of glucagon is in the treatment of acute hypoglycemic episodes that are too severe to permit the patient to ingest glucose orally and if intravenous glucose infusion therapy is not available. It is physiologically benign, with glucagon hypersensitivity very rarely observed. Thus, glucagon can be used even when diagnosis of hypoglycemia is uncertain, as in anaphylaxis, or when its cause is unknown. Because glucagon leads to catecholamine release, pheochromocytoma is a contraindication.

Gastrointestinal Radiology and Esophageal Foreign Body Impaction (EFBI)

Because glucagon relaxes gastrointestinal smooth muscle, especially esophageal smooth muscle, a second standard use of glucagon is to relax the gastrointestinal tract before radiologic examination. Again, the main contraindication for this use of glucagon is pheochromocytoma.

Glucagon's effect to relax the esophagus has led to its use in emergency medicine to treat EFBI. A recent review,[2] however, indicates that glucagon is not an effective therapy for EFBI and, because it can elicit vomiting, increases the risks of aspiration and esophageal perforation.

Diabetes

The emerging role of relative hyperglucagonemia in diabetes mellitus described above has led to speculation as to the usefulness of glucagon antagonism in diabetes treatment, and promising results have been reported in animal models of both T1DM and T2DM.[1,6,7,12,15,25,26]

Obesity

Two studies[5,24] suggest that formulations with both glucagon and GLP-1 receptor-agonist properties reduce body weight in rodent models. Changes in both eating and energy expenditure contribute to the effects. Future work will have to address the conundrum that GLP-1 agonism plus glucagon antagonism appear beneficial in T2DM, which is most frequently caused by obesity, whereas GLP-1 agonism plus glucagon antagonism seem beneficial in obesity.

Chapter 151

Insulin

Bernadette E. Grayson and Stephen C. Woods

ABSTRACT

The pancreatic hormone, insulin, regulates circulating glucose levels, and in addition, it has a close relationship with the central nervous system to control food intake and body weight. Circulating insulin levels are directly associated with the levels of adiposity. Although most of its peripheral effects are anabolic, the central actions of insulin are specifically catabolic. These central effects of insulin are mediated largely through the arcuate nucleus of the hypothalamus, an important brain locale for modulation of food intake and body weight.

INTRODUCTION

Insulin is an approximately 5.8-kDa peptide hormone synthesized by the β-cells of the islets of Langerhans in the endocrine pancreas. Insulin has diverse functions *in vivo* which include regulating glucose and lipid metabolism, controlling food intake, maintaining long-term body weight, and influencing basic cell growth and replication. The actions of insulin first came to light in 1889 when Minkowski and von Mering found that the removal of the pancreas from a dog produces diabetes, a disease resulting from insufficient levels and/or action of insulin in the body. However, it was not until the work of Banting, Best, and Macleod that insulin was purified and its fundamental importance made evident. The role of insulin in the central nervous system (CNS) control of food intake and body weight in the context of its other roles is the focus of this review.

GLUCOREGULATORY ACTIONS OF INSULIN

Simply put, the primary role of insulin is to control the levels of circulating glucose by sequestering glucose into cells after meal ingestion. In response to a meal, the levels of glucose and other nutrients increase in the circulation. After entering the β-cells through facilitated diffusion via the glucose transporter, GLUT2, intracellular glucose directly stimulates glycolysis, increasing the intracellular ATP:ADP ratio. Consequent closure of the ATP-sensitive potassium channels (K_{ATP}) results in depolarization of the β-cell membrane, triggering calcium entry via voltage-dependent calcium channels and initiates a signal transduction cascade culminating in discharge of the releasable pool of insulin into circulation. Insulin secretion is consequently directly proportional to the concentration of glucose reaching the β-cell.

INSULIN ACTIONS

Insulin, with a half-life of only 2–3 min, exerts only a transient effect when secreted. Its major peripheral actions are in the liver, adipose tissue, and skeletal muscle although insulin receptors (IR) are ubiquitously found on most tissues including much of the CNS.[19] The IR is a transmembrane tyrosine kinase receptor with two extracellular α subunits and two transmembrane β subunits. Binding of insulin to its receptor initiates phosphorylation of catalytic substrates, which trigger two major signaling cascades: the phosphatidylinositol 3-OH kinase (PI3K) pathway and the mitogen-activated protein kinase (MAPK) pathway. Activity in these pathways results in translocation of tissue-specific glucose transporters (GLUTs), primarily GLUT2 in liver and GLUT4 in skeletal muscle and adipocytes, from the cytoplasm to the plasma membrane. Via these GLUTs, insulin stimulates an increase of glucose uptake by the cell. Because of this primary action of insulin, pharmacologic insulin administration results in decreased blood glucose and is used in the treatment of diabetic individuals who are unable to produce insulin in sufficient quantities to reduce blood glucose to a normal, low level. Insulin administration to non-diabetics results in hypoglycemia.

In the pancreatic islets, insulin inhibits the secretion of pancreatic glucagon, a hormone from α-cells that directly opposes the actions of insulin by increasing blood glucose, primarily by stimulating hepatic glucose production and secretion. In the liver, insulin stimulates glycogen synthesis and storage and inhibits the breakdown of glycogen, and at the same time inhibits the formation of *de novo* glucose by gluconeogenesis. In adipose tissue, insulin promotes the uptake of fatty acids by adipocytes and their conversion to stored triglycerides. Hence,

in the periphery, insulin is primarily anabolic, promoting a build-up of stored energy in many tissues. This is in direct contrast to the overriding catabolic action of insulin in the CNS.

INSULIN SECRETION

Fasting insulin levels in the plasma are low and stable (basal condition), and they increase concomitant with meal ingestion (prandial condition) or glucose administration (stimulated condition). Lean individuals have lower levels of basal, prandial, and stimulated concentrations of insulin, and obese individuals, particularly those with increased levels of visceral adiposity, maintain higher concentrations of basal insulin and they secrete proportionally more insulin in response to a standard meal[2] (Fig. 1). Because obese individuals require more insulin to maintain normoglycemia, they are considered "insulin resistant," and the term also refers to an inability of insulin to elicit glucose uptake in a tissue-specific manner.

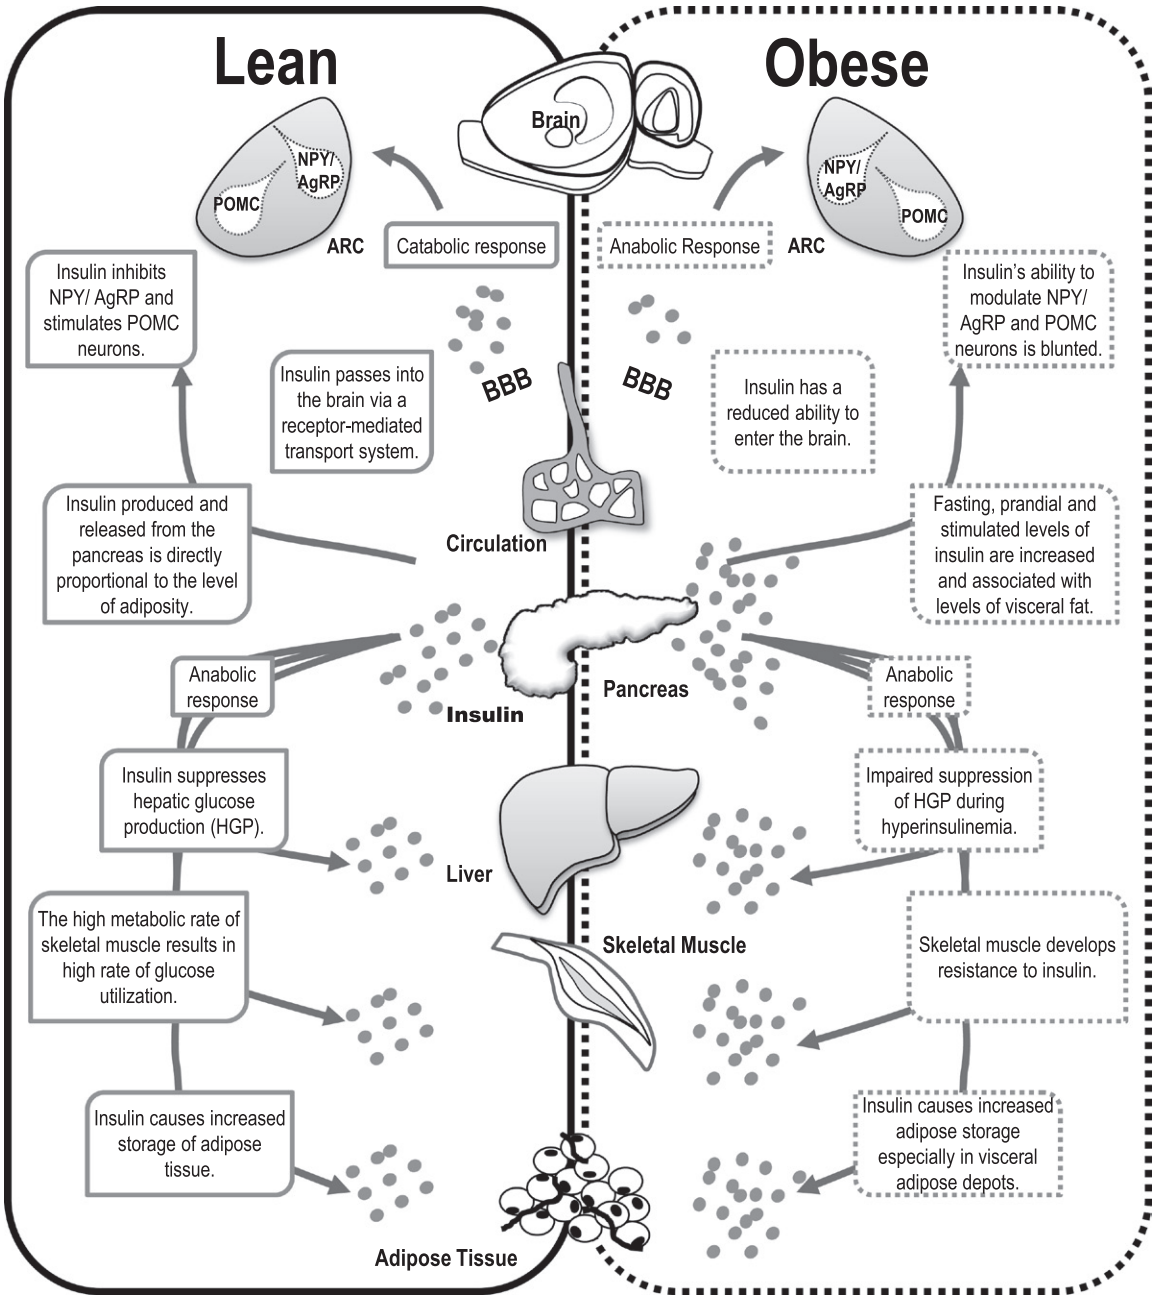

FIGURE 1 Central and peripheral activities of insulin in lean and obese states. Overall actions on the brain, pancreas, liver, skeletal muscle, and adipose tissue in lean and obese individuals (BBB, blood–brain barrier).

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Because its secretion is in direct proportion to the amount of body fat, and because it is able to penetrate the blood–brain barrier (BBB) from the circulation, insulin is considered an adiposity signal that provides information to the CNS that contributes to the homeostatic regulation of body fat. When an individual is food-restricted or voluntarily diets and loses weight, less insulin is secreted and reaches the brain; and the catabolic tone of the hypothalamus is consequently reduced. Food intake increases in this circumstance until body weight and the central insulin signal are restored to the predieting level. In instances of forced-overfeeding or voluntary overconsumption of nutrients, adiposity and the insulin signal rise, increasing the catabolic tone of the hypothalamus and eliciting hypophagia until the excess weight is lost (Fig. 1). Thus, the amount of insulin, together with that of leptin (an adipose-derived hormone),[16] directly correlates with adiposity and conveys a key index of the degree of peripheral adipose stores.

INSULIN AND THE BRAIN

The brain has an obligate need for glucose as a fuel source, and it uses upwards of 25% of total circulating glucose throughout the day. Unlike most tissues, the brain is exempt from the direct need for insulin to uptake glucose from the extracellular fluid. Rather, in the CNS, GLUT3 is located on the plasma membrane of neurons and GLUT1 is expressed by nonneuronal cells such as glia and ependymal cells. Both transporters are insulin-independent and allow glucose uptake in the CNS.[26] Thus, rather than stimulating glucose uptake by brain cells, insulin functions as a hormonal messenger to the CNS regarding peripheral nutrition and stored fat.

The BBB is a physical and functional wall created by endothelial cells riveted with tight junctions surrounding brain capillaries and buffered by a layer of astroglia. The BBB prevents the entry of most large molecules from the circulation into the brain interstitial fluid. Many molecules that are needed by brain cells, such as glucose and amino acids, therefore gain entry to the brain via specific molecular transport systems, and this is also true for insulin. A saturable, IR-mediated transport system on brain capillary endothelial cells moves insulin through the cell and releases it into brain interstitial fluid biologically intact.[3] Some of the insulin diffuses into the cerebrospinal fluid (CSF) where its levels can be determined and reflect insulin activity in the brain.[28] CSF insulin therefore correlates with plasma insulin and secondarily with body adiposity[34] (Fig. 1).

There are important consequences based on the entry of insulin into the brain being IR mediated. For one, the transport system can become saturated. Thus, as circulating insulin increases, the entry of insulin does not increase beyond the point of saturation.[3] Another consequence is that insulin transport into the CNS is regulated. As an example, it is decreased in fasting and weight loss, and increased after meals.[31] Animals with compromised insulin receptors have reduced ability of insulin to enter the brain. Although most brain areas express some IR, many brain regions have particularly high levels. The olfactory bulb densely expresses IR, as does the cortex, hippocampus and regions of the hypothalamus, the latter being important for the integrative control of food intake and body weight regulation.[6,15]

When exogenous insulin is administered directly into the brain, near or directly within the mediobasal hypothalamus, animals behave as if they have excess fat in the body; they eat less food and lose weight[6,29] (Fig. 1). This response is dose dependent; has been documented in numerous species including mice, rats, sheep, and nonhuman primates; and the hypophagia is not secondary to illness.[11] Conversely, if the insulin signal is reduced in the brain, either by local administration of specific insulin antibodies[22] or else by compromising the action of the IR locally in the mediobasal hypothalamus,[17] animals overeat and gain weight. When insulin levels in the brain are held constant for long intervals by means of slow, steady local infusions, body weight is maintained and defended at a level determined by the dose of insulin administered.[10] Although insulin has not been administered directly into the brain of humans, it has been administered intranasally to humans with a consequent increase of insulin in the cerebrospinal fluid. Humans administered insulin intranasally eat less food and lose body fat[18] Males are more sensitive to the intranasal insulin administration than females consistent with an observed sex difference in rats.[13] This basic sex difference is consistent with the observation that, in general, males have higher levels of visceral adiposity and concomitant higher levels of circulating insulin than females.

INSULIN AND THE ARC

The hypothalamic arcuate nucleus (ARC) borders the floor of the third cerebral ventricle near the median eminence and contains two classes of neurons that project to other brain areas. One class is considered catabolic, eliciting decreased food intake when stimulated and loss of body weight and body fat when stimulation is prolonged. Primary neurotransmitters of these neurons include the peptides, α-melanocyte-stimulating hormone (αMSH, a cleavage product of proopiomelanocortin, or POMC) and cocaine and amphetamine-related transcript (CART). The other class of ARC neurons is anabolic, and when stimulated these neurons elicit increased food intake and body weight. These neurons secrete the neurotransmitters, neuropeptide Y (NPY) and agouti-related peptide (AgRP). αMSH is an agonist of melanocortin 3 and 4 receptors, MC3/4R, whereas AgRP is an inverse agonist/antagonist at those

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

same MC3/4R. The role of these peptides in the control of food intake is the subject of other chapters in this volume and is reviewed only briefly here. Insulin acts on IR in the ARC to elicit inhibition of NPY/AgRP neurons and stimulation of αMSH/CART neurons, and its local administration into or near the ARC causes anorexia and weight loss. This dual anabolic/catabolic circuitry of the ARC is sensitive to numerous other metabolic signals in addition to insulin, including leptin, meal-elicited satiation signals such as cholecystokinin (CCK, see below), and nutrients including glucose and some fatty acids and amino acids.[14,20] The outputs of these ARC neurons are projections to other areas in the hypothalamus important in the homeostatic regulation of body weight, such as the paraventricular nuclei (PVN), dorsomedial nuclei (DMH) and lateral hypothalamic areas (LHA). Thus, the ARC is a site of integration of myriad metabolic signals, with the output projecting to areas that influence autonomic, hypothalamus–pituitary–adrenal (HPA), and ingestive responses in many parts of the brain.

Insulin binds to IR on NPY/AgRP neurons, inhibiting both the expression and secretion of both transmitters. Conversely, insulin stimulates the activity of a subset of αMSH-containing neurons, leading to reduced activity that is partially dependent on the melanocortin receptor system because insulin's catabolic action is greatly reduced in the presence of MC3/4R antagonists.[8] The binding of insulin to its receptor on ARC neurons uses the same PI3K pathway as in peripheral tissues, and local administration of drugs that block the PI3K pathway prevents the catabolic actions of insulin.[24] The administration of insulin mimetics that bypass the extracellular portion of the insulin receptor, stimulating the intracellular insulin signaling cascade directly, reduces food intake and body weight, and suppresses hepatic glucose production.[1] These findings reveal the importance of insulin signaling to the normal regulation of energy homeostasis, because disruption of insulin signaling cascades within the hypothalamus can lead to hyperphagia, obesity, and glucose dysregulation.

INTERACTION OF BRAIN INSULIN WITH GUT HORMONES

The homeostatic regulation of body weight relies on control over food intake, and this is accomplished by the brain's influencing meal size as opposed to meal initiation.[33] Meal size and the phenomenon of satiation (fullness, in humans) are governed in part by gastrointestinal (GI) hormones that are secreted in response to the food entering the GI tract during meals. As an example, CCK is secreted in response to nutrients (especially lipids) entering the duodenum, and it acts locally on its receptors on nearby sensory nerve endings that transmit a signal to the brain via the vagus nerve and contribute to the process of satiation.[23] The administration of CCK to humans and rodents during meals results in ingestion of fewer calories than occurs in controls; and administration of CCK antagonists results in consumption of larger meals. The efficacy of the combined satiation signal generated by CCK and other GI peptides such as glucagon-like peptide-1 (GLP-1)[4] and peptide YY (PYY)[5] can be modulated by insulin and leptin. When these adiposity signals are elevated, they act in the brain to increase sensitivity to CCK and other satiation signals[27,32] (Fig. 1). Thus, when an individual has gained a little weight (fat) and consequently has increased secretion of insulin and leptin, meals that are initiated will end sooner because of an enhanced satiation signal, contributing to a homeostatic reduction of body weight. Conversely, if the insulin signal is reduced in the brain, animals eat larger meals and tend to gain weight over time.[22] The interaction of satiation signals and adiposity signals provides a robust negative feedback mechanism that opposes changes of body weight.

Molecular-genetic tools have been used in recent years to gain new insights into the actions of insulin in the CNS at a cellular and neuronal-circuit level. Using cre/loxP technology, Brüning et al. originally created neuron-specific IR knockout (NIRKO) mice.[9] These animals have obesity, hyperleptinemia, hyperinsulinemia, and mild insulin resistance, and the females are hyperphagic. Selective decrease of IR by use of an antisense oligonucleotide in predominantly NPY/AgRP neurons in the ARC results in a rapid onset of hyperphagia and increased adiposity as well as suppression of endogenous glucose production.[25] Deletion of IR specifically in AgRP ($IR\Delta^{AGRP}$) or POMC ($IR\Delta^{POMC}$) neurons in the ARH[7] results in no alterations in food intake, energy expenditure, or adiposity in comparison with that of controls. However $IR\Delta^{AGRP}$ animals do exhibit a selective reduction in hepatic glucose production under hyperinsulinemic–euglycemic clamp conditions. Selective deletion of IR from VMH neurons under the SF-1 promoter ($SF\text{-}1\Delta^{IR}$) results in diminished PI3K signaling in SF-1 neurons leading to overall protection from diet-induced leptin resistance, weight gain, adiposity, and impaired glucose tolerance whereas over-expression results in driving PI3K signaling pathways.[21] Thus, insulin acts on several neuronal types and areas of the hypothalamus, stimulating some circuits and inhibiting others, with a net catabolic effect of decreased food intake and body fat, increased energy expenditure, and reduced hepatic glucose production.

PATHOPHYSIOLOGIC IMPLICATIONS OF BRAIN INSULIN DYSFUNCTION

There are two categories of diabetes mellitus. Type I or insulin-deficiency diabetes mellitus (IDDM) is an autoimmune disease in which pancreatic β-cells are destroyed.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Symptoms of insulin deficiency include hyperglycemia, glycosuria, and other metabolic problems, as well as extreme hyperphagia, and patients with IDDM require insulin maintenance throughout their lives. When insulin is added into the CNS of animals with IDDM, the hyperphagia is eliminated without any improvement of the peripheral metabolic symptoms, showing that the hyperphagia is a consequence of absent brain insulin in IDDM.[30]

Type II diabetes mellitus or noninsulin dependent diabetes mellitus (NIDDM) occurs when target tissues such as skeletal muscle become resistant to insulin's action. It is most commonly associated with obesity, fatter individuals having a greater degree of insulin resistance; and losing weight is typically accompanied by improved insulin sensitivity. Patients with NIDDM and mild insulin resistance can take insulin-sensitizing drugs that enhance the body's ability to respond to its own insulin. When those compounds are no longer effective, patients with NIDDM often must take exogenous insulin to maintain health. Obese individuals are also resistant to insulin's ability to reduce blood glucose and make other metabolic improvements, and the brain of these animals is also resistant to the ability of insulin to reduce food intake and body weight.[12] The important point is that the brain insulin system has a major role in both types of diabetes mellitus.

CONCLUSIONS

The insulin system consists of insulin originating from the pancreas and ubiquitously expressed insulin receptors throughout the body. Insulin is transported via the plasma throughout the body including the brain. Peripherally, insulin provides a conduit for glucose sequestration into cells. Along with leptin and perhaps other molecules, insulin acts in the brain to signal the amount of adiposity stored in the body. Through its integration with other hormonal signals, insulin is a potent catabolic influence reducing energy intake and storage. Insulin resistance, either centrally or peripherally, leads to global and local dysfunction.

Chapter 152

Leptin

Martin G. Myers Jr. and Megan Greenwald-Yarnell

ABSTRACT

Leptin is an adipocyte-derived polypeptide hormone that acts via its receptor (LEPR-B) to inhibit feeding and regulate other aspects of energy balance. Alterations in leptin levels during changes in nutritional status regulate feeding and energy expenditure; low leptin concentrations in states such as starvation promote increased hunger and decreased energy expenditure. The major sites of leptin action are in the brain. Although much work has focused on the hypothalamic arcuate nucleus (ARC), leptin controls feeding via a broadly distributed network of LEPR-B neurons in regions that include the hypothalamus, midbrain, and brainstem. The roles for specific LEPR-B signaling pathways in leptin action have been defined, with each mediating distinct aspects of the control of feeding. The apparently reduced anorectic efficacy of leptin in states of nutritional surfeit and obesity remains a major area of investigation and may result from multiple mechanisms, including processes that interfere with LEPR-B signaling.

LEPTIN AND FEEDING BEHAVIOR

Leptin was identified through the study of the spontaneous loss-of-function mutation (*obese* or Lep^{ob} allele) in mice that causes hyperphagia and obesity in the homozygous ($Lep^{ob/ob}$) state.[8] As implied by the elegant parabiosis studies of Coleman,[3] and later proven by the positional cloning of Lep^{ob},[35] the gene encodes a secreted polypeptide. This protein was named leptin (Greek: *leptos* = thin), because injection of leptin into obese $Lep^{ob/ob}$ animals resulted in a profound weight loss. Physiologically, leptin, which is produced primarily by adipocytes, communicates the status of body energy stores from adipocytes to the brain to control the intake and expenditure of calories.[2,8] Leptin treatment of $Lep^{ob/ob}$ animals results in decreased caloric intake and increased energy expenditure. Leptin is a crucial controller of many central nervous system (CNS) peptides that regulate feeding and energy expenditure.[6,26]

THE ABSENCE OF LEPTIN ACTION

Because of the decades-long existence of $Lep^{ob/ob}$ mice, there is a long-standing literature regarding the phenotype of mice with loss-of-function mutations for leptin (and mice null for the leptin receptor (LEPR; $Lepr^{db/db}$ mice)).[8,28] These $Lep^{ob/ob}$ and $Lepr^{db/db}$ mice have similar phenotypes of hyperphagia, low metabolic rate, and consequent obesity. Additionally, $Lep^{ob/ob}$ and $Lepr^{db/db}$ mice display a stereotypical neuroendocrine starvation response (even in the face of nutrient excess and obesity) that is characterized by hypothyroidism, hypothalamic infertility, decreased growth, and decreased immune function.[2] In $Lep^{ob/ob}$, but not in $Lepr^{db/db}$, mice exogenous leptin therapy reverses all these phenotypes. Similar phenotypes have been observed in rare human patients null for leptin or its receptor.[7] Thus, leptin action not only suppresses feeding, but it also increases metabolic rate and permits neuroendocrine energy expenditure; absent leptin action results in an increased drive to feed and initiates a series of energy-sparing events.

LEPTIN PRODUCTION AND THE CONTROL OF CIRCULATING LEPTIN

Leptin is produced primarily by adipocytes.[8] Although no tissue-specific null mice have been generated to probe the physiologic relevance of leptin production by specific tissues, the phenotypes of lipodystrophic patients and rodent models (which lack adipose tissue) are remarkably similar to the phenotype of leptin deficiency (with the exception of adipose mass).[21] Lipodystrophy is characterized by low circulating leptin concentrations, increased feeding, decreased metabolic rate, and neuroendocrine dysfunction similar to that observed in starvation or genetic leptin deficiency. Further, most of these phenotypes are partially or completely remedied by treatment of lipodystrophic patients or animals with exogenous leptin,[21] suggesting that adipose tissue is the main source of circulating leptin. The placenta also produces substantial quantities of leptin, although the physiologic role for the resulting increased leptin concentrations in pregnancy remains relatively poorly understood.[16]

In adipocytes, leptin production is regulated by nutritional status: generally speaking, increased stored triglyceride results in greater leptin production, whereas decreased stored fat diminishes leptin.[8] The regulation of

leptin production by body fat stores positions leptin well to function as an indicator of body energy stores. Thus, in times of inadequate energy stores (e.g., starvation) leptin levels decrease; these low leptin levels enhance appetite and decrease energy use, whereas leptin treatment reverses these effects.[1,25] Conversely, with adequate energy stores, appropriate leptin levels moderate the drive to eat and permit the use of energy.

Leptin secretion is constitutive: Leptin is synthesized and extruded into the secretory pathway for release by mass action, as opposed to being packaged into secretory vesicles for release in response to an acute stimulus.[24] Thus, although there is modest diurnal variation in circulating leptin concentrations, leptin secretion and circulating leptin concentrations depend primarily on the rates of transcription and translation of the leptin mRNA dictated by adipose energy stores, and circulating leptin concentrations vary little on a minute-to-minute or hour-to-hour basis.[1] That circulating leptin concentrations change only after prolonged alterations in nutritional status predicts that leptin acts to set the chronic tone of the feeding and neuroendocrine systems, as opposed to acutely regulating the activity of the neural circuits by which it acts (short-term regulation is probably accomplished by more acutely regulated factors, such as insulin and ghrelin).

LEPTIN RECEPTORS

Multiple LEPR isoforms exist; all are products of a single *Lepr* gene and result from alternative mRNA splicing and/or proteolytic processing.[24,28] LEPR isoforms fall into three classes: secreted, short, and long. The secreted forms are alternative splice products (e.g., the murine LEPR-E) or proteolytic cleavage products of membrane-bound LEPR forms. These secreted receptors contain only extracellular domains (including the leptin binding site) and bind circulating leptin with an affinity similar to that of cell-associated LEPRs. Short (LEPR-A, LEPR-C, LEPR-D, etc.) and long form (LEPR-B) receptors contain identical extracellular and transmembrane domains and the same first 29 intracellular amino acids, subsequently diverging in sequence secondary to alternative splicing of the *Lepr* 3′-exons.[24,28] LEPR-B is highly conserved among species and possesses an intracellular domain of approximately 300 residues.

Although the function of the short LEPR forms remains unclear, LEPR-B is crucial for leptin action. Indeed, the originally described $Lep^{db/db}$ mice lack only LEPR-B (as a consequence of a mutation that results in missplicing of the LEPR-B-encoding mRNA) but exhibit a phenotype similar to that of leptin-deficient $Lep^{ob/ob}$ animals and of $Lepr^{db3J/db3J}$ mice (which are deficient in all LEPR isoforms).[24,28]

The concentration and bioavailability of circulating leptin are also modulated by the presence of circulating LEPR-extracellular domain that is devoid of transmembrane or intracellular components (that cleaved from cell surface LEPRs, along with LEPR-E). Although the acute elevation of free extracellular LEPR, as by injection, can decrease leptin bioavailability, chronic increases in circulating LEPR stabilize leptin in circulation, and may serve to increase the amount of active, as well as total, leptin in the circulation;[34] mice that overexpress LEPR-E are leaner with reduced food intake.[15]

SITES OF LEPTIN ACTION

Most leptin effects on energy balance are attributable to effects in the CNS. CNS administration of leptin recapitulates the anorectic and neuroendocrine effects of peripherally delivered leptin.[8] Further, brain-specific transgenic expression of LEPR-B rescues the anorectic and neuroendocrine phenotypes of $Lepr^{db3J/db3J}$ mice, and brain-specific disruption of *Lepr* increases feeding and adiposity.[24,28] Much attention has been paid to two distinct populations of LEPR-B-expressing neurons in the arcuate nucleus (ARC) in the mediobasal hypothalamus: neurons that express proopiomelanocortin (POMC), and neurons that coexpress neuropeptide Y (NPY) and agouti-related peptide (AgRP).[6,26] POMC is processed to α-melanocyte stimulating hormone (αMSH) in the ARC POMC neuron. αMSH mediates a powerful anorectic (appetite-suppressing) signal; LEPR-B stimulates the expression of POMC and activates the POMC neuron. AgRP is an antagonist/inverse agonist of central melanocortin signaling, and NPY is itself an orexigenic (appetite-stimulating) peptide that also acts to suppress the central growth and reproductive axes. Leptin inhibits the NPY/AgRP neurons and suppresses expression of these neuropeptides, stimulates the production of anorectic neuropeptides, and suppresses levels of orexigenic peptides in this circuit. Conversely, when leptin action is decreased or deficient (e.g., starvation, $Lep^{ob/ob}$ or $Lepr^{db/db}$ mice), appetite is stimulated via the suppression of anorectic neuropeptides (e.g., POMC-derived peptides) and by increased expression of orexigenic peptides (e.g., NPY and AgRP).

Genetic ablation of LEPR-B from POMC and AgRP neurons either individually or collectively produces only a small increase in body weight and does not significantly change many other parameters that are perturbed in $Lepr^{db/db}$ mice,[29] indicating the importance of LEPR-B signaling in other neurons for leptin action. Indeed, many LEPR-B-expressing neurons reside in a number of brain regions associated with the regulation of energy balance, including various hypothalamic, midbrain, and brainstem nuclei.[19]

Within the hypothalamus, the ARC, ventromedial hypothalamic nucleus (VMH), dorsomedial hypothalamic nucleus (DMH), ventral premammilary nucleus (PMv), lateral hypothalamic area (LHA), and preoptic area (POA) contain large numbers of LEPR-B neurons (Figure 1).[19]

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

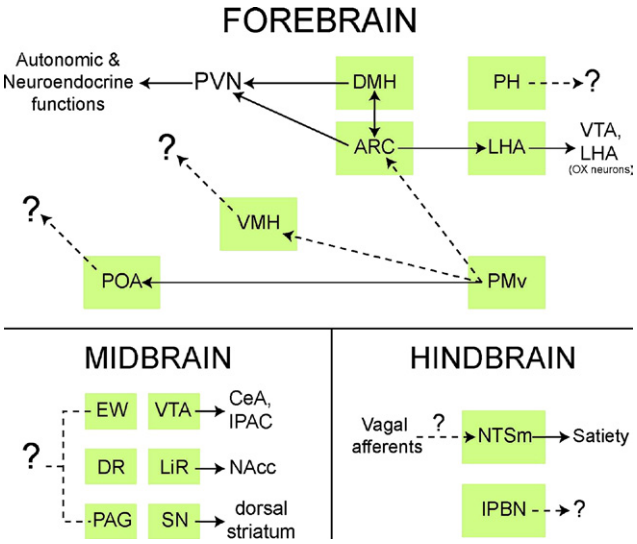

FIGURE 1 A distributed network of LEPR-B neurons mediates leptin action. Brain areas containing substantial numbers of LEPR-B neurons in the forebrain, midbrain, and hindbrain are designated by grey boxes. The known inputs, targets, and functions of the LEPR-B neurons in each area are identified, where known, but our understanding of many components of this network of leptin-responsive neurons remains incomplete, and some connections remains speculative (dashed lines). PVN, paraventricular nucleus; POA, preoptic area; DMH, dorsomedial nucleus of the hypothalamus; ARC, arcuate nucleus; VMH, ventromedial nucleus of the hypothalamus; PH, posterior hypothalamus; LHA, lateral hypothalamic area; PMv, ventral premammillary nucleus; EW, Edinger–Westphal nucleus; DR, dorsal raphe; PAG, periaqueductal gray; VTA, ventral tegmental area; LiR, linear raphe; SN, substantia nigra; NTSm, medial nucleus of the tractus solitarius; lPBN, lateral parabrachial nucleus.

VMH-specific LEPR-B deletion leads to a modest metabolic phenotype but fails to recapitulate most of the *Lepr*$^{db/db}$ phenotype.[5] Leptin action via LHA LEPR-B neurons modulates local neurons that express orexin (aka hypocretin), as well as innervating the midbrain ventral tegmental area (VTA).[13] Deletion of LEPR-B from neurotensin-containing LHA neurons also produces only a modest increase in body weight and fat mass, along with a decrease in energy expenditure that is associated with alterations in orexin and VTA function.

Within the midbrain, LEPR-B neurons lie in the VTA, substantia nigra (SN) and several nearby midline nuclei.[19] Most of the VTA and SN LEPR-B neurons contain the neurotransmitter dopamine (DA).[9,11] Although leptin administration to the midbrain decreases food intake, deletion of LEPR-B from DA neurons produces no detectable change in parameters of energy balance; indeed, some lines of evidence suggest a potential role for these neurons in the regulation of anxiety-like behaviors, rather than feeding.[11,14] Although the dorsal raphe (DR) also contains a population of LEPR-B-expressing neurons, these neurons do not (as previously reported) contain serotonin, and thus, genetic deletion of LEPR-B in serotonergic neurons produces no effect on energy balance.[12]

LEPR-B is also found in the hindbrain, primarily within the medial nucleus tractus solitarius (mNTS) and lateral parabrachial nucleus (lPBN).[19] Although partial genetic deletion of LEPR-B from the hindbrain produces little phenotype, viral-mediated RNAi knockdown of LEPR-B in the area of the NTS alters meal size and slightly increases body weight, suggesting some role for direct hindbrain leptin action in the regulation of energy balance.[10,27]

Thus, no single discrete site of leptin action has yet been revealed to mediate the majority of leptin action on energy balance. Several larger groups of neurons play a crucial role, however. Deletion of LEPR-B from the entire hypothalamus promotes severe obesity rivaling that observed in *Lepr*$^{db/db}$ animals.[22] Similarly, deletion of LEPR-B from neurons that express the vesicular GABA transporter (vGAT) produces dramatic hyperphagic obesity.[31] LEPR-B/vGAT neurons lie primarily in the hypothalamus and comprise most LEPR-B neurons in the ARC, DMH, and LHA, suggesting that the LEPR-B neurons in these nuclei mediate crucial components of leptin action on energy balance. Interestingly, although LEPR-B/vGAT neurons are distinct from POMC neurons, they participate in the regulation of POMC neurons, suggesting that hypothalamic melanocortin action is regulated by the concerted action of a distributed set of LEPR-B neurons, as are most other leptin effects.

LEPR-B SIGNALING PATHWAYS AND THE CONTROL OF ENERGY BALANCE

The initially observed homology of LEPR-B with other type I cytokine receptors (e.g., the gp130 subunit of the IL-6 receptor family) suggested that leptin binding to LEPR-B activates Jak kinases to mediates cytokine receptor-like signals.[24,28] Jak2 represents the Jak kinase primarily involved in signaling by the intracellular domain of LEPR-B.[24] All functional cytokine receptors contain a proline-rich "Box 1" motif that is required for Jak kinase interaction and activation; additional less-conserved sequences (sometimes referred to as "Box 2") COOH-terminal to Box 1 are also important for Jak kinase interactions and likely function in Jak kinase isoform selectivity.[24] Intracellular residues 31–36 of LEPR-B (i.e., sequences immediately downstream of the alternative splice junction after amino acid 29) represent Box 2 and are required for Jak2 activation. This motif is absent from all described short LEPR isoforms, explaining the inability of these molecules to mediate leptin action in *Lepr*$^{db/db}$ animals. Figure 2

There are three conserved tyrosine residues on the intracellular domain of LEPR-B (Tyr_{985}, Tyr_{1077}, and Tyr_{1138}), all of which are phosphorylated to mediate downstream signaling.[24] In human LEPR-B, there exist two additional

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

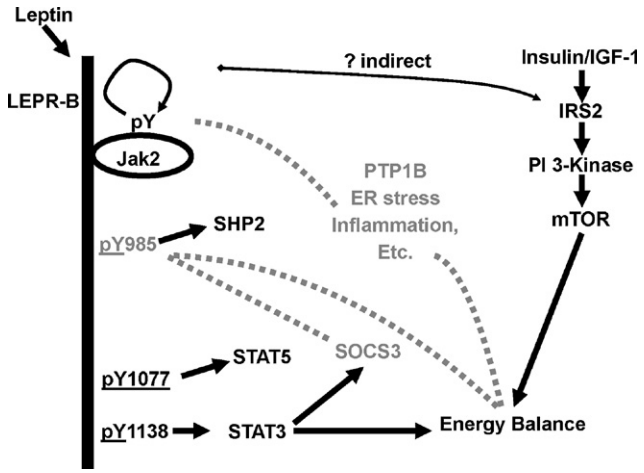

FIGURE 2 LEPR-B signaling, inhibitory pathways, and the control of energy balance. Leptin binding to LEPR-B activates the associated Jak2 tyrosine kinase, resulting in the tyrosine phosphorylation (pY) and activation of Jak2 and subsequently the phosphorylation of LEPR-B on Tyr_{985}, Tyr_{1077}, and Tyr_{1138}. Tyr_{1138} recruits STAT3 to mediate its transcriptional activation; STAT3 is also an important mediator of energy balance regulation during leptin action. Tyr_{1077} mediates the majority of STAT5 recruitment and activation, while Tyr_{985} recruits SHP-2. LEPR-B also engages inhibitory (gray/dashed lines) signals: one transcriptional target of STAT3 is the inhibitory SOCS3, which binds Tyr_{985} to feedback on and attenuate LEPR-B signaling. Other cellular processes that may inhibit LEPR-B to promote obesity/impair the control of energy balance include protein tyrosine phosphatases (such as PTP1B), ER stress, and inflammatory signaling pathways. Insulin-like signals that act via IRS2, PI3K and mTOR also contribute to the control of energy balance, although it is not clear whether these act primarily downstream of LEPR-B, or rather provide a converging/supporting signal resulting from the much stronger activation of these pathways by the insulin and IGF-1 receptors.

intracellular tyrosine residues, although little is known about their potential function (or lack thereof).[28] There are thus four known sites for the initiation of intracellular signaling by LEPR-B: those originating directly from Jak2, along with those stemming from Tyr_{985}, Tyr_{1077}, and Tyr_{1138} of LEPR-B. In cultured cells, Tyr_{985} interacts with SHP-2 (aka PTPN11) to mediate the majority of extracellular regulated kinase (ERK) activation; the remainder of ERK signaling is mediated by Jak2 independently of tyrosine phosphorylation sites on LEPR-B.[24] Tyr_{985} also binds to the suppressor of cytokine signaling-3 (SOCS3). Tyr_{1077} recruits the signal transducer and activator of transcription (STAT)-5, to control the majority of LEPR-B-mediated STAT5-dependent transcriptional events in cultured cells. Tyr_{1138} recruits STAT3.[24] In addition to mediating a variety of positive signals, the LEPR-B Tyr_{1138}→STAT3 pathway induces SOCS3 expression; SOCS3 interacts with phosphorylated Tyr_{985} of LEPR-B to limit LEPR-B signaling. This LEPR-B Tyr_{1138} →STAT3→SOCS3→Tyr_{985} pathway represents a major feedback loop to inhibit LEPR-B signaling.[24]

In cultured cells, Jak2 tyrosine phosphorylation during LEPR-B stimulation may mediate some signals independently of tyrosine phosphorylation sites on LEPR-B, but most Jak2 tyrosine phosphorylation sites studied to date function to regulate Jak2 activity rather than mediating downstream signaling.[23] Indeed, Jak2-dependent leptin signals fail to modulate parameters of energy balance in the absence of LEPR-B tyrosine phosphorylation sites, suggesting a crucial role for LEPR-B tyrosine phosphorylation in the control of feeding and energy expenditure.[23] By contrast, mice in which LEPR-B is replaced by a mutant that contains a substitution mutation of Tyr_{1138}, which abrogates LEPR-B→STAT3 signaling, display hyperphagia and decreased energy expenditure, resulting in massive early-onset obesity; similar hyperphagia and obesity have been observed in mice null for STAT3 in the brain. Thus, the LEPR-B Tyr_{1138}→STAT3 signal is central to the regulation of body weight by leptin.[24] By contrast, mutation of Tyr_{985} produces lean mice, consistent with a role for the Tyr_{985}/SOCS3 pathway in feedback inhibition/LEPR-B signal attenuation *in vivo*, as in cultured cells.[24]

Many insulin-like signals (including insulin receptor substrate (IRS)-2, phosphatidylinositol 3′-kinase (PI3K), and mammalian target of rapamycin (mTOR)) are modulated by leptin in the brain, and are required for the full efficacy of leptin action *in vivo*.[4,20] Delineating the direct pathway from LEPR-B to these signals in cultured cells has not been straightforward, however, and PI3K and mTOR are regulated oppositely by leptin in different neuronal populations.[30,32] Because blockade of these pathways does not interfere with melanocortin action, they are required in neurons upstream of the melanocortin-responsive neurons crucial for the control of energy balance.[4,20] Hence, although the integrity of these pathways in the hypothalamus, and even in subsets of LEPR-B neurons, is crucial for energy balance, leptin may modulate these pathways indirectly and/or these pathways may primarily function to relay insulin signals to leptin-regulated neural pathways in support of leptin action. Similarly, the cellular energy sensing AMP-dependent protein kinase (AMPK), which interferes with leptin action, may not be controlled by LEPR-B directly, but may serve to integrate additional physiologic data with the leptin signal in the leptin-regulated neural circuitry.[17,33]

"LEPTIN RESISTANCE" AND CELLULAR MECHANISMS THAT IMPAIR LEPR-B SIGNALING

More than one quarter of adult Americans are obese, and the incidence of obesity continues to increase in the U.S. and other industrialized nations.[18] Obesity is a major risk factor for Type 2 diabetes, cardiovascular disease, and some forms of cancer. Because administration of leptin to $Lep^{ob/ob}$ animals and other lean rodents acutely decreases food intake

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

and body weight, resulting in the loss of fat mass, leptin was initially hailed as a potential cure for obesity.[8] With the exception of rare human patients with genetic leptin deficiency, however, circulating leptin concentrations correlate with BMI and total body fat mass, and most obese individuals have elevated circulating leptin concentrations, but the abundant leptin in obesity fails to restore body weight and adiposity to normal levels. This, along with the minimal anorectic response to even heroic doses of exogenous leptin in many obese humans and rodent, has given rise to the notion of "leptin resistance," where the efficacy of leptin is diminished in states of obesity and/or nutritional surfeit.[18] Since leptin levels are expected to be increased in proportion to adipose mass in obesity, defining leptin resistance as obesity in the face of hyperleptinemia seems rather tautological, however, although (practically speaking) it will be useful to understand the limited response to leptin in obesity.

Although it is not clear whether they are primary to the genesis of obesity, or rather secondary and permissive, it is clear that many mechanisms limit leptin action in obese or overnourished animals. The proposed mechanisms of the so-called leptin resistance are many and range from the trivial (leptin action is near maximal at levels observed in obesity, and additional leptin fails to appreciably increase leptin action), to decreased leptin transport into the CNS, to cellular mechanisms that limit LEPR-B signaling. Although each of these processes may play a role, a substantial amount of genetic evidence support the notion that feedback pathways (including Tyr_{985}/SOCS3), tyrosine phosphatase action (e.g., via PTP1B/PTPN1), ER stress, inflammation, and many other cellular process activated during increased feeding or obesity impair LEPR-B signaling to decrease the efficacy of endogenous and exogenous leptin.[18] Thus, leptin action must be assessed in young lean subjects to determine whether a particular lesion that promotes obesity actually interferes with leptin action *per se*, lest these mechanisms confound the results. Clearly, however, although the term "leptin resistance" is used to convey numerous concepts and does not imply a specific mechanism, understanding genetic and cellular mechanisms that may interfere with leptin action will be crucial, as they may represent potential targets for therapy in obesity.

Chapter 153

Melanocortins

Joram D. Mul and Roger A.H. Adan

ABSTRACT

The central melanocortin (MC) system consists of neurons that express the POMC-derived peptides α-melanocyte-stimulating hormone (α-MSH), β-MSH, and γ-MSH, which are endogenous melanocortin-receptor 3 (MC3R) or MC4R agonists, and neurons that express AgRP, an MC4R inverse agonist. Downstream, subpopulations of neurons express MC3R and/or MC4R. The activity of the MC system plays a key role in the regulation of energy homeostasis. Mutations in MC system components, in either humans or rodents, result in obesity by affecting several aspects of energy homeostasis including ingestive behavior, energy expenditure, insulin sensitivity, and adipose metabolism. Here, we aim to provide an update of how the MC system modifies ingestive behavior. We first describe how ingestive behavior is altered in humans and rodents with mutations in the MC system followed by a description of how the MC system modulates the different neural circuits involved in feeding.

THE MELANOCORTIN SYSTEM

To maintain a stable body weight, one has to balance energy intake or ingestive behavior (by eating and drinking) and energy expenditure (by exercise, basal metabolism, and thermogenesis). Recent advances in scientific research have shown a large number of neuronal effectors to be essential for the central regulation of ingestive behavior. Perhaps one of the best-characterized neuronal pathways in the regulation of energy homeostasis is the melanocortin (MC) system.[1,8,12,28] The central MC system includes two distinct subpopulations of neurons in the arcuate nucleus expressing agouti-gene-related protein (*AgRP*) or proopiomelanocortin (*POMC*), as well as a subpopulation of neurons in the brainstem expressing *POMC*, and downstream targets of these neurons expressing melanocortin-3 and/or melanocortin-4 receptors (*MC3R* and *MC4R*).[1,8,12,28] Processing of the POMC precursor generates several products, including adrenocorticotropin (ACTH), the opioid receptor agonist β-endorphin, and the endogenous MCR3/4 agonists α-melanocyte-stimulating hormone (α-MSH), β-MSH, and γ-MSH.[1,8,12,28] AgRP functions as an inverse agonist on constitutively active MC3Rs and MC4Rs.[1,8,12,28] Out of the five MC receptors, all of which are G-protein-coupled receptors, MC3R and MC4R are the main brain MCRs.[1,8,12,28]

Leptin, a key modulator of energy homeostasis, strongly regulates neuropeptidergic circuits in the arcuate nucleus of the hypothalamus to modulate food intake and energy expenditure.[25] Within the arcuate nucleus, leptin activates neurons expressing *POMC* but inhibits neurons expressing *AgRP*.[25] During a positive state of energy balance, high levels of leptin inhibit POMC neurons and stimulate AgRP neurons, whereas a negative state of energy balance results in the opposite situation. The unique presence of endogenous agonists and an inverse agonist acting within the same receptor system indicates that the activity of the central MC system is tightly regulated and implicates the importance of the MC system in regulating energy homeostasis. Although the activity of the MC system also affects energy expenditure, insulin sensitivity, adipose metabolism, blood pressure, heart rate, natriuresis, and erectile function,[8,28] this chapter mainly focuses on how and via which neural circuits the central MC system modulates ingestive behavior.

INGESTIVE BEHAVIOR IN HUMANS WITH MUTATIONS IN THE MC SYSTEM

Genetic Variance

Single-nucleotide polymorphisms in *MC4R* or genetic variances near *MC4R* are highly associated with increased body mass index (BMI), adipose mass, early-onset obesity, and risk to develop obesity.[26] Moreover, a plethora of mutations in *MC4R*, predominantly with a negative effect on MC4R function, have been reported to date in humans.[28] This makes haploinsufficiency of *MC4R* the most common monogenic cause of severe human obesity, accounting for approximately 4% of all cases.[8,12,28] However, strong variation in the prevalence of MC4R haploinsufficiency levels is observed depending on ethnic origin, grade of obesity, and obesity onset of the population screened.[28] Human genomewide association

studies (GWAS) show that variation at the *MC4R* locus also explains some of the variability in BMI in the general population. In addition, a GWAS analysis has also shown that variation near *POMC* affects susceptibility for obesity.[26]

Mutations in MC4R

Loss-of-function mutations in *MC4R* result in hyperphagia, hyperinsulinemia, and increased mass and lean body mass.[11] However, the hyperphagia seemed to subside with age in children carrying a heterozygous loss-of-function mutation.[11] In general, heterozygous carriers for loss-of-function mutations in *MC4R* show an intermediate metabolic phenotype compared with homozygous or wildtype carriers, suggesting that the regulation of energy balance in humans is sensitive to the variation in functional MC4R levels.[11]

Mutations in MC3R

In addition to *MC4R*, some humans carry mutations in *MC3R*. A primary study showed that a locus on human chromosome 20q encoding *MC3R* is linked to BMI, subcutaneous fat mass, and glucose metabolism.[23] Subsequently, numerous mutations were discovered in *MC3R*, which affect a variety of phenotypes, including fat storage, BMI, lipid metabolism, glucose metabolism, and ingestive behavior.[23] However, despite a clear obese metabolic phenotype in MC3R-deficient mice (discussed below), a similar striking phenotype for humans carrying a loss-of-function mutation in *MC3R* has not yet been found.[23]

Mutations in POMC

Humans with mutations in *POMC*, which either interfered with the synthesis of α-MSH and ACTH or abolished *POMC* translation, are hyperphagic and obese.[16] The usual suspect for causing these POMC-deficient phenotypes is α-MSH, which is the main peptide for signaling through the MC4R receptor. However, disruption of β-MSH function in humans also results in an obese phenotype, supporting a significant role for β-MSH in the regulation of human body weight[3]; ingestive behavior was not analyzed. Although rodents do not process endogenous β-MSH, in contrast to humans, administration of exogenous β-MSH to rats decreases ingestive behavior in rodents, whereas the abovementioned mutant form of β-MSH does not.[3]

Mutations in AGRP

Loss-of-function mutations in *AgRP* have not yet been reported in humans. However, several polymorphisms in *AgRP* are associated with leanness and differences in macronutrient intake.[17] Moreover, the results regarding these polymorphisms seem to be parallel to the results observed in genetic rodent models with loss of AgRP function, as they negatively influence energy balance.[17]

INGESTIVE BEHAVIOR IN RODENT MODELS WITH DISRUPTION OF MC4R FUNCTION

A major breakthrough promoting the involvement of MC4R in the regulation of body weight was the discovery that agouti was an MC4R antagonist. Two naturally occurring obese mouse models, *lethal yellow* (A^y) and *viable yellow* (A^{vy}), show central ectopic overexpression of *agouti*, which is normally expressed in the skin to antagonize MC1R. The overexpression of agouti results in obesity because agouti in the brain blocks MC4R function.[10]

Using embryonic stem cell manipulation, Huszar and colleagues generated mice lacking MC4R ($MC4R^{-/-}$) on a mixed 129/Sv and C57BL/6J background and showed that chronic full-body MC4R-deficiency in the mouse results in a late-onset obesity, hallmarked by hyperphagia, reduced locomotor activity, increased body length, hyperleptinemia, and hyperinsulinemia.[14] Heterozygous male and female $MC4R^{-/-}$ mice showed an intermediate phenotype, showing a gene dosage effect of MC4R-ablation on body weight regulation.[14] The intermediate phenotype observed in $MC4R^{+/-}$ mice is in agreement with the intermediate phenotype observed in humans carrying a heterozygous loss-of-function mutation.[11,14] The observation that loss of one functional MC4R allele results in an intermediate phenotype is unusual for G protein-coupled receptors. This observation is, in addition to having endogenous agonists and an inverse agonist working on the same receptor system, another unique feature of the MC system.[8] To investigate whether the hyperphagia in these MC4R-deficient mice is the main contributor for their obesity, a subsequent study comparing pair-fed female $MC4R^{-/-}$ mice with wildtype controls observed that the body weight of the pair-fed female $MC4R^{-/-}$ mice was intermediate between wildtype and non-pair-fed $MC4R^{-/-}$ mice, suggesting that changes in feeding are not solely responsible for the obese phenotype.[27] However, body weights of male $MC4R^{-/-}$ mice used in the same pair-feeding paradigm were not significantly different from wildtype mice.[27] Further, ambulatory activity of *ad libitum*-fed female $MC4R^{-/-}$ mice was normal, whereas ambulatory activity of *ad libitum*-fed male $MC4R^{-/-}$ mice was significantly lower compared with that of wildtype controls, predominantly during the dark phase.[27] These observations indicate that MC4R-deficiency in this specific mouse line has significant gender-specific effects on body weight regulation.

The majority of genetic models of the MC system are in mice. However, a rat model on a Wistar background with chronic full-body functional loss of MC4R ($MC4R^{K314X/K314X}$)

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

has been generated and characterized.[20] MC4R$^{K314X/K314X}$ rats show early-onset obesity, hallmarked by hyperphagia, reduced locomotor activity, increased body length, hyperleptinemia, and hyperinsulinemia.[20] Although not tested for all the aforementioned parameters, MC4R$^{+/K314X}$ rats show an intermediate phenotype.[20]

Nutrient Sensing

Using the same genetic line of MC4R$^{-/-}$ mice, MC4R$^{-/-}$ mice that are exposed to nutritional deprivation lose equal amounts of body weight as wildtype controls and after resumption of *ad libitum* feeding quickly return to their premalnutrition body weight.[5] This indicates that MC4R is not necessary for sensing nutritional deficits or for producing the homeostatic response that returns body weight to the original set point level after an involuntary negative energy balance. However, when fed a moderate-fat (25%) diet, the same study also showed that MC4R$^{-/-}$ mice have a marked increase in body weight gain. Analysis of the feeding behavior of these mice switching between a standard low-fat diet and the moderate-fat diet reveals that wildtype controls adjust their food intake according to the increased amount of calories in the moderate-fat diet (i.e., they remain isocaloric compared with the low-fat diet), whereas MC4R$^{-/-}$ mice lack this adjustment. In addition, MC4R$^{-/-}$ mice become even more hyperphagic compared with wildtype controls on the moderate-fat diet compared with the hyperphagia observed with the low-fat diet.[5] Thus, MC4R does not seem to be critical for nutrient sensing, but loss of MC4R function dysregulates the adequate metabolic response to handle increases in caloric density.

Feed Efficiency

When male or female MC4R$^{-/-}$ mice are fed a moderate-fat diet (without choice), the feed efficiency (weight gain per kilocalories ingested) is significantly increased compared with that of wildtype controls on a moderate-fat diet or compared with that of MC4R$^{-/-}$ mice fed the low-fat diet.[5] MC4R$^{-/-}$ mice have increased feed efficiency because they do not adjust their feeding behavior regarding the increased caloric content of the moderate-fat diet and because they are unable to increase their energy expenditure in response to the moderate-fat diet.[5] Moreover, MC4R$^{-/-}$ mice display normal activity (wheel turns) compared with that of wildtype mice when housed in wheel cages with low-fat diet. However, on a moderate-fat diet, wildtype mice increase their wheel turns, which may be important to burn excess calories, whereas MC4R$^{-/-}$ mice do not increase their number of wheel turns.[5]

On a low-fat diet, no difference in feed efficiency is observed between MC4R$^{-/-}$ and wildtype mice, either male or female.[5] In MC4R$^{K314X/K314X}$ and MC4R$^{+/K314X}$ rats, feed efficiency (weight gain per effective kcal ingested (ingestion minus secretion)) is equal as well as when fed a low-fat diet.[20] Further, locomotor activity measured during 24-h after a 24-h acclimatization period using a home-cage monitoring system is decreased in MC4R$^{K314X/K314X}$ rats compared with that of wildtype controls.[20] The latter observations suggest that excess body weight gain on a low-fat diet in MC4R-deficient rats results from hyperphagia and reduced locomotor activity, whereas the contribution of the energy expenditure component to the obese phenotype of this rat model still remains to be studied in detail. In addition, it has been proposed that the reduced locomotor activity observed in MC4R-deficient rodent models results from the finding that the measurements are performed shortly after introduction to the 'novel' environment, suggesting that the hypoactive phenotype might be stress related.[5,20,27] However, an additional study has shown that MC4R$^{-/-}$ mice exhibit a hypoactive phenotype during the dark phase over a period of 8 days,[29] suggesting that these different observations regarding locomotor activity are related to the technique used to measure activity (i.e., home-cage monitoring versus wheel running cages).

Response to Orexigenic and Anorectic Peptides

Because MC4R-deficient mice display prominent hyperphagia, it was hypothesized that MC4R function modulates food intake by altering the postingestive responsiveness. However, Vaughan et al. showed that MC4R-deficiency-induced hyperphagia does not result from diminished responsiveness to a nutrient preload or the gut satiety hormones cholecystokinin (CCK) or bombesin.[31] In addition, anorexia induced by peripherally administered CCK is equal between MC4R$^{-/-}$, MC4R/MC3R double knockout and wildtype mice.[2] These studies suggest that at least CCK or bombesin function does not seem to be affected by MC4R signaling. However, other studies have shown that MC4R is required for early CCK action.[28] Further, obese MC4R$^{-/-}$ mice have feeding responses similar to central neuropeptide-Y, peptide-YY$_{3-36}$, orexin-A, orexin-B, and urocortin administration compared with that of wildtype mice.[19] Peripheral leptin treatment does not affect ingestive behavior in obese MC4R$^{-/-}$ mice compared with that in wildtype controls, whereas young lean MC4R$^{-/-}$ mice or lean adult MC4R$^{-/-}$ mice pair fed to wildtype mice are sensitive to the anorectic effects of central leptin, albeit sensitivity is reduced compared with that in control mice.[19]

Motivational Aspects of Feeding, Meal Size, and Meal Frequency

When investigating motivational aspects of feeding behavior in MC4R-deficient mice, Vaughan and colleagues observed

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY
Copyright Elsevier 2024

in an initial study that MC4R$^{-/-}$ mice are not hyperphagic compared with control mice and lose weight when they work for food pellets in operant chambers using a procurement-consummatory dual cost foraging protocol.[32] Surprisingly, this weight loss is not accompanied by a compensational increase in feeding behavior. Further, meal size and meal frequency seem to be normal in MC4R$^{-/-}$ mice compared with that of wildtype mice during this behavioral paradigm.[32] However, during the 3- to 4-week intertesting phase, mice resided in their home cage and although *ad libitum* food intake was not measured during that period, body weights recover to their original level or even higher as indicated by the body weights at the start of their next experimental testing phase.[32] Further, MC4R$^{-/-}$ mice work for normal amounts of food and increase their work efforts for pellets on more stringent lever pressing ratios, indicating that the mice work more at a higher unit cost. Therefore, it is unlikely that the hypoactivity of MC4R$^{-/-}$ mice underlies the inability to compensate for the body weight loss as hypoactive leptin-deficient mice are able to sustain hyperphagia during the same behavioral paradigm.[32] To investigate the motivational aspects of feeding behavior in MC4R$^{-/-}$ mice in more detail, the same group subsequently studied MC4R$^{-/-}$ mice in operant chambers in a closed economy-feeding paradigm under a fixed ratio (FR) or progressive ratio (PR) and looked at their meal patterns. This time MC4R$^{-/-}$ mice are hyperphagic in an FR3 schedule (3 lever presses to earn a pellet).[30] Moreover, MC4R$^{-/-}$ mice exhibit a higher level of motivation to work for food compared with that of control mice, indicated by higher breakpoint values.[30] Finally, MC4R$^{-/-}$ mice have increased mean meal size and decreased meal frequency during this closed economy-feeding paradigm.[30] The striking differences between these two studies might result from the different lever set-ups used (two lever-system versus one lever), the different consequences of not responding over time, or a combination of both. A third and more recent article from this group showed with a closed economy food demand paradigm (mice were in chambers 23 h per day) in self-administration chambers that MC4R$^{-/-}$ mice are hyperphagic at a low fixed unit price (FUP2; two nose pokes per pellet) for food.[2] However, during the similar food demand paradigm, now at a much higher fixed unit price (FUP50; 50 nose pokes per pellet), MC4R$^{-/-}$ mice are hypophagic compared with wildtype mice, indicating increased elasticity of food demand.[2] Moreover, the mean meal frequency does not differ significantly between MC4R$^{-/-}$ and wildtype mice when increasing the fixed unit price, whereas the mean meal size of MC4R$^{-/-}$ mice drops from overeating approximately 4 pellets per meal compared with control mice at FUP2 to undereating approximately 3 pellets per meal at FUP50.[2] Thus, these three studies indicate that MC4R$^{-/-}$ mice are hyperphagic when the pellets can be obtained with minimal efforts, that is, approximately 10 responses or less per pellet. By contrast, when costs per unit increase further if a procurement-consummatory dual cost foraging protocol is used, the hyperphagia disappears or even changes to hypophagia.[2]

Nutrient Preference

During a home-cage food-choice paradigm, MC4R$^{K314X/K314X}$ rats show increased preference for fat and a decreased preference for carbohydrates.[20] The latter observation fits with the carbohydrate to fat preference shift observed after acute pharmacological blockade of MC3/4R signaling.[20]

Summary

The above-described general phenotypes observed in MC4R-deficient rodent models are rather similar to the phenotypes observed in humans with loss-of-function mutations in *MC4R* or *POMC*,[11,14,16] suggesting that these rodent models are *bona fide* tools to study the effects of dysregulated MC4R function in humans. However, the hyperphagia observed in children carrying a heterozygous loss-of-function mutation seem to subside with age,[11] a phenomenon that is not observed in rodents. Overall, observations in obese MC4R-deficient rodent models have led to the conception that excess weight gain in MC4R$^{-/-}$ rodents predominantly results from increased ingestive behavior, changes in energy expenditure, and reduced locomotor activity. These observations imply that MC4R is important for the limitation of ingestive behavior and the stimulation of energy expenditure.[1,8,12,28]

INGESTIVE BEHAVIOR IN RODENT MODELS WITH DISRUPTION OF MC3R FUNCTION

General Phenotypes

Using embryonic stem cell manipulation two laboratories generated mice lacking MC3R (MC3R$^{-/-}$) on a mixed 129/Sv and C57BL/6J background. Male full-body MC3R$^{-/-}$ on low- or moderate-fat diets show no clear body weight phenotype despite hypophagia, increased body fat content, increased fat mass, and lower lean mass compared with wildtype siblings.[4,6] Moreover, MC3R$^{-/-}$ mice display stunted growth, hyperleptinemia, and mild hyperinsulinemia.[6] Female MC3R$^{-/-}$ mice, maintained on a moderate- or high-fat diet, showed normal or increased body weight growth, respectively, and normal food intake.[4,6] Although full-body MC3R$^{-/-}$ mice do not display clear feeding and body weight phenotypes, a recent study using an MC3R partial agonist reduced food intake in MC4R$^{-/-}$ mice suggesting

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

that MC3R plays a small but significant role in the regulation of ingestive behavior.[15] Analysis of energy expenditure and ambulatory activity, on either low-fat or high-fat diet, do not reveal consistent phenotypes in male or female full-body MC3R$^{-/-}$ mice.[4,6]

Nutrient Sensing

As previously mentioned for MC4R$^{-/-}$ mice, MC3R$^{-/-}$ mice that are exposed to nutritional deprivation also lose equal amounts of body weight, and after resumption of *ad libitum* feeding quickly return to their premalnutrition body weight compared with controls, indicating that both MC3R and MC4R are not necessary for sensing nutritional deficits or for producing the homeostatic response that returns body weight to the original set point level.[5]

Feed Efficiency

Although male MC3R$^{-/-}$ mice maintained on a regular chow diet are hypophagic, they show increased feed efficiency.[6] In addition, female MC3R$^{-/-}$ mice, showing normal food intake on a low or high-fat diet, also show increased feed efficiency.[6]

Summary

The main phenotype of MC3R$^{-/-}$ mice is an increase in feed efficiency. This suggests that the increased feed efficiency, and not changes in ingestive behavior, is underlying the increased adipose mass in MC3R$^{-/-}$ mice. Although humans with mutations in *MC3R* show phenotypes that are reminiscent of the *Mc3r* knockout mouse model, the effect of MC3R function on feed efficiency in humans remains to be studied in more detail.

INGESTIVE BEHAVIOR IN RODENT MODELS WITH DISRUPTION OF AGRP FUNCTION

Using embryonic stem cell manipulation Qian et al. generated mice lacking AgRP (AgRP$^{-/-}$) on a mixed 129/Sv and C57BL/6J background and observed that AgRP$^{-/-}$ mice display normal food intake, body weight gain, and energy expenditure.[22] However, a subsequent study that compared younger (~3 months old) and older (~6-months old) AgRP$^{-/-}$ mice found that ~6-month-old AgRP$^{-/-}$ mice display an age-dependent lean phenotype predominantly resulting from metabolic changes because food intake is still normal,[33] indicating that AgRP-deficiency does result in a metabolic phenotype albeit at a later age. Moreover, a set of very elegant studies have shown that toxin-induced ablation of AgRP neurons during embryogenesis results in compensatory adaptations resulting in relative normal energy homeostasis compared with that in wildtype controls, whereas ablation of AgRP neurons postembryogenesis results in a lean phenotype hallmarked by decreased caloric intake or even death.[13,18] AgRP neurons coexpress γ-aminobutyric acid (GABA), which inhibits POMC neuron function.[34] Wu and Palmiter showed that the loss of AgRP neuron-specific γ-aminobutyric acid (GABA) expression induces the hypophagia and severe loss of body weight after ablation of AgRP neurons during adulthood, whereas chronic blockade of MC4R is inadequate to rescue these phenotypes.[34] Finally, transgenic overexpression of *AgRP* also results in obesity hallmarked in part by hyperphagia.[21]

INGESTIVE BEHAVIOR IN RODENT MODELS WITH DISRUPTION OF POMC FUNCTION

Using embryonic stem cell manipulation Yaswen et al. generated mice lacking POMC (POMC$^{-/-}$) on a mixed 129/Sv and C57BL/6J background and showed that POMC deficiency in the mouse results in obesity resulting in part from hyperphagia.[35] Further, POMC$^{-/-}$ mice are unable to properly adjust their energy intake and expenditure as wildtype mice do when switched to a high-fat diet.[35]

POMC$^{-/-}$ mice also display corticosterone (CORT) deficiency.[7] Moreover, rescuing plasma CORT concentrations in POMC$^{-/-}$ mice even further elevates the preexisting hyperphagia, whereas no effect of CORT administration on ingestive behavior is observed in wildtype mice.[7] This suggests that CORT deficiency observed in POMC$^{-/-}$ mice might partially mask the adverse metabolic consequences induced by deficiency of POMC-derived peptides.[7]

PHARMACOLOGICAL STUDIES WITH MCR LIGANDS MODULATING INGESTIVE BEHAVIOR

A vast collection of data is available regarding pharmacological manipulation of the MC system. Some excellent reviews address this subject.[1,8,12,28] Briefly, acute central administration of (nonspecific) MC3/4R agonists results in decreased feeding, whereas (nonspecific) MC3/4R antagonists increase food intake. Taken together, pharmacological manipulation of the MC system clearly indicates that the MC system plays an important role in modulating ingestive behavior in rodents. Further, observations regarding meal size, meal duration, and modulation of MC system function when food intake is expected suggest that the MC system is rather involved in meal termination rather than meal initiation.[1]

BRAIN SITES WHERE MC RECEPTOR SIGNALING AFFECTS INGESTIVE BEHAVIOR

Sites of Melanocortin Signaling

POMC expression is mainly found in the neurons of the arcuate nucleus, where it is coexpressed with the anorectic peptide cocaine amphetamine-related transcript (CART).[8] These POMC/CART neurons project fibers to several nuclei in forebrain, midbrain, and hindbrain.[8] The brainstem also contains a local smaller subset of *POMC*-expressing neurons.[8] Neurons coexpressing *Npy* and *AgRP* are also predominantly found in the arcuate nucleus, and these neurons project fibers to a subset of hypothalamic and septal brain regions identical to those containing dense POMC innervation.[8] Finally, a striking difference between the projections of the POMC/CART and NPY/AgRP neurons, in the rat at least, is that the NPY/AgRP neurons seem to be much less widely distributed.[8]

Mc4r is expressed in many brain regions, which are located in the hypothalamus, forebrain, and hindbrain. Moreover, the paraventricular nucleus (PVN), dorsomedial hypothalamic nucleus (DMH), and medial preoptic area were identified as primary sites of MC4R action using MCR ligands.[1] However, MCR-ligand-induced modulation of feeding in the PVN, in either a positive or negative direction, is only observed under conditions where food intake is stimulated by either the onset of darkness, fasting, or central NPY administration.[1] These observations have generated the notion that MC4R signaling in the PVN is important for meal termination but not for meal initiation.[1] More detailed analysis of the PVN neurons expressing *Mc4r* has shown that a subpopulation of these neurons express corticotropin-releasing hormone (CRH) or thyrotropin-releasing hormone. These hormones, especially CRH, seem to function downstream of MC4R signaling in the PVN and contribute to the mechanisms by which the MC system mediates ingestive behavior.[1]

MC4R signaling in the DMH also affects ingestive behavior. For example, the administration of [norleucine;^{4} D-phenylalanine^7]-α-MSH to the DMH decreases food intake, whereas AgRP administration functions in opposite direction.[1] Further, AgRP administration to the DMH increases sucrose intake, suggesting that MC4R signaling in the DMH modulates the palatability of a diet.[1]

In the brainstem, *Mc4r* is expressed in the dorsal motor nucleus of the vagus nerve and in the nucleus of the solitary tract (NTS), both being important brain sites for autonomic control.[8] Several pharmacological studies have shown that administration of an MC4R agonist or antagonist in the fourth ventricle or into the dorsal vagal complex (DVC) mediates similar effects on food intake as comparable with lateral ventricle administration.[1] In addition, the anorexigenic effects of MTII, an MC3/4R nonspecific agonist, in the fourth ventricle resulted from a reduction in meal size, and not meal frequency.[1] Finally, MC4R signaling in the brainstem is important for the inhibition of food mediated by CCK.[28] Other brain regions that express *Mc4r* are the central amygdala (CeA) and the lateral hypothalamus (LH). Administration of the agonist NDP-MSH into the CeA does not modify food intake, whereas the administration of the antagonists AgRP or HS014 increases food intake.[1] However, the orexigenic effect is not as strong as observed for administration to the PVN, DMH, or DVC. In the LH, administration of AgRP seems to modify activity of orexin neurons or gene expression of the orexigenic peptide melanin-concentrating hormone,[1] but it remains unclear what the function of these neurons and/or genes is related to AgRP-induced hyperphagia. Finally, administration of an MC4R agonist into the LH, arcuate nucleus, ventromedial hypothalamus (VMH), or nucleus accumbens did not or very modestly modify food intake. In sum, although many brain regions express *Mc4r*, the PVN, DMH, and DVC/NTS seem to be the predominant regions modulating the effects of the MC system on ingestive behavior. Further studies need to be performed to clarify the function of the other brain regions where MC4R activity can be modulated.

In rodents, central expression of *Mc3r* is more moderate compared with the wide expression of *Mc4r*. Strongest expression of MC3R is observed in the hypothalamus, predominantly in the arcuate nucleus and the ventromedial hypothalamus.[23] Other central brain regions that express *Mc3r* include the medial habenula, the ventral tegmental area, and the raphe.[23] An interesting absentee in this list is the NTS as *Mc3r* expression is not observed or is very limited in the hindbrain.[23,28] Intracerebroventricular or peripheral administration of the stabilized γ-MSH analog D-Trp^8-γ-MSH, an agonist with significant selectivity for MC3R over MC4R, increases food intake.[23] In addition, a study using JRH322-18, a new tetrapeptide compound which has a mixed MC3R partial agonist/antagonist and MC4R agonist function, indicates that central MC3R plays a small but significant role in the regulation of food intake.[15]

Conditional Mutant Models of Melanocortin Function

Because lifelong loss of gene expression in genetic rodent models can result in developmental compensatory effects and acute injections only have short-lasting effects, a preferred genetic approach, to date only used in mice, is the Cre-lox system, which uses Cre recombinase to locally activate a gene of interest in mice carrying a lox-stop-lox allele for that particular gene of interest. Using this system, reactivation of *Mc4r* in mice carrying a loss-of-function allele for *Mc4r* specifically in PVN and a subpopulation

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

of MC4R neurons in the CeA normalizes the hyperphagia and reduced body weight, whereas this specific strategy does not affect energy expenditure.[1,12] Reexpression of MC4Rs in cholinergic neurons (ChAT-Cre, loxTB MC4R mice) modestly reduces body weight gain without altering food intake and is sufficient to normalize energy expenditure, whereas restoration of MC4R expression in brainstem neurons including those in the dorsal motor nucleus of the vagus (Phox2b-Cre, loxTB MC4R mice) does not rescue the obese nor the hyperphagic phenotype in MC4R knockout mice.[24]

Viral Manipulation of Melanocortin Function

A different but complementary approach to the above-mentioned Cre-lox system is the use of adeno-associated virus (AAV)-mediated expression. AAV-mediated expression of *Agouti* to inhibit MC signaling in the PVN results in increased food intake and body weight.[1] In studies with AAV-mediated overexpression of AgRP, overexpression in the PVN, LH, and VMH increases body weight predominantly by increasing meal size.[9]

CONCLUDING REMARKS

Functional disruption of the central MC system (e.g., at the level of *AgRP*, *POMC*, *Mc3r*, or *Mc4r*) reveals a wide variety of metabolic phenotypes. Increased body weight is often observed in both rodents and humans with mutations in the central MC system, characterized by hyperphagia, changes in meal size, food preference, and energy expenditure. These changes seem to be mediated by distinct brain sites expressing MC receptors. So far, the PVN seems to be an especially important brain site for MCR-mediated hyperphagia. However, further research is warranted to unravel how the MC system exactly modulates the energy balance through changes in energy expenditure and ingestive behavior.

Chapter 154

NPY

Simona Perboni, Marzia Vignoni and Akio Inui

ABSTRACT

Feeding behavior is tightly regulated by peptidergic transmission within the hypothalamus.

Neuropeptide Y (NPY) is one of the most abundant and most potent known orexigenic peptides found in the brain. It has been shown that NPY plays a pivotal role in the control of food intake and body weight in the hypothalamus. Peripheral and central signals of energy balance are integrated within the ARC both via the NPY and melanocortin systems. Therefore, the actions of NPY extend throughout the hypothalamus and affect the heterogeneous population of neurons, and many of them are associated with the regulation of energy homeostasis. NPY can act on several Y receptors, but only Y1, Y2, and Y5 receptors are implicated in the ARC feeding circuitry. Ligands for Y receptors may be of benefit for the treatment of obesity.

NPY AND THE CENTRAL REGULATION OF FOOD INTAKE

The central nervous system (CNS) has developed a meticulously interconnected circuitry to keep us fed and in adequate nutritional state. Specific areas in the hypothalamus and in the brainstem are important in coordinating signaling molecules, such as the hormones insulin and leptin, which circulate in proportion to body fat mass and are critical for normal energy homeostasis. Peripheral and central signals of energy balance are integrated within the arcuate nucleus (ARC) both via the Neuropeptide Y (NPY) and melanocortin systems. ARC neurons in turn send dense projections to various hypothalamic neurons, including the paraventricular nucleus (PVN), the ventromedial nucleus (VMN), the lateral hypothalamic area (LHA), and the dorsomedial nucleus (DMN). Therefore, the actions of NPY extend throughout the hypothalamus and affect a diverse and heterogeneous population of neurons,[26] many of them associated with the regulation of energy homeostasis or mediating food reward, such as in the nucleus of the tractus solitarius, the nucleus accumbens, and the ventral tegmental area.[28]

NEUROPEPTIDE Y AND FEEDING

Feeding behavior is tightly regulated by peptidergic transmission within the hypothalamus. NPY is one of the most abundant and most potent known orexigenic peptides found in the brain.[1] It plays a pivotal role in the control of food intake and body weight within the hypothalamus. The feeding stimulatory effect of NPY is approximately 500 times more potent on a molar basis than norepinephrine.[15] Central administration of NPY by intracerebroventricular injection or its direct injection into specific hypothalamic sites, especially the perifornical area (PFA), the PVN, and the VMN stimulates robust feeding responses in a dose-dependent manner. Chronic administration of NPY produces a sustained hyperphagia and increased body weight leading to obesity.[6,14] NPY stimulates appetite and consummatory ingestive behaviors under a variety of conditions.[7] In several animal models of obesity, the levels of NPY gene expression and NPY itself are increased. Similarly, increases in levels of NPY gene expression and in peptide itself precede hyperphagic behavior and are directly correlated with conditions of increased energy deprivation and energy demand.[27] In effect, food deprivation is one of the most important factors that increase the expression of hypothalamic NPY. The NPY release is enhanced immediately before the onset of feeding and gradually decreases as food intake continues. The actions of the NPY, even fasting-induced refeeding, can be blocked by the pharmacological application of NPY antagonists.[31] NPY produces a shift to positive energy balance by increasing food intake, by decreasing energy expenditure primarily with a reduction in thermogenesis in brown adipose tissue and by facilitating fat deposition in white adipose tissue partly through an increased insulin activity. Taken together, these studies show that NPY administration is directly correlated with a state of positive energy balance.[15]

Prostaglandin (PG) D(2), the most abundant PG in the CNS, stimulates food intake after intracerebroventricular administration in mice. The orexigenic activity of PGD(2) is also abolished by an antagonist for NPY Y1 receptor. PGD(2) may stimulate food intake through central DP(1)

receptor coupled to the NPY system.[29] Moreover, the complement C5a stimulates food intake by activating the orexigenic PGD(2) system. The orexigenic activity of C5a is inhibited by an antagonist for NPY Y1 receptor, which is activated downstream of the PGD(2)–DP(1) system. These results suggest that C5a stimulates food intake via a PGD(2)- and NPY-dependent mechanism. C5a is the first example of orexigenic peptides acting through the PGD(2)–NPY system in the CNS.[30] As described in the nesfatin chapters in the Brain and Gastrointestinal Peptides sections of this book, nesfatin-1-induced inhibition of feeding might be mediated through the inhibition of orexigenic NPY neurons in ARC.[32]

NPY IN THE ARC NUCLEUS

The ARC is an important hypothalamic nucleus in the control of appetite and plays a primary role in the interaction between peripheral organs and the brain. The main source of NPY within the hypothalamus is from specialized neurons in the ARC.[1] Two distinct subsets of neurons are involved in the control of food intake in the ARC.[24] One group contains neurons expressing the orexigenic peptides, NPY and agouti-related peptide (AgRP).[24] The other group expresses anorexigenic peptides derived from proopiomelanocortin (POMC) and cocaine- and amphetamine-regulated transcript (CART); POMC is a precursor to the anorectic alpha melanocyte stimulating hormone (α-MSH). Activation of these neurons has the effect of decreasing food intake and increasing energy expenditure.[24] The arcuate POMC and NPY/AgRP neurons constitute a functional unit in which neural inputs to NPY/AgRP cells may rapidly affect both NPY/AgRP and POMC neurons. NPY neurons provide a dominant inhibitory tone onto POMC. The majority of POMC neurons are contacted by terminals containing both γ-aminobutyric acid (GABA) and NPY and express the Y1 receptor on the soma. Fasting and weight loss lead to the activation of anabolic effectors and inhibition of catabolic effectors in the brain, increasing food intake. A decrease in the release of the POMC-derived peptide γ3-MSH and an increased release of the AgRP are seen in rats in response to fasting. Over time, accumulation of excess calories causes weight gain until body fat content is restored to its original value.[5]

PERIPHERAL SIGNALING INVOLVED IN THE REGULATION OF FOOD INTAKE IN THE ARC

The central representation of the metabolic state is mediated in part by the levels of distinct circulating factors, including insulin, leptin and ghrelin.[13] During and after a meal, signals in the periphery, including taste signals from the oral cavity, gastric distension, and humoral signals from the gastrointestinal tract are generated. These afferent signals are transmitted mainly by the vagus nerve and by the sympathetic nervous system to the hindbrain, particularly the nucleus of the solitary tract. This brain region communicates with higher brain areas such as the hypothalamus and the cerebral cortex. As stated above, the ARC is a prominent region in the hypothalamus for integrating these peripheral signals. This information is then relayed to various second-order hypothalamic targets.[5]

Insulin was the first circulating signal proposed to be involved in energy homeostasis. Insulin receptors are present on ARC NPY neurons and insulin can act locally to inhibit its neuronal firing. However, in overweight animals, these neurons are activated by insulin resistance, suggesting that, in obese animals, insulin action at ARC NPY neurons can contribute to positive energy state of the animal.[15] Leptin reaches the ARC within the hypothalamus, directly affecting neurons which coexpress POMC/CART or NPY/AgRP. For example, leptin depolarizes POMC neurons and simultaneously hyperpolarizes the soma of neuropeptide Y/GABA neurons, reducing the release from these terminals. This diminished release of GABA disinhibits POMC neurons. The POMC–CART- and NPY–AGRP-containing neurons, which are regulated in an opposing manner by leptin, project further to other brain centers. These include the VMH and DMN, which also express NPY, and the PVN and the LHA, which express melanin concentrating hormone (MCH). The LHA and other brain areas communicate with the cerebral cortex, where feeding behavior is finally coordinated.[21] There are functional and anatomical connections between ghrelin and NPY signaling. Ghrelin acts directly on ARC NPY neurons to depolarize them and increase their spontaneous firing frequency.[19] Conversely, ARC POMC neurons are indirectly inhibited by ghrelin. The ghrelin-mediated increase in the activity of ARC NPY neurons that innervate the POMC neurons results in an inhibition of the latter. This effect is GABA mediated. In addition, the ARC POMC neuron expresses functional Y1 and Y2 receptors, which inhibit the POMC neuron when activated by NPY.[5] The involvement of the Y5 receptor has been implicated in the regulation of spontaneous release of alpha-MSH from POMC neurons, further supporting the NPY-mediated inhibition of the melanocortin system.[26] Taken together, ghrelin, by activating ARC NPY neurons and indirectly suppressing the activity of ARC POMC neurons, will further reinforce the NPY/AgRP dominant state. These observations show that elevated peripheral levels of ghrelin can induce food intake by the activation of orexigenic NPY-mediated signaling, which also results in the concomitant inhibition of the anorexigenic pathways.[5]

NPY RECEPTORS IN THE ARC

As described in the NPY chapter of the Brain Peptides section of the book, NPY can act on several Y receptors, but only Y1, Y2, and Y5 receptors are implicated in the ARC

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

feeding circuitry. There is a distinct division in the location of the Y1 and Y2 receptors on the ARC neurons with Y1 located only at the postsynaptic membrane, whereas Y2 receptors are found post-synaptically and at the presynaptic terminal. Further, Y5 receptor activation can depress ARC synaptic transmission.[5]

As mentioned above, NPY has long projections, and all hypothalamic nuclei receive NPY-ergic projections to some extent. The actions of NPY are almost always inhibitory, however, depending on the site of its action this may lead directly to a postsynaptic inhibition or to presynaptic effects in which excitatory inputs are suppressed. Thus, the overall or net effect of NPY in each hypothalamic region does not result from the same action. For example, although NPY can directly inhibit to suppress anorexigenic tone, NPY inhibits excitatory orexin neurons in the LHA as part of a short negative feedback loop with ARC NPY neurons.[26]

THE ROLE OF NPY IN THE DMN

NPY can also be produced by hypothalamic DMN neurons, though only transiently during certain states of negative energy balance. Interestingly, NPY gene expression in the DMN increases in response to chronic food restriction and long-term exercise[3] but not to acute food deprivation.[2] This finding suggests that, unlike arcuate NPY neurons, DMN-NPY neurons may play an important role in maintaining energy homeostasis only in response to long-term alterations in energy intake or expenditure.[3] Unlike NPY in the ARC, the regulation of NPY gene expression in the DMN is independent of leptin changes.[2] The elevation of NPY gene expression in DMN is closely associated with melanocortin and cholecystokinin (CCK) signaling. The α-MSH fibers are probably derived mainly from the ARC, and their presence suggests that they can regulate the NPY expression presynanptically. By contrast, CCK-1 and CCK-2 receptors are located on DMN NPY neurons. The DMN neurons are negatively regulated by α-MSH and CCK signaling, so that their anorectic signals are mediated, at least in part, by an inhibition of DMN NPY neurons.[21] As previously mentioned, neurons in the DMN are able to transiently express NPY, perhaps to maintain hyperphagia in conditions of real or perceived energy demand. In support of this idea, Yang et al.[35] showed that bilateral AAV-mediated NPY overexpression in the DMN of lean rats increases food intake and body weight and exacerbates diet-induced obesity. Conversely, NPY knock-down using adeno-associated-virus (AAV)-RNA in the DMN of genetically obese rats causes reductions in food intake and a significant improvement in obesity and glucose tolerance.[12] The reduced food intake is the result of decreased nocturnal meal size, indicating a more specific role for DMN NPY in meal size modulation, in contrast to the actions of NPY in the PVN where it affects meal frequency.[4]

NPY ACTION IN THE PVN

The PVN has emerged as one of the most significant target of NPY-ergic fibers and its critical role in energy balance regulation is highlighted by studies in which PVN lesions lead to an obesity syndrome characterized by hyperphagia and increased body weight gain. Increased NPY release is seen in the PVN both of food deprived rats and in hyperphagic rodents with streptozotocin induced diabetes.[8] Acute injections of NPY into the PVN can induce a strong feeding response. Sustained local overexpression and release of NPY in the PVN lead to increased food intake via increased meal frequency. Reducing levels of NPY in the PVN with anti NPY antibody injections lead to reduced food intake in rats. NPY modulates PVN neuronal activity by both presynaptic and postsynaptic mechanisms. In the former, NPY inhibits GABA release from a population of GABA-ergic terminals that synapse on a subset of hypocellularity neurons within the PVN. This inhibitory presynaptic action of NPY is reduced in obese Zucker rats compared with that in lean controls, which is consistent with the reduced sensitivity of obese rats to NPY. The postsynaptic effect of NPY is evident specifically at PVN neurons that express the melanocortin 4 receptor (MC4R). Here, NPY inhibits the firing frequency of MC4R-expressing PVN neurons by directly eliciting a membrane hyperpolarization. The presynaptic effect of NPY in the PVN is already prominent very early in postnatal development and is mediated by more than one NPY receptor subtype, that is, Y1, Y2, and Y5. Interestingly, the postsynaptic response seems to be mediated entirely by Y1 receptor.[7]

NPY ACTIONS IN VMN

The VMN is one of the most sensitive targets for NPY-mediated feeding. Microinjections of NPY directly into the VMN robustly increases food intake. Although electrolytic lesions to the VMN produce a hyperphagic phenotype, electrical stimulation of VMN suppresses food intake. This suggests that VMN activity exerts an anorexigenic tone.[5] Although NPY is found within the VMN, its presence is markedly less abundant than in other hypothalamic regions such as ARC and PVN. The density of NPY fibers reaching the core of the VMN is sparse, but the VMN expresses a high density of Y1 receptors. VMN neurons are nearly all glutaminergic, meaning that their output is excitatory to their downstream contacts. NPY reduces the firing activity of VMN by the direct activation of postsynaptic Y1 receptors which hyperpolarizes VMN and reduces their excitability. In addition to this prominent postsynaptic action, NPY also acts at the presynaptic terminals on VMN neurons inhibiting the synaptic transmission. Although NPY suppresses both excitatory glutamatergic and inhibitory GABA-ergic synaptic inputs to NPY-sensitive VMN

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

neurons, the suppression of excitatory input is the dominant action. The NPY-mediated inhibition of VMN neurons may have significant consequences for energy balance regulation. Although NPY acts on a wider population of neurons, it seems to preferentially affect neurons expressing the signaling form of the leptin receptor. Interestingly, these neurons are inhibited by increasing glucose levels, whereas VMN neurons that respond to glucose are excited by elevated glucose levels.[20]

NPY ACTION IN THE LHA

LHA plays a key role in the hypothalamic regulation of feeding. Acute NPY injections into the perifornical area of LHA strongly induce food intake, but evidence from diffusion studies of NPY injected in his manner does not exclude the possibility that they are the neighboring regions of the LHA that mediates this NPY-induced feeding response. Similarly, long-term ectopic overexpression of NPY in the LHA using AAV injections leads to sustained hyperphagia and weight gain with increased meal size.[12] Two major classes of orexigenic neurons are present in the LHA, the orexin and the MCH neurons. Orexin is generally excitatory to hypothalamic neurons and orexin neurons have feedback connections with ARC NPY neurons. Orexin increases NPY tone in the ARC by both increasing NPY mRNA expression and by increasing neuronal activity of NPY neurons. In turn, ARC NPY neurons also innervate orexin LHA neurons, which are inhibited by NPY release. Like orexin neurons, MCH neurons of the LHA also receive innervation from NPY-containing fibers and express mRNA for the Y5 receptor.[9] LHA neurons are directly inhibited by the application of NPY, as evidenced by the NPY-mediated membrane hyperpolarization and reduced firing rate. Intracerebroventricular infusion of MCH leads to a significant increase in NPY mRNA, suggesting a feedback circuit between NPY and MCH neurons similar to that seen between NPY and orexin neurons. Interestingly, NPY does not elicit the major orexigenic system in LHA. This might imply that the LHA orexigenic system acts in part by helping to initially activate the ARC NPY system, and once activated, the NPY neurons in turn suppress the LHA neurons.[34]

NPY AND FEEDING BEHAVIOR

It seems that we can no longer think of NPY as only a potent orexigenic agent that acts to increase food intake in all circumstances. There is a more complex role of NPY in organizing feeding behavior than is apparent when only the total amount of food consumed is measured.[33] Both NPY microinjections and injections of Y1 receptor agonist in the third ventricle of Siberian hamster markedly increase foraging and food hoarding to a greater extent than food intake.[7] Conversely, Y5 receptor agonists stimulate food intake to a greater degree than foraging or hoarding.[6] Accordingly with these results, NPY microinjections into the PVN and perifornical area (PFA) of the hypothalamus can alter the ingestive behavior of foraging and food hoarding in starving rats. Specifically, NPY injected into the PVN or PFA increases food hoarding to a greater extent than foraging or food intake. Moreover, the NPY Y1 receptor seems to play a role in controlling food hoarding through the PVN and PFA on the basis of the ability of an Y1 receptor antagonist to inhibit increases in food hoarding in refed rats.[6,22] Therefore, understanding the NPY-mediated control of human foraging and food storing (hoarding) could provide an additional target for pharmaceutical or behavioral manipulations in the treatment or prevention of obesity[7]

INSIGHT FROM GENETIC MODELS

Research investigating the effects of genetic manipulation of NPY expression and feeding behavior belies the complexity of food intake regulation. For example, mice engineered to overexpress central NPY do not display increased feeding, and NPY knockout mice on a mixed background have normal food intake and body weight and are able to respond to fasting with hyperphagia.[17,18,31] C57BL/6 NPY−/− mice even develop mild obesity when access to food is unrestricted. Concomitant knockout of NPY and AgRP in ARC does not prevent mice from developing to normal body weight or displaying hyperphagia in response to negative energy balance.[18] Similarly, knockout mice for the Y1 receptor do not show an obesity-resistant phenotype and none of the knockout models for a singular receptor produce significant changes in body weight. It is perhaps not surprising that the knockout of any single NPY receptor has such a modest effect on the feeding response to NPY itself, because multiple Y receptors participate in the regulation of food intake. Double knockout involving multiple Y receptors leads to enhanced susceptibility toward diet-induced obesity in mice.[21] Plastic changes to NPY-ergic signaling networks occur throughout development. Neonatal ablation of ARC NPY/AgRP neurons has minimal effects on feeding. However, ablation of these NPY/AgRP neurons in adults causes fatal starvation. Given that melanocortin signaling pathways are not mature in neonates, the loss of NPY neurons does not result in an anorexigenic phenotype in this early stage of development. In adults, however, the potent melanocortin system is established; it is probable that ablation of NPY neurons will cause an imbalance in which excessive melanocortin signaling could lead to anorexia and starvation. Such a situation appears in animal models of cachexia, where the anorexia can be substantially reversed with melanocortin receptor antagonists.[5,27]

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

REGULATION OF NPY RECEPTORS IN FEEDING BEHAVIOR

Studies have been devoted to the identification of NPY receptor subtypes responsible for the regulation of energy homeostasis and the development of obesity.[14] Y1, Y2, and Y5 receptors may affect energy homeostasis through different mechanisms, which have been shown by sustained activation of these receptors in the brain.[20] Changes in feeding behavior and energy balance induce a marked plasticity in the Y1 function and expression in specific regions of the hypothalamus, reinforcing the involvement of this receptor in stimulation of food intake.[11] Fasting induces an increase in NPY orexigenic activity and a decrease in Y1 receptor expression in the ARC and PVN in rats. Neither Y2 nor Y5 mRNA levels are affected by fasting. Decreased activity of Y1 in ARC and PVN induced by food deprivation is attenuated by glucose ingestion and counteracted by leptin treatment, supporting the regulation of NPY Y1 system by leptin in the PVN. Activation of central Y5 receptors leads to weight gain and adiposity through a combination of hyperphagic and nutrient-partitioning effects by metabolizing carbohydrate and decreasing energy metabolized per energy ingested. Chronic activation of central Y1 causes weight gain by altering nutrient partitioning alone, and chronic activation of central Y2 causes transient weight loss mainly through hypophagia and has little effect on energy expenditure. Ligands for Y receptors may be of benefit for the treatment of obesity, and there is a promising role of Y2 and Y4 receptor agonists in protecting against diet-induced obesity.

Intracerebroventricular administration of selective Y1 receptor agonist consistently shows orexigenic activity by stimulating food intake and inducing body weight gain. Several studies have shown that Y1 antagonists injected in hypothalamus reduce NPY-induced hyperphagia.[22] A newer antagonist, BMS-193885, shows significant ability to cross the brain–blood barrier and reduce food intake and body weight in rats without any adverse cardiovascular effects. This study highlights the possibility of Y1 antagonism as an antiobesity agent.[21] The peripheral administration of Y2 receptor agonist reduces food intake and promotes fat metabolism in wild-type mice. Blockade of Y2 receptor in the ARC with selective Y2 antagonist leads to increase feeding in satiated rats. This result is consistent with Y2 receptor tonically inhibiting NPY neurons. Thus, an Y2 antagonist would increase NPY neuronal activity resulting in an elevated release of both NPY and AgRP that stimulate food intake in satiated animals. Similar results have been found in targeted deletion of Y2 receptors in NPY neurons in a mouse model with increased food intake and body weight gain, heightened NPY expression, and reduced POMC expression. These results support the anorexigenic role for the Y2 receptor, with its loss leading to disinhibition of NPY neurons.[16,21] Pharmacological stimulation of Y5 receptor leads to potent increase in food intake in rats. This finding leads to the hypothesis that antagonism of this receptor may be a good target for antiobesity treatments. Two Y5 receptor antagonists have completed phase II clinical trials as antiobesity agents. Velneperit in combination with a low calorie diet causes significantly more weight loss than in control subjects, though the total amount is modest. Those treated with velneperit also show decreased waist circumference and improved serum lipid profile.[10] These studies indicate that Y5 antagonism in humans is well tolerated and may produce significant weight loss in obese populations. Numerous Y5 antagonists remain in development as antiobesity agents, with improved oral bioavailability, brain penetrance, and increased effects on food intake and body weight in obese animal models.[10,21] In mice, the Y4 receptor agonist BVD-74D was administered to C57BL/6 J mice that were fed with a normal or high-fat diet, and to fatty liver Shionogi (FLS)-ob/ob mice to clarify the role of the novel Y4 agonist in the regulation of food intake. The novel Y4 receptor agonist BVD-74D shows suppressive effects on food intake, water intake, and weight gain in normal mice fed with normal diets and on food intake in normal mice fed with high-fat diets and in FLS-ob/ob mice. These findings indicate that the Y4 receptor and its agonist would be promising targets for obesity.[23] 7TM Pharma (Horsholm, Denmark) has reported results from its clinical phase I/II study with the compound TM30338 and the planning of its phase II clinical study.[25] TM30338 is a dual NPY Y2–Y4 receptor agonist developed for the treatment of obesity and related diseases. According to 7TM Pharma, single subcutaneous doses of TM30338 administered to healthy obese subjects are safe and well tolerated. Food intake is suppressed compared with that of placebo both once a day and twice a day for multiple days. They also report their previous start on a preclinical development of a selective Y4 receptor agonist peptide TM30339, which has effects on reduction of food intake and weight loss, and their plan to initiate phase I/II studies.

CONCLUSIONS

NPY remains among the most potent orexigenic influences known. Multiple peptide and hormone systems from the periphery and from within the hypothalamus can affect NPY expression and release. It has been difficult to study the critical components of the NPY system because it is integrated within a network of densely redundant system. There are multiple high-affinity receptors for NPY that contribute to the persistence of NPY system over evolution. Given the complexity afforded by diverse peripheral and central energy balance signals and the intricate network

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

of redundant NPY receptor systems, future studies of NPY physiology might reconsider the use of other techniques and more sophisticated genetic models. A better understanding the NPY-mediated feeding could provide an additional target for pharmaceutical or behavioral manipulations in the treatment or prevention of obesity.

Chapter 155

Opioids

Blake A. Gosnell, Catherine M. Kotz, Charles J. Billington and Allen S. Levine

ABSTRACT

Opioid agonists and antagonists cause increases and decreases, respectively, in food intake. Based on studies of taste and diet preferences, it seems that opioid peptides play a role in mediating palatability and/or the hedonic aspects of feeding. Studies with selective opioid ligands indicate a role for mu, delta, and kappa receptors, and microinjection studies have identified many brain areas in which opioids influence feeding. Opioid systems can be influenced by the intake of palatable foods and by changes in energy balance. The effects of several other feeding-related peptides may be influenced by or dependent on opioid activity. In humans, genetic variation in mu opioid receptors may explain some variability in preferences for palatable food, and pharmacological approaches that include opioid receptor antagonism may be useful in the treatment of obesity.

EFFECTS OF OPIOIDS ON FEEDING BEHAVIOR

Exogenous and endogenous opioids affect the intake of a variety of foods and liquids. Generally, opioid agonists increase food intake, whereas antagonists reduce intake. After decades of research into the role of opioids in feeding, a few general observations can be made. Agonists, particularly those acting on mu opioid receptors, seem to be particularly important in the hedonic or rewarding aspects of feeding. For example, injections of opioid agonists increase the intake of sweet solutions, and the opioid receptor antagonist naloxone decreases sucrose solution intake much more effectively than water intake. Similarly, agonists and antagonists more readily affect the intake of highly palatable food than that of standard laboratory chow. In taste-reactivity tests, which measure hedonic responses to tastes rather than actual intake, agonists increase, and antagonists decrease positive responses to palatable tastes. Importantly, opioid antagonism does not seem to affect taste perception. Finally, several studies with opioid antagonists suggest that opioids are more involved in the maintenance of feeding than in the initiation of feeding. These findings, based on laboratory animal studies, are generally supported in human studies on the effects of opioid antagonists. Details of many of these general findings can be found in a historical perspective on opioids and feeding,[4] a review of human studies with opioid antagonists,[32] and a more recent review with an emphasis on opioid involvement in food reward.[11] Also, see the Opioid Peptides section of this book.

Given the effectiveness of opioid antagonists in reducing the intake of palatable foods and fluids, Levine and colleagues examined whether continuous naltrexone (NTX) infusions would influence the preference for a high-sucrose diet (vs. a high-starch diet). Although NTX reduced total intake during the 10-day infusion period, preference for the sucrose diet was generally unaffected. However, if rats were given only the starch diet for a 10-day period before the start of NTX infusions, subsequent preference for the sucrose diet was decreased for the duration of the infusions and returned after termination of the infusions.[20] Although this study showed that NTX can affect the re-expression of an unlearned preference, it does not directly address the role of opioids in learned preferences. Sclafani et al. have conducted extensive research on the acquisition and expression of learned flavor preferences. In studies in which a flavor preference was conditioned based on its pairing to either the taste of sucrose or intragastric carbohydrate infusions, naltrexone did not significantly influence the acquisition or the expression of the preference. The authors suggest the possibility of a differential involvement of opioids in unlearned versus learned preferences.[28]

Although the effect of opioid agonists on the intake of sweet foods has been well documented, diet selection studies indicate a role for opioids in macronutrient selection. Taha[27] has written a detailed review and analysis of studies in which the intake and preference for diets differing in fat and carbohydrate content were measured after the administration of opioid agonists (primarily morphine and D-Ala^2, NMe^4, Glyol^5-enkephalin (DAMGO)) and antagonists (primarily

naloxone and naltrexone). In most situations, agonists cause a preferential increase in fat intake. When several doses are tested, higher doses tend to have a more selective effect on fat intake than do the lower doses. This primary effect, however, is modulated to a degree by baseline diet preferences, such that agonists are less effective in stimulating fat intake in rats with a low baseline fat preference.[27] In contrast to evidence suggesting that opioids preferentially influence fat intake, injections of DAMGO into the ventromedial prefrontal cortex cause a preferential increase in the intake of a high carbohydrate.[23] This effect is observed in both fat-preferring and carbohydrate-preferring rats. Further testing of the effects of opioids injected into other brain sites should provide a clearer picture of the opioid influence on diet selection.

STUDIES FROM GENETIC MANIPULATIONS OR MUTATIONS

Relatively few studies have been conducted with feeding in animals with genetic modifications of the opioid system. In one study, mu-receptor-deficient CXBK mice preferred saccharin less than intact mice.[33] Mice lacking β-endorphin and enkephalin work less for food on a progressive ratio schedule than wildtype mice.[13] Also, mu opioid receptor knockout mice have diminished food-anticipatory activity compared with that of wildtype mice, as measured by schedule-induced running wheel activity before food intake.[15] Davis et al. published a psychogenetic analysis to determine whether variability in the human mu opioid receptor gene (OPRM1) is associated with variability in preference for sweet and fatty foods. In a study of 300 men and women, subjects with the G/G genotype of the functional A118G marker of this gene reported higher preferences for foods with high fat, high sugar, and high sugar and fat than did subjects with the GA and AA genotypes. At another marker of the OPMR1 gene, rs495491, subjects with the G/G genotype reported lower preferences for foods with high fat and high sugar and fat.[8] Thus, genetic manipulations and analyses support the results of pharmacological studies that indicate a role for opioids in mediating food palatability and reward.

FUNCTIONAL RESPONSE OF OPIOIDS TO METABOLIC AND FEEDING STATES

Levels of brain opioid peptides and their receptors can be affected by the intake of palatable foods and by food deprivation. Some of the many studies of feeding-related changes in gene expression have been summarized by Bodnar[4] in a historical perspective. Food deprivation causes an increase in mu opioid receptor (MOR) mRNA in the ventral medial hypothalamus and arcuate nucleus.[2] When a sweetened fat diet is available concurrently with chow, or is presented in an intermittent pattern that also includes intermittent food restriction, the levels of MOR mRNA are decreased in the nucleus of the solitary tract.[3] Similarly, in mice maintained on a high-fat diet, MOR mRNA levels are decreased in the ventral tegmental area (VTA), the nucleus accumbens (NAcc), and the prefrontal cortex. Levels of proenkephalin mRNA are increased in the NAcc, prefrontal cortex, and hypothalamus.[29]

It has been argued that under some conditions, sugar (particularly sucrose and glucose) can be addicting. Two lines of evidence supporting this possibility involve the presentation of sugar in a cyclic pattern that also involves cyclic access to standard laboratory chow. First, this regimen alters mu opioid receptor binding in several brain areas, including an increase in the nucleus accumbens. Second, after a nine-day period of cyclic presentation of chow and glucose, injections of the opioid antagonist naloxone cause somatic signs and neurochemical changes that resemble those observed during opioid withdrawal.[1]

OPIOID LIGANDS AND RECEPTORS: SITES OF ACTION AND NEURAL NETWORKS AFFECTED

Opioid peptides and receptors are distributed in many brain sites, including those known to affect reward and food intake.[18] Endogenous opioid peptides include β-endorphin, methionine- and leucine-enkephalin, dynorphins, and endomorphins. For research purposes, most studies use nonpeptide agonists (e.g., morphine) or peptides that have been modified for increased stability and/or receptor selectivity (e.g., DAMGO). Microinjection studies show that opioid agonists and antagonists can influence food intake when injected into many specific sites throughout the brain.[4,10] The use of selective ligands indicates a role for mu, delta, and kappa receptors. Interestingly, although, mu and kappa receptor activation typically produces opposing physiological effects, which suggests that these two types of opioid receptors contribute via different neural systems to the control of feeding.[30]

Kelley et al. measured Fos-like immunoreactivity to show that stimulation of DAMGO injection into the NAcc increases the intake of a high-fat diet and activated neurons in the lateral hypothalamus (LH), dorsomedial hypothalamic nucleus (DMH), medial preoptic area, supramammillary nucleus, VTA, substantia nigra, and the intermediate nucleus of the solitary tract (iNST).[34] The functional significance of activation of these areas is seen in a second study that combined injections of DAMGO into the NAcc with inactivation of several brain areas via an injection of muscimol, a GABAA agonist. Inactivation of the LH, DMH, VTA, or iNTS blocks feeding elicited by NAcc injections of DAMGO.[31] Thus, feeding produced by opioid activation of

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

the NAcc seems to involve areas related to reward, energy balance, and autonomic function.

MacDonald et al. found that feeding induced by unilateral injection of DAMGO into VTA is dose dependently decreased by bilateral injections of the dopamine receptor 1 antagonist SCH 23390 into the NAcc.[22] When DAMGO is injected into NAcc, its orexigenic effects are diminished by SCH 23390 injected into VTA but not by the administration of a dopamine receptor 2 antagonist. Injections of SCH 23390 into NAcc inhibit feeding induced by intra-NAcc DAMGO but not by a delta-opioid agonist. Together, these results indicate the presence of an opioid–dopamine interaction important to feeding within NAcc and VTA. As noted above, opioid injections into several brain sites will produce feeding. By combining injections of DAMGO into one site and naltrexone into a second site, the connections between the paraventricular nucleus of the hypothalamus (PVN), central nucleus of the amygdala (CeA), NTS, NAcc, and VTA have been investigated. Pairs of sites tested include: CeA and NTS, PVN and VTA, NAcc and CeA, PVN and CeA, and NAcc and VTA. The effect was bidirectional in most sites because DAMGO injection in one site enhances feeding and opioid-receptor blockade in the corresponding site pair reduces DAMGO-induced feeding.[19] One exception occurs when DAMGO is injected into PVN and naltrexone in CeA, and vice versa.[9] In this situation, intra-PVN naltrexone blocks the intra-CeA DAMGO effect, but naltrexone injected into CeA (and DAMGO injected into PVN) is ineffective. Together, these studies indicate that feeding is regulated in part by a widely distributed complex central opioid network.

INTERACTIONS WITH OTHER NEUROCHEMICAL SYSTEMS

Opioid systems involved in the control of feeding seem to interact with many peptidergic systems, including neuropeptide Y (NPY) and α-melanocyte-stimulating hormone (α-MSH). Injection of naltrexone into the NTS or CeA decreases the food intake stimulated by injection of NPY into PVN.[17] However, there is only a minor effect of naltrexone on NPY-induced feeding when both compounds are injected into PVN. Naltrexone administered chronically (subcutaneously) via minipump increases NPY mRNA levels in the arcuate nucleus.[16] α-MSH is an agonist at melanocortin (MC) receptors, and agouti-related protein (AgRP) is an endogenous antagonist at MC-3/4 receptors. The combined blockade of mu- and kappa-opioid receptors prevents AgRP-induced feeding.[5] Similarly the long-term feeding (24–48 h) elicited by the SHU-9119, an MC-3/4 antagonist, is reduced by the mu opioid antagonist β-funaltrexamine.[12] In addition, β-endorphin-induced feeding is reduced by melanotan-II, an MC-3/4 agonist.[12]

Orexin neurons may also mediate reward-based feeding via an interaction with opioids. Feeding induced by orexin-A (OxA) is blocked by central opioid antagonist injections.[26] Peripheral naloxone also blocks OxA-induced feeding;[6] however, this effect results from an action on central pathways because naloxone methiodide, a form of naloxone that does not cross the blood–brain barrier, does not block OxA-induced eating.[26] The opioid–orexin interaction also seems to be reciprocal. The injection of an orexin antagonist into the ventral tegmental area blocks the hyperphagic effect of DAMGO injected into the NAcc, and intraaccumbens injection of DAMGO in orexin-deficient mice does not increase food intake.[35] More indirect evidence for orexin–opioid interactions also exists. Like opioids, OxA selectively enhances high-fat consumption when animals are given the choice of high- and low-fat diets.[6] However, also like opioids, when a low-fat diet is the only choice available, OxA enhances consumption.

Opioids may also mediate some of the effects of melanin-concentrating hormone (MCH) on food intake. Injections of MCH into the lateral ventricle increased food intake and the hedonic response to sucrose (taste reactivity); preinjection with selective mu, delta or kappa-opioid antagonists blocks or blunts these effects.[21] A previous report[6] found no effect of systemic naloxone on food intake induced by injections of MCH into the third ventricle and it was suggested that it may be related to the route of injection or nonspecific nature of naloxone.[21]

As mentioned above, it is believed that opioids are involved in maintaining rather than in initiating ingestion. One possible mechanism is via an interaction with the oxytocin (OT) system. OT has been shown to decrease food intake, and OT neuronal activation (as measured by double immunostaining for OT and cFos) is greater at a time associated with the termination of feeding than at a time associated with the initiation of feeding. Treatment with the opioid agonist butorphanol, which causes an increase in food intake, causes a decrease in oxytocin neuronal activation.[24]

Finally, the endogenous cannabinoid system, like the opioid system, is believed to play a role in mediating food reward. The primary evidence supporting an interaction comes from studies that show that combined opioid and cannabinoid antagonists decrease food intake at doses that are ineffective when tested individually.[7] Collectively, the results summarized in this section indicate that opioids interact with a number of broadly distributed neuroregulators that alter feeding.

PHYSIOLOGICAL AND PATHOPHYSIOLOGICAL IMPLICATIONS

Opioids are synthesized in the central and peripheral nervous system and affect both physiology and behavior. They

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

involve processes such as learning and memory; nociception; stress and immunological responses; and intestinal, renal, and hepatic functions. The wide distribution of opioids, the variety of receptor subtypes, and involvement in so many other systems suggest that in addition to effects on palatability and food reward, opioids may also indirectly influence feeding via effects on these systems.

The clear demonstration of the effects of opioid compounds on feeding in laboratory animals has led to the efforts to determine whether similar effects are observed in humans. The antagonists naloxone and naltrexone have been found to reduce food intake in normal-weight and obese humans, and reduced bingeing behavior in subjects with bulimia.[32] As has been observed with rats, the antagonists generally reduced food pleasantness but not taste perception. However, opioid antagonists alone have not proven to be effective long-term treatments for obesity, because of side effects and limited weight loss. In one study, functional magnetic resonance imaging was used to evaluate the effects of GSK1521498, a compound that acts as a selective antagonist at mu opioid receptors and in some situations, acts as an inverse agonist. In the open label study of healthy adult males, scans were performed after oral administration of a palatable liquid food or a neutral stimulus. An oral dose of GSK1521498 causes a significant attenuation of the food-induced fMRI activation of the amygdala. This effect is not observed after an oral dose of naltrexone.[25] The development of more selective opioid compounds, therefore, may lead to an effective long-term treatment of obesity. Given the complex neurochemical networks involved in the control of feeding and energy balance, it is also possible that the combination of opioid antagonism with a second drug may offer a better weight loss treatment. For example, the combination of naltrexone and bupropion (a dopamine/norepinephrine reuptake inhibitor) can cause significant weight loss.[14]

CONCLUSIONS

Strong evidence implicates opioids in the control of food intake. Behavioral, neurochemical, and genetic studies suggest that opioids are particularly involved in mediating the hedonic or rewarding properties of food. Opioids participate in a network of areas throughout the brain and interact with many other neurochemically defined systems in areas generally associated with homeostatic, reward, and autonomic function. In short-term studies in humans, opioid antagonists cause a reduction in food intake. However, the usefulness of opioid antagonists in the long-term treatment of obesity will probably depend on the development of more selective antagonists and/or their use in combination with drugs acting on other neurochemical systems.

Chapter 156

Orexin

Jon F. Davis and Stephen C. Benoit

ABSTRACT

Orexigenic hypothalamic peptides have been studied extensively for their ability to regulate feeding behavior. The traditional theory regarding orexigenic peptide function suggested that orexigenic peptides produced within the mediobasal hypothalamus exert their effects on feeding through local hypothalamic centers, including the lateral hypothalamus. However, recent reports indicate that orexigenic peptides are also capable of regulating food intake through their actions at extrahypothalamic centers, including endogenous reward circuitry. This observation expands the complexity of feeding behavior and indicates that feeding can be regulated by extra-hypothalamic reward centers. Here, we review work on the hypothalamic orexin system, its functional–anatomical importance, as well as the ability of this system to interact and modulate mesolimbic reward circuitry with respect to food intake. In addition, this chapter will detail the ability of central effector signals that regulate feeding behavior to impact orexin-induced feeding behavior.

INTRODUCTION

The primary focus of this chapter is to review how orexin peptides influence feeding behavior. In particular, this chapter will focus on how orexin peptides produced in the lateral hypothalamus (LH) interact within and outside hypothalamic nuclei to regulate feeding. The traditional contention regarding food intake suggests that peptides capable of influencing feeding behavior exerted their effects primarily by acting within local hypothalamic centers, with a major emphasis on the LH. It is now recognized that orexin acts within extra-hypothalamic centers, including the brain's endogenous reward circuitry, to modulate food intake. This chapter will review studies that detail orexin's input to these areas. Additionally, it has become clear that a variety of centrally and peripherally produced signals are capable of influencing feeding behavior. Here, the ability of such factors will be discussed in relation to their ability to influence orexin function and orexin-induced increases in feeding behavior. Finally, the ability of metabolic status and aspects associated with this parameter, for example, obesity and caloric restriction will be examined regarding the regulation of orexin-induced feeding. To begin our discussion of how this peptide regulates feeding behavior, it is first important to describe the history and origin of orexin.

OREXIN

Orexins (also called hypocretins) are neurotransmitters produced in small neuronal populations within the lateral (LH) and perifornical (PFA) areas of the hypothalamus. The name orexin originated from the Greek root word for appetite, orexis.[27] Orexin peptides are known to regulate arousal, wakefulness, food intake, and reward-related behaviors through their actions in a disturbed set of brain nuclei (for a review, please see the Hypocretin/Orexin chapter in Brain Peptides section of the book). Orexin peptides exist in two forms, both produced from the cleavage of preproorexin: orexin-A (33 amino acids) and orexin-B (28 amino acids). Orexin-A can bind to both orexin-1 receptor (O×1R) and, with lower affinity, orexin-2 receptor (O×2R) while orexin-B has preferential binding affinity for O×2R. Both orexin receptors are G protein-coupled receptor subtypes[27] and are widely distributed throughout the central nervous system.[20] Due to the lack of an effective and commercially available O×2R antagonist, orexin-A signaling on O×1R has been more widely studied and is much better characterized.

Orexin neurons receive reciprocal connections with mediobasal hypothalamic structures implicated in the control of food intake. In particular, orexin-producing neurons in the LH receive input from neuropeptide Y-/agouti-related peptide-expressing neurons of the arcuate nucleus leading to the contention that LH orexin neurons are 'second-order' neurons in the integration processes involved in promoting food intake.[31] However, other evidence suggests that orexin neurons may serve as "first-order" neurons. In this capacity, they are sensors of metabolic status, that are directly modulated by circulating factors such as leptin, glucose, and ghrelin.[3,4,27,28] Orexin neurons probably take on both first- and second-order properties during the complex integrations of neuropeptide and adipostatic signals which exert counter regulatory effects on feeding behavior (i.e. those that increase and decrease food intake). In terms of feeding behavior, numerous reports have described the orexigenic properties of orexin-A on food intake. For example,

intracerebroventricular (icv) administration of orexin-A increases food intake in rodents.[27] When given a choice, orexin administration in rats will selectively increase intake of preferred diets and more specifically diets that are high in saturated fat.[7] Further, pharmacological antagonism of the orexin-1 receptor is effective in blocking orexin-A-induced hyperphagia and behavioral satiety.[26]

LATERAL HYPOTHALAMUS

As mentioned above, orexin neurons originate in the LH of the hypothalamus and reach many areas of the CNS. The LH has been studied for many years for its ability to regulate "brain stimulation reward" or (BSR). In this model, rats will actively seek out stimulation of the LH[24] and early studies investigating the effects of metabolic factors on BSR indicated that factors that modulate food intake also regulate BSR. More than 20 years after this discovery, orexins were discovered in the LH, and soon after, it was shown that orexin-A possesses the ability to regulate a variety of reward behaviors (for reference please see the Hypocretin/Orexin chapter in Brain Peptides section of the book). These demonstrations were particularly impressive in that (1) they established that a neuropeptide produced in the LH was capable of regulating reward behaviors, thus providing a potential mechanism for BSR and (2) raised the possibility that orexin may be capable of regulating food reward.

MESOLIMBIC SYSTEM

Rewarding behaviors including food reward contain three basic functional components: (1) they induce learning, (2) they produce approach and consummatory behavior, and (3) they induce positive emotions regarding the behavior. Thus, reward and learning overlap to produce optimal conditions for obtaining a particular goal/reward. In rodents, rewarding behaviors are controlled by the mesocorticolimbic system which originates in the ventral mesencepahalon or ventral tegmental area (VTA). Dopaminergic fibers originating in the VTA send dense projections to the nucleus accumbens (Nacc) and the medial wall of the Prefrontal Cortex (mPFC). The projection of dopamine neurons from the VTA to Nacc constitutes the mesolimbic component of this system and the dopamine projection from the VTA to the mPFC make up the mesocortical component of this system. The mPFC along with receiving dopamine input from the VTA sends glutamatergic projections both back to the VTA and to the Nacc thus allowing a cortical interface to be superimposed onto rewarding behaviors. Although it is not the primary focus of this chapter, it should be noted that manipulations of orexin signaling within the mesolimbic system affect many aspects of reward behavior including self administration, relapse, and withdrawal from abused drugs.

OREXIN AND MESOLIMBIC SYSTEM

In terms of orexin regulation of food reward, studies suggest that orexin acts within mesolimbic structures to regulate reward-related appetitive behaviors. For example, orexin neurons in the LH send direct projections to the VTA in the midbrain where dopamine is produced[8] and VTA neurons express both orexin receptor subtypes.[20] The first demonstration that this orexin-VTA connection is physiologically relevant came from investigations of drug withdrawal. These findings suggested that neuroadaptations occurring secondary to psychostimulant exposure are regulated by orexin input into the VTA.[5] Indeed, orexinergic projections to the VTA signal specifically on a majority of dopamine neurons, increase dopaminergic neuron firing rates and activate the mesolimbic pathway.[23] Drug-associated cues activate orexin neurons, and central application of orexin-A reinstates drug-seeking behavior.[12] Moreover, orexin is critical for learning reward–stimulus associations as VTA O×1R antagonism attenuates acquisition of morphine conditioned place preference.[23] These associations are probably mediated by long-term plastic changes occurring within VTA neurons. When an O×1R antagonist is administered into the VTA, behavioral sensitization and neurophysiological changes that are typically associated with chronic cocaine use are blocked.[2] Similar results have been shown with other substances of abuse using O×1R blockade to attenuate operant responding for alcohol and the reinstatement of alcohol- and cocaine-seeking.[14] Further, studies that examine reproductive behavior indicate that orexin regulates the rewarding aspects of male sexual reward.[22]

Orexin has also been studied for its ability to regulate food reward and related behaviors. Orexin-A regulates operant responding for palatable food rewards.[2] Importantly, a seminal set of studies by Zheng and colleagues established that orexin-A action within the mesolimbic system, is necessary for opioid-induced high fat intake.[33] Together, these behavioral studies were the first to provide evidence that orexin has a functional role in the regulation of food reward through its actions within the mesolimbic system. These findings have been extended by examination of the propensity of orexin-A to modulate a variety of forms of food reward; specifically progressive ratio responding for food rewards and reward-based feeding. A progressive ratio (PR) schedule of operant responding, as used in this study, is considered a robust test of motivation to obtain rewards as the animal must work progressively harder for each subsequent food reward. When orexin-A is delivered centrally PR responding for sucrose is augmented. By contrast, blockade of orexin signaling with a pharmacological antagonist specific to the OR×1R reduces PR responding for chocolate.[6] These results suggest that the influence of orexin on feeding may occur through modulation of cognitive and emotional processes such as

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

motivation to obtain food. Feeding beyond homeostatic need, sometimes termed "nonhomeostatic feeding" is regulated by the palatability of a particular food and has been hypothesized to be a major contributor to the current increase in obesity. This behavior can be modeled by allowing calorically sated rats to feed selectively from a high fat butter diet. In this way, high fat feeding is driven by unconditioned endogenous regulation of reward-based feeding in contrast to drug-induced overconsumption of food which is commonly used. This behavioral paradigm was developed to model feeding in humans that occurs independent of caloric need. The data we collected using this paradigm indicate that blockade of orexin-A signaling is sufficient to reduce overfeeding from high fat diet under the condition of satiation.[6] The interpretation of these results is that, similar to conditioned responding for food rewards, orexin-A is also capable of regulating unconditioned reward-based high fat feeding. Collectively, these results further support a role for orexin in the modulation of cognitive-emotional processes, which orient an organism to food.

In support of this notion, the orexin system is activated in anticipation of a variety of rewards. In particular, the expectancy of morphine or sweet flavored cereal activates LH orexin neurons.[12] Separate studies have extended these findings by examining the ability of food rewards and restricted feeding to activate LH orexin neurons. Expectation of a chocolate food reward induces neuronal activation within LH orexin neurons and several brain regions implicated in the control of feeding and reward behavior. Importantly, rats trained to expect their daily ration of standard rodent chow also display increased c-Fos in LH orexin neurons. Thus, LH orexin neurons seem to be sensitive to either the expectation of food reward (chocolate) or feeding in general (chow) suggesting that cues associated with not only palatable food but also the anticipation of daily feeding activates orexin-A neurons.[6] One possible reason for this result may lie in the specific activation of other PFA-LH neuropeptide systems, such as melanin-concentrating hormone (see the MCH chapter in Brain Peptides section) also known to be involved in the regulation of feeding and reward-related behaviors. The increased activation of orexin-A expressing neurons under these conditions was further characterized to be selectively significant in the PFA, but not the LH region of the orexin field. This distinction is consistent with a previous results indicating that pharmacologically induced high fat feeding specifically activates PFA orexin neurons.[33] This is in contrast to that observed after expectation of drug-associated cues and may stem from the caloric value of food vs. drugs that contain no calories. It is also possible that the brains endogenous stress system may modulate LH or PFA orexin neurons differentially depending on the level of experience the organism has with the particular reinforcer. Moreover, it has been suggested that nonspecific activation of PFA orexin neurons may be indicative of heightened general arousal (please refer to the Hypocretin/Orexin chapter for more detail). A conditioned meal-feed response to limited chow access or a conditioned reward-based feeding response both probably require a learned increase in general arousal to maximize the animal's ability to benefit from such conditions. Based on these and other findings, the ability for PFA orexin to signal arousal-based activity to selectively act on reward processing may depend more on the specific sites of action (target regions) as opposed to the origin (PFA orexin activation).

OREXIN TARGETS

Identification of neuronal activation within known targets of the orexin system is achieved through visualization of c-Fos in neurons that also express the orexin-1 receptor (OR×1R). Rats trained to expect chocolate display increased c-Fos within the LH, PFA, VTA, mPFC NAcc, and paraventricular thalamic nucleus (PVT). Increased c-Fos immunolabeling in the PFA-LH, PVT, mPFC, and VTA of rats expecting chocolate is consistent with several similar reports investigating neuronal activation in rodents expecting food or drug reinforcers.[12] It is notable that expectancy of chocolate produced the most robust c-Fos response and in particular within the PVT neurons that express OR×1R.[6] The PVT receives a dense orexinergic projection from the LH orexin field, and these data indicate that during times of food reward expectancy, orexin-A targets OR×1R neurons to activate the PVT.

OREXIN AND THE PARAVENTRICULAR THALAMIC NUCLEUS

The paraventricular nucleus of the thalamus (PVT), a midline thalamic nucleus where thalamocortical projections originate, is most closely linked to attention and arousal. The PVT receives dense inputs from LH orexinergic fibers and expresses orexin receptors. Orexin can synapse within the midline thalamus to directly activate cortical-projecting PVT excitatory neurons as another mechanism for which orexin, sensitive to physiological and visceral information can enhance arousal and attentional tone. Studies showing that the PVT mediates reinstatement of extinguished alcohol-seeking and conditioned place aversion during morphine withdrawal[10] have established the possibility that the PVT is also involved in reward-related behaviors. In addition, excitatory PVT projections to the nucleus accumbens (NAcc), a major component of the mesolimbic reward circuit, occur on dopaminergic terminals and increase dopamine efflux independent of VTA function. Several recent studies have also implicated PVT orexin in affecting emotionality and addiction behaviors.[16,17] Taken together, these studies strongly support a role for orexin as a modulator of attention and arousal, to activate the necessary alertness required to promote and enhance goal-oriented, specifically reward-related, behaviors.

OREXIN AND METABOLIC STATUS

A central theme in the study of ingestive ascribes that factors produced in relation to an organism's state of energy balance (i.e. fed vs. fasted states) travel through the circulation to act centrally on hypothalamic structures to regulate food intake and energy expenditure. Specifically, leptin produced from adipocytes and insulin produced by the pancreas act within key hypothalamic structures contained in the mediobasal hypothalamus to negatively regulate food intake. Conversely, the stomach derived hormone ghrelin also acts within the hypothalamus to increase food intake in times of negative energy balance. One study in obese human patients reported that orexin-A in plasma is lower in obese patients relative to lean controls.[1] Earlier studies examining this phenomenon in rodents used a different approach to assay the central distribution of orexin peptide. In these studies, the central distribution of orexins in the hypothalamus and neighboring areas is higher in obese rats relative to lean controls.[21] The obese rodents used in these studies lacked functional leptin receptors. As leptin is known to negatively regulate orexin expression,[18] increased orexin expression in rodents that lack the ability to sense leptin fits with the conceptual framework regarding metabolic influence of orexin. These results indicate that in the context of disrupted leptin signaling, such as obesity, central orexin tone is increased. In terms of obesity, triglycerides and dietary fat have been reported to stimulate orexin tone.[30] A similar set of studies investigating orexin tone in hypoglycemic rats indicates that orexin-B levels in the hypothalamus are 10-fold higher than in control rats.[4] Together these studies indicate that orexin output is responsive to metabolic status. Reductionist approaches are often used to discern function of a particular gene or peptide. Many times, genetic knockout or ablation techniques are used to generate mutant mice to gain a better understanding a particular genes function. Genetic ablation of orexin neurons in the LH results in hyperphagia and obesity.[11] The interpretation of this result was that central orexin neurons represent a key node for counterregulatory mechanisms to maintain stable energy homeostasis. Thus, although metabolic status is capable of influencing orexin tone, orexin is also a critical factor regulating energy homeostasis.

OREXIN REGULATION BY FEEDING PEPTIDES

Melanocortins

Over the past two decades, factors that act on hypothalamic structures to regulate feeding behavior have continued to emerge. The melanocortin system has been studied extensively for its role in the regulation of food intake. This system is unique in that it possesses both an endogenous agonist and an inverse agonist with opposite effects on feeding behavior. Alpha-melanocyte stimulating hormone (α-MSH) and agouti-related peptide (AgRP) are the primary effector peptides of the melanocortin system (see the Melanocortin/AgRP chapters in Brain Peptides and Ingestive Peptides sections of the book). Increased α-MSH release decreases food intake, whereas increased AgRP drives food consumption. Under basal conditions, the expression of each peptide is regulated by caloric status as downstream targets of the adiposity hormone leptin. A unique feature of melanocortin-induced feeding is the duration in which feeding behavior is affected. When administered centrally, AgRP increases food intake each time an animal takes a meal for a period of five to seven days. The nature of this effect presumes that other neural systems become activated to maintain this increased food intake. In support of this idea, LH orexin neurons become activated 23 hours after AgRP injection[32] indicating that the long lasting effects of AgRP on food intake are correlated with increased orexin tone. In contrast, orexin-A stimulates electrical activity in AgRP neurons that reside in the mediobasal hypothalamus.[29] These results indicate that orexin-induced activation of AgRP neurons is critical for the release of AgRP and the maintenance of long-term energy balance. AgRP neurons also express neuropeptide Y (NPY), a potent inducer of feeding behavior. The increased feeding response elicited by orexin-A is inhibited by pharmacological antagonism of NPY receptors.[13] Thus, NPY seems to be a critical downstream target for orexin-induced feeding. These results describe a reciprocal role regarding the relationship of orexin and AgRP/NPY; the nature of this activation and its subsequent effects on feeding behavior require further investigation.

Ghrelin

Ghrelin is a feeding-related hormone derived in the stomach involved in the homeostatic and hedonic regulation of food intake[25] (see the Ghrelin chapters in several sections of the book). Ghrelin concentrations peak before expected meals, and when administered centrally, ghrelin induces food intake. Ghrelin receptors are present in the LH and when ghrelin is administered centrally LH orexin neurons become activated.[15] The appetite stimulatory effect of ghrelin is suppressed in mice that lack orexin[28] indicating that orexin mediates the effects of ghrelin on food intake. In the context of food reward, mice that form a place preference to high fat diet display elevated c-Fos expression in orexin neurons.[25] Further, ghrelin's ability to stimulate operant performance for high fat diet is attenuated in orexin-deficient mice.[25] Together these data indicate that ghrelin's ability to modulate feeding and food reward behaviors is mediated in part by the LH orexin system.

Leptin

Leptin is an adipocyte-derived hormone that acts centrally to reduce food intake (see the Leptin chapters in Brain, Endocrine, Ingestive, Gastrointestinal, and Cancer/Anticancer Peptides sections of the book). Leptin acts within the mediobasal and lateral hypothalamus to attenuate food intake. Leptin receptors are expressed in LH orexin neurons,[9] and when leptin is administered systemically, orexin neurons contain P-STAT3 the downstream marker of leptin receptor activation. Early studies investigating the effects of leptin on orexin expression reported that central (third ventricular) administration of leptin attenuated fasting-induced increases in preproorexin.[18] In addition, leptin treatment reduces expression of hypothalamic OR×1R.[18] However, more recent evidence indicates that systemic or direct application of leptin into the LH increases orexin mRNA.[19] The discrepancy in the directionality of orexin expression after leptin administration could be accounted for by the model system used (e.g. rats vs. mice) or the time period in which orexin expression was examined. In the context of counterregulation of feeding behavior, decreases in orexin secondary to leptin administration are in accord with appetite suppressant activity of leptin. More studies are required to determine the exact nature and directionality of leptin's effects on LH orexin expression.

Summary

From this collection of results, several themes emerge. It is clear that orexin can induce feeding behavior. The nature of this effect indicates that orexin may achieve this induction through its actions on mesolimbic reward circuits. Orexin receptors are expressed within neurocircuits that regulate brain dopamine and reward function. The orexin system along with the regions targeted by orexin is activated during anticipation of food rewards and feeding in general. In the context of feeding behavior, orexin seems to facilitate food intake primarily by modulating the motivation to consume food. Given that brain reward regions overlap with homeostatic control circuits in the control of ingestive behavior, it is not surprising that a centrally produced factor such as orexin is capable of influencing feeding behavior through its actions in both systems. Metabolic status, a potent modulator of food intake regulates the effects of orexin on food intake. More specifically, factors that regulate energy homeostasis to exert their influence on food intake do so by modulating orexin function. Overall, these results highlight the propensity of orexin to regulate food intake, neurobiological responses associated with feeding, and the motivation to obtain food rewards. As all these aspects of biology are associated with obesity, these results also underscore the utility of orexin as a laboratory tool to understand better the neurobiology of obesity.

Chapter 157

PYY

Rachel Troke, Tricia M. Tan and Stephen R. Bloom

ABSTRACT

Peptide YY (PYY) is a C-terminally amidated peptide hormone. It is named for the two tyrosine ("Y") residues which occupy both the C- and N-terminals of its 36 amino acid structure. PYY belongs to the "PP fold" family of peptides, which also includes Neuropeptide Y (NPY) and Pancreatic Polypeptide (PP). These peptides have a similar configuration, all with 36 amino acids, a large number of tyrosine residues, and a U-shaped tertiary structure designated the "PP-fold." PYY is secreted from the enteroendocrine L cells of the distal gut in response to a meal, especially protein rich. It exists in two forms, the full length 1-36 form and the processed 3-36 form which results after dipeptidyl-peptidase-4 removes the N-terminal dipeptide. PYY acts via the Y family of receptors (Y1, Y2, Y4, and Y5) to slow gastric emptying (the "ileal brake") and reduce secretion from the pancreas and gallbladder. PYY also acts as a satiety hormone.

DISCOVERY

Peptide YY (PYY) is a 36 amino acid peptide hormone predominantly released from enteroendocrine L cells of the distal gut in response to an oral nutrient load. It was discovered in 1980 by Tatemoto and Mutt at the Karolinska Institute in Stockholm, Sweden.[29] They isolated a novel peptide from porcine small intestine by developing a chemical assay method which identified the C-terminal amide structure, characteristic of a number of biologically active peptides.[29] On analyzing the peptide they had isolated to determine its amino acid sequence (Fig. 1), the investigators noted a large number of tyrosine residues within the amino acid structure of this peptide, including one at both the N- and C-terminals. It was therefore designated Peptide YY, Y being the single letter abbreviation for the amino acid tyrosine.

The amino acid sequence of PYY is related to Pancreatic Polypeptide (PP) and to Neuropeptide Y (NPY). These three peptides are named the "PP fold" family, as they form a common tertiary structure incorporating a hairpin-like U-shaped fold. Please see the relevant chapters on PP and NPY in the Brain and Ingestive Peptides sections of the book for further information.

STRUCTURE OF THE mRNA/GENE

The gene encoding PYY is found on chromosome 17q21.1.[16] The *PYY* gene consists of four exons and three introns,[10] and is in close proximity to the gene encoding PP (*PPY*), being located 10 kilobases away from *PPY* on the same chromosome. By contrast, the gene encoding NPY (*NPY*) is on chromosome 7. These three peptides represent an example of a multiple gene duplication event, giving rise to structurally similar but functionally different products. It is thought that *NPY* was the original gene with first *PYY* and then *PPY* arising as a consequence of gene duplication. The initial gene duplication probably occurred at the same time as a translocation event, explaining the alternative chromosomal location of *PYY* and *PPY*.[10,16]

PYY is synthesized as a prepropeptide which incorporates a signal peptide, the 36 amino acid active PYY sequence, and a carboxy terminal extension peptide.[16] Processing of preproPYY involves amidation of the carboxy terminal tyrosine, which is necessary for biological activity, and proteolytic cleavage by a prohormone convertase to give PYY(1-36), the 36 amino acid form of the peptide which is secreted. After secretion, the cell surface enzyme dipeptidyl-peptidase-4 (DPP-4) cleaves the N-terminal dipeptide from PYY(1-36) to give PYY(3-36), the predominant circulating form of PYY (see Peptide Biosynthesis/Processing section of the book).

Immunohistochemical studies confirm the presence of PYY in enteroendocrine L cells of the gastrointestinal tract. PYY colocalizes in these cells with glucagon-like peptide-1 (GLP-1), although the distribution of GLP-1 in the gut is different from that of PYY.[28] PYY mRNA tissue expression is similar to the distribution of the peptide seen by immunohistochemistry, and in rats, PYY mRNA is expressed at progressively increasing levels in the jejunum, cecum, and then the colon.[35]

RECEPTORS

PYY binds to the seven-trans-membrane-domain G protein-coupled receptors of the "neuropeptide Y receptor family,"

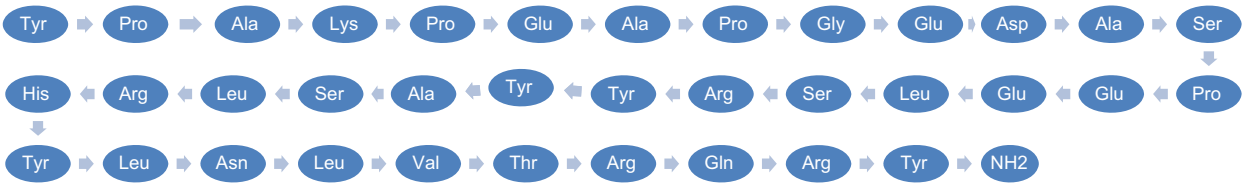

FIGURE 1 The amino acid sequence of peptide tyrosine-tyrosine (PYY). The C- and N-terminal amino acids are both tyrosine residues. In addition, the C-terminal is amidated.

Members of the Y receptor family, like the PP-fold peptides, appear to have arisen from a common ancestor gene through duplication.[19] In mammals, five receptor subtypes have been cloned, Y1, Y2, Y4, Y5, and Y6.[25] The Y3 receptor was initially thought to be a subtype that had a higher affinity for NPY compared with PYY, but has never subsequently been cloned, and no specific agonists or antagonists for this receptor subtype have been identified. As the "Y3" designation had already been allocated to this potential receptor subtype, it was decided not to use it further.[25] The Y6 receptor is functional in mice and rabbits,[19] but the human Y6 gene on chromosome 5 appears to be a pseudogene, inactivated by a frame shift mutation.[1] The Y6 receptor is absent entirely in the rat.

In humans, PYY(1-36) binds to all receptors in the Y family (Y1, Y2, Y4, and Y5). PYY(3-36), the predominant circulating form of PYY immunoreactivity, is more selective for the Y2 and Y5 receptors, and has a lesser affinity for Y1 and Y4 receptors.[18]

Signaling Pathways

Y receptors are coupled to inhibitory, pertussis toxin-sensitive G proteins, and their activation results in a reduction of cyclic-AMP (cAMP) accumulation, modulation of calcium and potassium channels, and the mobilization of intracellular calcium.[25] Y1, Y2, and Y4 are expressed on rabbit gastric smooth muscle cells, and in these cells, activation of Y2 and Y4 but not Y1 receptor types has been shown to cause smooth muscle contraction via inositol 1,4,5-triphosphate (IP_3) dependent calcium release.[26] All three receptors (Y1, Y2, and Y4) are coupled to the inhibition of adenylyl cyclase, the enzyme responsible for formation of cAMP from ATP.[26] Studies on the Y1 receptor in cardiac myocytes show that activation of the receptor by NPY causes a positive inotropic effect in these cells. This effect is the result of the action of phospholipase C (PLC), an element of the downstream signal transduction pathway that leads to IP_3 mediated intracellular calcium release.[15] While Y5 receptors are similar to Y1 receptors in mediating effects on feeding, a study using cloned Y5 receptors stably transfected into a human endometrial cancer cell line suggests that Y5 signal transduction (in response to NPY administration) is limited to inhibition of cAMP accumulation, without the increase in intracellular calcium seen with the other Y receptors, although this may be cell line specific.[6]

Y1 Receptors

Y1 receptors have a wide tissue distribution. By a variety of methods they have been localized in rodents to small arteries and arterioles of many organ systems.[23] Y1 receptors have been identified on enteroendocrine cells of the gut, and in rats Y1 mRNA is found in the proximal colon.[12] The majority of Y1 expression, however, is within blood vessels and nerves. Y1 receptor agonists mediate vasoconstriction in renal and splenic arteries.[22] The Y1 receptor antagonists SR 120107A and BIBP 3226 eliminate the prolonged vasoconstriction mediated by perivascular sympathetic nerves, suggesting an important role for the Y1 receptor in the sympathetic nervous system and blood pressure control. Furthermore, Y1 receptors are detected in the human brain, and throughout the central nervous system (CNS). They are present in the hypothalamic nuclei involved in the regulation of appetite and energy homeostasis.[28] Y1 receptors bind intact PYY (1-36), but PYY(3-36) does not bind well to this receptor.[18]

Y2 Receptors

Y2 receptors were first discovered when it was noted that a C-terminal fragment of PYY, PYY (13-36) had reduced potency in vascular preparations compared with NPY and PYY(1-36), while remaining potent in vas deferens preparations. This was the first suggestion there was more than one NPY receptor subtype, and at that time the two identified subtypes were named Y1 (receptors with poor affinity for C-terminal fragments of NPY) and Y2 (receptors with good affinity for these C-terminal fragments).[24] Y2 receptors have limited homology with Y1 receptors,[25] but a much higher affinity for PYY, particularly PYY(3-36). For Y1 receptor binding, the K_d for PYY(1-36) is 0.42 nM, with a calculated K_i value of 1050 nM for PYY(3-36). At the Y2 receptor, the K_d for PYY(1-36) is 0.03 nM with a K_i value for PYY(3-36) of 0.11 nM.[18] These values show that PYY(3-36) binds poorly to Y1 receptors, as specified above, while PYY(1-36) and PYY(3-36) have roughly equivalent binding affinities for the Y2 receptor. Like Y1 receptors, Y2 receptors are found throughout the peripheral

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

nervous system (PNS) as well as the CNS, particularly in the arcuate nucleus of the hypothalamus (ARC). In humans, the Y2 receptor mRNA has been localized in the mucosa of the ileum and ascending colon, as well as in the muscular wall of the ileum and descending colon.[12]

Y4 Receptors

Y4 receptors appear to be the principal receptor for Pancreatic Polypeptide. They have a relatively low affinity for PYY(3-36), and are discussed in further detail in the Pancreatic Polypeptide chapter in the Gastrointestinal Peptides section of the book.

Y5 Receptors

Y5 receptors, like Y1 and Y2, are found with a wide tissue distribution within the brain in murine studies.[27] By Northern Blot analysis, Borowsky et al. have shown that the Y5 receptor also has a wide tissue distribution in the human brain.[8] The potency of PP fold peptides for the Y5 receptor is in the order of NPY ≥ PYY(1-36) ≈ PYY(3-36) > PP.[25]

REGULATION OF PYY SECRETION

PYY is secreted from the enteroendocrine L cells of the distal gut in response to an oral nutrient load, with levels reaching a plateau within 1–2 h after a meal,[28] and remaining elevated for up to 6 h.[2] Plasma concentrations of PYY are lowest in the fasted state, and rise post-prandially. Peak post-prandial concentrations of PYY increase in response to an increasing calorific content of meals.[21] Early studies suggested that PYY release was most strongly stimulated by fat compared with protein or carbohydrate,[28] however Batterham et al. showed in rodents that protein was the most potent stimulus for PYY release, followed by fat and then carbohydrate.[5] PYY levels begin to rise within fifteen minutes of a meal, which suggests that while PYY is released from the distal gut, the mechanisms regulating its secretion may be located more proximally, implying the involvement of other neural or hormonal influences. Indeed, cholecystokinin (CCK), a hormone secreted from the duodenum in response to various fat and protein stimuli promotes PYY release.[28] In CCK receptor null mice, or on administration of a CCK receptor antagonist, PYY secretion is attenuated.[11] In addition to hormonal influences, it seems probable that the neural influence stimulating PYY release is via the vagus nerve.[28]

While nutrients sensed in the proximal gut have an effect on PYY secretion, it has also been shown that the infusion of amino acids,[1] and short chain fatty acids (SCFA) into the colon can stimulate PYY secretion.[1] PYY mRNA expression in the distal gut is inducible by administration of a diet high in resistant starch, which is known to increase the levels of SCFA in the distal gut by fermentation. The SCFA receptors GPR43 and GPR41 have been colocalized to the PYY-releasing enteroendocrine L cells of the distal gut.[17,30] PYY concentrations remain elevated for up to 6 h post prandially, and nutrient sensing in the distal gut, potentially via these SCFA receptors, may be the responsible mechanism for this prolonged elevation of peptide levels.

BIOLOGICAL ACTIONS OF PYY

Gastrointestinal Tract

Peptide YY reduces gastric emptying, and slows intestinal transit time. This effect is termed the "ileal brake" as it represents the ability of the distal small intestine (Ileum) to inhibit gastric emptying.[1] This slowing of intestinal transit is reproduced by infusion of PYY(3-36) to healthy volunteers.[1] In rats, specific PYY binding sites have been identified in the dorsal vagal complex (DVC), an area of the medullary brainstem that incorporates the area postrema (AP), the nucleus tractus solitarius (NTS), and the dorsal motor nucleus of the vagus (DMN). It is probably through these areas that PYY exerts control over the slowing of intestinal transit.[9]

In addition to its effects on gastrointestinal motility, PYY also inhibits gastric acid release when administered peripherally. However, when injected centrally into the DVC, PYY results in an increase in gastric acid secretion.[28] Guo et al.[13] showed that an intravenous infusion of PYY inhibits the cephalic (anticipation and smell/taste of food) and gastric (stimulated by gastric distension and chemical effects of food in the stomach) phases but not the duodenal phase (stimulated by small intestine dilatation and chyme entering the duodenum) of gastric acid secretion. They also noted that PYY does not act to reduce acid secretion via a reduction in gastrin release or binding.

PYY interacts with both GLP-1 and secretin to give an additive reduction of gastric acid output, but also reduces gastric acid secretion via vagal innervation of cells in the fundus of the stomach.[34] Once again, this vagal effect is mediated by the DVC.[34]

After the discovery of PYY in 1980, this peptide was further found to be a potent inhibitor of secretin- and cholecystokinin-mediated pancreatic exocrine secretion.[1] PYY(3-36) inhibition of pancreatic secretion is regulated for the most part via the Y2 receptor—found on vagal afferents. The vagus nerve therefore appears to play multiple important roles in mediating the effects of PYY on the gastrointestinal system.

Inhibition of Appetite and Food Intake

In 2002, Batterham et al. investigated the effects of peripheral administration of PYY(3-36) on feeding. They showed

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

in rats that PYY(3-36) had a potent inhibitory effect on food intake both when injected peripherally, and when injected centrally into the ARC, an area of the hypothalamus which is known to have abundant Y2 receptors.[3] They also established that there is no reduction in food intake in response to the administration of PYY(3-36) in Y2 receptor null mice, providing further evidence that PYY(3-36) acts via Y2 receptors to mediate its effects on food intake and satiety.[3] Subsequently, this group further showed a reduction in food intake by more than a third when compared with controls after a 90 min PYY(3-36) infusion in healthy human subjects. Peripheral infusions of 0.8 pmol/kg/min of PYY(3-36) were administered in order to mimic post-prandial concentrations. These healthy subjects had a significant reduction in hunger scores. There was no effect on gastric emptying with the PYY(3-36) infusion, and there was no reported nausea or vomiting.[3] PYY(3-36) infusion was, however, shown to reduce levels of the appetite stimulating hormone ghrelin.[2]

Studies in PYY null mice show that PYY has a physiological role in the control of appetite. These mice were hyperphagic, with a greater cumulative food intake than controls, and an augmented refeeding response after fasting.[5] They were fatter when total body fat was measured by MRI scanning when compared with controls,[5] and treatment with PYY(3-36) as a replacement therapy caused significant weight loss.

After this demonstration of the anorexigenic effects of PYY, many other groups have subsequently replicated these findings to show the effect of PYY on appetite and food intake. The mechanism of this reduction of food intake is mediated by the vagus, as well as areas in the brainstem and hypothalamus.

The hypothalamus is integral to the control of appetite. Neuronal populations within the hypothalamus detect peripheral signals in the circulation such as nutrients, and gut hormones, including PYY. PYY(3-36) administered directly into the ARC has been shown to have an anorexigenic effect.[3] There are two distinct neuronal populations within the ARC that control appetite: firstly, orexigenic (appetite stimulating) neurons expressing NPY and agouti gene-related peptide (AgRP); and secondly anorexigenic (appetite suppressing) neurons expressing Proopiomelanocortin (POMC) and Cocaine and Amphetamine Related Transcript protein (CART). PYY(3-36) inhibits the NPY/AgRP neurons in the hypothalamus in the ARC via presynaptic Y2 receptors, suppressing appetite. Although PYY(3-36) might also work by activating POMC/CART neurons, it still is able to exert anorexigenic effects even in mice bearing knockouts for the POMC gene, suggesting that the principal mechanism here is the presynaptic inhibition of NPY secretion by NPY/AgRP neurons.

In addition, PYY-induced satiety signals are carried to appetite-related areas in the brainstem such as the NTS via the vagus nerve. Such vagal afferent signals are triggered by PYY(3-36) activation of Y2 receptors on the vagus nerve itself.[11]

In contrast to the effects of PYY(3-36) on appetite, mediated via Y2 receptors, administration of PYY(1-36) into the central nervous system of rats causes an increase in food intake, mediated via Y1 receptors.[1] Interestingly, if PYY(1-36) is given peripherally, this causes a reduction in food intake, probably resulting from the peripheral conversion of PYY(1-36) to PYY(3-36) by DPP-4 before the peptide crossing the blood brain barrier.[1] Activation of the Y5 receptor, like Y1, has an orexigenic effect.[1] The effects of PYY(3-36) on food intake are reduced in both Y1 and Y5 null mice, implying that Y2, Y1, and Y5 also play a part in central control of appetite.[28] However, it seems that the major role in this pathway is played by Y2.

Effects on Glucose Metabolism and Energy Expenditure

Van den Hoek et al. in 2004 showed in mice that PYY(3-36) acutely augments insulin-mediated glucose disposal in euglycaemic clamp studies, i.e., it increases insulin sensitivity.[31] They went on to further investigate the effect of PYY on glucose metabolism and energy expenditure.[32] They were unable to show an increase in energy expenditure, heat production, or physical activity in mice treated with PYY(3-36), but they did show that PYY(3-36) treatment reduced the respiratory quotient (RQ), suggesting a shift from carbohydrate metabolism towards fat oxidation. The observed reduction in RQ was not attenuated by chronic administration of PYY(3-36), and the effect was sustained, in comparison to a pair fed group, suggesting that the reduction in RQ is not simply because of the anorectic effect of PYY(3-36).[32]

Further to their previous studies in 2004, they went on to confirm that PYY(3-36) augments chronic as well as acute insulin-mediated glucose disposal. In addition, this group showed that glucose uptake in adipose tissue was significantly increased after treatment with PYY(3-36) compared with controls.[32]

Neuroimaging Studies

Early studies using PYY(3-36) looked at expression of c-*fos*, a marker of neuronal activation, in order to establish which brain areas were involved in PYY action. PYY(3-36) increases c-*fos* expression in the ARC, NTS, AP, amygdale, and thalamus,[7] and studies specifically indicate that PYY(3-36) effects are mediated via Y2 receptors on NPY neurons in the ARC. Functional neuroimaging techniques such a manganese-enhanced magnetic resonance imaging (MEMRI) are now being used to look at the neurophysiology

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

underlying these actions. Manganese in particular is able to enter the hypothalamus, and act as an indirect marker of hypothalamic neural activation.[14] PYY(3-36), on subcutaneous administration in rats, was associated with a trend towards a decreased signal intensity in the hypothalamus during MEMRI, although this did not reach significance. A reduction in signal intensity would suggest reduced neuronal activity, in this case of the orexigenic NPY hypothalamic neuronal population. There was no effect of PYY administration on signal intensity in the AP.[14] The effect of PYY on various brain regions has been assessed using whole-brain blood-oxygen-level-dependent (BOLD) functional magnetic resonance imaging of subjects shown pictures of food. This study found that the brain area most modulated by PYY(3-36) administration is the caudolateral orbital frontal cortex (OFC).[4] This is an area which is implicated in reward, and is possibly activated through projections from the hypothalamic nuclei involved in energy regulation and food intake.

PATHOPHYSIOLOGICAL IMPLICATIONS

PYY Levels in Obesity

In obese subjects, PYY secretion in response to meals is blunted. This has been shown in humans with obesity,[21] and also in rodent models of diet induced obesity.[33] In these rodent models, not only is the post prandial secretion of PYY diminished in obesity, but there is also a reduced effect on food intake after administration of exogenous PYY(3-36) in diet-induced obese animals. In human studies, Le Roux et al. showed a significantly lower fasting PYY concentration in obese subjects compared with normal weight controls.[21] Furthermore, they also showed a blunted post-prandial PYY response to meals, with obese people requiring double the amount of calories to achieve post prandial PYY levels equivalent to those of normal weight controls. This study also showed that the lower post-prandial PYY levels achieved in obese subjects are matched by a reduced feeling of satiety. In addition, the results of this research suggest that low fasting PYY levels are a consequence rather than a cause of obesity.[21] Obesity does not appear to confer a peripheral resistance to PYY, unlike leptin.[2] A reduction in PYY secretion in obese individuals suggests an attenuation of satiety signals, and subsequent increased food intake.

PYY LEVELS AFTER GASTRIC BYPASS SURGERY

Obesity has become a major public health issue of epidemic proportions, and there is little to offer in the form of pharmacological therapy. As a result, bariatric surgery procedures are becoming more popular as the only obesity treatment that has been shown to confer long term, sustained weight loss and clear health benefits. The most common bariatric procedure is the Roux-en-Y gastric bypass. Weight loss and reduced appetite are evident very soon after gastric bypass, and for the most part, these are sustained in the long-term. Interestingly, post-prandial levels of PYY and GLP-1 are seen to be elevated as early as two days after gastric bypass surgery, both in humans and in experimental animal models.[20] It has been postulated that these raised post-prandial levels of gut hormones play a large role in the satiety and weight loss that makes bariatric surgery such a successful therapy for obesity. The elevated levels of these gut hormones are also proposed as an explanation for the rapid resolution of diabetes after gastric bypass, although the exact mechanism of this effect remains to be elucidated.

PYY in Disease

Certain disease states are known to be associated with raised levels of PYY. Elevated levels are seen in celiac disease, active Crohn's disease, and in patients with ileal resection.[28] Levels may be raised in these individuals because of malabsorption and therefore increased luminal nutrients in the distal gut triggering increased PYY secretion. Circulating concentrations are also raised in patients with hepatic cirrhosis—a recognized anorectic state.[28] The number of cells expressing PYY in the colon is increased in diabetic gastroparesis, a condition associated with delayed gastric emptying and abnormalities of intestinal transit time.[28]

PYY and PYY Analogs as Potential Obesity Therapies

PYY significantly decreases food intake and increases satiety, as well as slows gastric emptying and intestinal transit. PYY potentially has effects on insulin-mediated glucose disposal and insulin sensitivity. All of these are desired characteristics for an anti-obesity therapy. While natural sequence PYY has a very short halflife when infused (less than 10 min), a long acting analog of PYY that can be administered subcutaneously could have huge potential as a pharmacological therapy for obesity. In combination with other anorectic gut hormones such as oxyntomodulin or GLP-1, the effect of PYY on satiety could be further augmented. Such combination therapies are currently in the early stages of development as obesity and diabetes treatments.

Chapter 158

Adrenomedullin

Mitchell L. Schubert and Shijian Chu

ABSTRACT

Adrenomedullin, isolated in 1993 from human pheochromocytoma, is a member of the calcitonin family of peptides. It is expressed in gastrointestinal tissues including liver, pancreas, stomach, duodenum, small intestine, colon, and pancreas. The activities of adrenomedullin are mediated via CGRP receptors and specific adrenomedullin receptors, termed AM_1 and AM_2, primarily through the activation of adenylate cyclase. In the stomach, adrenomedullin (1) stimulates somatostatin and thus inhibits histamine and acid secretion; (2) protects against injury by increasing mucosal blood flow, stimulating epithelial cell proliferation, and promoting angiogenesis; and (3) inhibits gastric emptying. In the intestine, adrenomedullin stabilizes gut barrier function. In the colon, it inhibits sodium absorption and ameliorates colitis. Adrenomedullin also inhibits amylase secretion in the pancreas and may contribute to the hemodynamic alterations observed in cirrhosis. More potent and selective adrenomedullin receptor antagonists will be required to define the precise physiological and pathophysiological roles of adrenomedullin in regulating gastrointestinal function.

DISCOVERY

Adrenomedullin, a member of the calcitonin peptide family that also includes calcitonin, calcitonin-gene-related peptide (CGRP), and amylin, was first isolated in 1993 from human pheochromocytoma and termed "adrenomedullin" based on the high concentration in the normal adrenal medulla.[12] In 2004, using sequences from the calcitonin peptide family, a 47-amino-acid peptide termed adrenomedullin-2 (AM-2) or intermedin was identified in mammals. Although AM-2 displays high homology to adrenomedullin and shares similar biological actions, only 18 amino acids are conserved between the peptides, and they are coded by different genes.

Although initially identified as a vasodilator, adrenomedullin is present in the human digestive system and has been implicated in a variety of physiological functions and pathophysiological conditions.

STRUCTURE OF THE mRNA/GENE

Human adrenomedullin is a 52-amino-acid peptide with a ring structure and an amidated C-terminal tyrosine residue.[23] The adrenomedullin gene is located on the short arm of chromosome 11 in humans whereas in mice, it is located on chromosome 7. The adrenomedullin promoter region contains several protein-binding sites including nuclear factor for interleukin-6 expression (NF-IL6) and activator protein 2 (AP-2).

PROCESSING OF THE PRECURSOR

The initial translation product of the gene is preproadrenomedullin, a 185-amino-acid peptide, which is converted to proadrenomedullin. Proadrenomedullin undergoes proteolysis and amidation to yield adrenomedullin and proadrenomedullin N-terminal 20 peptide (PAMP); the latter may possess biologic activity.

Adrenomedullin is characterized by the presence of a six-amino-acid ring formed by a disulfide bridge between residues 16 and 21 at the N-terminus. Its structure is conserved across species, the rat peptide only differing by six substitutions and two deletions compared to the human peptide.

DISTRIBUTION OF THE mRNA/PEPTIDE

Adrenomedullin and its mRNA are expressed not only in the adrenal gland but also in a variety of tissues and cells including lung, heart, kidney, brain, thyroid, bone, skin, nerve, vascular endothelial and smooth muscle cells, submandibular gland, stomach, duodenum, small intestine, colon, pancreas, and liver.[10,27]

In human and rat pancreas, adrenomedullin is expressed in most islet cells, colocalizes with pancreatic polypeptide in islet F cells, and inhibits insulin secretion from β cells. A few adrenomedullin immunoreactive cells are scattered among the exocrine parenchymal cells.

In the hollow digestive system, adrenomedullin is concentrated in mucosal neuroendocrine cells. In the stomach, adrenomedullin has been localized to histamine-containing enterochromaffin-like (ECL) cells and chief cells within the oxyntic mucosa and to gastrin cells within the pyloric mucosa.[5,13,34] In the colon, adrenomedullin immunoreactivity has been localized to serotonin-containing enterochromaffin (EC) cells.[20]

Adrenomedullin circulates in the plasma in picomolar concentrations. In normal subjects, plasma concentrations range from 2 to 4 pmol/l. Plasma concentrations of adrenomedullin increase with fasting and pregnancy as well as a variety of disease states including acute myocardial infarction, ischemic heart disease, congestive heart failure, essential hypertension, chronic renal failure, hyperparathyroidism, sepsis, and cirrhosis.[15,27] One common denominator may be bacterial infection and/or inflammation as exposure of gastric epithelial cells to various strains of bacteria including *Helicobacter pylori* as well as various cytokines such as interleukin-1, interleukin-6, tumor necrosis factor, interferon, and lipopolysaccharide stimulate adrenomedullin production and secretion.[1] Circulating hormones such as corticosteroids, thyroid hormones, angiotensin II, and norepinephrine also stimulate adrenomedullin secretion. In contrast, interferon-γ, vasoactive intestinal peptide (VIP), and thrombin suppress adrenomedullin production.

In plasma, adrenomedullin complexes with adrenomedullin-binding protein (AMBP). This binding protein was later isolated and found to be identical to complement factor H, a protein that inhibits the alternative complement pathway and modulates neutrophil and monocyte function.[22] It should be noted that only unbound adrenomedullin is measured in plasma by radioimmunoassay. Complement factor H enhances the biological activity of adrenomedullin by protecting the peptide from degradation while unaffecting its ability to bind to its receptor.

RECEPTORS AND SIGNALING CASCADES

Receptors for the calcitonin family of peptides are G-protein-coupled receptors known as calcitonin-receptor-like receptors. The calcitonin-receptor-like receptor (CRLR), a seven-transmembrane domain receptor, can function as either a CGRP receptor or an adrenomedullin receptor, depending on which members of a family of single-transmembrane domain proteins, called receptor-activity-modifying proteins or RAMPs, are expressed.[24] RAMPs function as accessory proteins that traffic CRLR to the plasma membrane and are required for pharmacological specificity. All three RAMPs contain about 160 amino acids and exhibit a common structure that comprises a large extracellular N-terminal domain, a single-transmembrane domain, and a short cytoplasmic C-terminal tail. When CRLR and RAMP1 were cotransfected into Xenopus oocytes, a CGRP pharmacological response was acquired, whereas transfection of CRLR and RAMP2 or RAMP3 resulted in the adrenomedullin receptors AM_1 and AM_2, respectively (Fig. 1).[19,20] Because of the structural similarities among the ligand peptides, there is some crossreactivity among adrenomedullin, amylin, and CGRP. Adrenomedullin can bind to CGRP receptors with an affinity approximately 10-fold less than that of CGRP itself.[6] CGRP binds to the AM_2 receptor with around 50-fold lower affinity than adrenomedullin and has a much lower affinity at AM_1 receptors

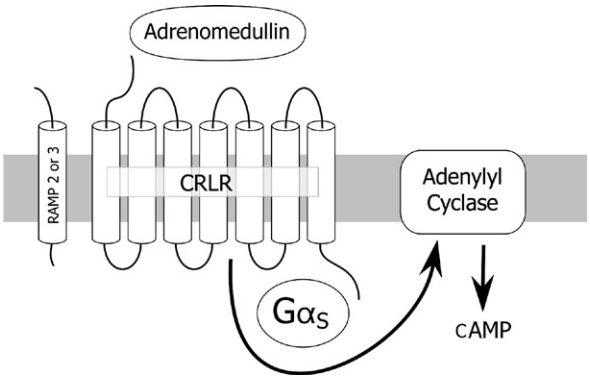

FIGURE 1 Model illustrating the adrenomedullin receptor showing the interactions between the seven-transmembrane domain G-protein-coupled receptor known as the calcitonin-receptor-like receptor (CRLR) and the single domain receptor-associated membrane proteins (RAMPs). Their association forms a high-affinity receptor coupled to $G\alpha_s$ that activates adenylyl cyclase to generate cAMP. The subtype of adrenomedullin receptor formed by the association of CRLR with RAMP2 is termed AM_1, whereas that formed by association with RAMP3 is termed AM_2. Adapted from Ref. 24.

Adrenomedullin22-52 (AM22-52), which lacks the disulfide bond, functions as a low affinity selective adrenomedullin receptor antagonist in some but not all circumstances. It seems to antagonize the effects of adrenomedullin but not CGRP and has significant selectivity for AM_1 receptors over AM_2 receptors.[7] The AM_1 receptor recognizes adrenomedullin over CGRP with a selectivity of two to three orders of magnitude and is more effectively antagonized by AM22-52 than by the CGRP receptor antagonist, CGRP8-37.[16] The AM_2 receptor is sensitive to both CGRP8-37 and AM22-52, although rat and mouse AM_2 receptors show a preference for CGRP8-37 over AM22-52. The amylin receptor antagonist, AC187, can also antagonize specific adrenomedullin receptors but only at high concentrations (>5 μM).

The biologic activities of adrenomedullin are mediated primarily through the activation of adenylyl cyclase although in some cell types adrenomedullin may also release calcium from inositol 1,4,5-trisphosphate-sensitive intracellular stores and stimulate nitric oxide synthase and mitogen-activated protein kinases (MAPKs) (Fig. 1).

BIOLOGICAL ACTIONS WITHIN THE GASTROINTESTINAL TRACT

Gastric Acid Secretion

Adrenomedullin circulates in the plasma and intravenous infusion of the peptide inhibits basal, histamine-stimulated, pentagastrin-stimulated, and 2-deoxy-D-glucose-stimulated

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

acid secretion in conscious rats equipped with gastric fistula.[26] The effect is partly, 50–60%, blocked by a selective somatostatin receptor antagonist, suggesting that systemic adrenomedullin inhibits acid secretion via both somatostatin-dependent and -independent pathways. The adrenomedullin receptor antagonist, AM22-52, however failed to significantly antagonize the effect of adrenomedullin. The findings are consistent with those reported in pylorus-ligated rats in which the inhibitory effect on acid secretion of subcutaneous injection of adrenomedullin was more potently blocked by the CGRP receptor antagonist, CGRP8-37, than AM22-52, suggesting that the antisecretory effect is mediated predominantly via CGRP receptors.[28] In the stomach, CGRP is capable of stimulating somatostatin and inhibiting gastrin and acid secretion.[17,29] It should be cautioned, however, that rodent AM_2 receptors display a preference for CGRP8-37.[16]

Studies in isolated mouse stomach and superfused rat fundic segments, preparations that retain intact intramural neural and paracrine pathways but eliminate hormonal influences such as gastrin, indicate that adrenomedullin acts locally, that is, within the oxyntic mucosa, to stimulate somatostatin and inhibit histamine and acid secretion (Fig. 2).[9] The effect is abolished by the axonal blocker, tetrodotoxin, indicating that the effect of adrenomedullin is mediated via the activation of intramural neurons. The identity of the neurotransmitter responsible for adrenomedullin-induced somatostatin secretion is not yet known. In dog mesenteric arteries, adrenomedullin receptors have been identified on adrenergic nerve endings.[3]

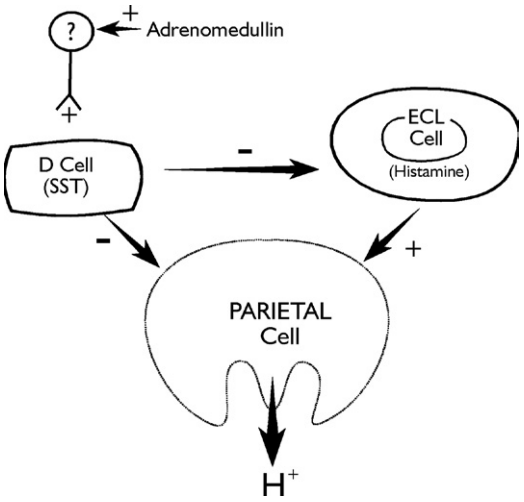

FIGURE 2 Model illustrating the regulation of acid secretion in gastric oxyntic mucosa by adrenomedullin. Adrenomedullin, acting via an as yet unidentified intramural neuron, stimulates somatostatin (SST) and thus inhibits histamine secretion from enterochromaffin-like (ECL) cells and acid secretion from parietal cells. Reproduced by permission from Ref. 9.

Gastrointestinal Protection and Repair

Inhibition of acid secretion and increased mucosal blood flow play important roles in preventing gastric mucosa injury. In rats, central and peripheral administration of adrenomedullin prevents gastric damage induced by 70% ethanol, reserpine, and pylorus ligation. The effect of intracisternal adrenomedullin was blocked by central injection of the CGRP antagonist, CGRP8-37, in one study but not in another.[2,11] The effect was significantly attenuated by subdiaphragmatic vagotomy as well as peripheral injection of atropine, indomethacin, and the nitric oxide synthase inhibitor, N^G-nitro-L-arginine methyl ester (L-NAME). The results suggest that adrenomedullin exerts a gastroprotective effect centrally that is mediated via the vagus nerve with activation of peripheral prostaglandin- and nitric oxide-dependent protective mechanisms.

Peripherally administered adrenomedullin also prevents gastric damage induced by noxious stimuli. The protection is accompanied by inhibition of acid secretion and vasodilation. Studies using CGRP8-37 to block the CGRP receptor and AM22-52 to block the adrenomedullin receptor suggest that the acid effect is mediated predominantly via CGRP receptors, whereas the vasomotor effect is mediated predominantly via adrenomedullin receptors.[28]

Expression of adrenomedullin and its receptor is increased in rat gastric mucosa after direct instillation of ethanol and during gastric ulcer healing,[33] suggesting that adrenomedullin may contribute to gastric mucosal injury repair, perhaps in a paracrine or autocrine manner. In support of this notion, adrenomedullin promotes epithelial restitution, as measured by potential difference, in human oxyntic mucosal sheets mounted in Ussing chamber following injury induced by 0.5 M saline.[5]

The intestinal mucosa constitutes an important barrier between the host and luminal contents containing microbes and noxious substances. Accumulating evidence suggests that adrenomedullin can stabilize gut barrier function. In rat intestinal cells and jejunal epithelium, lipopolysaccharide increases adrenomedullin expression. In a rat model of septic shock, adrenomedullin reduces intestinal permeability as measured by translocation of labeled dextran from the gut into the systemic circulation.[31] Adrenomedullin also preserves gut barrier function after hemorrhagic shock and gut ischemia reperfusion.[35] It reduces the incidence of diarrhea, the severity of colonic damage, and improves survival in trinitrobenzene sulfonic acid (TNBS)-induced colitis in rats.[30]

Gastric Emptying

Intracisternal injection of adrenomedullin dose dependently inhibits gastric emptying in rats.[18] Central injection of PAMP, however, was ineffective in rats[18] but inhibited

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

gastric emptying in mice.[21] Intravenous adrenomedullin has been reported to either inhibit[25] or have no significant effect[18] on gastric emptying in rats.

Colonic Transport

Adrenomedullin is present in human and rat colonic mucosa. In rat distal colon mounted in Ussing chamber, adrenomedullin inhibits sodium absorption and stimulates chloride secretion.[4] The effects were inhibited by the axonal blocker, tetrodotoxin, implying that they are mediated via the activation of intramural neurons.

Pancreatic Exocrine Secretion

Adrenomedullin is present in pancreatic islet cells and capable of binding specifically to pancreatic acini.[32] In isolated rat pancreatic acini, adrenomedullin inhibits amylase secretion induced by cholecystokinin and the calcium ionophore, A23187.[32]

Gastrointestinal Malignancy

Adrenomedullin and its receptor are highly expressed in a variety of gastrointestinal cancers where it induces angiogenesis and proliferation, including pancreatic and colorectal cancer.[8] Expression of adrenomedullin is upregulated through a hypoxia-inducible factor-1 (HIF-1)-dependent pathway.

Cirrhotic Portal Hypertension

Peripheral arterial vasodilation leading to decreased systemic vascular resistance is the most outstanding hemodynamic alteration in liver cirrhosis. There is increasing evidence that arterial vasodilation contributes to portal hypertension and the formation of ascites through arterial hypotension, increased cardiac output, and activation of renal sodium retentive mechanisms. The precise cause of the vasodilation remains unknown, but overproduction or reduced degradation of endogenous vasodilators is believed to play a role.

Adrenomedullin causes vasodilation by increasing cAMP in vascular smooth muscle cells and releasing nitric oxide from vascular endothelial cells. Plasma levels of adrenomedullin are increased in patients with cirrhosis and are highest in patients with refractory ascites. Studies in CCL_4-induced cirrhotic rats suggest that overproduction of adrenomedullin may contribute to the observed vascular hyporeactivity to vasoconstrictors.[14]

PATHOLOGICAL IMPLICATIONS

Adrenomedullin is a relatively recently discovered peptide. Although we have made significant progress in understanding its structure, molecular biology, distribution, plasma levels in health and disease, receptors, second messenger systems, and bioactivity in experimental circumstances, questions remain regarding its true physiological role. Recent studies suggest that it may play a role in the pathogenesis of peptic ulcer disease and the hyperdynamic circulation in cirrhosis as well as a growth factor in certain cancers. Endogenous adrenomedullin may also ameliorate damage caused by shock, ischemia reperfusion, and colitis.

Although adrenomedullin circulates in plasma, it is likely that it acts predominantly as an autocrine and paracrine agent. In the gastrointestinal tract, adrenomedullin inhibits gastric acid secretion, protects the stomach as well as intestine and colon from injury, inhibits gastric emptying, inhibits sodium absorption, inhibits amylase secretion, and may contribute to the hemodynamic alterations observed in cirrhotic portal hypertension. More potent and selective adrenomedullin receptor antagonists will be required to define the physiological roles of adrenomedullin in the regulation of gastrointestinal function.

Chapter 159

Angiogenic Growth Factors

Sandor Szabo, Xiaoming Deng, Tetyana Khomenko, Ganna Tolstanova, Brankica Paunovic, Longchuan Chen, Ximing Xiong and Zsuzsanna Sandor

ABSTRACT

The etiology and molecular pathogenesis of gastrointestinal (GI) ulcer diseases, for example, duodenal ulcer (DU) and ulcerative colitis (UC), are poorly understood. Our laboratory first postulated that stimulation of angiogenesis alone might be sufficient to accelerate GI ulcer healing. We showed that therapy with genes or peptides of angiogenic growth factors, for example, bFGF, PDGF, and VEGF significantly accelerated healing of experimental DU, whereas blockade of these angiogenic factors delayed DU healing. Because histologically DU and UC look similar, we also predicted that the healing of UC might be also improved by stimulating angiogenesis. However, UC healing apparently involves abnormal "pathologic" angiogenesis, enhanced by VEGF and placental growth factor (PlGF), and anti-VEGF therapy improves experimental UC. Expression of PlGF is apparently decreased in DU but increased in UC. Here, we review similar and differential actions of angiogenic factors in GI ulcer healing and make suggestions for the development of angiogenesis-related drugs.

INTRODUCTION

Gastrointestinal (GI) ulcers are essentially internal wounds that resist normal healing. Because their pathogenesis is poorly understood, and the etiologic (e.g. gastric acid, aspirin-like drugs, stress, innate immunity, environmental exposure) and aggravating factors (e.g. *Helicobacter pylori*) are not well characterized, the remaining therapeutic option is to accelerate healing. Superficial mucosal lesions, that is, erosions usually heal by epithelial regeneration and restitution, but ulcers damage the muscularis propria and smooth muscle cells do not divide/regenerate. These deep lesions are filled by granulation tissue, that is, angiogenesis followed by proliferation of connective tissue fibroblasts that deposit collagen over which adjacent surviving and dividing epithelial cells migrate to complete the healing.

Gastric and duodenal ulcers (GU and DU) are more prevalent than the idiopathic ulcerative colitis (UC) and Crohn's disease (CD), especially because some of the GI ulcers are related to stress, environmental exposure, excessive alcohol and drug use. In most countries of the world, DU is the most prevalent form of "peptic ulcers." At one time during their lives, 8–10% of the US population suffers from DU disease and another 1% from GU.[24,25] Despite advancement in the etiology and the pathogenesis of gastric ulceration, especially after the discovery of the role of *H. pylori*, the pathogenesis of ulcer disease in the GI tract is still poorly understood. Hence, no etiologic and effective therapy is available.

UC and CD that are also known as inflammatory bowel disease (IBD) are associated with substantial inflammation, much more prominently and extensively than gastroduodenal ulcers. In UC, the ulcers are surrounded by acute (e.g. neutrophils) and/or chronic (e.g. lymphocytes, plasma cells, macrophages) inflammatory cells, hence often leading to the mistaken pathogenic target of treating UC by anti-inflammatory drugs to suppress the secondary inflammation response to the previously induced ulcerative lesions. Unlike the more diffuse UC, CD is regional, segmental, leaving uninvolved small or large bowels interspersed by areas of deep lesions, fissures, often fistulas, that are the results of transmucosal involvement. For unknown reasons, nevertheless, UC, unlike CD, often leads to carcinomas.

This chapter focusses on discussing the similar and different expression and actions of angiogenesis and angiogenic factors such as basic fibroblast growth factor (bFGF), platelet growth factor (PDGF), vascular endothelial growth factor (VEGF), placental growth factor (PlGF), and Rac1 in healing of DU and UC. It also provides an overview of the developments of the last 10 years of GI ulcer research, mostly published from our laboratory.

ANGIOGENESIS IN CHRONIC GI ULCER DEVELOPMENT AND HEALING

Angiogenesis is the generation of new blood vessels from an existing vascular bed. The process involves extensive interaction between several cells and molecules.[9,25] The switch to angiogenesis involves a change in the local equilibrium between positive and negative regulators of

Handbook of Biologically Active Peptides. http://dx.doi.org/10.1016/B978-0-12-385095-9.00159-7

Copyright Elsevier 2024

microvessels. The proliferation of endothelial cells and tube formation are crucial elements in granulation tissue production. The formation of granulation tissue, that is, angiogenesis followed by proliferation of fibroblasts and deposition of collagen, on the other hand, is a rate-limiting step in the repair of major damage to tissues that do not regenerate (e.g. after the loss of cardiac or stomach muscle). Only in certain organs such as liver, adrenal cortex, and kidney, does the regeneration involve the proliferation of original parenchymal cells that rapidly replace the lost tissue. The healing process needs the granulation tissue, which forms the basis for proliferation and migration of epithelial cells in the GI tract. The migrating cells cannot grow over necrotic tissue, unless it is gradually replaced by angiogenesis-dependent granulation tissue. Thus, stimulation of only epithelial cell proliferation is counterproductive in the healing of internal and external wounds, unless it is accompanied by the expression of a loose or solid granulation tissue, which provides the basis and physical framework for the migration of epithelial cells to complete the healing process.[29] The healing of deep ulcers that reach or penetrate the muscularis propria almost always requires initial angiogenesis and proliferation of other elements of granulation tissue.[30] Endothelial cell migration, proliferation and microvascular structure formation are initiated and regulated by angiogenic growth factors, such as VEGF which is the most potent and specific stimulator of angiogenesis.[9,30,31]

In normal wound/ulcer healing angiogenesis, known as physiologic angiogenesis, is closely controlled by multiple growth and tissue factors resulting in minimal changes in microvascular permeability, proteolysis, and inflammation. However, abnormal or pathologic angiogenesis, such as that observed in malignant tumors and UC, is characterized by abnormal vasculature, which exhibits defective architecture, increased permeability, and increased inflammatory and thrombogenic potential. Basic and clinical research of the last two decades indicate that angiogenesis plays a crucial role in the healing of both upper[4,10,11,16,17,26,27,31,33] and lower GI tract ulcers.[2,3,12,18,21,32] Development of new vasculature during chronic inflammation may play a negative or "pathologic" role by contributing to increased inflammatory responses resulting from dysfunctional new vessel architecture and increases in the recruitment of inflammatory cell types.[23,32] Indeed, angiogenic inhibition during chronic inflammatory diseases attenuates further inflammation and disease progression.[3,32] However, the microvascular changes that occur during UC have not been closely investigated, and we are only beginning to understand their involvement in the disease process. As such, expanding our knowledge of how pathologic angiogenesis occurs during UC will further our ability to treat patients with these diseases.[2,23,32]

ANGIOGENIC GROWTH FACTORS AND GI ULCER HEALING

Advances in basic sciences such as cell and molecular biology and pharmacology of growth factors provide new methods and new results in the study complex and multifactorial disorders such as ulcer and inflammatory diseases of upper and lower GI tract. Until recently, the pathogenesis of GI ulceration has been investigated mostly from the point of view of aggressive factors and the therapeutic interventions affected the healing process only indirectly. Angiogenic growth factors, for example, bFGF, PDGF, and VEGF are new modulators of ulcer disease, these peptides are relatively large molecules and structurally different from the small molecular mediators and modulators such as glucocorticoids, dopamine, somatostatin, sulfhydryls/antioxidants, endothelins and angiosteroids.[25,29] Furthermore, although the small molecules usually exert multiple effects, the growth factors usually have a single mechanism of actions, that is, stimulating the proliferation of a single or several types of cells.

Similar Therapeutic Effects of bFGF on GU, DU, and UC

bFGF is an 18-kDa polypeptide first isolated under this name from the brain as a fibroblast stimulator. It was later found to be identical to the most potent heparin-binding angiogenic stimulator. Indeed, bFGF is a direct mitogen for vascular endothelial cells, fibroblasts, smooth muscle cells, certain epithelial cells, and neural cells. It has diverse roles in wound healing, tissue regeneration, and embryonic development, and probably in carcinogenesis as well. The high affinity of bFGF for the components of the extracellular matrix, such as heparin and heparan sulfate proteoglycans, might sustain a microenvironment with high availability of bFGF to the target cells.

bFGF Treatment in GU and DU

Our laboratory was the first to show that *per os* (po) treatment with either naturally occurring bFGF or its acid-resistant mutein (bFGF-CS23, in which the second and third cysteines are replaced by serine residues) accelerates the healing of cysteamine-induced chronic DU.[10,27] The results reveal that the ulcer-healing effect of bFGF derivatives is more potent than that of orally administered cimetidine (10 mg/100 g, twice a day for 3 weeks) but that only the acid-resistant mutein bFGF-CS23 significantly decreases both size ($p < 0.01$ vs. control) and prevalence ($p < 0.05$ vs. control) of the remaining chronic ulcers (Fig. 1a). Nevertheless, we also detected an additive ulcer healing effect between bFGF and cimetidine.[10,27,30]

Novel derivatives of recombinant human (rh)bFGF were also tested in the treatment of experimental chronic DU in rats. These included Ser 78,96-rhbFGF (which is bioequivalent to

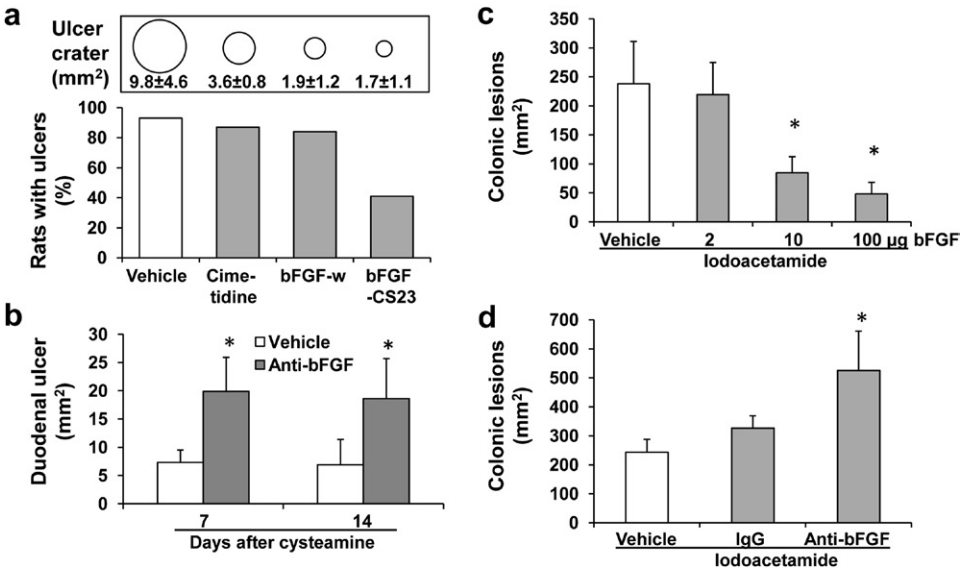

FIGURE 1 Effects of bFGF on DU and UC in rats. (a): Healing of cysteamine-induced DU by cimetidine, wild-type bFGF (bFGF-w) or mutein bFGF (bFGF-CS23). (b): Aggravation of cysteamine-induced DU by bFGF neutralizing antibody. (c), (d): Colonic lesions in iodoacetamide-induced UC after treatment with recombinant rat bFGF or neutralizing anti-bFGF antibody (anti-bFGF). $*p < 0.05$.

rbFGF-CS23), CMC-hrbFGF 9 (a carboxymethyl cysteine derivative of rhbFGF) and PEG-rhbFGF (a polyethylene glycol derivative of hrbFGF). Oral administration of these novel derivatives for 21 days accelerates the healing of cysteamine-induced chronic DU, and PEG-rhbFGF is more active than the other analogs.[28,29]

In a series of experiments, po administration of a mutein of rhbFGF twice a day for 2 weeks significantly accelerates the healing of acetic acid-induced GU in rats: the size of the ulcers decreases, whereas regeneration of the mucosa is enhanced. The same mutein of rhbFGF has no effect on the development of ethanol-induced acute gastric erosions when given to rats before ethanol administration (unpublished results). These results suggest that although bFGF accelerates ulcer healing, it does not exert acute gastroprotection.

Besides the ulcer healing and angiogenic actions, bFGF promotes the reinervation of the newly formed microvessels and regeneration of autonomic nerves in the granulation tissue in the experimental GU induced by acetic acid in rats.[16,17] One human study tested the efficacy and safety of bFGF-CS23 in healing of NSAID-associated GU, which are resistant to or relapse after conventional treatment.[16] Five patients with nine ulcers were treated po and after four weeks, four ulcers had healed, and there was a significant reduction in the size of other ulcers. This is a clinical confirmation of the potent antiulcer effect of bFGF, initially discovered in our animal model.[11] We now know that several forms of bFGF are available, and there is additive antiulcer effect between bFGF and H2 receptor antagonists.[10,27,30]

Our results also support a physiologic role for endogenous bFGF in ulcer healing. Endogenous bFGF was visualized by immunostaining techniques in the normal rat duodenum after administration of the duodenal ulcerogen cysteamine, and bFGF immunoreactivity was time dependently reduced in the mucosa, submucosa, and muscularis propria.[33] The localization of bFGF immunoreactivity was also studied in acetic acid-induced experimental GU in rats. bFGF binding sites, observed in the basal portion of the gastric mucosa in the control rats, are markedly increased in the regenerated tissues around the acetic acid-induced ulcer.[15]

Western blot analysis of rat duodenal mucosa revealed a rapid depletion of mucosal cytoplasmic 18 kDa bFGF and increased synthesis of nuclear 21–25 kDa bFGF in cysteamine-induced ulceration in rats. At 12 h, we found a 2- to 3-fold increase in nuclear forms of bFGF, with a 50% decrease in the cytoplasmic form, whereas 48 hours after the administration of cysteamine, the samples showed a trend toward the pattern seen in control rats. We used ELISAs to actually measure the changes in duodenal mucosal concentration of bFGF during DU development in rats. Endogenous levels of duodenal mucosal bFGF started to increase at 12 h; they reached maximal values at 48 h, when they were significantly higher than the basal value. Despite intragastric administration of cysteamine, bFGF concentrations in the gastric mucosa did not change. Studies with neutralizing anti-bFGF antibodies in cysteamine-induced chronic DU models also support a role for endogenous bFGF in spontaneous ulcer healing: daily injection of these antibodies markedly delays the healing of experimental DU (Fig. 1b).

bFGF Treatment in UC

The effect of bFGF on UC healing was studied in a new chemically induced animal model of UC.[22] We showed that

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

intracolonic administration of bFGF improved healing of UC induced by iodoacetamide (Fig. 1c), extending our previous demonstration that intragastric administration of bFGF accelerated healing of chronic DU induced by cysteamine in rats.[18,29] Both pharmacologic and histologic results showed that bFGF treatment significantly improves UC healing which, on the other hand, is impaired by the administration of anti-bFGF antibody (Fig. 1d). The potential molecular mechanisms of the therapeutic actions of bFGF on healing of UC seem to involve increasing angiogenesis and mucosal regeneration, and reducing the inflammatory response in the colon. bFGF seems to accelerate the healing of UC via increasing angiogenesis and cell proliferation in colonic mucosa. Our results showed that angiogenesis and proliferation of other cells (shown by Ki-67-positive staining) are significantly increased around ulcer craters in colonic mucosa treated with bFGF.[18] The finding of increased neovascularization indicates that bFGF facilitates healing via enhancing "normal" angiogenesis which is needed in UC healing. The increased Ki-67-positive cells in bFGF-treated rats with UC indicate that bFGF stimulates cell proliferation in colonic mucosa. Surprisingly, bFGF markedly decreases TNF-α levels and MPO activity in colonic tissues during healing of UC.[18] Matsuura et al.[14] also showed that gene expression of TNF-α is significantly reduced in DSS-induced UC after treatment with bFGF. TNF-α is one of the most important proinflammatory cytokines and directly influences intestinal epithelial cells. TNF-α disrupts the epithelial barrier, and induces apoptosis of epithelial cells and stimulates the secretions of chemokines from intestinal epithelial cells. It also activates the adaptive immune system of the bowel by recruiting and activating neutrophils and macrophages. MPO activity reflects the degree of neutrophilic infiltration and, therefore, is a specific biomarker of inflammation. The concentrations of both TNF-α and MPO in colonic tissues are strongly associated with the intensity of UC inflammation. Thus, reduced TNF-α and MPO levels by bFGF in healing of UC indicate that bFGF may play anti-inflammatory role in UC. These findings suggest that bFGF, unlike VEGF, is a beneficial angiogenic growth factor that provides a promising option for the treatment of UC. bFGF enema may be a clinically safe and useful route that may provide a new therapy way for UC. Moreover, our study showed that the effective doses of bFGF that we used are 4- to 10-fold less than the doses others used to treat UC induced by dextran sulfate sodium (DSS) in rats and mice.

Similar Therapeutic Effects of PDGF on Experimental DU and UC

PDGF was originally described as a product of platelets, but it is also synthesized and secreted by activated macrophages. It consists of two disulfide-linked polypeptides: chain A (14 kDa) and chain B (17 kDa) sharing 60% similarity. Thus, the PDGF dimer has three isoforms: PDGF-AA, -AB, and -BB.[1] Previous studies have shown that various cell types, including macrophages (major source), fibroblasts, capillary endothelial cells, and neutrophils express PDGF-A and/or -B mRNAs and proteins. Macrophage-derived PDGF induces chemotaxis and proliferation of monocytes and fibroblasts during inflammation and wound repair. PDGF plays a central role in the repair process, particularly in fibroblast and endothelial cell proliferation and angiogenesis after acute and chronic tissue injury. PDGF also signals and induces tissue remodeling, cellular differentiation, and morphogenesis. In addition, PDGF directs the migration, differentiation and function of a variety of specialized mesenchymal and migratory cell types during wound healing. Clinical studies showed that PDGF-B (Becaplermin) prevents the formation of diabetic foot ulcers and accelerates the healing of chronic lower extremity diabetic ulcers.[15]

Effect of PDGF on Experimental DU

Soon after recognizing the potent ulcer-healing effect of bFGF, our laboratory tested whether PDGF also accelerates the healing of experimental DU. Macroscopic and microscopic evaluations revealed that treatment with PDGF accelerates the healing of chronic cysteamine-induced ulcers (Fig. 2a), whereas anti-PDGF treatment with a specific neutralizing antibody shows significant aggravation and delayed healing of DU (Fig. 2b). It is important to stress that gastric acid secretion is not influenced by any dose of PDGF.

As with bFGF, ELISA and western blot studies investigated the changes of PDGF concentration in duodenal mucosa during DU development in a rat model.[33] The duodenal mucosal PDGF-AB concentration is elevated at 12 h and reaches its peak at 24 h after cysteamine administration. It decreases to the control value at 48 h after the first dose of cysteamine and decreases further during the healing phase of experimental DU. A high degree of organ specificity for the changes in PDGF-AB in the proximal duodenum is implied by the failure to detect any alteration of PDGF level in the gastric mucosa, despite the intragastric administration of cysteamine.[33] Western blot studies confirm the presence of duodenal mucosal PDGF during the natural history of experimental DU.

As a follow-up to our studies, the effects of bFGF and PDGF were investigated on the migration and proliferation of cultured rabbit gastric epithelial cells. Although any dose of bFGF has virtually no effect on the epithelial cells, PDGF significantly increases the migration of cultured epithelial cells in a dose-dependent manner. The action of PDGF-BB was investigated in addition to the confluent rabbit gastric epithelial cells after wounding.[35] PDGF-BB dose dependently accelerates the migration and proliferation of cultured cells.

Therefore, PDGF-BB may have a role in gastric epithelial cell restoration during the healing of GU.

PDGF Treatment in Experimental UC

We also tested the effects of PDGF-BB on the healing of UC induced by iodoacetamide in rats. PDGF-BB treatment significantly decreases the severity of colitis and extent of adhesions after 5 days of treatment. All parameters, that is, the colonic lesions, severity of colitis, extent of adhesions, and colon wet weight significantly improved 10 days after the treatment (Fig. 2c). Histologically, the ulcer size is smaller, the signs of inflammation are reduced, and in most situations extensive reepithelization is seen. Furthermore, we tested the effects of gene therapy with adenoviral vector (AV) encoding PDGF-BB on the healing of UC. The results showed that treatment with a single dose of AV-PDGF-BB significantly reduces colonic lesions (Fig. 2d). The colonic dilation, colonic thickness, colon wet weight, pericolonic adhesions, and body weight loss are significantly diminished in the group treated with double doses of AV-PDGF-BB. Histology showed advanced reepithelialization of the ulcer after AV-PDGF-BB treatment (Fig. 2e). This is the first demonstration that intracolonic PDGF-BB significantly accelerates the healing of UC in rats.

Different Effects of VEGF on Experimental DU and UC

VEGF is a heparin-binding glycoprotein that occurs in four molecular forms, consisting of 121, 165, 189, and 206 amino acids derived from the same gene by alternative mRNA splicing. In addition to stimulating endothelial cell proliferation, migration, and tube formation (angiogenesis), VEGF, also known as vascular permeability factor (VPF), acts specifically on vascular endothelial cells to increase vascular permeability.[29] Its unique combination of properties largely result from its specific receptors on endothelial cells. VEGF also increases blood flow and apparently prevents endothelial cell apoptosis. Its expression is highly regulated by hypoxia, providing a physiologic feedback mechanism to accommodate insufficient tissue oxygenation by promoting blood vessel formation.[8]

VEGF Treatment in Experimental DU

Because VEGF is the most specific angiogenic peptide, and when this peptide became available for pharmacologic studies in 1997, we again tested the hypothesis that stimulation of angiogenesis alone is sufficient for chronic ulcer healing.[31] The results revealed that treatment with angiogenic factor VEGF significantly reduces the size of DU (Fig. 3a), histologically accompanied by complete healing, prominent angiogenesis, and granulation tissue production. The density of blood vessels is significantly increased in the VEGF-treated rats. Our anti-VEGF study on DU healing showed that inhibition of VEGF by a specific neutralizing antibody significantly delays the healing of DU induced by cysteamine (Fig. 3b).

After we showed that daily intragastric administration of angiogenic growth factors such as bFGF, PDGF, or VEGF accelerates the healing of chronic DU in rats, we hypothesized that a single dose of gene therapy related to these

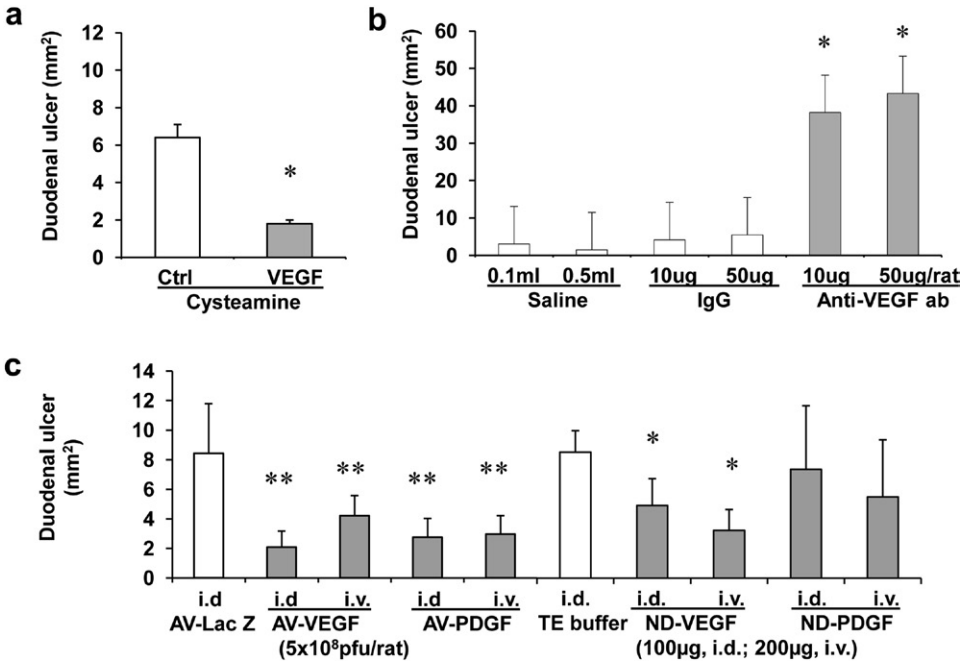

FIGURE 3 Effect of VEGF on DU induced by cysteamine in rats. (a), (b): Healing of DU after recombinant human $VEGF_{165}$ or neutralizing anti-VEGF antibody (anti-VEGF ab). (c): Gene therapy with naked DNA (ND) or adenoviral vector (AV) encoding VEGF in the experimental DU. i.d.: intraduodenal injection; i.v.: intravenous injection; $*p < 0.05$; $**p < 0.01$.

growth factors may be enough to accelerate the healing of DU through enhancement of synthesis of endogenous angiogenic growth factors. Our results showed that a single dose of naked or adenoviral vector DNA of VEGF or PDGF significantly accelerates the healing of DU (Fig. 3c, d). It suggests that gene therapy with either VEGF or PDGF may be a rapid approach to achieve DU healing.[4]

Because VEGF/VPF is highly specific for endothelial cells, we tested the hypothesis that the slightly increased vascular permeability (creating a "histodilutional barrier") might induce gastroprotection. The results showed that pretreatment with the doses (0.04 and 0.2 μg/100 g) of VEGF/VPF significantly reduces the gastric mucosal lesions (Fig. 4a). Histology showed mildly or moderately increased gastric edema in lamina propria or submucosa and only superficial or no gastric erosions in the rats treated with VEGF/VPF (Fig. 4b).

From these results, we concluded that oral treatment of rats with VEGF/VPF accelerates the healing of cysteamine-induced chronic DU and that this healing is accompanied by the stimulation of angiogenesis and granulation tissue production and complete mucosal restoration, VEGF/VPF also provides gastroprotection, which might be related to a histodilutional barrier induced by VEGF/VPF.

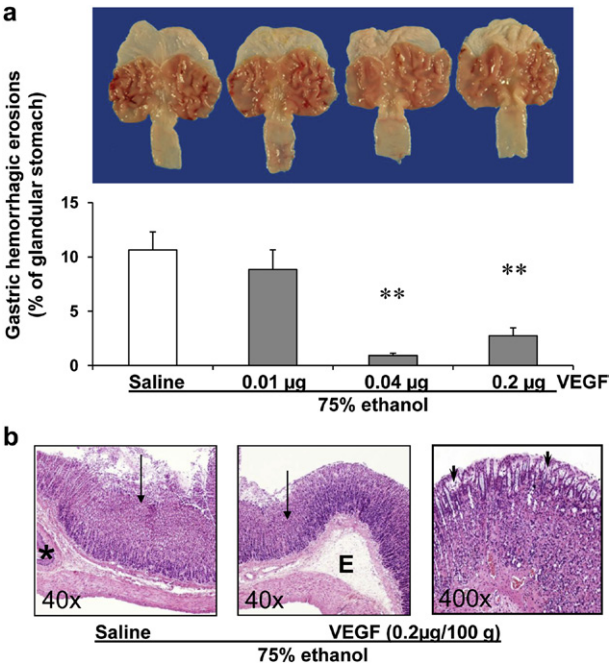

FIGURE 4 Gastroprotection by VEGF in experimental gastric erosions. (a): Gross appearance and quantitative analysis of gastric hemorrhagic erosions induced by 75% ethanol in rats pretreated with recombinant rat $VEGF_{164}$. (b): In control rats, hemorrhagic erosions involve about half of the gastric mucosa (arrow) in the glandular stomach (*). In VEGF-pretreated rats, only mild superficial (arrow) or no mucosal damage is seen, in addition to edema (E) in lamina propria (arrowheads) and submucosa.$**p < 0.01$. See color plate 42.

VEGF Role in Experimental UC

VEGF is a most potent angiogenic factor in the growth factor family. After we showed that therapy with peptide,

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

especially, gene of VEGF produces fast healing of experimental DU,[31,25] we predicted a similar beneficial effect of this angiogenic growth factor in experimental UC. We were not only surprised that we did not get the predicted results, but VEGF slightly aggravated experimental UC. Subsequently, we showed a concurrently increased expression of angiogenic VEGF and antiangiogenic endostatin and angiostatin in experimental UC, creating an "angiogenic imbalance" or inappropriate angiogenic response.[21] Furthermore, we realized that the initial name of this peptide was VPF because it increased vascular permeability that represents the first step in inflammation.[5] Thus, the next logical step was to determine the possible mechanistic role of VEGF in the pathogenesis of UC. In the first experiment, we neutralized VEGF in rats with the specific anti-VEGF antibody. Treatment with anti-VEGF antibody has a beneficial effect on the course of iodoacetamide-induced UC, reducing diarrhea and lethargy scores and the macroscopic and microscopic lesions in the colon.[32] Neutralization of VEGF not only reduces VEGF levels but also counteracts the increased vascular permeability in the early stages of experimental UC and decreased the number of infiltrated inflammatory cells in the pathogenesis of UC. Moreover, we found significantly decreased number of leukocytes in the advanced stages of experimental UC after anti-VEGF therapy.[32] However, the widely used antiangiogenic agent bevacizumab (an anti-VEGF antibody) is associated with an increased risk of gastrointestinal perforation and skin ulcers in patients.[20]

Matsuura et al. [14] found that rectal administration of human recombinant bFGF to normal mice significantly increases the expression of VEGF in colonic tissue, but the expression of VEGF in mice with experimental UC after bFGF treatment is lower than that in the untreated mice with colitis in a dose-dependent manner and directly correlates with a beneficial dose of bFGF. We proposed that the beneficial effect of anti-VEGF therapy in experimental UC results from attenuation of VEGF-induced vascular permeability, resulting in reduced vascular leakage and inflammatory cell infiltration. It has been postulated that VEGF produces an abnormal "pathologic" angiogenesis in UC, which plays a critical role in the pathogenesis of UC.[2,32] Scaldaferri et al. [23] showed that VEGF directly links angiogenesis and inflammation in the pathogenesis of both human and experimental UC. Increasing evidence suggests that VEGF is one of the major pro-angiogenic factors involved in pathologic angiogenesis. Blockade of VEGF, that is, antiangiogenesis, may represent a new therapeutic option for IBD.

In addition to bFGF, PDGF, and VEGF, epidermal growth (EGF) has been used to heal experimental gastric, duodenal, and colonic ulcers in animal models.[10,13,26,27,30] Among these, only EGF has an effect on gastroduodenal secretion, whereas the other peptides stimulate virtually all the cellular elements of ulcer healing.[25] Thus, the most consistent common effect of these growth factors in ulcer healing is the stimulation of cell proliferation, especially angiogenesis. The molar potency of bFGF, PDGF, and VEGF is 2–7 million times higher than that of cimetidine in the healing of cysteamine-induced chronic DU in rats.[25] Because VEGF has no major effects other than stimulation of angiogenesis, it is probably safe to conclude that enhancement of angiogenesis, which is accompanied by granulation tissue production, is the most important cellular event leading to ulcer healing. Apparently, spontaneous proliferation and migration of epithelial cells over dense granulation tissue then complete the healing process.

Differential Expression and Pharmacologic Effects of PlGF on Experimental DU and UC

PlGF is a pleiotropic cytokine that stimulates endothelial cell growth, migration, and survival; chemoattracts angiocompetent macrophages and bone marrow progenitors. PlGF selectively binds to VEGFR-1. Besides indirect effects,[19] PlGF signals directly via VEGFR-1, thus, acting independently of VEGF in endothelial cells, macrophages, bone marrow progenitors, and tumor cells, which primarily express VEGFR-1.[19] Gene inactivation studies have revealed that PlGF deficient mice are viable and healthy, indicating that endogenous PlGF is redundant for vascular development. Genetic studies show that PlGF is redundant for vascular development and physiologic vessel maintenance in healthy adults and maintenance but contributes to the angiogenic and inflammatory switch in various diseases, including tumor growth, ischemia, and chronic inflammation. Many cell types express PlGF in pathologic conditions, including endothelial cells, smooth muscle cells, fibroblasts, leukocytes, and bone marrow progenitors.[6,7] Furthermore, PlGF is readily upregulated in pathologic conditions by various stimuli, such as hypoxia, nitric oxide, inflammatory cytokines (e.g. interleukin 1 and TNF-α), and growth factors (e.g. VEGF-A and transforming growth factor-β). Overall, the expression profiling and genetic findings raise the question of whether PlGF is a specific pathologic angiogenic factor.[6,7] If this is shown to be the case, PlGF could be an attractive drug target, because a PlGF inhibitor would be expected to selectively inhibit pathologic angiogenesis without affecting the growth or maintenance of normal vessels and, unlike VEGF/VEGFR inhibitors, would therefore be likely to cause fewer side effects.

Differential Expression of PlGF in Experimental DU and UC in Rats

Because PlGF has been reported as markers of pathologic angiogenesis, we tested the hypothesis that the expression of PlGF might be different between experimental DU and UC. Western blotting showed that the expression of PlGF

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

is markedly decreased on the 3rd and 7th days after cysteamine administration but highly increased on the 3rd and 7th days after iodoacetamide administration in rats. This is the first demonstration that PlGF is clearly expressed in the intestines of rats, and the differential expression of PlGF in DU and UC may indicate two distinct angiogenic processes, for example, normal and pathologic angiogenesis occurring during the development and healing of DU and UC, respectively (unpublished results).

Differential Effect of PlGF Inhibition on DU and UC Rats

To determine the pharmacologic role of PlGF in DU and UC, we tested the effect of neutralizing anti-PlGF antibody on cysteamine-induced DU and iodoacetamide-induced UC in rats. The results showed that inhibition of PlGF significantly reduced colonic lesions from 249.1 ± 77.1 (control) to 110.1 ± 73.7 mm^2 ($p < 0.05$), whereas the sizes of DU were not significantly different between controls and anti-PlGF antibody-treated rats. This may further indicate that different angiogenesis are involved in these two GI ulcers. Thus, upregulated PlGF may indicate novel mechanisms of pathologic angiogenesis in UC (unpublished results).

Different Pharmacologic Effects of Rac1 on Experimental DU and UC

Rac1 is a key member of the Rho GTPase family involved in the regulation of cell migration, proliferation, survival, and cell–cell junctions by virtue of its ability to regulate the actin-based cytoskeleton and nuclear gene expression. The activation of Rac1 is mediated by guanine nucleotide exchange factors in response to cytokine stimulation. Rac1 is essential for embryonic angiogenesis and selective deletion of the Rac1 gene in endothelial cells caused defective neovascularization, which was incompatible with life. Endothelial cell culture studies show essential roles for Rac1 in stretch-provoked proliferation, directed migration toward the gradient of thrombin, sphingosine 1-phosphate, VEGF, and Ephrin-A1 and tube formation in a three-dimensional in-gel environment.[34] The genetic deletion of Rac1 causes reduced endothelial cell migration, tube formation, adhesion, and increased vascular permeability. Rac1 has been also suggested to regulate the functions of endothelial progenitor cells, which crucially contribute to neovascularization. Rac1 is also essential for epithelial stem cell function during dermal and oral mucosal wound healing in mice and active Rac1 improves pathologic VEGF neovessel architecture and reduces vascular leak,[34] whereas expression of a dominant inhibitory mutant of Rac1 delays epidermal wound healing. In these studies, excisional wound healing of the skin is also delayed by conditional deletion of the Rac1 gene. The development of the Rac1 specific inhibitor (NSC23766) and agonist (SEW2871) will support the investigation of the roles of Rac1. The technical advance made with these new tools to specifically stimulate or inhibit Rac1 function *in vivo* provides an opportunity for us to reveal the roles of Rac1 in upper and lower GI ulcer diseases such as DU and UC.

Accelerated DU Healing but Impaired UC Healing by Inhibition of Rac1 in Rats

Because Rac1 has been shown to play an important role in epidermal wound healing,[34] we tested the hypothesis whether inhibition of rac1 would affect healing of experimental DU and/or UC. The results show that treatment with a selective inhibitor of Rac1 (NSC23766) accelerates DU healing but delays UC healing. Quantitative data showed that DU craters are significantly reduced from 15.4 ± 3.2 (controls) to 8.7 ± 1.1 mm^2 and UC lesions are increased from 68.3 ± 9.4 (controls) to 102.6 ± 11.7 mm^2. We thus conclude that, in contrast to VEGF, Rac1 seems to play a beneficial role in UC healing but a harmful role in DU healing, indicating that Rac1 may reverse VEGF actions in these two ulcer models (unpublished results).

SUMMARY

Increasing evidence indicates that angiogenesis is a novel and crucial element in the pathogenesis of DU and UC. In this review, we mostly summarized our recent results on ulcer healing with either peptides or genes of angiogenic growth factors, such as bFGF, PDGF, and VEGF without affecting HCl and pepsin secretion. Studies performed in animal models and in humans also show a key role of these endogenous angiogenic peptides in ulcer healing. The molar potency of angiogenic growth factors is 2–7 million times better than the antiulcerogenic effect of antisecretory H2 antagonists. Because histologically gastroduodenal ulcers look similar to the ulcers in the lower GI tract, we also predict that the healing of experimental UC might be also improved by these angiogenic growth factors. Rectal enemas containing bFGF or PDGF indeed accelerate the healing of chemically induced UC in rats. However, the results from our study and those of other studies show opposite effects of angiogenic or antiangiogenic therapies targeting VEGF on the healing of experimental UC. Thus, VEGF induces a "normal" angiogenesis, which accelerates DU healing but a pathologic "abnormal" angiogenesis, which impairs UC healing. It is also important to recognize the inducers and modulators of pathologic angiogenesis because anti-VEGF may also affect angiogenesis needed in normal tissue and organ regeneration. PlGF may be a marker of pathologic angiogenesis and may play critical roles in abnormal angiogenesis, for example, inhibition of PlGF does not affect quiescent vessels in healthy organs.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

In addition, activation of Rac1, a small GTPase, markedly improves VEGF-induced neovessel architecture defect and reduces vascular permeability in an established angiogenic model. Because anti-VEGF therapy causes gastric perforation and skin ulcers in patients, and pathologic angiogenesis is associated with architecturally defective and leaky blood vessels, PlGF and Rac1 may be selected as attractive therapeutic targets for the development of safe antiangiogenic drug. We thus conclude that stimulation of angiogenesis and cell proliferation is the most consistent mechanism of both upper and lower GI ulcers healing by growth factors such as bFGF and PDGF either with peptides or gene transfer. Although VEGF plays a critical role in pathogenesis of lower GI ulcer, for example, UC, enhancement of angiogenesis and granulation tissue production of VEGF is apparently beneficial for the healing of upper GI ulcers. Selective inhibition of pathologic angiogenesis targeting specific markers, for example, PlGF and Rac1 should be considered for GI ulcer healing. Hence, growth factors are potent, endogenously derived agents, which are directly associated with GI ulcer healing in which angiogenesis seems to be the most important process.

Chapter 160

Apelin

Song Han, George H. Greeley Jr. and Ella W. Englander

ABSTRACT

Apelin, the endogenous ligand for the APJ receptor was discovered about a decade ago. The aim of this chapter is give an overview of the physiology and pharmacology of apelin in the gastrointestinal tract and pancreas. Signaling cascades activated by apelin and its pathophysiology involvement are also discussed.

DISCOVERY

Apelin is the endogenous ligand for the APJ receptor, a receptor related structurally to the type 1 angiotensin receptor and a member of the seven transmembrane-domain G protein-coupled receptors (GPCRs).[5,30] Since the APJ receptor was characterized before apelin, apelin was identified by means of a "reverse pharmacology" approach in extracts of the cow stomach.[30] APJ is currently the only apelin receptor identified.

STRUCTURE OF THE APELIN mRNA/GENE, PRECURSOR PROCESSING

The apelin cDNA encodes a 77-amino-acid peptide, preproapelin, which is processed to apelin-36 and several smaller variants including apelin-17, -16, -13 and other forms. The human apelin gene is located on chromosome Xq25-26.1. Apelin-36 is most probably the parent peptide.[18,30] With the exception of a single amino acid, the C-terminal apelin-13 sequence [(Q/P) RPRLSHKGPMPF] is fully conserved in all species cloned to date implying that this segment is essential for activation of APJ. Comparison of amino acid sequences across species shows that goldfish preproapelin has a 97% homology with zebrafish preproapelin, a 43% homology with *Xenopus* preproapelin and an about 35% homology with mammalian preproapelins. The promoter regions of rat and human apelin gene have been cloned.[34] Upstream stimulatory factor (USF)-1/-2, a ubiquitous transcription factor that regulates numerous genes involved in metabolism exerts a stimulatory role over breast apelin expression during pregnancy and lactation in the rat.

APELIN DISTRIBUTION

Like many of the peptides expressed in the gastrointestinal tract (GI) tract and pancreas, apelin has a wide distribution in the body. Apelin is synthesized in the brain, heart, lung, kidney, liver, mammary gland, pituitary, white adipose tissue, skeletal muscle, GI tract, and pancreas.[5,7,15,18,23,24,30,32,34] APJ also has a wide distribution in the body. In the GI tract of the adult rat, apelin expression levels (mRNA) are maximal in the stomach and ileum with lower expression levels in the duodenum, jejunum and colon (Fig. 1). Although apelin expression levels are high in the fetal and postnatal rat stomach,[32,33] apelin peptide synthesis is apparently not activated until weaning since apelin immunopositive cells are not detected until weaning. In the adult rat stomach, apelin immunoreactivity is identified in mucous neck, parietal and chief cells (Fig. 2).[17,28] Apelin is also detected in gastric cells immunopositive for chromogranin A (CGA), a marker of enteroendocrine cells.

The ontogeny of enteric apelin and APJ expression have been studied in detail mainly in the mouse and rat.[33] In the mouse stomach, apelin expression levels are maximal at postnatal day 4 (P4), then decreases at the P16 and adult stages (Fig. 3). Apelin expression levels are significantly lower at embryonic day 18.5 (E18.5) when compared with levels at P4. In the duodenum, apelin expression levels are highest at the E18.5 and P4 stages, and then decrease at the P16 and adult stages. In the colon, apelin expression levels are maximal at the E18.5, P4, and P16 stages and much lower in the adult. In the mouse, overall apelin expression levels are of similar magnitudes in the stomach, duodenum, and colon. With regard to ontogeny of APJ expression in mice, expression levels are maximal at the E18.5 stage in the duodenum and colon (Fig. 3). In the mouse stomach, maximal APJ expression is at the E18.5 and P4 stages. Stomach, duodenal and colon APJ expression levels then decrease postnatally and into adulthood.

In the rat, breast apelin expression increases dramatically during pregnancy and lactation, and large amounts of

apelin occur in milk.[7,32,34] Milk-borne apelin is mentioned since it may have a tropic role via the luminal route on gut development and growth. APJ is expressed in the neonatal rodent GI tract[33] and apelin stimulates gastric and intestinal epithelial cell proliferation.[10,32]

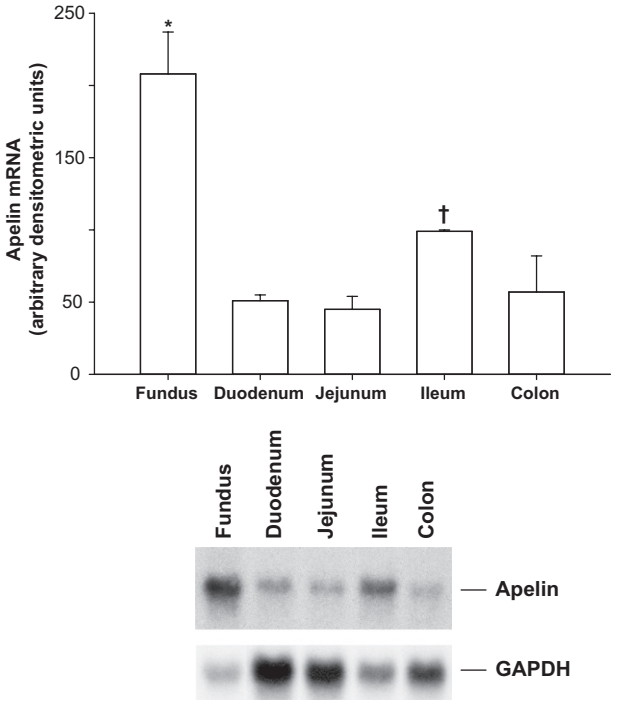

FIGURE 1 Apelin expression in the adult rat gastrointestinal tract. Mean apelin mRNA levels ± SEM of three rats is shown (top panel). Northern hybridization shows apelin mRNA levels in the rat GI tract (bottom panel). Apelin mRNA levels are not shown as a ratio. *, $P < 0.05$ vs. small and large intestine; †, $P < 0.05$ vs. duodenum, jejunum, and colon. (With permission from Wang G, Younes A, Wei W, et al. Apelin, a new enteric peptide: localization in the gastrointestinal tract, ontogeny, and stimulation of gastric cell proliferation and of cholecystokinin secretion. Endocrinology 145:1342–1348, 2004.)

SIGNALING CASCADES

Most of the studies that investigate intracellular signaling cascades activated by apelin use cell lines stably transfected with the APJ receptor, primarily Chinese hamster ovary (CHO) cells. In this experimental model, apelin inhibits forskolin-induced cAMP production.[21] Apelin also causes a sharp elevation in intracellular Ca^{++} levels in human NT2.N neurons.[20] In CHO cells, apelin induces phosphorylation of p70S6 kinase via two transduction cascades, a phosphatidylinositol 3-kinase (PI3 K)/Akt-dependent and an extracellular-regulated kinase (ERK)-dependent pathway.[20] Apelin also activates ERK via a pertussis toxin (PTX)-sensitive G protein in CHO cells. In mouse osteoblastic (MC3T3-E1) cells transfected with APJ, apelin signals by activating JNK and PI3 K/Akt pathways.[29] Apelin is also thought to signal via a nitric oxide (NO)-dependent mechanism to regulate blood pressure.[31] In mice, apelin-activated glucose uptake in skeletal muscle and adipose tissue involves endothelial NO synthase AMP-activated protein kinase and Akt.[3] Apelin's effects on glucose uptake and Akt phosphorylation are mediated partly by Gi and AMPK-dependent pathways.[35]

GI AND PANCREATIC ACTIONS OF APELIN

Apelin has been shown to influence GI secretion, motility, and cell proliferation. In the stomach, apelin secreted by parietal cells exerts a negative feedback action on ECL cells which lowers acid secretion.[17] In mice, central administration of apelin inhibits GI motility.[19] Apelin also stimulates duodenal electrolyte secretion which is apparently mediated by intestinal cholecystokinin (CCK) secretion.[6] Apelin injected intravenously reduced pancreatic juice volume, protein and trypsin outputs in a dose-dependent manner.[14] Apelin given directly into the intestinal lumen increases pancreatic protein and trypsin secretion through a vagal

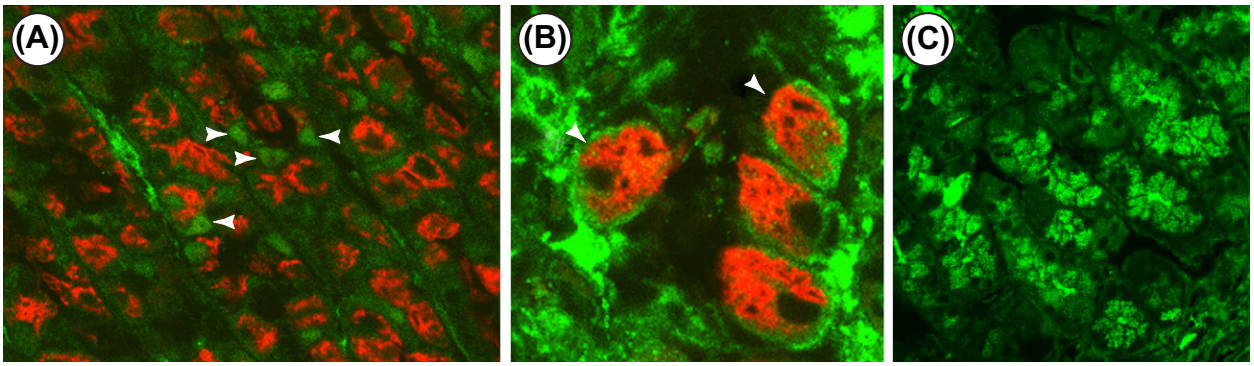

FIGURE 2 Immunofluorescence detection of apelin containing cells in rat stomach. **Panel A**. In the isthmus–neck region of the rat gastric mucosa, mucous neck cells produce apelin (green fluorescence, arrowheads) whereas parietal cells do not produce apelin. Parietal cells are identified by immunostaining for the H^+/K^+ATPase/proton pump (red fluorescence). **Panel B**. In the upper portion of the gastric mucosa parietal cells stain for apelin (arrowheads). Notice that apelin staining (green fluorescence) is stronger at the cell periphery suggesting that cellular localization of the proton pump differs from that of apelin. **Panel C**. Immunofluorescence detection of apelin-containing cells in the base region of the stomach mucosa (green fluorescence). Notice the granular nature of the apelin staining. mechanism. Additionally, apelin-13 can stimulate proliferation of human gastric (SIIA) epithelial cells.[32] Apelin-36 is less potent than apelin-13. Together, these findings indicate that apelin affects a wide array of GI functions.

Apelin and APJ have been localized in pancreatic beta cells of several mammalian species.[25,26] Apelin expression is also detected in human and mouse alpha cells and in a subpopulation of pancreatic polypeptide (PP) cells in human islets. Interestingly, apelin has been shown to inhibit as well as to enhance insulin secretion.[13,25,26] *In vitro*, a high dose (10^{-6} M) of apelin-36 enhances glucose-stimulated insulin secretion by 30% and lower apelin doses (10–100 nM) potently inhibit insulin secretion (50%).[25] In mice, iv administration of apelin-36 (2 nmol/kg) inhibits iv-glucose-induced insulin secretion by 35%.[26] Apelin-36 (10^{-9} M) inhibits glucose-induced insulin secretion from mouse islets. Centrally administered apelin causes hyperinsulinemia, hyperglycemia, glucose intolerance, and insulin-resistance.[4] These findings suggest that CNS apelin has a role in the regulation of glucose and insulin homeostasis.

Apelin exerts a potent glucose-lowering effect that is associated with increased glucose use in skeletal muscle and adipose tissue in mice.[3] Apelin signaling involves endothelial NO synthase, AMP-activated protein kinase, and Akt apelin-provoked glucose uptake. In whole body apelin gene knockout mice (APKO), chronic apelin deficiency results in reduced insulin sensitivity, hyperinsulinemia, and lower circulating adiponectin levels.[35] Soleus muscle lysates have a diminished insulin-induced Akt phosphorylation. *In vivo*, apelin replacement restores insulin sensitivity. In terms of a mechanism underlying the impaired insulin sensitivity in APKO mice, apelin increases glucose uptake and Akt phosphorylation in isolated C2C12 myotubes. Apelin's actions are blocked by pertussis toxin, compound C, and siRNA knockdown of AMPKα1, reduced by phosphoinositide 3-kinases inhibitor, LY-294002, and unaffected by NO synthase inhibitor, L-NAME treatment. Apelin's effects on glucose uptake and Akt phosphorylation are mediated partly by a Gi and AMPK-dependent pathways. In adipocytes, apelin signaling may be mediated by pathways involving Gq, Gi, and AMP-activated protein kinase.[35]

PATHOPHYSIOLOGICAL IMPLICATIONS

Effects of Intestinal Inflammation on Apelin Production

In rodents, induction of experimental colitis with either dextran sodium sulfate (DSS) or trinitrobenzenesulphonic acid (TNBS) results in increased colonic apelin mRNA and peptide levels (Fig. 4).[10] In the DSS model, intestinal elevations in apelin production occur during the inflammatory and repair phases. Increased apelin immunostaining occurs at the surface epithelium, in epithelial cells along the length of the tubular glands of the colon, and in the stem cell region at the gland base. Apelin administration during the recovery phase of DSS-induced colitis increases colonic epithelial cell proliferation, implying that the increased production of endogenous apelin during the recovery stage has a role in epithelial repair. Increased colonic apelin immunostaining is observed in human subjects with ulcerative colitis (UC) and Crohn's disease.[10]

Numerous studies have shown that cellular hypoxia occurs during intestinal inflammation in patients with inflammatory bowel disease (IBD) and in laboratory animals with experimental colitis.[11] Since cellular hypoxia activates production of a hypoxia sensitive transcription factor, hypoxia-inducible factor-1 (HIF-1), the influence of hypoxia on activation of apelin expression has been examined.[9] Exposure of rat pups to acute respiratory hypoxia

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

increases hepatic, stomach-duodenal, and colonic apelin mRNA levels 10-, 2-, and 2-fold, respectively. Furthermore, hypoxia increases colonic APJ mRNA levels. *In vitro* studies confirm the *in vivo* findings and show that exposure of cultured cells to hypoxia elevates apelin and APJ mRNA levels. The hypoxia-induced elevation in apelin expression is mediated by HIF, since HIF-activated apelin transcriptional activity is dependent on an intact, putative HIF binding site in the rat apelin promoter (Fig. 5). Site-directed mutagenesis of putative HIF binding sites abrogates HIF-1 induced apelin promoter activity.

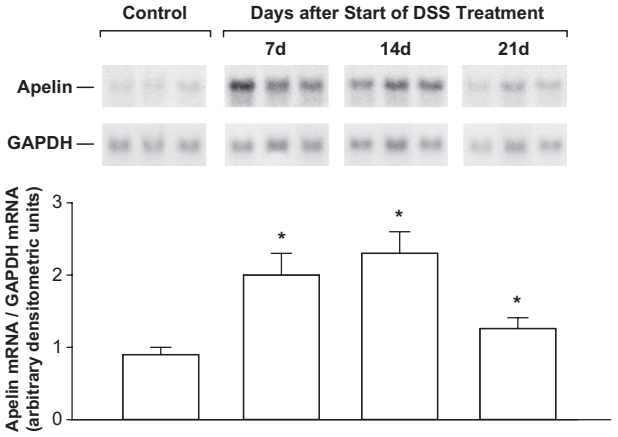

FIGURE 4 Northern analysis of colonic apelin expression in rats with DSS-induced colitis. DSS was given in drinking water ad lib for 5 days and replaced with tap water at the end of day 5. Colonic apelin mRNA levels were measured using poly(A)$^+$ RNA extracts of colon tissue harvested at different times after induction of colitis. Apelin expression was normalized to colon GAPDH mRNA levels. The mean ± SEM of three rats is shown. $^*P < 0.05$ vs. controls. (With permission from Han S, Wang G, Qiu S, et al. Increased colonic apelin production in rodents with experimental colitis and in humans with IBD. Regul Pept 142:131–137, 2007.)

The Jak/Stat signaling pathway is involved in the stimulatory influence of elevated proinflammatory cytokines on apelin promoter activity and expression lebels.[8] *In vivo* and *in vitro* experiments used lipopolysaccharide (LPS) — activated proinflammatory cytokine production and proinflammatory cytokine-treated [interleukin-6, (IL-6) and interferon (IFN)-γ] rodents or enteric cells to activate apelin expression. Pharmacological blockade of Jak/Stat signaling or IL-6 antibody administration inhibits elevations in enteric apelin expression. Furthermore, transient transfection experiments showed that LPS, IL-6 or IFN-γ increase apelin expression by stimulating apelin promoter activity. Blockade of Jak/Stat signaling suppresses IL-6- and IFN-γ-induced apelin promoter activity and elevations in enteric apelin expression in cultured ileal cells exposed to media harvested from LPS-treated macrophages. More importantly, transient transfection experiments in macrophages showed that the LPS-induced elevation in apelin promoter activity is abolished by mutation of a putative Stat3 binding site in the rat apelin core promoter (Fig. 6). Chromatin immunoprecipitation (ChIP) assays showed that phospho-Stat3 is recruited to the apelin promoter. Together, these results indicate that binding of phospho-Stat3 to the apelin promoter is the final step behind proinflammatory cytokine-induced enteric apelin up-regulation during intestinal inflammation.

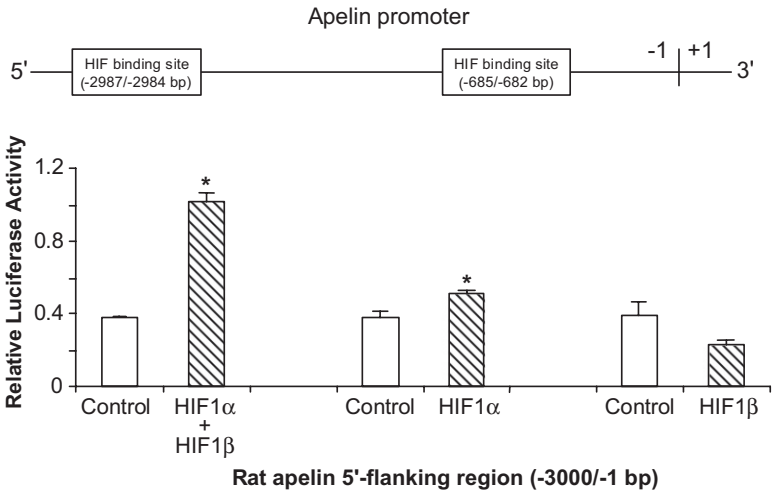

FIGURE 5 Overexpression of HIF-1α- and HIF-1β-stimulated apelin promoter activity. Top: schematic showing that sequence analysis identified 2 putative HIF binding sites in the rat apelin 5′-upstream region (–2987/–2984 and –685/–682 bp). Bottom: transient transfection experiments using an apelin promoter-luciferase reporter construct (–3000/–1 bp) in liver (HepG2) cells showed that overexpression of HIF-1α plus HIF-1β increased apelin promoter activity significantly. Transfection of HIF-1α alone increased promoter activity marginally, whereas transfection with HIF-1β was ineffective. Liver (HepG2) cells were transfected with either an empty expression vector (control) or a HIF expression plasmid. $^*P < 0.05$ vs. control. (With permission from Han S, Wang G, Qi X, et al. A possible role for hypoxia-induced apelin expression in enteric cell proliferation. Am J Physiol Regul Integr Comp Physiol. 294:R1832–R1839, 2008.)

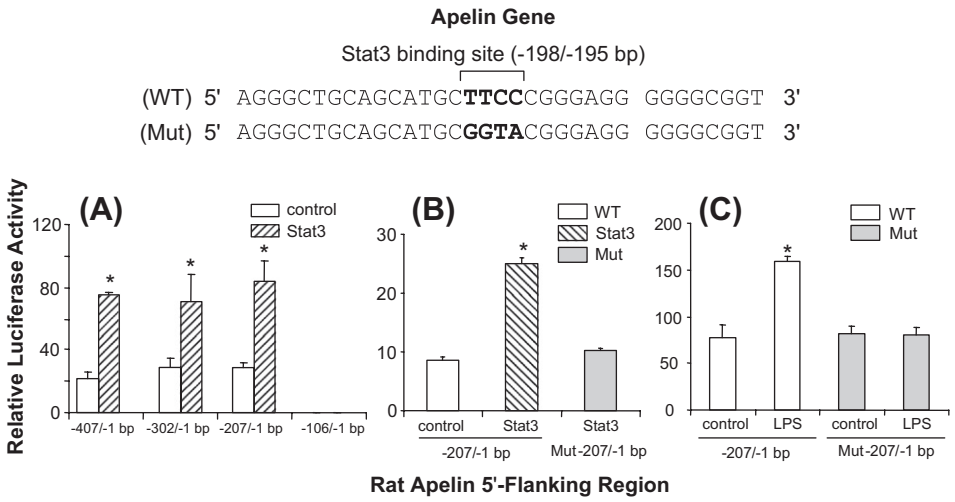

FIGURE 6 A putative Stat3 binding site regulates apelin promoter activity. Top schematic: a putative Stat3 binding site is identified in the wild-type (WT) apelin promoter sequence of the rat (–198/–195 bp); mutated nucleotides are indicated in bold in the mutated (Mut) sequence. Only partial sequences of WT and Mut promoters are shown. A: transient transfection experiments show that Stat3 overexpression increases apelin promoter activity in apelin promoter deletion-luciferase reporter constructs (–407/–1, –302/–1, –207/–1 bp). Promoter activity of the –106/–1 bp apelin promoter reporter construct was not influenced by Stat3 overexpression. B: mutation of a putative Stat3 binding site (–198/–195 bp) in the rat apelin core promoter abolished the elevation in apelin promoter activity induced by Stat3 overexpression. C: mutation of the putative Stat3 binding site inhibited the elevation in apelin promoter activity induced by LPS treatment. $*P < 0.05$ vs. control levels. (With permission from Han S, Wang G, Qi X, et al. Involvement of a Stat3 binding site in inflammation-induced enteric apelin expression. Am J Physiol Gastrointest Liver Physiol 295:G1068–G1078, 2008.)

Apelin and Metabolic Disorders

There is much interest in the physiological role of apelin in obesity and diabetes. Apelin is expressed in adipocytes.[1] Apelin is thought to be secreted by adipose tissue into the systemic circulation and therefore is considered an adipokine. Several human studies show that plasma apelin levels are increased and correlate with body mass index in obese subjects.[1,12] Further reports argue that obesity itself does not increase apelin production but instead speculate that insulin regulates apelin gene expression in adipocytes.[1,26] This idea is based on the finding of large elevations in both adipose tissue apelin expression and plasma apelin plasma levels in mice with hyperinsulinemia-associated obesity. A reduced apelin expression in adipocytes of insulin deficient mice having streptozotocin-induced diabetes was also shown. Additionally, as with pancreatic insulin content, apelin expression in adipose tissue is reduced by fasting and restored by refeeding. Insulin-stimulated apelin expression in fat tissue is associated with stimulation of phosphatidylinositol 3-kinase, protein kinase C and MAPK. Together, these results show that insulin exerts a direct control over apelin gene expression in adipocytes. Treatment of either mice or adipocytes in culture with tumor necrosis factor (TNF)-α, a secretory product of adipose tissue, stimulates apelin expression.[2] The systemic elevation in TNF-α levels may drive the increased blood apelin levels during obesity. Growth hormone (GH) has also been shown to stimulate apelin expression and secretion in mouse 3T3-L1 adipocytes.[15] The stimulatory action of GH is mediated partly by janus kinase 2 and phosphatidylinositol 3-kinase. Lastly, although numerous reports describe obesity-associated changes in circulating apelin levels, a recent paper showed numerous hurdles in measuring authentic apelin in the general circulation.[22]

Chapter 161

Bombesin-Related Peptides

Robert T. Jensen and Terry W. Moody

ABSTRACT

Bombesin is an amidated tetradecapeptide originally isolated from frog skin that is the prototype of a large number of related peptides, many of which only occur in invertebrates. The mammalian homologs are gastrin-releasing peptide (GRP) and neuromedin B(NMB). Each of these interacts with a distinct G protein-coupled receptor, the GRP-R(BB2) and NMB-R(BB1), respectively. Furthermore, an orphan receptor, with close structural homology to GRP-R an NMB-R has been discovered, bombesin receptor subtype-3(BRS-3)(BB3), whose natural ligand is unknown but is included in the Bn receptor class. Both mammalian Bn peptides (GRP, NMB) as well as their receptors and BRS-3 are widely distributed, but they have been particularly well studied in the gastrointestinal tract and in the CNS. Both the peptides act primarily as neurotransmitter/modulators but have other widespread actions in many tissues, with their CNS effects and their effects on growth of normal and neoplastic tissue receiving the most attention. In this chapter, primarily the mammalian Bn peptides and their receptors will be discussed.

DISCOVERY (BN PEPTIDES AND THEIR RECEPTORS)

The 14-amino acid peptide Bn was isolated from the skin of the European frog *Bombina bombina*,[4] and subsequently a family of related peptides was isolated from other frog skins and named after the genus of the frog from which they were isolated.[13] In general, they could be divided into three families: the Bn group with a carboxyl terminus of Gly-His-Leu-Met-NH_2; the ranatensin–litorin family with a carboxyl terminus of Gly-His-Phe-Met-NH_2, and the phyllolitorin family with a carboxyl terminus of Gly-Ser-Phe/Leu-Met-NH_2.[13] Subsequently, two mammalian members of the Bn-family were isolated: GRP, a 27-amino acid peptide isolated from porcine stomach, which shares seven carboxyl-terminal amino acids with Bn[13] and neuromedin B, from porcine spinal cord[13] a decapeptide sharing seven of its carboxyl amino acids with ranatensin. Studies of GRP and NMB immunoreactivity and mRNA studies demonstrate that these peptides and their mRNAs are widely distributed in mammals in both peripheral tissues, particularly the gastrointestinal tract and in the CNS.[13] In 1990, a mammalian G protein-coupled receptor was described, which interacted with high affinity with GRP (the GRP-R, BB_2) and in 1991 a G protein-coupled receptor with high affinity for NMB was described (NMB-R, BB_1).[13] In 1992/1993, a closely related orphan receptor, BRS-3 (bombesin receptor subtype-3) was described which had 47–51% amino acid identities with the human GRP-R/NMB-R and is thus included in the mammalian Bn-R family, although the native ligand is still unknown.[13] The GRP-R and NMB-R are widely distributed in the CNS and peripheral tissues, whereas the BRS-3 distribution has been less extensively investigated although it appears in many tissues also and particularly in the CNS and gastrointestinal tract.[13,25,27,31] In nonmammalians, other Bn-Rs have been isolated including a bombesin receptor subtype 4(BB4) and a unique Bn-R from chickens termed chBRS-3.5, which at present have no mammalian equivalents.[13]

STRUCTURE OF THE mRNA/GENE

The gene for GRP is located on chromosome 18 and for NMB on human chromosome 15-q11 pter region.[25] The GRP gene has two introns and three exons.[13] Two major transcription start sites for the human GRP-R have been described at location 43 and 36 bp downstream of a TTTAAA motif, which is identified as 407 to 402 bp upstream of the ATG start codon.[13] Similar to the GRP gene, NMB is encoded in the NMB gene in three exons.[25] In humans, NMB is encoded in preproNMB, a 76-amino acid precursor that contains a 24-amino acid signal peptide, NMB-32 and a 17-amino acid carboxyl-terminal extended peptide.[25] The human GRP-R is localized to Xp22 and consists of three exons spanning >27 kb.[13] The human NMB-R is localized to a chromosome 6p21-pter, whereas in the mouse, it is localized to chromosome 10[13] and spans >10 kb. The human BRS-3 receptor is localized to chromosome Xq25 and in the mouse on chromosome XA7.1-7.2.[13]

PROCESSING OF THE PRECURSOR

Alternative splicing with the GRP gene from a single mRNA produces three isoforms of ProGRP.[13] These three isoforms encode for three peptides of 148, 141, and 138 amino acids, which are identical in the first 122 amino acids. PreproGRP is a 148 prepropeptide, which after removal of the 23-amino acid signal peptide, becomes $ProGRP_{1–125}$ and is subsequently processed to $proGRP_{31–125}$ by a Lys–Lys cleavage at positions 29–30. A carboxypeptidase removes the COOH terminus to produce $GRP_{1–127gly}$ that is subsequently amidated resulting in $GRP_{1–27amide}$, which is finally cleaved at arginine 17 to yield $GRP_{18–27amide}$.[13] In humans, NMB is encoded in preproNMB, a 76-amino acid precursor, which contains a 24-amino acid signal peptide, NMB-32 and a 17-amino acid carboxyl-terminal extended peptide, which is preceded by a Lys–Lys cleavage site.[25] The NMB-32 is subsequently cleaved to yield the decapeptide, NMB. The human preproNMB is similar to that of the rat except that it is 117 amino acids because it contains a 52-amino acid extension peptide rather than the 17 amino acids found in humans.[25]

The three exons of the human GRP-R encode for different parts of the 384-amino acid GRP-R.[13] The first exon encodes for the first three-membrane spanning domains of the GRP-R, and the second exon encodes for transmembrane regions 4 and 5 and most of the third intracellular loop, whereas exon 3 encodes for transmembrane region 5 and the cytoplasmic carboxyl terminus.[13] The three exons of the human NMB-R gene also encode for different parts of the 390-amino acid human NMB-R.[13] The first exon encodes for the amino acids up to a region between the NMB-R transmembrane regions 3 and 4, and the second for a region between transmembrane regions 5 and 6, and exon 3 for the remainder of the NMB-R.[13] Similar to the genes for GRP-R and NMB-R, the gene for the 399-amino acid human BRS-3 receptor has three exons and two introns and spans >5 kB.[13] In human, rat, and mouse, the exon/intron splice sites occurred at Arg^{145} in the second intracellular loop and at Ile^{264} in the third intracellular domain.[13]

DISTRIBUTION OF THE RNA/PEPTIDE

Studies of the distribution of GRP and NMB, as well as their receptor's immunoreactivity (IR) or mRNA studies show that these peptides, their receptors and their mRNAs are widely distributed in both the CNS and peripheral systems, occurring in almost all tissues.[13] The distribution in the gastrointestinal tract will be concentrated on here. In the alimentary tract, GRP-like IR occurs primarily in neurons in the submucosal and/or myenteric plexuses and not in endocrine cells.[13] The highest levels of Bn IR (primarily GRP-10, GRP-27) vary between human and different species,[13] In humans, the amount does not vary between the different areas of the gut, whereas in the rat, the highest amounts are found in the colon followed by the gastric antrum, duodenum, and midileum.[13] A study[20] using PCR of human biopsies from different locations found GRP mRNA in all locations (esophagus, duodenum, ileum, colon, rectum, stomach, pancreas) except for the gallbladder. Northern blot analysis showed the highest amounts of NMB mRNA in the stomach and colon, although it is also detected in the pancreas.[13] In the rat and guinea pig, NMB-IR is found throughout the gastrointestinal tract and in the pancreas.[23] The highest concentrations are found in the esophagus and rectum and immunocytochemistry localized the NMB-IR to nerve fibers in the gastrointestinal tract.[23]

GRP-R-mRNA expression levels are reported in human, mouse, and monkey.[13,31] In the monkey, in which it was studied in detail, the highest levels appear in the pancreas with the next highest (7-fold lower) in the stomach followed by the intestine.[31] A detailed study[7] of GRP-R mRNA distribution in human biopsy species taken from epithelial cells in different locations shows that GRP-R expression is limited to the gastric antrum and not the small intestine or proximal or distal colon. In other studies, GRP-Rs have been described in pancreatic acinar cells, gastric antral G cells, other gastric mucosal cells (D cell, mucus cell, parietal cell), and in epithelial cells lining the normal antrum.[13] NMB-R-mRNA/IR/binding site levels have been reported in human GI tissues as well as in mouse, rat, and monkey.[13,31] In the monkey, the NMB-R-mRNA levels are the highest in the stomach compared with that in the small intestine and pancreas, but much lower than the levels found in the testis or areas of the CNS.[31] In different reports, NMB-R-mRNA/IR/binding sites are distributed in esophageal tissue, stomach, urogenital, and gastrointestinal smooth muscle, human, and rodent adipose tissue and normal colonic mucosal cells.[13] BRS-3 expression has been less well investigated than that of GRP-Rs or NMB-R, but levels in various tissues have been reported in rat, sheep, monkey, human, and guinea pig.[13] In the GI tract, the highest levels in monkeys for BRS-3 mRNA are in the pancreas followed by the stomach and small intestine, and in each of these tissues, it is 4–5 fold lower than in the testis or various CNS regions.[31] BRS-3 IR in the gastrointestinal tract is seen in the tunica muscularis of all regions studied, including the antrum, duodenum, ileum, and colon in nerves and nonneuronal cells but not in muscle cells.[27] It was expressed in both myenteric and submucosal ganglia as well as in nerve fibers and in the cell bodies and process of the c-kit containing interstitial cells of Cayal, lending anatomical support for a potential important role in GI pacemaker function.[27] Animals with targeted knockout of the BRS-3 develop mild obesity, hypertension, impaired glucose metabolism associated with a reduced metabolic rate, as well as increased feeding behavior suggesting

BRS-3 is important in glucose homeostasis and metabolism.[13,26] BRS-3 receptors are present on pancreatic islets and are involved in glucose regulation.[13] Detailed studies of BRS-3 distribution in all endocrine tissues or adipose tissues that might regulate glucose metabolism have not been done.

GRP-R, NMB-R, and BRS-3 are one of the groups of G protein-coupled receptors that are most frequently ectopically/overexpressed by many common tumors including those of the gastrointestinal tract (colon, pancreatic acinar cells, gastric) as well as other common tumors (breast, prostate, lung, CNS tumors).[13,14,29] In many cases, GRP and/or NMB have an autocrine growth effect on these tumors or can affect their growth.[13,14] Because of this, there is increased interest in the Bn family and their receptors as possible targets for novel tumor treatments, tumor imaging or receptor-direct cytoxicity.[14,29] Each of these areas is specifically dealt with in a separate chapter in the Cancer section of this Volume and therefore will be discussed only briefly in this chapter.

RECEPTORS AND THEIR SIGNAL CASCADES

Receptors for Bn-related Peptides

The actions of GRP are mediated by the GRP-R(BB2), which in humans is a 384-amino acid G protein-coupled receptor; those due to NMB are mediated by the NMB-R (BB1), which is a 390-amino acid G protein-coupled receptor and by an unknown ligand for the orphan receptor BRS-3(BB3), which has a 46–49% homology to GRP-R/NMB-R and is a 399-amino acid G protein-coupled receptor.[13] The human GRP-R has 55% amino acid identities with the human NMB-R and 51% with the human BRS-3.[5,13] The GRP-R, NMB-R, and BRS-3 each has multiple glycosylation sites.[13] There are two consensus potential sites for PKC phosphorylation in the human GRP-R.[13] There is the presence of a putative disulfide bond between cysteines at the end of extracellular domain-1 and middle of extracellular domain-2 (Cys^{113} and Cys^{196} in human GRP-R), which is preserved in all species studied.[13] Detailed studies of the GRP-R show that the mature receptor has a molecular mass of 60 kD in human and 82 kD in mouse with a deglycosylated mass of 43 kD, showing that 35% of the mass of the mature human GRP-R and 47% of the murine GRP-R result from glycosylation.[13] The mouse GRP-R has four potential glycosylation sites, the human two potential sites and detailed studies in the murine GRP-R show that all four potential N-linked glycosylation sites are glycosylated (Asn^5, Asn^{20}, Asn^{24}, Asn^1).[13,16] The amount of glycosylation differs in each site, all of the glycosylation on the mouse GRP-R is N-linked, and the glycosylation moieties are four triantennary and/or tetraantennary complex oligosaccharide chains.[13,16] The presence of the Asn^{24} and Asn^1 glycosylation is especially important for sorting and expression of the murine GRP-R; however, full glycosylation at each site is not needed for receptor expression.[13] The human NMB-R has two consensus sites for potential PKC phosphorylation and three potential N-Linked glycosylation sites.[13] The mature human NMB-R has a molecular mass of 72 kD and a deglycosylated mass of 43 kD. Detailed studies in the rat NMB-R show that there are no O-Linked carbohydrates but that the mature receptor was a sialoprotein,[16] with each of the N-linked sites glycosylated with triantennary and/or tetraantennary complex oligosaccharides.[13,16] The human BRS-3 has a predicted mass of 44 kD, and there are two potential N-linked glycosylation sites and consensus sites for potential PKC phosphorylation in the third cytoplasmic loop and carboxyl terminus.[5,13] There have been no cross-linking studies to establish the extent or type of phosphorylation of the mature BRS-3.

Similar to other G protein-coupled receptors, numerous studies show that GRP-R and NMB-R can undergo numerous regulatory processes when stimulated.[13] These include rapid receptor phosphorylation, receptor internalization when stimulated by agonists, but not antagonists. With prolonged agonist stimulation (>30 min), surface receptors decrease in number and undergo downregulation and the receptors also become desensitized, such that subsequent agonist doses are less potent and efficacious.[13] In various studies, PKC activation has been shown to be important for receptor internalization and receptor interaction with clathrin-coated pits.[13] Both acute (short-term) and long-term desensitization of the GRP-R has been reported, and numerous findings support the conclusion that chronic desensitization and downregulation are coupled processes and occur in a PKC-dependent and independent manner.[13]

The human GRP-R has a very high affinity for Bn and GRP(14–27) (0.07–1.9 nM), the human NMB-R has a very high affinity for NMB (0.052–0.54 nM),[35] and the human BRS-3 has a low affinity (>3000 nM) for Bn, NMB, and GRP, as it does for all naturally occurring Bn-related peptides.[13,35] GRP has >700-fold selectivity for the hGRP-R over the human NMB-R and NMB has a >600-fold selectivity for the human NMB-R over the human GRP-R.[35] Many amphibian peptides (litorin, ranatensin, P-GL, alytesin, Bn) have high affinities (nanomolar range) for both human GRP-R and human NMB-R.[13,35] The natural ligand of the BRS-3 receptor remains unknown. However, two synthetic compounds, which both function as agonists, have been described with high affinity for human BRS-3 which are [D-Phe^6, β-Ala^{11}, Phe^{13}, Nle^{14}) Bn(6–14) (and its analogs)[13,30] and MK-5046 [(2S)-1,1,1-trifluoro-2-[4-(1H-pyrazol-1-yl) phenyl]-3-(4-[[1-(trifluoromethyl) cyclopropyl] methyl]-1H-imidazol-2-yl)propan-2-ol.[11] [D-Phe^6, β-Ala^{11}, Phe^{13},

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Nle[14] Bn(6-14) (and its analogs) have the unique property of interacting as a full agonist with all three Bn-R subtypes with high affinity,[13,30] whereas MK-5046 is selective for the BRS-3 receptor.[11]

Receptor antagonists, which are widely used in various pharmacological and physiological studies, have been described for each classes of human Bn-Rs.[13] Ten different chemical classes of Bn receptor antagonists have been described, of which six classes are GRP-R selective antagonists.[8,13] These GRP-R selective antagonists are all peptide or peptoid analogs, some with high selectivity and affinity for GRP-R in all species.[8,13] Two different classes of antagonists are selective for the NMB-R, with the most selective and potent being the peptoid, PD168368[8] and one class of selective BRS-3 antagonist has been described, Bantag [Boc-Phe-His-4-amino-5-cyclohexyl-2,4,5- trideoxypentonyl-Leu-(3-dimethylamino)benzylamide *N*-methylammonium trifluoroacetate].[10]

Signal Cascades for Bn-Rs

GRP-R, NMB-R, and BRS-3 activation in human cells and all species examined are coupled to activation of phospholipase C(PLC) resulting in the generation of inositol phosphates and diacylglycerol with activation of protein kinase Cs (PKCs) and mobilization of cellular calcium.[13] Each also activates various tyrosine kinase cascades, which in different cells include the activation of focal adhesion kinases (PYK-2, $p125^{FAK}$); MAP kinase (ERK1/2, p38, Jun kinase); Src kinases; various docking proteins including $p130^{Cas}$, paxillin, CRK; and transactivation of EGF receptors.[13] The GRP-R activation in various species has been particularly well studied and also results in the activation of phospholipases A and D. In some, but not most cells, ligand–GRP-R interaction causes the activation of adenylate cyclase; activation of both classical and novel PKCs; activation of PKD in a PKC-dependent and independent manner; activation of p70s6 kinase resulting in an increased expression of immediate early response genes (c-myc, c-jun, c-fos); and activation of various small GTP-binding proteins such as rac or rho.[13]

One of the main signaling cascades of GRP-R, NMB-R, and BRS-3 in both gastrointestinal cancers and in cancers of other sites (lung, prostate) is linked with the transactivation of the epidermal growth factor receptor (EGFR) receptors.[13] This cascade involves the activation of phospholipase C, changes in cytosolic calcium and PKC as well as activation of Src kinases, matrix metalloproteinases with the generation of a EGF-like peptides resulting in EGFR transactivation and the generation of reactive oxygen species.[13,21] This is addressed in detail in the chapter on Bn peptides in the Cancer/Anticancer Peptides section of this book and will not be dealt with further here.

BIOLOGICAL ACTIONS OF BN PEPTIDES WITHIN THE GASTROINTESTINAL (GI) TRACT

General

In older studies, the particular Bn receptor subtype (GRP-R or NMB-R) mediating the various reported responses is frequently not clear because Bn was usually used, and this peptide has high affinity for both GRP-R and NMB-R in both humans and the various nonhuman species studied.[13,35] A second point that can make it difficult to interpret the actions of Bn peptides is that they have the unique ability to not only stimulate tissues directly but also they very frequently stimulate the release of other biologically active peptides, gastrin, cholecystokinin, (CCK), glucagon-like peptide, insulin, motilin, gastric inhibitory polypeptide, enteroglucagon, neurotensin, vasoactive intestinal peptide, peptide YY, which in turn can cause indirect effects.[13] A third point complicating many reported GI actions of various Bn peptides is that it is often unclear as to which are only pharmacological and which are physiological. In the following sections, some of the main actions will be discussed.

Bn stimulating either activation of GRP-R or NMB-R has contractile effects on all gastrointestinal smooth muscle, similar to its effects on smooth muscle in the urogenital tract, and has prominent effects on gastrointestinal motility, especially on stimulating gastric emptying, small intestinal transit and gallbladder emptying.[3,13] Peristalsis is important in both the large and small intestine for the propulsion of intestinal content. In rat colon, activation of GRP-Rs is important in mediating the descending phase of the peristaltic reflex with GRP acting as a modulatory neurotransmitter.[9]

Bn has potent growth effects on various normal gastrointestinal tissues and gastrointestinal tumors through, autocrine and nonautocrine mechanisms.[14] Bn administration in neonatal rats causes hyperplasia of the G cells in the gastric antrum as well as hyperplasia of duodenal and pancreatic acinar glands.[32]

The Action of Bn Peptides in the Esophagus

NMB-Rs were originally described on esophageal muscle, and its activation causes contraction of esophageal smooth muscle.[13] The effect of bombesin infusion on 8 healthy humans was examined.[13] Bn significantly increases lower esophageal sphincter pressure, which is not blocked by atropine or somatostatin and affects esophageal body motility by increasing peristaltic wave amplitude and duration.[13] In cat, lower esophageal sphincter Bn dose dependently increases lower esophageal sphincter tone.[13]

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

The Action of Bn Peptides in the Stomach

Activation of GRP-R in gastric smooth muscle results in contraction,[13] which is tetrodotoxin and atropine resistant.[19] Both NMB-R and GRP-Rs are found on isolated gastric smooth muscle cells.[13] In human studies, the use of a GRP-R antagonist inhibits gastric emptying[3] and administration of monoclonal antibombesin antibodies to dogs leads to increased gastric retention.[13,32] GRP-R stimulates both gastrin release from antral G cells and somatostatin release from D cells as well as stimulating gastric acid output.[13] Studies in the isolated vascularly perfused rat stomach show that peptone and various protein nutrients stimulate gastrin release from the stomach antrum by activating stimulatory cholinergic and bombesin/GRP neurons.[13] Activation of GRP-Rs in the stomach stimulates somatostatin secretion in the fundus and antrum by distinct mechanisms. In the fundus, GRP acts indirectly on somatostatin cells by activating stimulatory noncholinergic neurons and to a lesser degree, inhibitory cholinergic neurons. However, in the antrum, GRPs act indirectly on somatostatin cells by stimulating the release of gastrin and to a lesser degree by activation of inhibitory cholinergic neurons.[13]

The Action of Bn Peptides in the Small Intestine

Activation of GRP-R in small intestinal smooth muscle results in the contraction of duodenal circular muscle strips in a atropine- and tetrodotoxin-insensitive manner,[19] as well as contraction of ileal longitudinal muscle strips.[13] *In vivo* infusion of GRP results in a slower propulsive force in the small intestine and inhibition of GRP-R by a GRP-R antagonist *in vivo* accelerates small intestinal transit in humans.[3,13,32] Bn infusion in either an isolated intestinal loop in the dog or in pig produces a 50% reduction in water and electrolyte absorption (Na, Cl) and an increase in bicarbonate secretion.[13] In the isolated mouse jejunum, the effects of Bn on short circuit current and potential difference changes are proposed to be mediated by three levels of action of the peptide: acting on noncholinergic nerves; at preganglionic and postganglionic levels and directly on the enterocyte.[28] Bn has important growth and cytoprotective effects in various small bowel injury models.[13] Bn administration increases absorptive capacity and improves biochemical values in the absence of elemental nutrition in experimental models of short bowel syndrome; it minimizes impairment of interstitial cells of Cajal, the pacemaker cells, induced by FK506 used in small bowel transplantation;[2] its administration can protect the rat small bowel allograft from ischemic reperfusion injury and the use of a selective GRP-R antagonists attenuates the release of proinflammatory cytokines *in vitro* and *in vivo* and improves survival in models of sepsis.[2,13]

The Action of Bn Peptides in the Large Intestine

Activation of NMB-R in colonic smooth muscle results in contraction;[13] however, infusion of GRP increases contractions of colon muscle, which results in slower propulsive force.[32] In various studies, GRP-R/Bn-R are reported to be possibly important in various colonic inflammatory responses. Specifically, a GRP-R antagonist reduces the severity of the colitis in an experimental model of inflammatory bowel disease associated with a reduction in the expression of TNF-alpha,[13] and GRP-R expression is decreased in inflamed and noninflamed colon of Crohn's disease patients but not those with ulcerative colitis. The trefoil factor TFF3 is a peptide produced by mucus-secreting cells in the small and large intestine (see the chapter in this section of the book), which has been implicated in intestinal repair and protection. In the rat colon, Bn induces a dose-dependent increase in the release of TFF3. GRP stimulates colonic ion transport including K and Na secretion across the porcine distal colonic epithelium, and these processes were partially dependent on a bumetanide-sensitive transport pathway in the basolateral membrane.[13,34] GRP can also affect colonic ion transport by modulating the action of prostaglandin E2 on electrolyte transport.

The Action of Bn Peptides Action in the Pancreas

Pancreatic acinar cells from all species examined (rat, man, dog, mouse, guinea pig) possess GRP-Rs, and their activation causes enzyme secretion.[13] Furthermore, *in vivo* Bn stimulates pancreatic secretion in man and in many species (rat, dog, mouse).[32] Because activation of Bn receptors can stimulate CCK release, one of the important questions is whether it stimulates pancreatic secretion indirectly by stimulating the release of CCK. In rats, the CCKAR antagonist L-364,718[1] completely inhibits CCK-stimulated pancreatic enzyme secretion but has no effect on Bn-induced pancreatic secretion, leading to the conclusion that Bn stimulates pancreatic secretion by interacting directly with the acinar cells, which is similar to the findings in humans. Bn can also stimulate pancreatic bicarbonate and fluid secretion, and studies demonstrate that it is mediated by activation of GRP-R.[33] The secretion of the bicarbonate rich fluid stimulated by Bn results from the direct action on interlobular ducts of the pancreas.[33]

Chronic Bn administration increases pancreatic weight and DNA content, and pancreatic enzyme content.[13] Most, but not all studies,[17] especially in the rat, show that these trophic effects of Bn on the pancreas are not mediated by CCK release but are mediated by a direct action.[12]

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Bombesin stimulates insulin secretion from pancreatic islets and recent studies show both GRP-R and BRS-3 receptors are present on pancreatic islets.[13] In normal mice, GRP administration potentiates glucose-stimulated insulin secretion, which is at least partially mediated by the activation of autonomic nerves, and the GRP potentiation effect on glucose-stimulated insulin release is not seen in GRP-R knockout mice.[13] Bn/GRP is reported to have variable effects on the stimulation of other islet hormones pancreatic polypeptide and glucagon with increases in some, but not all, studies reported in the human, dog, and sheep.[13] By contrast, in porcine pancreas, GRP infusion results in the stimulation of insulin and pancreatic polypeptide with inhibition of somatostatin secretion, no effect on glucagon secretion, and no effects are altered by muscarinic cholinergic blockade.[13] Mice with a target disruption of BRS-3 develop hyperphagia, obesity, hypertension, and impaired glucose metabolism.[26] BRS-3 receptors occur in pancreatic islets and BRS-3 knockout mice have elevated insulin levels.[13] Various studies[13] conclude that the BRS-3 receptor activation can contribute to regulating plasma insulin concentrations and/or its secretion and the impaired glucose metabolism in these animals results from impairment of glucose transporter 4 translocation in adipocytes.[13] BRS-3 is highly expressed in human mouse, rhesus monkey, and dog pancreatic islets, (but not rat), and the silencing of BRS-3 with either small interfering RNA or a receptor antagonist reduces glucose-dependent insulin release, showing the widespread importance of this receptor in insulin regulation.[6]

The Action of Bn Peptides Action in the Gallbladder

Activation of Bn receptors in gallbladder muscle results in gallbladder contraction.[13] Studies in the human, dog, guinea pig, and other species show that Bn/GRP can stimulate gallbladder contraction and that it is inhibited by muscarinic cholinergic blockade.[13] Detailed studies in the dog show that bombesin stimulated gallbladder contraction requires involvement of prejunctional cholinergic-, somatostatingeric-, and VIPergic-pathways.[13]

PATHOPHYSIOLOGICAL IMPLICATIONS OF BN PEPTIDES WITHIN THE GASTROINTESTINAL (GI) TRACT

General

At present, no specific diseases have been shown to result from alterations in the genes for Bn peptides or their receptors.[13] Furthermore, at present, no specific therapies for any disease are directed at Bn peptides or their receptors. However, Bn peptides and their receptors are receiving considerable interest in relation to their growth effects on GI and other neoplasms and their overexpression/ectopic expression by many common tumors.[13,14] With regard to the GI tract, numerous experimental studies suggest that they may be particularly important in mucosal protection, regulation of insulin secretion and feeding behavior each of which will be briefly discussed below.

PATHOPHYSIOLOGICAL IMPLICATIONS OF BN PEPTIDES IN GASTROINTESTINAL AND OTHER CANCERS

General: Bn and Cancer

Activation of all three Bn-Rs can have growth effects in various normal tissues and in neoplastic tissues.[13,14] Because Bn-Rs are one of the groups of G protein-coupled receptors that are the most frequently overexpressed/ectopically expressed many common tumors, and these peptides can have a potent effect on their growth and some cases, their differentiation (often by an autocrine mechanism), they are receiving much attention.[13,14] This attention arises both from their role in growth and differentiation of neoplasms and therefore as a target for novel therapies and from their role in imaging tumors related to receptor overexpression for identifying primaries and establishing the extent of the disease. This provides a possible approach for molecular targeting of antitumor therapies (either radioactively labeled Bn analogs or cytotoxic Bn analogs).[13,14,29] This area is specifically dealt with in detail in another chapter on Bn peptides in Cancer in this book and therefore will only be briefly addressed here. Furthermore, only a few key references will be repeated.

POSSIBLE TREATMENTS DIRECTED AT BN PEPTIDES AND/OR THEIR RECEPTORS GROWTH EFFECTS ON TUMORS

Ever since the original description of Bn-like peptide secretion by small-cell lung cancers and the subsequent demonstration that Bn-like peptides have autocrine growth effects on numerous tumors including those in the GI tract, there has been interest in developing novel therapies against this growth cascade.[14] Bn-like peptides have growth stimulatory/differentiating effects in numerous common GI tumors (pancreas, colorectal, gastric, intestinal) and non-GI tumors (lung, prostate, ovarian, CNS, head/neck squamous cell cancers, renal, breast).[14] Promising effects of inhibition of the Bn peptide stimulatory effects by either receptor antagonists or by antibodies have been reported in many experimental

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

tumoral models. Furthermore, anti-GRP antibody infusions have been reported in patients with lung cancer with 8% of patients responding.[15] Particularly promising are the reports that inhibition of GRP-R activation may potentiate the inhibitory actions of EGFR inhibitors on various tumors as well as the observation that Bn-R activation often stimulates growth by transactivating the EGFR receptor.[13] These results suggest that inhibition of these cascades could be a novel antitumor treatment approach.

POSSIBLE USE OF BN RECEPTOR OVEREXPRESSION/ECTOPIC EXPRESSION BY TUMORS FOR IMAGING/TUMOR LOCALIZATION

With >70% of many common tumors overexpressing at least one of the three Bn-R subtypes (GRP-R, NMB-R, BRS-3),[14] there is increased interest in using this feature as a means of imaging these tumors for clinical therapies.[29] This possible approach is being considered because of the success of the use of radioactively labeled somatostatin analogs for imaging neuroendocrine tumors, which are now widely used clinically and is the most sensitive imaging modality available.[29] Unfortunately, most common GI tumors, and common tumors in other locations, do not show somatostatin receptor overexpression, so some other G protein receptor, such as the Bn-R family, is being investigated for this purpose instead.[29] Tumor localization is essential in all stages of tumor management including the decision of whether surgery should be done, the extent of surgery, the assessment of the immediate results of surgery or other antitumor treatments, and the follow-up of the patient to assess the effects of treatment or need for a change in treatment approaches. There have been >200 articles published on the use of various labeled Bn analogs to image various tumors, most in the last 5 years and most in experimental studies in animals, and many report promising results.[29] Many COOH terminal Bn/GRP analogs have been used, and they have been labeled with different isotopes depending on whether they were primarily going to be used for imaging, the type of imaging or for Bn receptor-mediated cytotoxicity (next section). Isotopes used including ^{99m}Technetium, ^{111}Indium, ^{64}Copper, ^{125}Iodine, $^{185/187}$Rhenium, ^{18}Fluorine, ^{68}Gallium, ^{90}Yttrium or ^{177}Lutetium.[29] In various *in vitro* and *in vivo* studies, either conventional gamma radiation detection or PET imaging (positron emission tomography) is used to image the tumors.[29] In the original studies, radioactively labeled Bn receptor agonists were used based on analogies to results with somatostatin analogs and numerous studies, which showed that only agonists are internalized and thus believed to give better imaging.[29] Radioactively labeled Bn receptor antagonists may be superior targeting agents to agonists.[13]

POSSIBLE USE OF BN RECEPTOR OVEREXPRESSION/ECTOPIC EXPRESSION BY TUMORS FOR MOLECULAR TARGETING OF CYTOTOXIC AGENTS

Similar to the use of frequent Bn-R overexpression/ectopic expression to image tumors, there is increased interest in using this as a molecular target to deliver cytotoxic agents selectively to the tumor (radioactively labeled or other cytoxic Bn analogs).[29] This occurs, similar to the situation with imaging, because of the success of this approach with radioactively labeled somatostatin analogs in patients with advanced, malignant neuroendocrine tumors[NETs].[29] Using this approach, promising therapeutic effects have been obtained in many studies of patients with advanced NETs and large Phase 3 clinical trials are now being conducted. This has resulted in a similar approach to common GI and other tumors that overexpress/ectopically express Bn-Rs, and there are now >100 articles, primarily published within the last few years using this approach.[29] Similar to the imaging studies discussed above, numerous synthetic agonist COOH terminal analogs of Bn-related peptides are used in these cytotoxic studies.[29] For Bn receptor-mediated radiocytotoxicity, the isotopes primarily used include ^{68}Gallium, ^{90}Yttrium, or ^{177}Lutetium,[29] which are coupled to various Bn analogs with various linkers/chemical groups avidly binding the isotopes.[29] Many of these reports describe radioactively labeled Bn analogs that retain high affinity for the Bn-R bearing tumors *in vivo* and have tumoricidal effects *in vivo*.[29]

Besides coupling Bn analogs to radioactively labeled Bn-related peptides, there is increasing interest in targeting other cytotoxic agents to tumors overexpressing/ectopically expressing Bn receptors.[29] Cytotoxic Bn analogs with Bn-related peptides coupled to chemotherapeutic agents (doxorubicin) (AN-215) inhibit growth of pancreatic, lung, prostate, and gastric cancers[14,29] and GRP analogs coupled to camptothecin inhibit lung cancer growth.[18,22,29] The camptothecin-coupled Bn analogs mediate their cytotoxic effects by interacting with tumoral Bn-Rs.[22] Bn analogs coupled to the marine toxins, hemisasterlin, dolastin, and their conjugates, have cytotoxic effects on various tumors.[13] Conjugation of Bn agonist analogs to magainin, an antimicrobial peptide, markedly enhances (10-fold) its cytotoxicity for tumor cells.[18]

SERUM LEVELS OF BN PEPTIDES AS TUMOR MARKERS

In several studies, plasma levels of GRP precursors (i.e. such as proGRP) in patients with non-small-cell lung cancer or small-cell lung cancer give important prognostic information and are useful in some studies to assess the response to therapy.[13,24]

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

OTHER POSSIBLE BN PEPTIDE PATHOPHYSIOLOGICAL IMPLICATIONS IN NONNEOPLASTIC DISEASES

GRP is protective to the small intestine in various injury models[2,13] including by enhancing gut barrier function, preventing atrophy of enteric ganglia caused by FK506 in small intestine and preventing atrophy of Peyer Patches/dysfunction of M cells in rabbits receiving long-term parenteral hyperalimentation, which has led to the suggestion that GRP agonists may have a potential therapeutic role in diseases causing this types of injury.[13]

Studies suggest GRP-R, NMB-R, and BRS-3 are important in regulating metabolism and obesity.[13] This involves both central and peripheral mechanisms including vagal mediated effects.[13] This has led to interest developing antiobesity approaches. Lastly, numerous studies show that BN-R activation (particularly GRP-R and BRS-3) has important roles in regulating insulin release or glucose stimulated insulin release. An increased understanding of the mechanism of their effects may lead to newer approaches to treat diabetes mellitus.

Chapter 162

CCK

Travis E. Solomon, Ayman I. Sayegh and Joseph R. Reeve, Jr

ABSTRACT

Peripheral cholecystokinin (CCK) occurs in intestinal endocrine cells and neurons. It regulates gastric acid secretion, gastric emptying, gallbladder contraction, exocrine pancreatic secretion, and may influence feeding. Characterization of CCK-58 as the most abundant endocrine form and recognition that its physiology differs from that of CCK-8 have important implications for the physiological role of CCK. Circulating levels of CCK may be higher than that previously recognized because of ex vivo degradation of CCK-58 and its lower immunoreactivity. CCK-58 may act in a paracrine manner to activate both CCK_1 and CCK_2 vagal receptors. Higher circulating peptide levels and vagal afferent actions suggest recalibration of "physiological" actions of CCK. Previous conclusions that CCK has minimal therapeutic value in obesity came from CCK-8's reduction of meal size and also the interval between meals. CCK-58 reduces meal size but not intermeal interval. Therefore, the physiology of CCK should be reexamined using the predominant circulating form, CCK-58.

HISTORY

Early classical studies in gut physiology found that extracts of intestinal mucosa caused gallbladder contraction (termed "cholecystokinin") and pancreatic digestive enzyme secretion (pancreozymin).[17] Decades of painstaking chemical and physiological experimentation resulted in the elucidation of the structure of the bioactive peptide now commonly known as cholecystokinin (CCK). Pioneering work by Mutt and Jorpes[22] culminated in reports of full amino acid sequences for peptides containing 33 and 39 residues (CCK-33 and CCK-39). Subsequent studies reported by many investigators indicated that multiple molecular forms of CCK existed in the gut mucosa, brain, and blood.[11] Of particular importance was the discovery of CCK-8.[8] This form and related small analogs proved to be relatively easy to synthesize chemically and demonstrated clear differences in actions from the structurally related gastrin peptide. This resulted in thousands of publications on the physiology and pathophysiology of CCK, based almost exclusively on the use of CCK-8 as a representative probe for bioactivity.

More recent work by Reeve and coworkers has indicated that the major molecular form of CCK in several species is much longer and more structurally complex than the originally characterized form; the peptide has 58 amino acids and is termed CCK-58.[11] Fig. 1 shows the sequence of CCK-58 peptides that have been isolated from dog, cat, and rabbit. The structure of the endogenous peptide that causes cholecystokinin bioactivity and the site of its action are still debated. However, current evidence shows that CCK-58 is the only detectible form in the blood of rats[23] and is the most abundant endocrine form in other species.[10,11] CCK-58 and CCK-8, the most studied peptides, have notable differences in some physiological actions[29] suggesting that the biochemistry, physiology, and pharmacology of cholecystokinin require more investigation.

STRUCTURE OF THE PRECURSOR GENE/ mRNA

The gene for rat cholecystokinin was isolated by Deschenes et al.[7] There are three exons separated by two introns spanning 7 kb. The methionine codon that initiates peptide synthesis is 2 bases into exon 2. A "TATA"-like sequence precedes the transcription initiation site at position 34. The sequence AT-TAAA is found 22 bases 5′ to the site determined to be the polyadenylation addition site. The message-encoding preprocholecystokinin begins with a putative initiator methionine and terminates with a serine followed by a stop codon, TAC. The prepropolypeptide is 115 amino acids long. The cDNA contains 33 nucleotides in the 5′-noncoding region, 199 nucleotides in the 3″-coding region and 345 nucleotides coding for preprocholecystokinin. The amino acid sequence of CCK-58 is flanked by both amino-terminal (45 amino acids) and carboxyl-terminal flanking (12 amino acids) peptides.

PROCESSING OF THE PRECURSOR

Processing of preprocholecystokinin has been suggested by the forms of cholecystokinin observed in tissue extracts. Preprocholecystokinin is processed into procholecystokinin

FIGURE 1 The primary sequence of dog, cat, and rabbit CCK-58 and CCK-8. The * indicates the presence of a sulfate group on the tyrosine 7 amino acids from the carboxyl terminus, the Phe< indicates that the carboxyl terminus of all CCK peptides are amidated, the underlining indicates amino acids that differ between cat and rabbit CCK-58 from dog CCK-58. A difference of one amino acid in the amino terminus between dog and cat CCK-58 causes an 18-fold difference in carboxyl-terminal immunoreactivity.

by signal peptidase. The amino terminus of proCCK peptide was determined by its purification and sequence analysis from human intestine.[9] The carboxyl-terminal flanking peptide adjacent to the phenylalanine amide (the carboxyl-terminal amino acid in all cholecystokinin forms) is cleaved from procholecystokinin by PC1 to form CCK-83-Gly-Arg-Arg-COOH. The phenylalanine-amide carboxyl terminus is formed by the actions of two enzyme complexes; first carboxypeptidase D in the duodenum or carboxypeptidase E in the brain[25] removes the two basic groups, then peptidylglycine-α-amidating monooxygenase hydrolyzes the –Phe Gly-COOH to form the carboxyl terminal-Phe-NH_2. This produces CCK-83 with the carboxyl-terminal amide found on all forms of cholecystokinin with accepted bioactivity. Endopeptidase cleavage at single or double basic residues can produce CCK-8, CCK-22, CCK-33, CCK-39, or CCK-58, all with the same phenylalanine-amide carboxyl terminus.

Another distinctive posttranslational modification of cholecystokinin is the sulfation of its carboxyl-terminal tyrosine, seven residues from this end of all cholecystokinin forms. The only gastroenteric peptides with a sulfate group are gastrin and cholecystokinin, which have identical carboxyl-terminal penptapeptide structures with a tyrosine in the sixth and seventh positions from the end of the peptides, respectively. Both gastrin and cholecystokinin exist in sulfated and nonsulfated forms. In dogs, the proportion of sulfated to total gastrin or cholecystokinin is about 66% for both peptides. Importantly, nonsulfated-CCK-58 is as potent, but less efficacious, as the sulfated peptide for stimulation of pancreatic protein and fluid secretion[29] in the intact rat. The fact that nonsulfated-CCK-58 is a full agonist for the CCK_2 receptor but not the CCK_1 (see below), suggests that the *in vivo* pancreatic action may be mediated by the CCK_2 receptor.

However, previous studies lacked an important control for defining the tissue forms of cholecystokinin (and most bioactive peptides), an external indicator of artificial degradation of the endogenous peptide. During extraction and processing of tissue, the peptides are exposed to a plethora of proteolytic enzymes from cellular organelles caused by membrane dissociation during extraction. Some of the enzymes, such as those in the lysozymes, are specifically designed to degrade peptide hormones. Reported cholecystokinin forms (peptides with a carboxyl phenylalanine-amide) include peptides with 4, 5, 8, 22, 33, 39, 58, and 83 amino acids. Other forms have been identified in one species, but this list may well indicate that many of the forms are artifacts of extraction and processing of the tissue being examined. This is especially pertinent for neutral extracts of intestine where active pancreatic enzymes could be responsible for many of the observed forms. Without an external standard that indicates the extent of degradation, there is no validation of observed forms in any studies on intestinal or brain molecular forms, including results reported from our own laboratory.

However, our laboratory has developed a method—"RAPID (Refrigerated, Acidified, Protease inhibitors, Indicator, Dilution)"—for determining the molecular forms of cholecystokinin in blood.[23] In this method, a very important aspect is the use of an indicator to quantify peptide stability and loss. When conditions were developed where the external standard, ^{125}I-CCK-58, was not degraded and all other forms were recovered by >90%, the only detectible molecular form of cholecystokinin in rat blood was CCK-58.[23] In earlier studies in which no indicator was included, CCK-58 was the major form in human and canine blood and tissue.[11] These studies of humans and dogs need to be repeated with indicator before strong conclusions can be drawn. One is tempted to suggest that CCK-58 is the only form in tissue because it is the only detected form in blood. However, this may not be accurate because the liver could remove most or all of CCK-8 before it reaches the general circulation. Others would suggest that CCK-8 is probably present because it is the only molecular form of cholecystokinin observed in the brain. However, this may be premature because CCK-58 is a major form in canine brain,[12] and again, there have been no studies on brain forms of cholecystokinin that have included an indicator of degradation.[23]

Future studies need to include not only indicator, but also recovery studies of most suggested molecular forms including CCK-8, CCK-22, CCK-33, nonsulfated-CCK-58 and sulfated-CCK-58. This quintet of standards reflects the range of size and charge that have been observed in previous studies. At this time, we feel the most probable processing that occurs will produce only CCK-58 or only CCK-58 and CCK-8. The presence of nonsulfated-CCK-58 must be

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

evaluated using an indicator such as "heavy CCK-58" (a peptide with five N^{15} atoms) or radioactive sulfated-CCK-58 during extraction and purification of tissue or blood.

PERIPHERAL DISTRIBUTION

The major location of CCK in the periphery is the gastrointestinal tract. CCK has been localized by immunohistochemical methods to a morphologically distinct open-type endocrine cell, the I cell.[5] These cells are found in the proximal small intestine in most species, and immunoassay of tissue extracts also indicates that the highest amounts of CCK are in the proximal intestine but substantial immunoreactivity is also present in the ileum. The peptide has also been detected in secreto-motor nerves in the enteric nervous system in several species.[13] Although no definitive data exist, it is likely—based on the number and density of I cells versus ENS neurons—that most circulating CCK is produced and secreted by mucosal endocrine cells.

RECEPTORS AND SIGNALING CASCADES

It is being increasingly recognized that peripheral cholecystokinin can act at two receptors (CCK_1, CCK preferring, and CCK_2, CCK, and gastrin specific) located on multiple tissues (Fig. 2). There are the classic actions at CCK_1 receptors on the gallbladder and pancreas causing contraction and secretion; in addition, electrophysiological experiments[16] and antagonist studies suggest the CCK_1 receptor is on vagal afferents where it is postulated to regulate pancreatic secretion and at high concentrations meal size (satiation). There is accumulating evidence that CCK_2 receptors are also on the vagus and that both receptors are present on sympathetic nerves.[4]

At this point, it is important to point out a controversial aspect of our work. Many have suggested that only gastrin can activate CCK_2 receptors because of much higher circulating concentrations of gastrin versus cholecystokinin. If CCK is released near receptors containing CCK_2 receptors (as accepted for regulation of meal size by CCK_1 receptors), then CCK could activate the CCK_2 receptor, even if gastrin is circulated at much higher levels. In addition, our group has challenged the concept that CCK circulates at very low levels. We have repeatedly shown that only 20% of endocrine CCK is recovered if plasma is formed and stored before measuring immunoreactive CCK. Many have reported that rats fed a high protein meal (one of the best stimulants of CCK release) have sustained 5–10 pM levels of CCK. If one accounts for the loss of CCK during plasma formation and the diminished immunoreactivity of CCK-58 (Table 2), then the calculated levels would be 25–50 pM, levels that are near the reported gastrin levels in rats (50 pM). Using the above-described method for processing blood and a CCK-58 standard for the immunoreactivity that eluted during HPLC in the region of CCK-58, we observed that protein feeding released 15–25 pM immunoreactive CCK-58 and that no other molecular form was detected (unpublished observation).

The isolated pancreatic acinar cell has been used to study the receptor binding and intracellular signals that respond to CCK.[6] Studies with isolated acinar cells indicate that CCK-evoked specific Ca^{2+} signals are generated through interactions with their respective Ca^{2+}-releasing messengers such as IP_3, cyclic adenosine diphosphoribose (cADPR), and nicotinic acid adenine dinucleotide phosphate (NAADP). In this model, CCK, acting through cADPR generation, would activate the IP_3Rs and RyRs release stimulating the subsequent Ca^{2+} release from the endoplasmic reticulum. At physiological levels (5–50 pM), CCK-8 and CCK-58 cause release of Ca^{2+} spikes near the apical pole (Fig. 3A). Supra physiological levels (5–1000 nM) of both the peptides cause global release of calcium (Fig. 3B).

BIOLOGICAL ACTIONS OF PERIPHERAL CHOLECYSTOKININ

In Fig. 1, the structures of CCK-58 from three species are presented, demonstrating differences in the amino-terminal

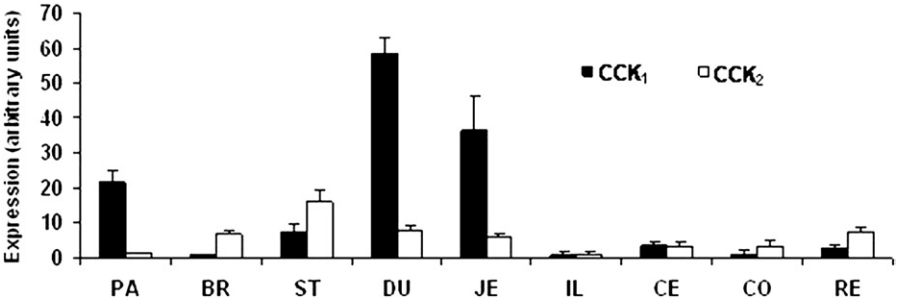

FIGURE 2 Distribution of CCK receptors, CCK_1 and CCK_2, mRNA in whole tissue in the pancreas (PA), brain (BR), stomach (ST), duodenum (DU), jejunum (JE), ileum (IL), cecum (CE), colong (CO), and rectum (RE). Most of CCK_1 receptor mRNA was found in the duodenum, jejunum, and pancreas, whereas CCK_2 receptor mRNA was mostly found in the stomach, duodenum, brain, jejunum, and rectum.

The American Physiological Society has not endorsed the content of this adaptation or translation, or the context of its use.

sequences, and importantly the identity of the recognized biologically active carboxyl-terminal region. In the following discussion, it is important to take into account the observations on the impact of differences in primary structure in the amino-terminal region of CCK-58 on both bioactivity and immunoreactivity. This region, which is separate from the C-terminal portion of CCK that defines bioactivity and immunoreactivity, can nevertheless alter both properties of intact CCK-58. As shown in Tables 1 and 2, CCK-58 forms from different species show altered receptor binding and immunoreactivity, even though they have identical C-terminal bioactive regions. Importantly, canine CCK-58 is more potent for CCK_1 receptor binding than CCK-8 or rabbit CCK-58, suggesting that tertiary structure plays an important role in determining biological activity.

Several experimental criteria must be met to conclude that a circulating factor plays a quantitatively significant role in regulating a specific physiologic response. In the case of gastroenteric peptide hormones and regulation of gastrointestinal responses to ingestion of food, a useful set of such criteria was described by Grossman.[14] These included (1) circulating levels of the hormone should increase after ingesting food; (2) exogenous administration

TABLE 1 Canine and Rabbit CCK-58 Binding to CCK_1 and CCK_2 Receptor Acinar Cell or Brain Membranes

Peptide	IC_{50} CCK_1 receptor binding (pM)	IC_{50} CCK_2 receptor binding (pM)	$\frac{IC_{50}CCK_1}{IC_{50}CCK_2}$

of the hormone should reproduce the physiologic response. In the decades after Grossman's explication of these criteria, many other requirements for accepting a particular hormone as a physiologic regulator have become apparent. CCK provides a useful example of the complex nature of the steps necessary to prove that a peptide acts as a circulating hormone to regulate a specific gastrointestinal response to a meal. (1) As discussed above, the quantitation of circulating peptide levels requires detailed consideration of potential sources of nonphysiologic loss of the peptide during sampling and measurement. (2) The exact molecular forms of peptide that circulate in postprandial blood must be defined. (3) The time course of changes in circulating peptide levels must be known. (4) The cellular localization and density of specific receptors for the peptide should be known. A complicating factor is the possibility that the peptide may act as both a hormone and a local neurotransmitter to cause certain responses, requiring information about the neural distribution and release of the peptide. Thus, (5) the effects of specific receptor antagonists on a response can be a powerful tool, but it must be recognized that such antagonists may be acting to block a peptide delivered by blood or by local release from endocrine cells on nerves acting in a paracrine/neurocrine fashion on a variety of local targets. Furthermore, some specific receptor antagonists may also act centrally, depending on their permeability through the blood–brain barrier, adding a further degree of complication in interpreting experimental results in intact subjects. (6) Inhibitory or facilitative actions of other mediators may be required: exogenous administration of a single mediator in a fasting subject may not reproduce the actual physiological response.

With these criteria in mind, what is the evidence for CCK as a regulator of gastrointestinal motor and secretory responses? In humans, blood levels of CCK increase within minutes of ingesting a meal.[20] Most or all of this response seems to occur in the intestinal phase: circulating CCK concentrations are increased when individual macronutrients (fat, protein, carbohydrate) are infused into the intestine.[2] There is also evidence that bitter taste receptor agonists can induce CCK release.[15] Assuming that these effects occur by the secretion of CCK from mucosal I cells, the cellular mechanisms involved in nutrient sensing by I cells are beginning to be characterized. In all species examined, fat-induced CCK release requires luminal digestion of triglycerides into component fatty acids and monoglycerides, and only fatty acids with chain lengths of ≥12 are effective.[24] More recent findings indicate a role for specific fatty acid transporters in I cell secretion, although there may also be direct effects of fatty acids after absorption by simple diffusion.[16] Evidence suggests that intact (undigested) dietary protein and peptides and free amino acids all increase CCK secretion. Intact protein may act by serving as a luminal protector against proteolytic digestion of specific CCK releasing peptides secreted by mucosal cells and pancreas (LCRF, DBI, monitor peptide), which bind to receptors on I cells.[21] Stimulation of CCK release by peptides and amino acids is in part mediated by the Ca^{2+}-sensing receptor on I cells.[26] The cellular mechanism of the small but reproducible effect of glucose on CCK release is not known. Another releaser of CCK is gastrin releasing peptide (GRP)[18] and conversely, somatostatin[19] inhibits its release. These actions on CCK release could be a function of enteric nervous system (ENS) secreto-motor fibers acting as neurocrine modulators of I cell responses to luminal nutrients. The long held traditional view of CCK as a circulating hormonal regulator of various gastrointestinal functions was based on the assumption that on its release by mucosal I cells, CCK entered the circulation via submucosal capillaries (and subsequently traversed the liver and heart to become an arterial plasma component) and then exerted its effects on distal target cells bearing appropriate receptors. Thus, induction of a particular motor, secretory, or other event during replication of postprandial circulating levels and molecular forms of CCK by exogenous venous administration was thought to be a necessary and sufficient condition for establishing CCK as a regulator of the studied response. Although this is certainly the case, it is now clear that another mechanism—local, paracrine effects of I cell CCK on vagal sensory neurons in gut mucosa—is quite likely to mediate many of the actions of CCK. This pathway, although not yet rigorously proven to exist, seems compatible with a substantial amount of data accumulated in the past two decades showing that CCK often exerts its gastrointestinal actions via a cholinergic mediator rather than or in addition to direct effects on smooth muscle or secretory cells.

Substantial evidence supports an important role for CCK in the inhibition of gastric acid secretion and gastric emptying,[27] stimulation of gallbladder contraction,[20] and stimulation of digestive enzyme secretion by the exocrine pancreas.[1] Small exogenous doses of CCK decrease the gastric acid response to various stimuli, slow down gastric emptying, contract the gallbladder, and increase pancreatic enzyme secretion. All these actions seem to depend on a pathway involving the activation of CCK_1 receptors on afferent vagal sensory neurons. There may also be a nonneural component of CCK activation of CCK_1 receptors on gastric somatostatin cells (inhibition of gastric acid secretion), smooth muscle cells (gastric emptying and gallbladder contraction), and pancreatic acinar cells. Specific CCK_1 receptor antagonists block part or all of the effects of intestinal fatty acids on the inhibition of gastric acid and emptying and stimulation of gallbladder contraction and pancreatic enzyme secretion. There are many other actions of exogenous CCK, including the ability of CCK to decrease the amount and frequency of food intake. This action, because of its extreme importance for the occurrence and treatment of obesity, is a major focus of research.

PATHOPHYSIOLOGICAL IMPLICATIONS

Potential involvement of CCK in various diseases is suggested by the multiple alterations in gastrointestinal, metabolic, and feeding responses seen in mice and rats with genetic deficiencies in CCK production and CCK_1 receptors. It has not, however, been easy to confirm these findings in humans because of differences in physiological mechanisms, difficulties in accurately measuring CCK release, and limitations on the type and risk of experimental manipulations that can be performed.[3]

FUTURE POSSIBILITIES

CCK-58 is a potential tool for determining the mechanisms that cause pancreatitis. CCK-8 and CCK-58 both stimulate pancreatic digestive enzyme secretion, but only CCK-58 stimulates pancreatic fluid. Even large doses of CCK-58 do not cause pancreatitis, whereas CCK-8 does so in rats.[28] Therefore, defining the differences in acinar intracellular messengers stimulated by CCK-8 and CCK-58 may yield candidate mechanisms resulting in pancreatitis.

Surprisingly, 40 years after a structure of cholecystokinin was reported, there are several aspects of primary structure that require further study. These include the actual forms of CCK in brain and peripheral neurons, the presence or absence of nonsulfated peptides in tissue and blood, the relative contribution of CCK to activation of the CCK_2 receptor, new methods for studying the enteric paracrine actions, and the integrative physiological response of CCK in the intact animal, which may not be the same as in isolated cell systems.

The role of cholecystokinin in feeding needs to be reevaluated using the major endocrine form of cholecystokinin, CCK-58. Our preliminary data are tentative, but there is an indication that this larger form differs from the actions of the most studied form, CCK-8. Several studies have shown that CCK-8 reduces meal size, but its utility as a weapon in the fight against obesity has been challenged by the observation that after a smaller meal there is a concomitant reduction in the interval until the next meal. However, although the most abundant form of CCK reduces meal size, CCK-58 does not decrease the interval until the next meal and even tends to extend the interval. This suggests that endogenous CCK-58 may be effective as a tool against obesity.

Chapter 163

CGRP

S. Evangelista

ABSTRACT

Calcitonin gene-related peptide (CGRP), a 37-amino acid peptide produced by the alternative processing of calcitonin gene transcripts, is widely distributed in both the peripheral and central nervous system of mammals. In the gut, CGRP is a marker of afferent fibers in the upper gastrointestinal tract, being almost completely depleted after treatment with the selective neurotoxin capsaicin that targets these fibers via transient receptor potential vanilloid type-1. Its receptor and stable antagonists have implications for migraine. Beside this, several studies have focused on the role of CGRP at the gastrointestinal level. CGRP-containing afferent fibers of the enteric nervous system are involved in the gastrointestinal defense against irritants, intestinal nociception, modulation of gastrointestinal motility and secretion, and experimentally induced models of colitis. Restoration of gastric CGRP levels was found in animals bearing ulcers in the healing state, but its main effects on stomach homeostasis rely on local vasodilator actions during increased acid-back diffusion.

DISCOVERY AND STRUCTURE OF mRNA GENE

Calcitonin gene-related peptide (CGRP) is the first biologically active neuropeptide identified through the molecular biology approach.[28]

In the central and peripheral nervous systems, the RNA transcript from the calcitonin gene yields an mRNA, which encodes the 37-amino acid residue peptide CGRP, proved to be an important physiologic mediator.[32,33] CGRP exists in two forms as CGRP-α, which is generated by transcription and alternative splicing of the calcitonin (CT)/CGRP-α gene, and CGRP-β, which is encoded by the CGRP-β gene. The two forms differ by one and three amino acids in rats and humans, respectively. CGRP-β has been shown to have a pattern of expression that overlaps, but is nonidentical to, that of CGRP-α, with CGRP-α having a higher level of expression in most neurons of the central and peripheral nervous system.[23] One exception is the intrinsic neurons of the enteric nervous systems, which express predominantly CGRP-β mRNA.

CGRP is a member of a family of peptides that share sequence homology and have some overlapping biological activities. The members of the family include amylin (see Ingestive Peptides section of this book), adrenomedullin (see Cancer/Anticancer Peptides, Brain Peptides, Endocrine Peptides, Gastrointestinal Peptides, Cardiovascular Peptides, Renal Peptides, and Respiratory Peptides sections of this book), and CGRP (also see Brain Peptides section).

DISTRIBUTION OF mRNA/PEPTIDE AND RECEPTORS

CGRP is one of the most abundant peptides produced in both peripheral and central neurons. In the spinal cord, the function and expression of CGRP may differ depending on the location of synthesis. CGRP is derived mainly from the cell bodies of motor neurons when synthesized in the anterior horn of the spinal cord and may contribute to the regeneration of nervous tissue after injury. Conversely, CGRP is derived from posterior root ganglion when synthesized in the posterior horn of the spinal cord and may be linked to the transmission of pain. In the trigeminal vascular system, the cell bodies on the trigeminal ganglion are the main source of CGRP. CGRP is believed to play a role in cardiovascular homeostasis and nociception.[32,33]

High levels of CGRP-like immunoreactivity (LI) have been found in the rat[29] and human[31] stomach, and the absence of CGRP-LI in endocrine cells suggests that it is more important as a neurotransmitter than as a circulating hormone. Because no positive CGRP cells are found in the stomach, most gastric CGRP is of extrinsic origin and is contained and released from peripheral endings of capsaicin-sensitive afferents.[18]

The use of capsaicin, a selective neurotoxin for sensory nerves, has led to the exploration of the functional role of these neurons at the gastric level and to the hypothesis of dual "sensory-efferent" functions mediated by capsaicin-sensitive neurons.[15,18] Capsaicin affects the afferent neurons by two distinct phases: an initial excitation followed by a long-lasting refractory state during which the neurons are not responsive to the neurotoxin and other stimuli. The refractory state is usually reversible in terms of weeks, but the systemic administration of high doses of the neurotoxin causes

Copyright Elsevier 2024

permanent neurotoxicity.[15] These neurons are important to transmit sensory information toward the central nervous system and also to release their neurotransmitters toward the periphery, playing a local effector role in several regulatory processes. Recent studies have shown that capsaicin specifically targets these afferent nerves via transient receptor potential vanilloid of type-1 (TRPV-1), a nonselective cation channel with high permeability for Ca^{2+}.[18] TRPV-1 belongs to a family of store operated Ca^{2+} channels and acts as a polymodal detector of potentially harmful stimuli including capsaicin, noxious heat, H^+ ions, anandamide, and several lipoxygenase products.[18]

An example of dual "sensory-efferent" functions is seen with gastric ulcers: animals pretreated with high doses of capsaicin show an aggravation of experimentally induced ulceration because of depletion of protective neurotransmitters. On the other hand, the local application of low doses of capsaicin affords gastric protection through the release of neuropeptides (among them: substance P and CGRP) in the periphery.[7,15,16,30] CGRP is considered to be the likely mediator of sensory neurons in the stomach and their marker in the upper gastrointestinal tract.

In the enteric nervous system, CGRP-β is expressed in a subset of Dogiel type II, intrinsic primary afferent neurons that are not sensitive to capsaicin, whereas CGRP-α is the primary isoform expressed in the sensory afferent neurons of the extrinsic nervous system originating from the dorsal root and vagal ganglia (Fig. 1).

In the past, CGRP receptors have been divided into two classes, CGRP1 and CGRP2. After the cloning of calcitonin receptor-like receptor (CLR) and receptor activity-modifying proteins (RAMPs), it became clear that the CGRP1 receptor was a complex between CLR and RAMP1 (Fig. 2). It is now apparent that the CGRP2 receptor phenotype is the result of CGRP acting at receptors for amylin and adrenomedullin. Accordingly, the term "CGRP2" receptor should no longer be used, and the "CGRP1" receptor should be known as the "CGRP" receptor. The CGRP receptor consists of a seven transmembrane-spanning protein designated RAMP1 and an intracellular component protein (RCP). RAMP1 is involved in receptor trafficking and is required for CGRP binding to CLR, whereas the interaction of CLR with other RAMP proteins forms adrenomedullin receptors.[8]

The human C-terminal fragment of the peptide, $hCGRP_{8–37}$, was the first and widely used tool for determining whether the action of CGRP and that of CT is mediated via specific CGRP receptors or CT receptors. It selectively antagonizes CGRP activity, being also an agonist for CT receptor.[32] So far, two chemically unrelated CGRP antagonists, olcegepant and telcagepant, are in development as a potential treatment for acute migraine attacks. This new class of drugs is designed to block and/or reverse CGRP-mediated dilation of intracranial vessels induced by the activation of the main sensory nerves in the brain.[9]

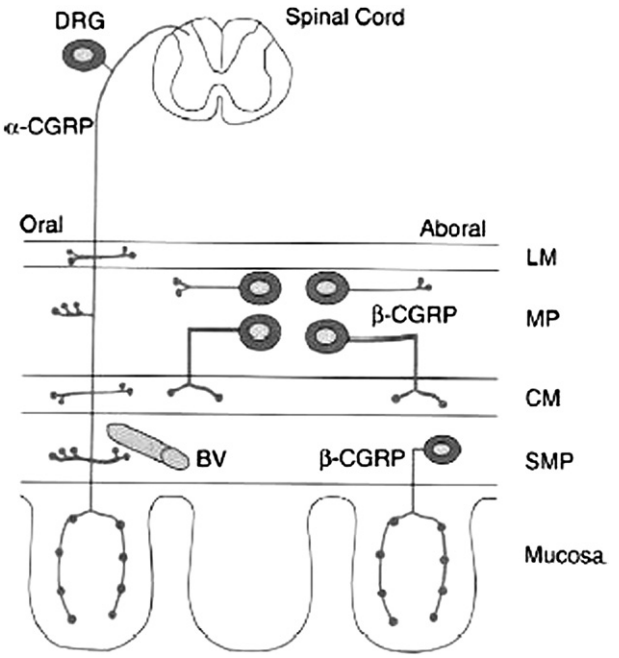

FIGURE 1 Schematic representation of the extrinsic and intrinsic CGRP-containing neurons in the rat intestine. Extrinsic spinal afferents have their cell bodies in the dorsal root ganglia and contain only α-CGRP. CGRP-containing extrinsic nerve terminals innervate the circular and longitudinal smooth muscle layers; the myenteric plexus; the submucosal plexus, where they densely innervate vascular structures; and the mucosa. CGRP-containing intrinsic enteric neurons express only β-CGRP. These neurons are localized in the submucosal and myenteric plexuses. Submucosal neurons innervate the mucosa, whereas myenteric neurons project orally and aborally, both within the myenteric plexus and to the circular muscle layer, and participate in the regulation of motility. BV, blood vessel; CM, circular smooth muscle; DRG, dorsal root ganglion; LM, longitudinal smooth muscle; MP, myenteric plexus; SMP, submucosal plexus.

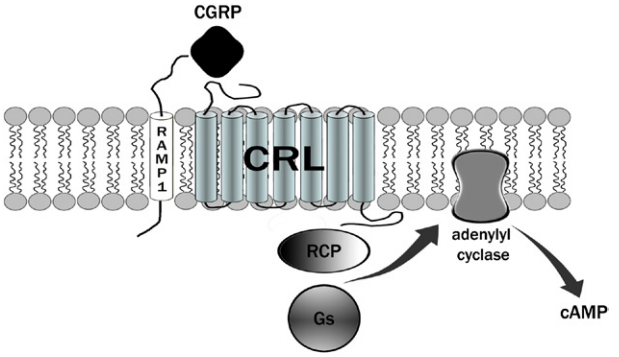

FIGURE 2 Schematic view of the CGRP receptor that consists of calcitonin receptor-like peptide (CLR), receptor activity-modifying protein 1 (RAMP1), and receptor component protein (RCP).

BIOLOGICAL ACTIONS WITHIN GASTROINTESTINAL TRACT

After its discovery, CGRP became the subject of many studies, which have been summarized in several reviews,[32,33] and among them, some have been addressed to study the

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

role of CGRP in the gut.[1,7,17,18] CGRP-containing pathways in the enteric nervous system have been shown to be involved in intestinal nociception, modulation of gastrointestinal motility, and secretion and to play a role in experimentally induced models of colitis.

Concerning the motility, two distinct effects seem to be important for CGRP action on intestinal smooth muscle: a direct relaxant effect, observed in the longitudinal and circular muscles of intestinal segments from various species and indirect effects, produced via the stimulation of neuronal receptors leading to the release of other transmitters which, in turn, affect intestinal motility.[1] Similar to other species, the human gut (especially the circular musculature) is relaxed by capsaicin, but this effect seems to be under the control of different neurotransmitter agents, nitric oxide (NO) and VIP, neither of them of intrinsic neuronal origin. The "local efferent" effect of extrinsic afferent neurons can also be demonstrated *in vivo*, in both animals and man. Yet, nearly the normal motility of the small and large intestines is maintained in animals with functionally inhibited capsaicin-sensitive nerves. CGRP is involved also in the peristaltic reflex elicited by muscle stretch and mucosal stimulation.[14] Peristaltic reflexes are subjected to the activity of several neurotransmitters: both the 5-HT_4 receptor antagonists and the CGRP antagonist $hCGRP_{8–37}$ inhibit ascending contraction and descending relaxation. Thus, the reflex in the mouse, like that in rat and human intestine, is initiated by mucosal release of 5-HT and activation of 5-HT_4 receptors on CGRP sensory neurons and is relayed via somatostatin and opioid interneurons to VIP/nitric-oxide synthase inhibitory motor neurons and via cholinergic interneurons to acetylcholine/tachykinin excitatory motor neurons. The importance of this system in regulating GI movements may be exaggerated under pathophysiological conditions, first of all inflammation. The afferent function of capsaicin-sensitive nerves plays a role in sympathetic reflexes, such as the inhibition of GI motility after laparotomy or by peritoneal irritation and diabetic gastroparesis.[1]

CGRP is a potent suppressor of basal and secretagogue-stimulated gastric acid and pepsin secretion in humans, dogs, rabbits, and rats.[7,27] Multiple mechanisms seem to be involved in the release of somatostatin from D cells,[27] where CL ands RAMP1 mRNAs has been found to be involved in the direct inhibition of gastrin- and cholinergic-dependent stimulatory effects and the stimulation of mucus and bicarbonate from gastroduodenal mucosa.[7]

For the ion and fluid intestinal transport, CGRP exhibited concentration-dependent dual actions on rat colonic epithelia acting directly on colonic enterocytes. At low concentrations (i.e. 0.03–10 nM), CGRP produces antisecretory effects that are abolished by pretreating tissues with tetrodotoxin (TTX). At higher concentrations (30–200 nM), secretory responses predominate, and these effects are not abolished by TTX.[5] In guinea-pig colon, CGRP depolarizes myenteric neurons that are synaptically coupled to submucosal neurons. Cholinergic neurons using nicotinic and muscarinic synapses for transmission of information to the epithelium are involved in inducing chloride secretion. CGRP is also present in human epithelia but it is not known as to whether the described secretory effects are of physiological relevance. During inflammation, the activation of CGRP receptors may result in effects on tight junction permeability not observed in normal tissue.[18]

It is known that the vascular system of the gastrointestinal tract is innervated by both sympathetic vasoconstrictor and parasympathetic vasodilator neurons but splanchnic blood vessels receive also a dense supply of fibers containing CGRP.[13,29] These fibers innervate blood vessels of the entire body, and their density is greater around arteries than veins. In the gastrointestinal tract, CGRP-containing nerve fibers are surrounding the mucosa and submucosa blood vessels and species differences are known concerning their presence, being scarce in human and porcine stomach.[13] CGRP exerts also a potent vasodilator and past studies have shown it as a noncholinergic and nonadrenergic transmitter able to dilate mesenteric artery after periarterial stimulation.[17] When released from extrinsic afferent nerve fibers in acid-threatened stomach, CGRP causes a NO-dependent vasodilation that has been shown to be a defensive signal in the face of pending acid injury in the gastric mucosa.[16] The vasodilator effect of CGRP has been widely studied in the upper gastrointestinal tract (see below) and is working under pathological conditions.

PATHOPHYSIOLOGICAL IMPLICATIONS

Role of GCRP in Gastrointestinal Protection

Systemic administration of $hCGRP_{8–37}$ enhances indomethacin- or ethanol-induced mucosal lesions while low dose of capsaicin and/or TRPV-1 agonists have clearly shown to exert gastroprotection via the stimulation of sensory nerves and the local release of CGRP[18] indicating that endogenous CGRP plays a trophic role on mucosal defense of the stomach. Further, gastroprotection by capsaicin was dose dependently antagonized by the CGRP antagonist, $hCGRP_{8–37}$, and by a monoclonal antibody to CGRP.[7] Recent studies using CGRP-knockout mice[24] have strongly confirmed these findings: the protective action of capsaicin against ethanol-induced lesions was completely abolished in CGRP−/− mice (Fig. 3). The authors also showed that the adaptive gastroprotection induced by previous exposure of the stomach to mild irritants was mediated by CGRP being completely absent in CGRP knockout mice.[24]

Furthermore, several studies have reported a depletion of tissue CGRP-LI during the formation of several gastric ulcers.[7] Decreased levels of gastric CGRP-LI were observed after acetic acid-, cysteamine-, concentrated ethanol-, or water-immersion stress ulcers, whereas the ulcerogens did not affect the tissue content of other peptides[7] suggesting

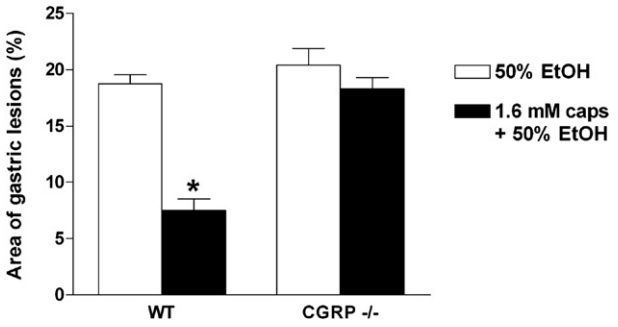

FIGURE 3 Lack of capsaicin (caps)-induced gastric mucosal protection against 50% ethanol-induced lesions in mice knockout to CGRP (CGRP–/–). Mean ± S.E values of 5–6 mice for group. *$P < 0.01$ between wild-type (WT) groups. Modified from Ref. 24.

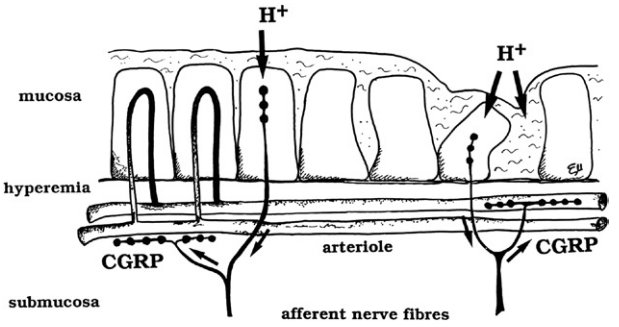

FIGURE 4 CGRP-mediated vasodilation induced by sensory fibers in the stomach. Hydrogen ions diffusing into the gastric wall of disrupted mucosal barrier may activate both mucosal and submucosal branches of afferent nerve endings to release CGRP and cause arteriolar dilation.

that reduction in gastric CGRP-LI cannot be attributed only to damage of the tissue. In humans, the TRPV-1 receptor and CGRP were detected by immunohistochemistry in patients with different gastric diseases[6,31] and TRPV-1 labeling was localized in the parietal cells of stomach from surgical specimens by means of immunohistochemistry, in situ hybridization, and Western blot analysis.[10] Furthermore, in healthy volunteers, low concentrations of capsaicin protect against gastric injuries induced by ethanol or indomethacin,[22] and a suspension of 20 g of chilli was able to protect the human gastroduodenal mucosa from the damage induced by a high dose of acetylsalicylic acid.[34]

Restoration of CGRP-LI was however observed in animals bearing ulcers during healing,[7] and intense CGRP immunostaining was observed in the ulcer margin of patients with gastric ulcers.[31] Healing of ulcer elicited by acetic acid in CGRP knockout mice was markedly delayed as compared with that of wild-type mice as well as the granulation tissue, and neovascularization at the base of these ulcers was poor in CGRP–/– animals.[24] Furthermore, in isolated rat stomachs exposed to hyperosmolar concentrations of sodium chloride, the addition of CGRP enhanced the recovery of mucosal integrity after mild but not severe damage produced by the lesioning agent.[21] These findings and the observation that there is a tonic flow of CGRP toward the peripheral endings of sensory fibers suggest that the peptide is restored in connection with the healing of ulcers after its release produced by the ulcerogen.

Concerning the known CGRP antisecretory effect[7] along with somatostatin releasing activity from gastric D cells,[27] other mechanisms have been explored to explain the CGRP protective role in the stomach. It is known that hyperemia induced by an injury is a physiological response to tissue damage and limits the extent of injury in the stomach.[16,17] Modulation of this response is an important defense mechanism, and it has been reported that CGRP released by capsaicin-sensitive fibers is involved in gastric hyperemic protective effects.[16]

Local application of low doses of capsaicin or TRPV-1 agonists able to stimulate gastric nerve endings[18,30] enhance gastric blood flow through the mucosa, dilate submucosal arterioles, and reduce concomitantly gross mucosal lesions produced by ethanol.[16,30]

Afferent nerve endings originating from dorsal root ganglia and passing through the celiac/superior mesenteric ganglion complex have been reported to modulate these effects, which are abolished by chemical ablation induced by the pretreatment with high doses of capsaicin.[16,30]

It is noteworthy that the gastric hyperemic responses to acid-back diffusion[16] or hypertonic solution[20] depend on sensory innervation of the tissue. On the other hand, it has been shown that exposure of isolated tissues of the rat stomach to low pH solution produces a selective release of CGRP.[12] Hydrogen ions diffusing into the gastric wall of disrupted mucosal barrier may promote protective vasodilation by activating the "efferent" function of capsaicin-sensitive afferent nerves (Fig. 4).

A mediator role of CGRP in this protective hyperemia induced by afferent fibers derives also from the following observations:

1. capsaicin released CGRP from isolated tissues of the rat stomach,[7,16] an effect that was abolished after disruption of capsaicin-sensitive neurons[16] or in CGRP–/– animals,[24]
2. intravascular application of capsaicin induced the release of CGRP into the vascular bed of the rat stomach followed by a marked vasodilator effect,[16,30]
3. low doses of locally applied CGRP dilated submucosal arterioles and enhanced gastric blood flow,[16,18]
4. CGRP-induced vasodilation is in keeping with the distribution of this peptide around blood vessels in the stomach[29] and the large number of vascular CGRP receptors in this region,[11]
5. gastric vasodilating response to topical application of capsaicin was blocked, at least in part, by the antagonist $hCGRP_{8–37}$.[19]

TABLE 1 Percentage Vanilloid Receptor 1 (TRPV1), Substance P, and CGRP Immunoreactive Areas in Rectal Samples from Patients Characterized by Rectal Hypersensitivity and Controls. Values are Median with a 95% Range. Modified from Ref. 3

	Rectal hypersensitivity	Control	*p*
Mucosa			
TRPV1	0.44 (0.30–0.59)	0.11 (0.00–0.21)	0.0005
Substance P	0.45 (0.29–0.85)	0.39 (0.29–0.61)	0.43
Submucosa			
TRPV1	3.50 (2.20–3.90)	0.80 (0.62–1.30)	0.002
CGRP	24.3 (14.2–42.8)	4.30 (0.10–10.0)	0.0009
Circular muscle			
TRPV1	2.30 (1.20–3.00)	0.78 (0.19–1.62)	0.002
Longitudinal muscle			
TRPV1	1.13 (0.70–2.20)	0.32 (0.14–0.80)	0.01

Taken together, these observations strongly suggest that CGRP is the probable mediator of the protective function of sensory nerves in the stomach.

Similarly, other gastrointestinal disorders involving inflammation, infection or ulceration were reported correlated to change in CGRP innervation.[18] Experimental colitis induced by trinitrobenzensulfonic acid (TNB) and inflammatory bowel diseases were associated with tissue CGRP decrease[26] and upregulation of TRPV1 in nerve fiber of the colon.[35] Silencing of CLR or the use of the CGRP antagonist increased the severity of the TNB lesions.[4,26] This is only an example of how CGRP innervation can be used as a surveillance system that along other ones (immune, endocrine, etc.) can coordinate the defense of all gastrointestinal tracts from injury.

CGRP in Gastrointestinal Motility Disorders and Visceral Sensitivity

Infection, inflammation, intestinal anaphylaxis, trauma, and stress are known to induce change in motility, and all have been reported to be associated with the activity and release of tachykinins and CGRP from extrinsic afferents. Peptides are released from central endings of afferent neurons in the spinal cord and brainstem and mediate transmission to the efferent reflex arc. Likewise, CGRP released within the gut in response to an irritant may facilitate the excitation of afferents and participate in the transmission of nociceptive traffic between afferent neurons and second-order neurons in the spinal cord and brainstem.[2] As an example, the induction of colonic inflammation by acetic acid instillation facilitates the pain reaction to rectal distension, changing the pain threshold, and this hypersensitivity can be blocked by a CGRP antagonist.[2,25] The precise site at which CGRP and also tachykinin receptors mediate colonic hyperalgesia seems to be the spinal cord because CGRP was enhanced there after colonic irritation and its antagonist is more effective if given by intrathecal than intravenous route.[2,25] Because irritation, immune challenge, and inflammation release both tachykinin and CGRP from extrinsic afferents and from intrinsic neurons inside the gut, these peptides may either increase the peripheral sensory gain of extrinsic afferents or contribute to the afferent transmission of algesic signal within the central nervous system. As extrinsic afferents of the gut do not possess receptors for CGRP, it is probable that peptide-induced sensitization or excitation of sensory neurons is an indirect consequence of peptide action on gastrointestinal effectors.[18]

It is noteworthy that rectal biopsy samples taken from patients with well-characterized rectal hypersensitivity showed a marked increase in TRPV1 in muscle, submucosal, and mucosal layers as compared with that of controls[3] (Table 1). Submucosal immunoreactive CGRP expressed in ganglion cells but not SP was increased as well (Table 1). The increase in TRPV1 significantly correlated with the decrease in heat and distension sensory threshold confirming that both afferent and intrinsic fibers take part in the change of signaling pathways of visceral hypersensitivity.

Chapter 164

Galanin

Duan Chen, Yosuke Kodama, Bård Kulseng, Helene Johannessen and Chun-Mei Zhao

ABSTRACT

Galanin, a 29- to 30-amino acid peptide, was originally discovered in the gut, and the name came from the N-terminal glycine residue and the C-terminal alanine. Galanin nerve fibers are primarily intrinsic to the enteric nervous systems. Galanin receptors, that is, GalR1, GalR2, and GalR3, are coupled to Gβγ and/or $G\alpha_i$, $G\alpha_{q/11}$, and $G\alpha_{i/o}$ signaling pathways, respectively, and located in epithelial cells, smooth muscle, and submucosal and myenteric neurons throughout the gut. Galanin stimulates intestinal chloride secretion and inhibits gastric acid secretion, the release of glucagon-like peptide 1, and the mechanosensitivity of vagal afferents. Galanin modulates the motility and sphincters (both stimulation and inhibition) by acting directly on the smooth muscle and indirectly through the release of other transmitters. The discoveries of gut galanin and its biological actions have potential implications for understanding the pathogeneses of gastrointestinal dysfunction, inflammatory bowel disease, rotavirus- or *Salmonella enterica*-induced diarrhea, esophageal squamous cell carcinoma, and colon cancer.

DISCOVERY

Carboxyamidation is a general characteristic of many biologically active peptides. A technique of fragmentation analysis to reveal the occurrence of peptides with a COOH-terminal α-amide structure in tissue extracts was developed by Kazuhiko Tatemoto and Viktor Mutt at the Department of Biochemistry, Karolinska Institute in Stockholm in 1978. With this method, galanin was discovered in porcine intestinal extract. In brief, a total of 4000 kg of porcine upper intestines was boiled in water, frozen, minced, and extracted. Galanin was determined by the amount of alanine amide released after treatment of the sample with thermolysin. Structural analysis revealed that it consisted of 29 amino acid residues with N-terminal alanine amide (Fig. 1). Thus, this peptide was called galanin because of its N- and C-terminal amino acids (glycine and alanine).[30] Although the isolation work on galanin was already completed in 1980, the structure of galanin was neither determined nor reported until this peptide was found to have effects on plasma glucose levels in dog and rat smooth muscle preparations 3 years later. This natural galanin preparation was used for biological studies until 1986 when a synthetic preparation became available by the use of the trifluoromethanesulfonic acid deprotecting procedure.[13] Galanin isolated from human large intestines consists of 30 amino acid residues that share the sequence of the N-terminal 15 residues with galanin in other mammals but exhibit characteristic differences in the remaining part of the molecules.[3] Unlike the galanin in other mammals, the human galanin is not C-terminally amidated, which is unusual for many biologically active peptides (Fig. 1).

The first galanin receptor, named GalR1, was cloned from the human Bowes melanoma cell line (as a source of mRNAs), and the transcript was identified in human small intestine and fetal brain (by Northern blot analysis) in 1994. Subsequently, subtypes 1 and 2, that is, GalR2 and GalR3, were discovered.[4,12,27] Gene knockout mice were generated by targeted disruption of the endogenous galanin, GalR1 or GalR2, but did not display marked phenotype with respect to the growth rate, relative to their littermates.[7,14,34] Galanin and its receptors have widespread distributions throughout the gastrointestinal tract as well as in the central and peripheral nervous systems of many mammal species. A book entitled "Galanin" covers a variety of the biological and pathobiological functions of galanin in the nervous systems, neuroendocrine, and skin, but little is mentioned in the gastrointestinal tract.[13]

STRUCTURE OF THE GENE AND PROCESSING OF THE PRECURSOR

The structure of the gene encoding galanin is highly conserved among vertebrates. Galanin is mapped to chromosome 19 2.0 cM for mouse, 1q42 for rat, and 11q13.3 for human (http://www.ncbi.nlm.nih.gov/gene/?term=Galanin). The galanin gene is about 6 kB of genomic DNA, depending on the species, and it consists of 6 small exons and 5 introns, which are translated into a 123-(porcine, human) or 124-(murine) amino acid precursor. This preprohormone comprises a 5′ leader sequence followed by a single galanin coding region and a 59–60 amino acid C-terminally flanking

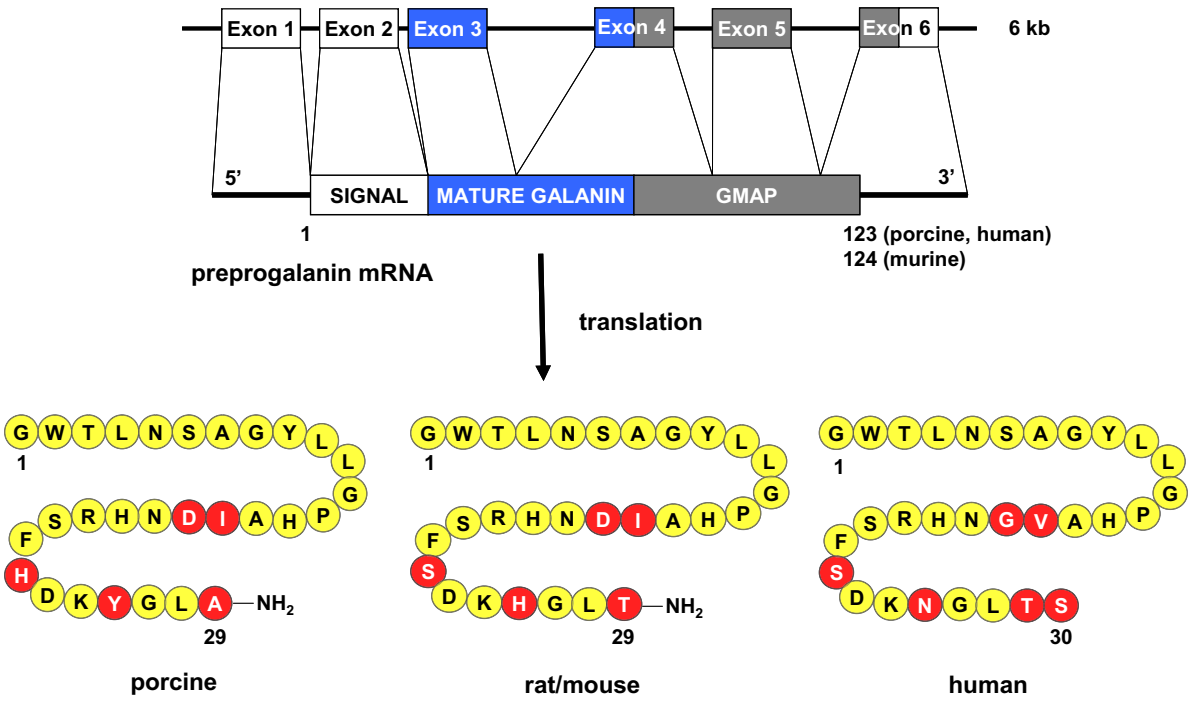

FIGURE 1 Schematic diagrams showing the predicted transcription of galanin gene and the translation of preprogalanin mRNA to produce the mature peptide galanin in porcine, rat, mouse, and human. The first exon encodes the 5′-untranslated region of preprogalanin mRNA. Exon 2 starts with a translation initiation codon of the signal peptide and terminates before the proteolytic site preceding the mature galanin peptide. The first 13 amino acids of galanin are encoded by exon 3; the remaining 16 amino acids and most of galanin message associated peptide (GMAP) by exons 4 and 5. The remaining portion of GMAP and the polyadenylation site are located in exon 6. Note: 29 amino acids with C-terminal amidation in the pig, rat, and mouse, but 30 amino acids without C-terminal amidation in humans, and red circles indicate residues that are different from human. See color plate 44.

peptide, named galanin message–associated peptide (GMAP) (Fig. 1).[13,16] By using radioimmunoassay, chromatographic separations, and tandem mass spectrometry, a series of variant forms of galanin with C-terminal amidation was purified from porcine upper intestine. The modified variants include three β-aspartyl-shifted forms, an oxidized form containing Trp monoxide, and an N-terminally truncated form.[21]

DISTRIBUTIONS OF GALANIN

After it was discovered from porcine intestine tissue extract, the identical galanin was isolated from the porcine gastric corpus tissue.[20] In mice, galanin content in terms of picomoles per gram of wet weight tissue was found in the following ranking order: ileum > duodenum > hypothalamus > stomach > cortex (measured by means of radioimmunoassay).[33] Immunohistochemical analysis has shown that galanin is localized in submucosal and myenteric neurons and in fibers projecting into the mucosa and muscle throughout the gastrointestinal tract in all mammalian species investigated, including humans (Fig. 2). Galanin fibers are primarily intrinsic to the enteric nervous systems and are quite abundant in the muscle layer. They have long descending projections with a dual termination in the myenteric ganglia and in the smooth muscle.[5]

RECEPTORS AND SIGNALING CASCADES

Galanin acts on three receptor subtypes, namely, GalR1, GalR2, and GalR3. All the three receptor subtypes are G protein-coupled receptors (GPCRs) superfamily, with a characteristic core consisting of seven-transmembrane α-helices that weave in and out of the plasma membrane. The chromosomal location of the genes encoding each receptor subtypes are shown in Table 1. A rat GalR1 homolog contains 346 amino acids and shares the same consensus sites with human GalR1 for N-linked glycosylation and intracellular phosphorylation with the exception of two additional phosphorylation sites in the human GalR1 C-terminal domain (Fig. 3A). A rat GalR2 contains 372 amino acids, including 2 consensus sites for extracellular N-linked glycosylation and several intracellular phosphorylation sites distinct from GalR1 (Fig. 3B). A rat GalR3 contains 370 amino acids with a similarity to GalR1 of 36% and to GalR2 of 55% (Fig. 3C).[4]

The mRNAs for these three receptors are expressed throughout the gastrointestinal tract. GalR1 seems to be more abundant in the large intestine than in the stomach and small intestine, GalR2 is present more in the stomach than in the intestine, whereas GalR3 is found only at a detectable level in the gut.[1] Immunohistochemistry shows that

TABLE 1 Galanin Receptor Subtypes GalR1, GalR2, and GalR3*

	GalR1	GalR2	GalR3
Name of gene	GALR1 (human) Galr1 (rat) Galr1 (mouse)	GALR2 (human) Galr2 (rat) Galr2 (mouse)	GALR3 (human) Galr3 (rat) Galr3 (mouse)
Location of chromosome	18q23 (human) 18q12.3 (rat) 18 E3-E4 (mouse)	17q25.3 (human) 10q32.3 (rat) 11 E2 (mouse)	22q13.1 (human) 7q34 (rat) 15 E1 (mouse)
Number of amino acids	349 (human) 346 (rat) 348 (mouse)	387 (human) 372 (rat) 371 (mouse)	368 (human) 370 (rat) 370 (mouse)

IUPHAR database (IUPHAR-DB): Galanin receptors: Last modified on 2008-07-21.

GalR1 is located in the enterochromaffin-like (ECL) cells in the oxyntic mucosa of stomach, the submucosal myenteric neurons, the nerve fibers distributed to the mucosa, plexuses, interconnecting strands, muscle layers, and blood vessels in the gut (Fig. 2). GalR1 immunoreactive fibers form a dense network in the deep muscular plexus in close association with interstitial cells of Cajal (ICC).[1] In the stomach of rats, GalR1 immunoreactive myenteric neurons are both ascending cholinergic/tachikinergic neurons and descending neurons containing nitric oxide or vasoactive intestinal polypeptide (VIP). In the small intestine of rat and guinea pig, GalR1 immunoreactive myenteric neurons are mainly cholinergic. Immunohistochemistry reveals that GalR2 is localized in submucosal and myenteric neurons that are mainly cholinergic in all gastrointestinal segments (Fig. 2).[1,23] There are no reports at present on GalR3 immunoreactivity in the gut, although the antibody is available.

GPCRs interact with heterotrimeric G proteins consisting of α, β, and γ subunits. The α subunits of G proteins are divided into four subfamilies: $G\alpha_s$, $G\alpha_i$, $G\alpha_q$, and $G\alpha_{12}$, and the subfamilies can be further divided into various subtypes. A single GPCR can couple to one or more families of Gα proteins. GalR1 is coupled to a Gβγ and/or $G\alpha_i$ signaling pathway to mediate mitogen-activated protein kinases (MAPK) activation.[15,16,31,32] However, GalR1 is coupled neither to $G\alpha_s$ because GalR1 stimulation does not cause an increase in cAMP accumulation, nor to $G\alpha_{io}$ because GalR1 stimulation is not dependent on protein kinase C (PKC) activity which is $G\alpha_{io}$-mediated MAPK activation. In addition, there is no coupling to $G\alpha_q$ because GalR1 stimulation does not activate inositol phosphate (IP) production.[31,32] Phosphatidylinositol 3-kinases (PI3K) are involved in Gβγ subunit-mediated extracellular-signal-regulated kinases 1 and 2 (ERK1/2) activation. However, the inhibition of PI3K

is without any effect on galanin-induced ERK1/2 activation, suggesting a $G\alpha_i$ pathway (Fig. 4A).[15] Both GalR1 and GalR2 mediate pertussis toxin-sensitive MAPK activity. GalR2-mediated MAPK activation can be abolished by the inhibition of PKC activity. Activation of GalR2 is associated with increased IP production, which was not affected by pertussis toxin, suggesting a linkage of GalR2 with $G\alpha_{q/11}$ (Fig. 4B).[31,32] GalR3 mediates the $G\alpha_{i/o}$ pathway. Activation of GalR3 receptors results in inward K^+ currents that are characteristic of $G\alpha_{i/o}$-coupled receptors (Fig. 4C).[28]

BIOLOGICAL ACTIONS WITHIN THE GASTROINTESTINAL TRACT

Regulation of Secretion

The vertebrate stomach performs a variety of functions, serving as a reservoir for food and exposing ingested food to hydrochloric acid and pepsin, which is converted by the acid from pepsinogen. Gastric acid secretion is regulated by endocrine, paracrine, and neurocrine pathways involving at least gastrin, histamine, somatostatin, acetylcholine, pituitary adenylate cyclase-activating polypeptide, gastrin-released peptide, and galanin. Gastrin stimulates histamine release from the ECL cells, which then induces the acid secretion from the parietal cells, whereas somatostatin inhibits the ECL cells and the parietal cells by acting on somatostatin receptor subtype 2 ($SSTR_2$). GalR1 is expressed on the ECL cells, and the expression is upregulated in mice that are deficient in $SSTR_2$. In addition to somatostatin, the ECL cells can be inhibited by galanin via the GalR1, leading to an inhibition of the acid secretion.[24,35]

Intestinal functions include fluid secretion and alterations of intestinal ion flux. Galanin acts on GalR1 in colonic epithelial cells to induce chloride secretion by a mechanism that is $[Ca^{2+}]_i$-dependent, pertussis toxin sensitive, but adenosine 3′,5′-cyclic monophosphate independent.[2]

Gut peptides optimize the process of digestion and nutrient absorption and also play important roles in the regulation of appetite. Galanin can suppress gastrin release evoked by the inhibition of acid secretion and glucagon-like peptide 1 release, which is induced by gastric inhibitory polypeptides.[6,11]

Modulation of Vagal Afferent Mechanosensation

Vagal, splanchnic, and pelvic nerves are three main pathways from the gastrointestinal tract into the central nervous system. Vagal afferent fibers have neuronal cell bodies in the nodose and jugular ganglia and are typically associated with sensations such as satiety and nausea. All three galanin receptors are expressed in the nodose ganglia. Galanin induces potent inhibition of mechnosensitivity of vagal afferents with respect to tension receptors and mucosal receptors, most probably through GalR1.[22] The role of galanin in the pathogenesis of gastrointestinal dysfunction, such as functional dyspepsia and gastroesophageal reflux disease needs further study.

Regulation of Motility

Gastrointestinal tract motility involves the movement of ingested food through the gut for absorbing nutrients, water, and electrolytes and eliminating waste products. The movement is accomplished by coordinating contractions and relaxations of the smooth muscles in the various parts of the gut. The regulation of gut motility is complicated, involving the enteric nervous system, ICC, hormones, paracrine substances, and inflammatory mediators. The enteric nervous system includes intrinsic neural plexuses and autonomic extrinsic neural pathways, which are of fundamental importance for generating major motor patterns and regulating the amplitudes of contractions. The smooth muscle response to external signals ultimately depends on the excitability of the ICC-smooth muscle syncytium. Galanin modulates the motility, either via direct action on the smooth muscle cells or by indirect neuromodulatory mechanisms, such as the release of other transmitters.[16] The effects of galanin on the gastrointestinal motility are both stimulatory and inhibitory, which is consistent with the projection pattern of galanin distribution (Fig. 2). However, it may also depend on the species and the gut segment examined.[16]

Regulation of Sphincters

The function of gastrointestinal sphincters is to serve as one-way valves by tonic contraction and closure to regulate and coordinate the caudal flow of gastrointestinal contents. The sphincters include both skeletal and smooth muscles located in specific sites throughout the gut. The skeletal muscle sphincters, upper esophageal sphincter, and external anal sphincter are under voluntary control. The smooth muscle sphincters are the lower esophageal sphincter, pyloric sphincter, sphincter of Oddi, ileocecal sphincter, and internal anal sphincter. These smooth muscle sphincters are autonomic organs and are controlled by complex interactions between extrinsic nerves from the central nervous system and intrinsic control by the enteric nervous system. Sphincteric relaxation in response to an appropriate reflex is mediated by intramural nonadrenergic noncholinergic (NANC) nerves with neurotransmitters, like VIP and nitric oxide. Most of the actions of galanin on basal smooth muscle sphincteric tone are explained by its actions directly on smooth muscle cells. However, some of the relaxant actions of the peptide may also result from the activation of NANC inhibitory neurons.[25] Galanin colocalizes with nitric oxide

synthase and VIP-immunoreactive neurons, suggesting the dynamic role of galanin in the regulation and modulation of sphincteric function. For example, in the lower esophageal sphincter, galanin may cause an increase in basal tone and suppression of NANC nerve-mediated relaxation. On the contrary, in the internal anal sphincter, the predominant effect of galanin is to cause smooth muscle relaxation and augmentation of NANC nerve-mediated relaxation.[25]

PATHOPHYSIOLOGICAL IMPLICATIONS

Inflammatory Bowel Disease

Inflammatory bowel disease (IBD) comprises the chronic relapsing inflammatory disorders including Crohn's disease (CD) and ulcerative colitis (UC). Crohn's disease involves any part of the gastrointestinal tract, most commonly the terminal ileum or the perianal region. Ulcerative colitis is limited to the colon. Pathogenesis of IBD involves multiple levels of interaction between the neural, immune, and endocrine systems. Neuropeptides serve as a viable link among all three systems, probably through activation of nuclear factor (NF)-κB, a transcription factor associated with the activation of proinflammatory genes and IBD pathogenesis.[8] There is a robust increased expression of GalR1 in the colonic tissues of patients with CD and UC. Activation of NF-κB induces GalR1 expression in epithelial cells lining the mouse colon. Cloning of the GalR1 gene has revealed multiple recognition sites for the inflammation associated transcription factor NF-κB. In the murine model of IBD, NF-κB activation is associated with increased GalR1 expression as well as excess colonic fluid secretion. Thus, the prominent role of galanin in intestinal fluid secretion and its connection to NF-κB, a critical participant in IBD, links the diarrhea associated with it to an NF-κB-mediated increase in GalR1 expression.[8]

Infectious Diarrhea

Enteric pathogens can alter the balance between absorption and secretion of fluid and electrolytes by the gut, leading to diarrheal disease. The pathogens can either directly modulate epithelial ion transport processes and barrier function or do so indirectly through inflammation, peptides, or loss of absorptive surface.

Rotaviruses are one of the important pathogens causing severe diarrhea in humans and many animal species, mostly the young. Rotavirus infection induces the activation of NF-κB. The NF-κB activation mediates the upregulation of GalR1.[9,17] The promoter region of the GalR1 gene has a recognition site for p50/p65 NF-κB complex.[9] Both constitutive GalR1 expression in the small intestine and rotavirus infection-induced GalR1 expression in the colon are age restricted.[10] Conceivably, the age-restricted GalR1 expression may be mediated by NF-κB signaling that in turn is easier to activate in infants. Rotavirus-infected small intestine could activate the colon remotely by inducing epithelial cells to release biological compounds that can then activate subepithelial nerves and the enteric nerve system with a specific and important role for galanin and GalR1.[10]

Salmonella enterica, including *Typhimurium*, *Enteritidis*, and *Typhi*, are also the important pathogens in causing diseases of the intestines (enteric means pertaining to the intestine). Humans infected with *S. enterica* respond differently according to age: infants develop diarrhea but not bacteremia and survive, whereas the elderly become bacteremic and die. The most common cause of food poisoning by *Salmonella* species is *Salmonella typhimurium* infection. Infection with *S. typhimurium* induces the GalR1 expression in the gut, resulting in increased colonic chloride and fluid secretion.[18] Moreover, galanin and GalR1 expression decline with aging, which is in line with the difference in response to *S. typhimurium* infection with age.[19] However, the infection-induced NF-κB activation is independent of age, probably suggesting that NF-κB activation alone may not regulate galanin and GalR1 expression.[19]

Cancer

Nerves and neuroendocrine peptides play a fundamental role in the function and growth of the normal as well as malignant gastrointestinal epithelium. The neural effects can directly take place on cancer cells or indirectly on the cancer microenvironments.

Esophageal cancers in humans include squamous cell carcinoma (SCC) and adenocarcinoma. Genetic changes that are consistently observed in the esophageal SCC include (i) alterations in tumor suppressor genes, leading to altered DNA replication and repair, cell proliferation and apoptosis; (ii) disruption of the G_1/S cell cycle checkpoint and loss of cell cycle control; and (iii) alterations in oncogene function, for example, *Ras*, leading to deregulation of cell signaling cascades. A study of esophageal SCC cell lines using array-comparative genomic hybridization revealed that the most frequently gained locus was 11q13.1-13.3 and the most commonly lost locus was 18q12.1-23 where GalR1 is mapped.[29] This suggests that GalR1 may function as a tumor suppressor gene. The growth regulation of SCC might be disrupted as a result of galanin overexpression and differential galanin receptors expression. Thus, the cell proliferation could be promoted synergistically by the downregulation of GalR1 and upregulation of galanin signaling via GalR2 or GalR3. Additionally, dysregulation of signaling proteins downstream from the individual receptors may also affect this regulation. Indeed, the activation of GalR2 induces MAPK activation, which is a well-established mitogenic pathway. Hence, the effects of galanin may be

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

regulated at the level of the receptor or by differential intracellular signaling mechanisms, and the galanin signaling cascade can be a candidate pathway regulating oncogenesis in the SCC.[29]

Galanin mRNA expression was increased in colon carcinoma tissue in patients. Galanin suppresses chemically induced carcinogenesis in colon cancer in rats. Galanin, together with the octreotide analog of somatostatin and serotonin, inhibited tumor growth in mice that were inoculated with human or rat colon carcinoma cells. The effect of galanin was speculated to be mainly through the inhibition of angiogenesis in the tumor. Whether galanin and its receptors are promising targets for diagnosis and treatment of gastrointestinal cancer needs to be further defined.[26]

Chapter 165

Gastrin

Arthur Shulkes and Graham S. Baldwin

ABSTRACT

Gastrin is synthesized in the gastric antrum as a large precursor, progastrin. After cleavage and processing, progastrin yields a variety of biologically active peptides including glycine-extended gastrin and the final end product gastrin amide. Gastrin amide acting via the cholecystokinin-2 receptor is the major regulator of meal-stimulated gastric acid secretion, and it also has important roles in epithelial cell proliferation in the gastrointestinal tract. Release of gastrin is stimulated by food, predominantly protein, and inhibited by a low gastric pH. The gastrin peptides, particularly the nonamidated forms, may also be autocrine growth factors in the development of colorectal cancers. Overexpression of gastrin as a result of a gastrin-secreting tumor (Zollinger–Ellison syndrome) results in peptic ulcers and thickening of the gastrointestinal mucosa. Gastrin is also overexpressed in some subjects with *Helicobacter pylori* infection. Gastrin immunoneutralization and radiolabeling of cholecystokinin-2 receptor ligands are currently under investigation for treatment and diagnosis of tumors expressing gastrin and/or the cholecystokinin-2 receptor.

DISCOVERY

In 1905, John Edkins provided the first evidence for a blood-borne factor that originated from the distal part of the stomach and stimulated gastric acid secretion. He named the factor gastrin and proposed that its mechanism of action was analogous to that of the pancreatic secretagogue secretin, which had been discovered in 1902 by Bayliss and Starling and shown to originate from the duodenum. However, for many years, the gastrin hypothesis was not accepted, as it was believed that the active agent in Edkin's preparations was histamine. In the 1930s, Simon Komarov, a Russian chemist working at McGill University in Montreal, isolated a gastric acid-stimulating peptide from antral mucosa, separated the peptide from histamine, and thus confirmed the existence of gastrin. The actual purification and sequencing of gastrin were performed by Rod Gregory and his assistant Hilda Tracey in the Department of Physiology at the University of Liverpool, in collaboration with the peptide chemist George Kenner. The arduous extraction of gastrin from hundreds of porcine antra culminated in the report in 1962 of the sequence of two 17 amino acid peptides (Gastrin I and Gastrin II) with Gastrin II having a sulfated tyrosine. Gastrin was the first gastrointestinal peptide to be sequenced and, with the development of a gastrin radioimmunoassay in 1967, it was soon realized that the antral mucosa contained much higher concentrations of gastrin (nanomoles per gram) than the duodenal concentration of the first discovered gastrointestinal hormone secretin (picomoles per gram).

STRUCTURE OF THE GENE/mRNA

The gastrin gene, which is located on chromosome 17 at band q21.2, comprises 3 exons and encodes an mRNA of 435 nucleotides (Fig. 1). Expression of gastrin mRNA may be regulated in response to several factors (see review by Merchant),[22] including mutational activation of either Ras or the Wnt signaling pathway, ligands of the epidermal growth factor (EGF) receptor, cytokines such as interleukin-1 acting via SMADs, or pathogenicity factors such as the *Helicobacter pylori* CagA protein. Moreover, gastrin was recently shown to increase expression of its own gene via an autocrine loop.[20]

Significant progress has been made in defining the regulatory elements that control transcription from the mouse gene *in vitro*. The Brand Laboratory in Boston pioneered work in this area with the identification of a CACC promoter element that activated transcription in rat insulinoma cells. The effects of EGF and related growth factors were later shown to be mediated by the binding of members of either of two families of zinc finger transcription factors (the Sp and ZBP-89 families) to a response element 68 base pairs upstream of the mRNA cap site (reviewed by Merchant[22]).

Less is known about control of expression of the mouse gene *in vivo* or about the corresponding elements in the human gene. The use of bacterial artificial chromosomes as vehicles for the expression of an enhanced green fluorescent protein reporter under the control of the mouse gastrin promoter, or of the human gastrin gene in gastrin-deficient mice, provides new models with which to remedy these deficiencies.

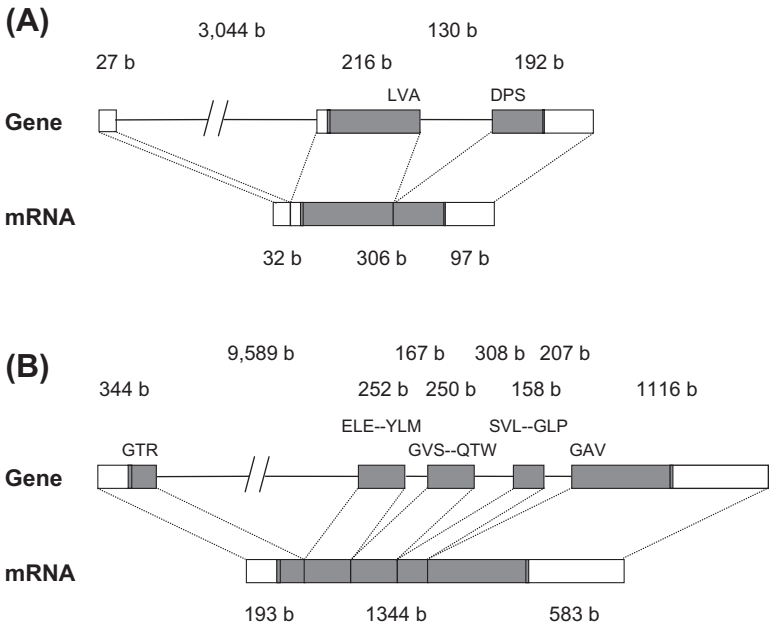

FIGURE 1 Structure of the genes and mRNAs encoding gastrin and the cholecystokinin-2 receptor. The gastrin gene (A) is located on the positive strand of chromosome 17q21.2 between bases 39,868,613 and 39,872,221. The gene contains two introns of 3,044 and 130 bases (b), of which the first occurs in the 5′ untranslated region and the second after the first base of the codon for D71. The mRNA of 435 bases encodes a protein of 101 amino acids. Amino acids at the intron–exon boundaries are shown in the one letter code. The gene encoding the cholecystokinin-2 receptor (B), which is not drawn to the same scale as the gastrin gene, is located on the positive strand of chromosome 11p15.4 between bases 6,280,966 and 6,293,356. The gene contains four introns, which interrupt the coding sequence after the first base of the codon for E51, after the first base of the codon for G135, after the second base of the codon for W218, and after the first base of the codon for G270, respectively. The mRNA of 2120 bases encodes a protein of 447 amino acids. Differential splicing generates several variants, as described in the text.

PROCESSING OF THE PRECURSOR

All forms of gastrin are generated from an 80-amino acid precursor, progastrin, which is cleaved at dibasic sequences by prohormone convertases (PCs) in the secretory vesicle (Fig. 2). Cleavage following Arg^{36}-Arg^{37} by PC1/3 generates the N-terminus of gastrin34 and cleavage following Arg^{73}-Arg^{74} by PC1/3 releases the C-terminal flanking peptide (CTFP). Subsequent removal of Arg^{73} and Arg^{74} by carboxypeptidase E yields glycine-extended gastrin34, and oxidative cleavage by peptidylglycine α-amidating monooxygenase results in C-terminally amidated gastrin34. Finally cleavage following Lys^{53}-Lys^{54} by PC2 exposes the N-terminus of gastrin17, which is then cyclized to a pyroglutamyl residue by glutaminyl cyclase.[7,26] Throughout the remainder of this review, the term gastrin(s) encompasses all progastrin-derived peptides, irrespective of length or amidation status, while gastrin34 and gastrin17 will refer solely to the naturally occurring amidated forms of the hormone, and Gamide and Ggly will refer to synthetic amidated gastrin17 and glycine-extended gastrin17, respectively. Ser^{75}, the residue immediately following Arg^{73}-Arg^{74}, may be phosphorylated *in vivo*, but this modification does not seem to alter the rate of cleavage by PC1 *in vitro*.

The characteristic amidated C-terminal sequence TrpMetAspPhe is also found in the hormone cholecystokinin (CCK), which is responsible for the stimulation of pancreatic enzyme secretion. A second similarity between the two peptides is the presence of a nearby Tyr residue, which is sulfated to varying degrees depending on age and tissue. Isolation and sequencing of both gastrin and CCK from the dogfish *Squalus acanthias*, which is a member of the Chondrichthyes or cartilaginous fishes, established that the gastrin and CCK genes diverged at least 528 ± 56 Myr ago. The evolution of the gastrin and CCK genes has been recently reviewed in detail,[3] and these peptides are also discussed in the Brain Peptides and Ingestive Peptides sections of this book.

A second characteristic of gastrins is an acidic polyGlu sequence. In human gastrins, the central three of the five consecutive glutamates are responsible for the binding of ferric ions.[2] The presence of ferric ions is essential for the biological activity of nonamidated gastrins *in vitro* and *in vivo*[9] but dispensable for amidated gastrins. Related acidic sequences are also found in marsupial gastrins and hence must have been acquired at least 173 ± 12 Myr ago.[3]

DISTRIBUTION OF THE mRNA/PEPTIDE

Progastrin is produced principally by the G cells of the gastric antrum and to a variable extent by the upper small intestine,

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

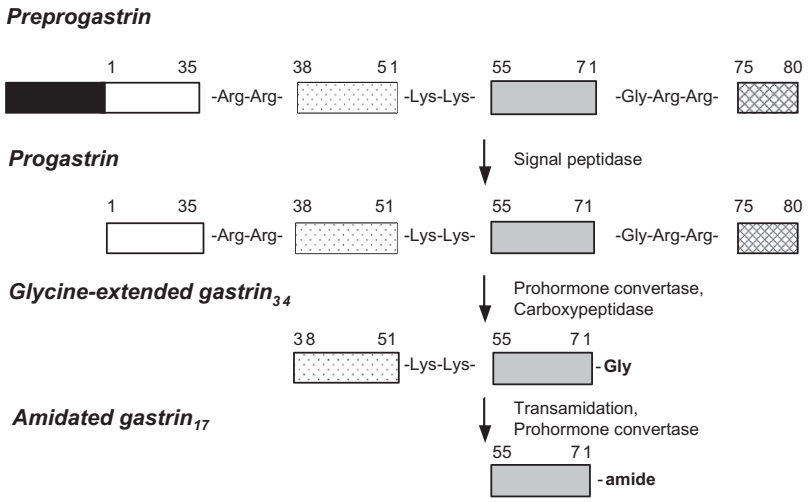

FIGURE 2 Progastrin processing. Preprogastrin (101 amino acids) is converted to progastrin (80 amino acids) by removal of its signal peptide (black box). The sequential action of prohormone convertases and carboxypeptidase E then converts the prohormone to glycine-extended forms such as glycine-extended gastrin$_{34}$ (progastrin$_{38–72}$) and glycine-extended gastrin$_{17}$ (progastrin$_{55–72}$, Ggly). Transamidation of glycine-extended gastrin$_{34}$ to amidated gastrin$_{34}$ by peptidyl α-amidating monooxygenase is followed by cleavage to amidated gastrin$_{17}$ (Gamide) by prohormone convertases, with the extent of cleavage dependent on the tissue. The amino acid sequence of Gamide is ZGPWLEEEEEAYGWMDFamide, where Z represents a pyroglutamate residue. Both nonamidated and amidated forms of gastrin are independently active via different receptors.

with much smaller amounts in the colon and pancreas. As discussed in the previous section, progastrin is processed into multiple forms with the extent of processing dependent on a number of factors, including the site of synthesis, the residence time within secretory vesicles, and the abundance of processing enzymes. In healthy humans, progastrin and the glycine-extended gastrins compose <10% of circulating gastrins. The major stored forms of amidated gastrins are tyrosine-sulfated and nonsulfated gastrin17, in about equal concentrations. Less than 10% of antral amidated gastrin is gastrin34, although the presence of gastrin34 as 50% of duodenal amidated gastrin indicates a decreased cleavage at Lys^{74}-Lys^{75}. The CTFP of progastrin is present in the antrum in at least equimolar concentrations to amidated gastrins (reviewed in Smith et al.[33]).

Human subjects with *Helicobacter pylori* infection have an increased antral concentration of amidated gastrins and decreased concentrations of the nonamidated gastrin forms (progastrin and glycine-extended gastrin). This observation is consistent with an increased conversion of gastrin precursors to amidated gastrins, the forms known to stimulate gastric acidity. By contrast, gastrinoma extracts have a much higher proportion (50–90%) of nonamidated gastrins.[26,33]

Most colorectal polyps and carcinomas synthesize progastrin. The concentrations of the gastrins are much lower than in the antrum, and there is a higher proportion of nonamidated gastrins including progastrin, Ggly, and the CTFP. The diminished processing is consistent with the tumor being the source of gastrin and the low concentrations may be a consequence of the peptides not being stored in secretory granules but secreted constitutively. The observation in a number of studies that gastrin concentrations return to normal after tumor resection confirms that the tumor is the source of the hypergastrinemia.[1] Many colorectal carcinoma (CRC) cell lines synthesize gastrins, again with a predominance of the nonamidated forms.[1]

Gastrin peptides are also found in small amounts in the ovary, pituitary, and in some neurons of the central nervous system. Importantly, gastrin mRNA and peptide are present in the fetal and neonatal pancreas and reappear in patients with Zollinger–Ellison syndrome, in which the gastrin-secreting tumors are predominantly of pancreatic origin.[26] The fact that the hypergastrinemia associated with gastrinoma and antral G cell hyperfunction has a higher proportion of nonamidated gastrins suggests that in the gastrin hypersecretory state the extent of processing is diminished.

Unlike the proportions in the antrum, the circulating concentrations of Gamide and Ggly are similar (around 25 pmol/l). Intact progastrin is present in much lower concentrations at around 1 pmol/l, while the CTFP has been reported to be the major circulating form, although this observation remains to be confirmed.[33] The clearance of gastrin34 is about fivefold slower than that of gastrin17, so although equal concentrations stimulate acid secretion to a similar extent, the effect of gastrin34 is more sustained. Between meals circulating gastrin34 is the predominant amidated form, probably as a result of preferential release of gastrin34 from the duodenum and its slower clearance from the circulation. By contrast, meal-stimulated gastrin is mainly gastrin17.[7]

RECEPTORS AND SIGNALING CASCADES

Many of the physiological effects of amidated gastrins are mediated by the cholecystokinin-2 receptor (CCK2R). The CCK2R (447 amino acids) shares 46% identity in amino acid sequence with the cholecystokinin1 receptor (CCK1R) (428 amino acids), and both are typical 7-transmembrane domain receptors. The CCK2R gene, which is located on chromosome 11 at band p15.4, comprises 5 exons, and encodes an mRNA of 2120 nucleotides (Fig. 2), whereas the CCK1R, which is located on chromosome 4 at band p15.1-15.2, comprises 5 exons, but encodes an mRNA of 1657 nucleotides.

Several splice variants of the human CCK2R have been described. An N-terminally truncated isoform lacking the first extracellular domain has been cloned from human stomach and was attributed to splicing of an alternative first exon. The alternative receptor had about 10-fold lower affinity for Gamide. Alternative splicing at the 5′ end of exon 4 resulted in a receptor with five extra amino acids in the third intracellular loop, or a receptor with 69 additional amino acids in the third intracellular loop due to the complete retention of intron 4.[14] Some controversy exists over whether the intron 4 variant is expressed in CRC and over whether or not the variant was constitutively active and stimulated cell growth. Multiple forms of the CCK2R, with various deletions in the retained intron 4 and in exon 5, have also been detected in pancreatic adenocarcinomas.

The minimum sequence requirement for high-affinity binding to both the CCK1R and the CCK2R is the amidated C-terminal tetrapeptide TrpMetAspPhe. The two receptors may be distinguished by the fact that the CCK1R binds CCK8 with 14-fold greater affinity than Gamide, whereas the difference for the CCK2R is only 2-fold (Table 1). The CCK1R also binds sulfated CCK8 with 500-fold greater affinity than unsulfated CCK8, whereas the difference for the CCK2R is only 10-fold (Table 1). The CCK2R does not bind either recombinant human progastrin or synthetic Ggly. A variety of potent and selective antagonists have been developed for both receptors (see review by Morton[23]). The Parke-Davis compound PD149168 and the Yamanouchi-Ferring compound YF476 have affinities <0.01nM and selectivity >900-fold for the CCK2R.

In contrast to the abundant structure–function information available for the CCK2R, the identities of the receptors for nonamidated gastrins such as progastrin and Ggly are still controversial. The failure of CCK1R and CCK2R antagonists to inhibit binding of ^{125}I-Ggly to the rat pancreatic cell line AR4-2J clearly differentiated the Ggly binding site from either of the known receptors. However, all attempts to clone the corresponding cDNA have so far been unsuccessful. The identification of annexin II as the progastrin receptor[32] has been disputed.[16]

The signaling pathways downstream of the CCK2R have been thoroughly investigated (reviewed by Rozengurt

TABLE 1 Comparison of Affinities of Agonists and Antagonists for the CCK1 and CCK2 Receptors

	IC_{50} for Binding (nM)		
	CCK1 Receptor	CCK2 Receptor	Company
Agonists			
Gastrin17	845	5.1	
Cholecystokinin8sulfate	0.12	0.27	
Cholecystokinin8	59	2.6	
CCK1 Receptor-Selective Antagonists			
CR 1409	7.1	>1000	Rotta

and Walsh[30] and by Dufresne et al.[8]). Like many other G protein-coupled receptors, occupation of the CCK2R by agonists activates phospholipase C, which hydrolyzes phosphatidylinositol 4,5-bisphosphate to inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol (DAG). IP_3 in turn stimulates the release of Ca^{2+} from intracellular stores, whereas DAG binds to and activates the isoforms of protein kinase C (PKC). The precise mechanisms by which the increased Ca^{2+} and activated PKC lead to an increase in mitogen-activated protein kinase (MAPK) activity, and hence to an increase in proliferation, differ between cell types.

The pathways by which CCK2R activation affects cellular apoptosis also seem to be cell-type dependent. Treatment of the mouse gastric cell line IMGE with Gamide decreases the expression of the proapoptotic protein Bax and increases the expression of the antiapoptotic protein Bcl-xl.[13] Similarly Gamide induces expression of the antiapoptotic protein mcl-1 in AGS-CCK2R human gastric carcinoma cells by a PKC- and MAPK-dependent pathway. By contrast, Gamide induces apoptosis in human CRC cell lines expressing CCK2R by a MAPK-dependent pathway.[24]

Early work indicated that CCK2R activation promoted cell migration via a signaling pathway that involved the GTPase Rho, the Rho-dependent kinase ROCK and focal adhesion kinase (FAK) (reviewed by Rozengurt and Walsh[30] and by Dufresne et al.[8]). A parallel pathway, which involves Gamide-dependent activation of the p21-activated kinase 1 (PAK1) by the GTPases Rac and Cdc42, has been reported recently.[13] The importance of the second pathway in CRC proliferation and metastasis has been clearly demonstrated by the observation in our laboratory that PAK1 knockdown suppresses xenograft growth and liver metastasis of CRC cell lines in animal models. The Rho guanine-nucleotide exchange factor p190RhoGEF, which forms a complex with FAK, has also been implicated in CCK2R-dependent CRC cell motility and invasion. That regulation of β-catenin signaling by Gamide is also dependent on PAK1[12] suggests that PAK1 may occupy a central, crucially important position in Gamide signaling.

Although nonamidated gastrins activate many of the same signaling pathways as amidated gastrins, some significant differences have been observed even in the same cell line. For example, in the mouse gastric cell line IMGE both Ggly and Gamide activate PAK1 with similar time courses.[12] By contrast, although both Ggly and Gamide rapidly activate MAPK in IMGE cells, activation by Ggly is sustained for a much longer period. The different time courses result in different biological effects, as the rapid burst of activation is essential for stimulation of proliferation, while stimulation of migration is dependent on the sustained activation. In the case of apoptosis, the same biological effect can be reached by different pathways, as in IMGE cells both Ggly and Gamide inhibit caspase 3 by activation of Rho, while Gamide can also use an alternative pathway that involves activation of Rac and/or Cdc42.[13]

BIOLOGICAL ACTIONS WITHIN THE GASTROINTESTINAL TRACT

The two major roles of gastrins are stimulation of gastric acid secretion and stimulation of cell proliferation. Recent results strongly suggest that gastrins may also be involved in iron homeostasis. These three areas, and other actions of gastrins, will be considered in turn in this section.

Gastric Acid Secretion

Gastrins are released by food, predominantly by protein. Gastrin gene expression is also increased by these luminal stimuli. Other regulators of gastrins include vagal cholinergic activation (both excitatory and inhibitory) and non-cholinergic excitation with gastrin-releasing peptide being the putative neurotransmitter.[7] Amidated gastrins acting through the CCK2R have a dual stimulatory effect on gastric acid secretion by the gastric parietal cell. The direct effect is via the CCK2R on the parietal cell, while probably the more important pathway involves stimulation by amidated gastrin of histamine synthesis (via an increase in expression of histidine decarboxylase) and of histamine release from fundic enterochromaffin-like (ECL) cells. Histamine in turn activates the parietal cell. The gastrin-acid feedback loop, whereby increased gastric acidity inhibits gastrin secretion and decreased acidity stimulates gastrin release, is central to the regulation of gastric acid secretion. Somatostatin is another important component as it inhibits both gastrin release and gastric acid secretion.[7]

Amidated gastrins are the major hormonal mediators of the gastric phase of acid secretion. Amidated gastrins also contribute to the cephalic and intestinal phases to a variable extent depending on the species, with amidated gastrins being more important in the dog than in the rat. The relative contribution of amidated gastrins to the nongastric phase in humans awaits further studies with CCK2R antagonists.

Studies with knockout mouse models (gastrin$^{-/-}$, CCK2R$^{-/-}$) and transgenic gastrin overexpressing mice have provided additional insight into the role of gastrins (see reviews by Samuelson and Hinkle[31] and by Friis-Hansen[11]). As expected gastrin$^{-/-}$ and CCK2R$^{-/-}$ mice have decreased acid secretion, decreased parietal cell number, and a reduction in functional activity of the histamine-containing ECL cells. Acute infusion of Gamide, cholinergic stimuli, or histamine have no effect, but partial restoration of acid secretion in gastrin$^{-/-}$ mice is achieved by high dose infusion of Gamide for six days. Transgenic mice overexpressing amidated gastrins initially have increased parietal and ECL cell numbers and increased gastric acid secretion, but as the mice age, gastric acid secretion decreases as a result of loss of parietal cells and gastric atrophy, which eventually results in gastric cancer.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

The precise role of nonamidated gastrins in the regulation of gastric acid secretion remains unclear. Ggly seems to contribute to the regulation of gastric acidity at least in the longer term. In gastrin$^{-/-}$ mice administered Gamide, acid secretion increases from very low levels and then gradually decreases over a period of two weeks, whereas in animals receiving Gamide plus Ggly secretion is maintained over many weeks.[4] The potentiation seems to result from a direct effect on the extent and duration of parietal cell activation. In a subsequent study, the same group showed that mice overexpressing Ggly have a normal acid secretion, whereas double transgenic mice overexpressing both Gamide and Ggly have an increased acid secretion compared with transgenic mice overexpressing only Gamide.[5] Taken together, it seems that Ggly increases gastric acidity by maintaining the integrity and activation state of the parietal cell by an unknown mechanism. This effect may be relevant to the sustained hyperchlorhydria seen in patients with either *H. pylori* infection or Zollinger–Ellison syndrome as these subjects tend to have increased ratios of nonamidated gastrins in the circulation.[1] The effect of progastrin on acid secretion has not been reported, whereas the CTFP of progastrin, which is present in high concentrations in the antra of a number of species (reviewed by Smith et al.[33]), does not alter gastric acid secretion after short term (5 min) infusions alone or together with Gamide. The CTFP stimulates histamine release but at 1% of the potency of Gamide. As noted in the previous section, the receptors mediating the effects of Ggly or other nonamidated forms of gastrin have not yet been characterized but are believed to be distinct from the CCK1R and CCK2R that interact with the amidated forms of gastrin and CCK.

Proliferation

Patients with gastrin-secreting tumors have increased thickness of the gastric mucosa and an increased number of parietal and ECL cells. These proliferative effects have been confirmed in cell lines, in transgenic animals overproducing gastrin, and in rodents administered Gamide, as well as in achlorhydric rodents and humans. The proliferative effect is dynamic with increases in gastric epithelial cell proliferation occurring in parallel with the meal-stimulated increase in gastrin secretion. The effects of gastrins are not necessarily direct but may be through a variety of intermediaries such as members of the EGF family. More recently, the nonamidated forms of gastrin including progastrin, Ggly, and the CTFP have been reported to stimulate proliferation in gastric and colorectal cell lines and in the colonic mucosa of mice overexpressing progastrin or Ggly. These mice also support more rapid growth of human CRC xenografts and are more susceptible to the carcinogenic effect of azoxymethane.[1,7,10,33]

Iron Homeostasis

The first indication of a connection between gastrins and iron homeostasis was the report that circulating gastrin concentrations are increased in mice and humans with hemochromatosis (iron overload) resulting from a mutation in the Hfe gene (reviewed in Refs 17, 18). Conversely, iron homeostasis is affected by changes in circulating gastrin concentrations, as seen in juvenile gastrin$^{-/-}$ mice in which saturation of the iron-transporting protein transferrin is reduced, while in juvenile CCK2R$^{-/-}$ mice transferrin saturation is increased.[19] In human patients with hypergastrinemia resulting from Multiple Endocrine Neoplasia Type 1, transferrin saturation positively correlates with circulating gastrin concentration.[19] When placed on a low iron diet gastrin$^{-/-}$ mice developed not only an anemia that was more severe than in their wild-type counterparts but also gross splenomegaly.[17] A possible mechanism based on the known interaction between gastrin and transferrin postulates that gastrin catalyzes the loading of transferrin with iron.[18]

Other Actions

Other actions of gastrins include stimulation of migration and invasion and inhibition of apoptosis. Gamide stimulates a large variety of genes that are involved in gastric acid secretion, proliferation, and organization of the gastrointestinal mucosa. The list includes the genes involved in the generation of parietal and ECL cells, and genes encoding somatostatin, CCK2R, cyclooxygenase-2, interleukin-8, plasminogen activator inhibitor-2, matrix metalloproteinase-7 and -9, trefoil factor 2, sonic hedgehog, transforming growth factor α, and heparin-binding epidermal growth factor.[6,26] Gamide acting via the CCK2R also increases its own expression and indeed may induce the expression of the CCK2R itself.[20] Conversely, in gastrin$^{-/-}$ mice there is a reduction in expression of the genes regulating both parietal and ECL cells. The reported increase in inflammation-related genes in gastrin$^{-/-}$ mice is believed to be the result of the bacterial growth associated with hypochlorhydria.[11]

PATHOPHYSIOLOGICAL IMPLICATIONS

Hypergastrinemia can be the result of a gastrin-secreting tumor, of reduction of gastric acidity as a result of chronic atrophic gastritis or proton pump inhibitors, of reduced clearance in subjects with diminished renal or hepatic function, of *Helicobacter pylori* infection, or of colorectal carcinoma in some patients (see reviews by Murugesan and colleagues[25] and by Rehfeld and colleagues[27]). For a diagnosis of Zollinger–Ellison syndrome, the fasting hypergastrinemia must be associated with a low gastric pH. The diagnostic challenges have been reviewed recently and include the issues of differential processing of the progastrin molecules,

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

and the use of radioimmunoassays that are specific for a single form of gastrin.[27] About a third of Zollinger–Ellison patients have a gastrinoma as part of the Multiple Endocrine Neoplasia type-1 syndrome and in these patients the gastrinoma is more probably located in the duodenum, whereas the sporadic type of gastrinoma is more often located in the pancreas.[25]

The hypergastrinemia resulting from *Helicobacter pylori* infection has two distinct mechanisms depending on the location of the infection. If *Helicobacter pylori* infection is predominantly in the antrum, somatostatin is inhibited resulting in an increase in gastrin and gastric acidity, and potentially the formation of a duodenal ulcer. However, if *Helicobacter pylori* infection is associated with chronic atrophic gastirits, the hypergastrinemia is a consequence of the hypochlorhydria.[25]

Sustained hypergastrinemia associated with the continuous administration of proton pump inhibitors to rats results in ECL cell hyperplasia within a few weeks and ECL carcinoids after 12 months. However, the human is less sensitive to chronic hypergastrinemia and even treatment with proton pump inhibitors for years results only in ECL hyperplasia rather than in carcinoids.[1]

The expansion of Barrett's esophagus and the transition to esophageal cancer seem to be related to circulating gastrin concentrations and the local expression of CCK2R. It is not clear whether the clinical advantage of reducing gastroesophageal reflux with proton pump inhibitors is outweighed by the associated increase in gastrins. Studies using specific CCK2R antagonists in patients with Barrett's esophagus have recently been proposed.[21]

Gastrin$^{-/-}$ mice have an increased rate of antral cancer as a result of hypochlorhydria, which permits bacterial growth with consequent inflammatory responses. The loss of trefoil factor (see the chapter in this section of the book) together with *Helicobacter pylori* infection are accelerating factors. Indeed, Gamide prevents the loss of trefoil factor expression and protects against gastric cancer in gastrin$^{-/-}$ mice.[34] Whether moderate hypergastrinemia is protective against the development of gastric cancer in humans is unknown.

Nonamidated gastrins have been implicated in the development and progression of CRC. There have been a number of recent reviews,[1,10] and only the key issues are presented here. Circulating concentrations of nonamidated gastrins are increased in patients with CRC, whereas in normal subjects, a circulating gastrin concentration above normal is associated with a nearly four-fold greater risk of developing CRC. Nonamidated gastrins increase the proliferation of CRC both *in vitro* and *in vivo* and potentiate the development of both chemically and genetically induced CRC. Gastrin expression occurs early in the progression from adenoma to carcinoma with most premalignant adenomatous polyps expressing gastrins, mainly as nonamidated intermediates. That this expression is maintained in CRC is consistent with the suggestion of a paracrine or autocrine role for gastrins. The gastrin gene is a downstream target of the mutated APC protein that is present early in the development of many CRC, and mice with an APC mutation and overexpression of Ggly have an increased number of intestinal polyps. The actions of both amidated and nonamidated forms of gastrin in stimulating proliferation, migration, invasion, and angiogenesis, and in inhibiting apoptosis, are consistent with a role for gastrins in the development of CRC. However in the absence of known receptors for the nonamidated gastrins, the therapeutic potential of blocking the effects of these gastrins remains limited.

The therapeutic options for gastrins include immunoneutralization and receptor antagonists. Gastrimmune is a gastrin–diphtheria conjugate, which elicits antibodies to the amino terminus of gastrin17. Some promising results have been reported in patients with advanced pancreatic and gastric cancers.[35] However, it is not clear whether the antibodies would inhibit all the bioactive forms of gastrin such as progastrin or gastrin34 (either amidated or glycine-extended). CCK2R antagonists have also been used directly for the treatment of ECL cell hyperplasia and gastric carcinoid development and, in combination with gemcitabine, for a phase I/II trial in patients with advanced pancreatic cancer. CCK2R antagonists have in the past been neglected as there are alternate therapies for the regulation of gastric acidity and because the available evidence suggested that CCK2R were not the most relevant target for CRC.[1] The recent surprising observation that the stimulatory effects of progastrin on CRC development in mice are blocked by treatment with CCK2R antagonists or in CCK2R$^{-/-}$ animals[16] suggests that this therapeutic option deserves greater attention.

Considerable effort has been expended in the development of radiopharmaceuticals based on gastrin and CCK for diagnosis and targetting of CCK2R-expressing tumors (reviewed by Roosenburg[29]). Typically chelating groups are attached to the N-terminus of CCK8 to permit radiolabeling with ^{68}Ga or ^{111}In. Further elongation of the CCK/gastrin peptide improves receptor-mediated tumor uptake but may lead to unacceptable levels of retention in the kidney. These ligands provide additional information in patients with neuroendocrine tumors with equivocal or absent somatostatin uptake.[28] As these ligands are internalized by tumor cells, there is potential for tumor therapy and localization.

Chapter 166

GIP

Nigel Irwin and Peter R. Flatt

ABSTRACT

Glucose-dependent insulinotropic polypeptide (GIP) is a 42-amino acid peptide hormone secreted from enteroendocrine K-cells. GIP is recognized as an incretin hormone that potentiates glucose-induced insulin secretion and regulates postprandial glucose homeostasis. The structure of mammalian GIP is well conserved through evolution; however, differential processing may give rise to more than one biologically active form in humans. The GIP receptor is a G protein-coupled receptor and ligand binding leads to stimulation of adenyl cyclase and activation of a number of cAMP-dependent and independent intracellular pathways. In addition to insulinotropic actions, GIP has numerous important effects outside of the pancreas. As such, GIP and GIP receptor mRNA is located throughout the body including adipose, brain, bone, cardiovascular system, and the gastrointestinal tract. Presently, there is optimism that long-acting GIP analogs may offer a new class of drugs for the treatment of diabetes, obesity, neurodegeneration, and bone disorders.

DISCOVERY

GIP is a 42-amino acid peptide hormone released from the proximal small intestine (duodenum and jejunum) in response to feeding. GIP was first isolated from impure preparations of porcine cholecystokinin (CCK; for a detailed account of CCK see the chapter in this section of the book) and shown to be a potent inhibitor of histamine-induced gastric acid secretion. Thus, it was originally named "gastric inhibitory polypeptide."[3] However, in 1973, it was demonstrated that intravenous infusion of a purified preparation of GIP in combination with glucose evoked a greater increase in insulin concentrations than the infusion of glucose alone.[5] This functional link between gut factors and the endocrine pancreas is now termed the "enteroinsular axis."[33] Furthermore, gut factors that stimulate insulin secretion in a glucose-dependent manner at physiological concentrations were later designated as "incretin" hormones.[16] The glucose-dependent nature of the insulinotropic properties of GIP was then later identified in dogs, perfused rat pancreas, and humans, confirming incretin status.[16] Recognition that this was indeed the most important biological property of GIP led to the renaming of the hormone to "glucose-dependent insulinotropic polypeptide" thereby still maintaining its original acronym GIP.[22]

The possible existence of an incretin companion for GIP arose when studies clearly revealed that GIP could not solely account for the full incretin effect in humans.[6] As such, discovery of a coding sequence for a glucagon-related peptide in Anglerfish cDNA contributed to the discovery of glucagon-like peptide-1[20] (see GLP chapters in this section and the Ingestive Peptides section of the book). The insulinotropic effect of GLP-1, as with GIP, is strictly glucose dependent and occurs at physiologically relevant levels corroborating its position as an incretin hormone. Thus, it is now widely accepted that both GIP and GLP-1 act in unison to account for the full incretin effect in humans.[16] Therefore, GIP and GLP-1 possess a unique characteristic in their ability to safeguard against inappropriate stimulation of insulin release, avoiding harmful hypoglycemic episodes and highlighting potential as possible antidiabetic therapy. This chapter will focus primarily on the biology GIP.

STRUCTURE OF THE mRNA/GENE

After purification and amino acid sequence determination of the originally isolated porcine GIP, it was initially believed to contain 43 amino acid residues.[3] However, more sophisticated sequencing techniques using characterization of cDNA clones from a genomic library indicated that an extra glutamine residue was incorporated incorrectly at position 30. This was removed, and the sequence was then corrected to contain 42 amino acid residues.[18] The sequence of bovine, rat, mouse, and numerous other species of GIP was subsequently elucidated and all shown to encode for a highly conserved 42 amino acid peptide.[15] These early studies concentrated on isolation and characterization of the mammalian GIP gene. However, the GIP gene has now been identified in chicken, frogs, and zebrafish with subtle differences between mammalian and nonmammalian species noted.[15] The variation in gene structure might suggest that the GIP gene has undergone rapid sequence modifications

early in mammalian evolution, possibly also reflecting differences in biological action of the hormone amongst species.[15] In addition, a recent study suggests that differential enzymatic processing of the proGIP hormone in mammalian gut may yield significant levels of a bioactive shorter version of GIP, GIP(1–30)amide,[21] the full biological significance of which remains to be elucidated. Furthermore, it has been suggested that GIP is expressed and secreted from pancreatic alpha cells, probably promoting insulin secretion.[21] Importantly, however, slight GIP species differences may have an impact on comparisons of studies from separate laboratories using slightly different GIP peptides or antibodies and in the biological activity of GIP within different biological systems.

The GIP hormone is derived from proteolytic processing of a 153-amino acid precursor. The gene coding for the human GIP precursor spans about 10 kilobase pairs and consists of six exons and five introns. Similar to genes encoding other members of the glucagon superfamily, each exon seems to encode a distinct region of the GIP precursor mRNA. For example, the GIP precursor, prepro-GIP is encoded for largely by exons 2 and 5, whereas the GIP(1–42) sequence is encoded by exons 3 and 4.[21] The GIP moiety is flanked on either side by polypeptide segments of 51 and 60 amino acids residues at its amino and carboxyl termini; respectively. The amino terminal flanking region can be additionally subdivided into two distinct regions; a putative signal peptide (21 amino acids) and a hydrophobic N-terminal peptide (30 amino acids) leading to the structural organization of the human GIP precursor. The human GIP gene has been assigned to chromosome 17q21.3→q22 through southern analysis of somatic cell hybrid DNAs and by in situ hybridization using a GIP cDNA.[14]

PROCESSING OF THE PRECURSOR

Processing of the proGIP encoding region occurs via trypsin-like cleavage by prohormone convertase (PC) enzymes at single arginine residues present at either side of the GIP coding sequence at positions 51 and 93. GIP and PC1/3 are colocalized in K-cells and GIP processing is severely impaired in PC1/3 deficient mice,[32] indicating the importance of this enzyme in GIP processing (Fig. 1) (see convertase 1/3 chapter in Peptide Biosynthesis/Processing section of this book). The 5′-upstream region of the human GIP gene contains potential binding sites for a number of transcriptional factors including Sp1, Ap-1 and Ap-2, suggesting regulation by protein kinases A and C.[21] Although the resulting N- and C-termini peptides do not possess biological activity, the C-terminal region of the human GIP precursor does have distinct similarities with amino acid domains within pancreastatin, known to be an inhibitor of insulin secretion in pancreatic beta cells.[31]

In addition, mammalian proGIP contains a highly conserved PC2 cleavage site between residues 52–55[21] (see convertase 2 chapter in Peptide Biosynthesis/Processing section of this book). Interestingly, there seems to be a subpopulation of K-cells that express PC2, representing about 5–15% of the total GIP-immunoreactive cells in mice.[21] This PC2 derived C-terminally truncated form of GIP, GIP(1–31), is probably converted by peptidyl-glycine α-amidating monooxygenase to amidated GIP(1–30). Furthermore, in most mammals GIP(1–42) contains a Gly^{31}-Lys^{32}-Lys^{33} sequence that may undergo cellular processing to also result in the production of GIP(1–30).[21] Therefore, as well as GIP(1–42), GIP(1–30) seems to be a naturally occurring biologically active form of GIP. In this context, GIP(1–30) shares similar insulinotropic properties to the full length molecule, and recently the biological effects of subchronic administration of enzyme-resistant analogs of GIP(1–30) and GIP(1–42) in mice was shown to be identical.[10] Thus, it is possible that biologically active circulating GIP levels have in been underestimated in many early studies owing to antibodies directed toward the C-terminus of GIP(1–42) that would therefore not detect GIP(1–30). Furthermore, GIP is known to exert effects on pancreas, brain, bone, adipose, and possibly cardiac tissue,[16,21] and the possibility of different responses to the two naturally occurring forms of GIP in each tissue necessitates further study.

DISTRIBUTION OF THE mRNA/PEPTIDE

Immunohistochemical and radioimmunoassay techniques showed that the highest concentrations of GIP were, as expected, found in the jejunum, duodenum, and ileum.[28] In the gastrointestinal tract of dogs and humans, GIP is present in cells primarily in the midduodenal region and, to a lesser extent, in the jejunum.[28] GIP may also be expressed and secreted from pancreatic alpha cells.[21] Other studies would now suggest that GLP-1 and GIP are colocalized throughout the gut in a subpopulation of cells.[24] Indeed Mortensen and colleagues (2003) identified mammalian cells in the upper small intestine that express both GIP and GLP-1 and are capable of coreleasing the two incretin hormones. In agreement with this, the secretion of GIP and GLP-1 to a mixed meal is highly correlated and both incretin hormones have additive, but not potentiating effects on insulin secretion.[25] In terms of the GIP-receptor (GIP-R), Northern blot, RT-PCR, and in situ hybridization studies have shown GIP-R mRNA to be present in the pancreas, adipose tissue, stomach, bone, intestine, pituitary, adrenal cortex, heart, lung, brain, and endothelium of major blood vessels.[34] In addition, there have been several reports of ectopically expressed GIP-Rs on adrenal glands, which are believed to be possibly involved in the onset of food-dependent Cushing's syndrome.[4]

RECEPTORS AND SIGNALING CASCADES

The human GIP-R gene is located on chromosome 19 and contains 14 exons and 12 introns with a coding region of approximately 12.5 kilobase pairs.[21] The GIP-R is a member of the secretin-vasoactive intestinal polypeptide family of G protein-coupled receptors possessing seven transmembrane domains. All mammalian GIP-Rs sequenced to date consist of 392–440 amino acid residues with the exception of the fox (*Felix catus*) whose GIP-R contains 388 residues.[21] The extensive N-terminal extracellular domain of the GIP-R contains numerous glycosylation sites that are important for ligand recognition and binding. As such, it has been demonstrated that the first 132 N-terminal amino acids of the GIP-R are important for high affinity binding and that the first 222 N-terminal residues are important for cAMP production following ligand–receptor coupling.[12] Furthermore, through the use of nuclear magnetic resonance and circular dichroism spectroscopy, the adoption by GIP of an alpha-helical secondary structure was revealed to be an intrinsic requirement for normal biological activity.[1] In addition, the crystal structure of the human GIP-R N-terminal extracellular domain bound to its ligand has also been reported.[27] This study concluded that the C-terminus of the GIP peptide binds to the surface of the extracellular GIP-R domain, with the N-terminal peptide region free to interact with other parts of the receptor. Thus, the N-terminus of GIP is important in the modulation of biological activity and control of agonist/antagonist activity, as demonstrated from numerous chimeric peptide studies.[13]

In addition, it seems the carboxy terminal tail of the GIP-R, although rich in potential phosphorylation sites, is not required for signaling although specific parts may play a role in binding affinity and downregulation of the receptor.[21] Interestingly, a number of studies suggest alternative mRNA splicing of the GIP receptor gene, resulting in GIP receptor variants.[9] For example, genomic analysis identified one exon, designated number 8a, that seems to be alternatively spliced, resulting in a variant mRNA transcript that encodes a truncated receptor with unknown functional properties.[21] Furthermore, a single point mutation of Thr^{340} to Pro^{340} in the sixth transmembrane spanning domain of the GIP-R results in the ligand-independent accumulation of cAMP without masking GIP binding or the GIP-induced cAMP response.[21] However, the biological significance and relevance to humans of these receptor mutants is largely unknown.

Although first identified as an inhibitor of gastric acid secretion, the main biological activity of GIP is associated with the glucose-induced potentiation of insulin secretion. Stimulation of the pancreatic GIP-R has been shown to stimulate adenylyl cyclase and elevate cAMP levels in a number of biological systems.[9] This correlates well with other members of the secretin-VIP family of receptors. Increased GIP-induced cAMP levels are known to increase the activity of protein kinase A (PKA) and the cAMP-specific guanine nucleotide exchange factor (GEF) II/exchange protein directly activated by cAMP (EPAC) 2.[29] The action of both these molecules results in increased insulin exocytosis from the pancreatic beta-cell. In brief, PKA phosphorylates the SUR1 subunit of the K_{ATP} channel, causing channel closure and beta-cell membrane depolarization. This in turns leads to opening of membrane voltage-dependent calcium channels, influx of calcium and exocytosis of insulin. Furthermore, PKA is known to phosphorylate important proteins involved in exocytotic beta-cell machinery.[29] In terms of GEF II activation, one of the main biological effects seems to be interaction with a secretory granule binding protein named Rab3, which is an essential part of the exocytotic system in beta-cells.[29] In addition, GIP is also believed to induce calcium-induced calcium release from intracellular stores, although the mechanism is still not fully understood.[21]

Other distinct signaling pathways for GIP have also been described. For example, GIP has been shown to be involved in the activation of mitogen-activated protein kinase (MAPK) via a wortmannin-sensitive pathway.[19] Indeed, it had been shown that wortmannin, a selective inhibitor of phosphatidylinositol 3-kinase, substantially inhibited

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

GIP-stimulated insulin secretion and that VIP and PACAP, two other members of this receptor family, also possess this wortmannin-sensitive signaling pathway.[30] In addition, GIP is thought to promote beta cell survival through cAMP maintained regulation of p38 mitogen-activated protein kinase phosphorylation in the INS-1 pancreatic beta-cell line.[8] Evidence has also emerged that there may be an involvement of phospholipase A_2 in GIP-stimulated insulin secretion mediated via cAMP-dependent and independent pathways.[7] Finally, GIP is known to activate extracellular signal-regulated kinase1/2 (ERK1/2) and has been shown to influence the activity of all known kinases of the ERK1/2 signaling system;[7] this regulation is known to occur via action of PKA and Rap1, a small GTPase.

There are also a number of factors known to control GIP secretion from K-cells of the gastrointestinal tract (Fig. 2). As such, G-protein-coupled receptors (GPRs), believed to mediate fat-induced GIP release, are located on the membrane of K-cells, in particular activation of the G_q-coupled receptors GPR40 and GPR120 augments protein kinase C and inositol (1,4,5)-trisphosphate activity resulting in enhanced secretion.[16] In agreement, genetic knockout of GPR40 in mice diminishes the stimulatory effect of fat on GIP secretion.[16] Furthermore, a small molecular agonist of the G_s-coupled receptor GPR119 was shown to elevate intracellular cyclic AMP levels and stimulate GIP secretion.[16] In addition, K-cells were recently shown to express an active variant of the sodium-coupled glucose transporter-1 (SGLT-1) and α-methyl-glucopyranoside (α-MDG), a transporter substrate, shown to evoke significant GIP secretion.[16] Thus, it is suggested that activation of SGLT-1 results in K-cell depolarization, calcium influx and subsequent secretion of GIP (Fig. 2). In keeping with this α-MDG administration to mice was associated with enhanced GIP secretion, and prolonged treatment for 13 days in *db/db* mice improved oral glucose tolerance.[16] However, the biological processes that trigger GIP secretion are as yet not fully understood.

BIOLOGICAL ACTIONS WITHIN THE GASTROINTESTINAL TRACT

As mentioned above, GIP was first identified as an enterogastrone that inhibited gastric secretions. However, the major recognized biological effects of GIP all occur outside of the gastrointestinal tract. More specifically, GIP has a fundamental role to play in various endocrine tissues including the pancreas, adipose, and bone.[16] However, GIP-Rs are present in several regions of the mammalian gastrointestinal tract, with some putative functions characterized to date. GIP is expressed in rabbit mandibular gland and has a reported inhibitory effect on sodium transport.[21] In addition, GIP can inhibit gastric emptying in rodents, but this effect is not observed in humans.[22] Interestingly, salivary GIP levels are thought to increase with fasting and swallowing in humans; however, the biological relevance of this effect is not known at present.[23] GIP also causes increased intestinal water, electrolyte, and glucose transport and potentiates acetylcholine- and CCK-stimulated pancreatic amylase secretion.[21] Effects on glucose transport seem to be mediated by GIP-induced regulation of the GLUT 2 and the sodium–glucose-transporter systems within the gut. The significance of most of the GIP-mediated effects listed above is uncertain.

Actions on the endocrine pancreas are the most pertinent biological effects of GIP. As detailed previously, GIP is insulinotropic at physiological concentrations and fulfills all the criteria of an incretin hormone.[9] The glucose threshold for GIP insulinotropic activity is about 4.4 mM, with a maximal effect observed at 16.7 mM.[9] Studies with GIP receptor antagonists demonstrate GIP to be the major physiological incretin.[9] Furthermore, genetic knockout of the GIP-R (GIP-$R^{-/-}$) in mice confirm the role of GIP in glucose homeostasis. As such, GIP-$R^{-/-}$ mice display mild glucose intolerance and reduced insulin secretory response to oral glucose.[9] However, isolated islets from GIP-$R^{-/-}$ mice respond normally to glucose, but the insulinotropic response to GLP-1 is augmented, suggesting compensatory upregulatory effects in the islets of GIP-$R^{-/-}$ rodents.[9] Interestingly, mice that have a specific and total destruction of GIP producing intestinal K-cells have remarkably reduced insulin levels in response to oral glucose.[16] Thus, it is possible that GIP producing intestinal K-cells may generate additional compounds that amplify or potentiate the insulin secretory response of incretin hormones. In addition, GIP may be involved in the secretion and action of other gastrointestinal related hormones such as GLP-1, glucagon, pancreatic polypeptide, and somatostatin.[16]

Other Emerging Biological Actions

Regarding effects on the gastrointestinal tract and endocrine pancreas, GIP now has established effects on bone, brain, and adipose tissue.[16] For instance, GIP exerts direct beneficial effects on bone turnover and health.[16] GIP-Rs have been evidenced at the surface of osteoblasts and osteoclasts and daily intravenous injection of native GIP for 6 weeks prevents bone loss in ovariectomized rats.[16] Furthermore, the GIP gene, protein and receptor have also been identified in numerous regions of the human brain.[16] GIP has been shown to induce proliferation of adult-derived hippocampal progenitor cells and potentially protects synapses from the detrimental effects of beta-amyloid accumulation.[16] In terms of adipose tissue, functional GIP-Rs were shown on adipocytes in 1998.[16] Established GIP-mediated effects on lipid metabolism include increased lipoprotein lipase activity, stimulation of lipogenesis, enhancement of fatty acid and

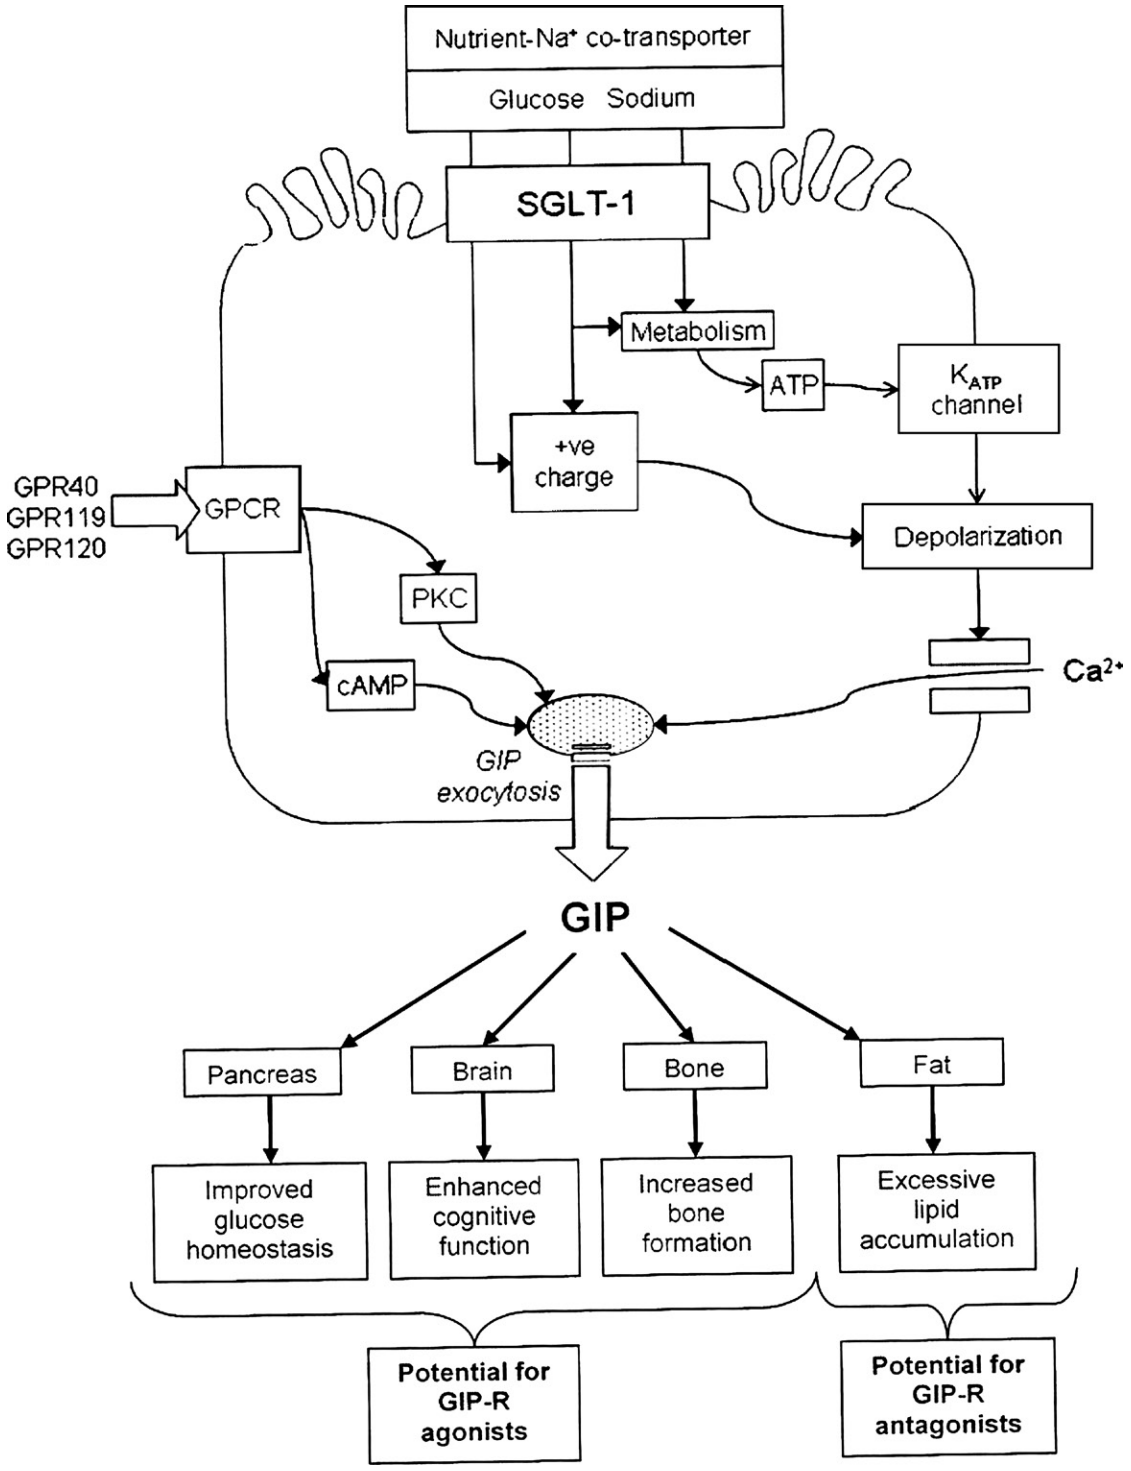

FIGURE 2 Scheme displaying the main signaling pathways involved in GIP secretion from intestinal K-cells together with major physiological functions of GIP and possible involvement in the pathophysiology of disease.

glucose uptake, augmentation of insulin-induced fatty acid incorporation, and inhibition of both glucagon- and adrenergic receptor mediated lipolysis.[16] Interestingly, recently GIP has been suggested to be involved in thermogenesis in brown adipose tissue and the metabolic adaptations to cold acclimation.[17] Putative effects of GIP on the cardiovascular system, pituitary, liver, and muscle have also been considered.[16] Taken together, GIP has several notable important biological

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

effects both within and outside the mammalian gastrointestinal tract.

PATHOPHYSIOLOGICAL IMPLICATIONS

There are a number of disease states for which GIP secretion, biological action, or receptor expression are postulated to be involved in the etiology. As discussed earlier, aberrant GIP-R expression is possibly involved in certain forms of food-dependent Cushing's syndrome.[4] However, to date, the major focus of the pathophysiological implications of GIP relate to effects in type 2 diabetes, obesity, bone disorders, and brain function. Much of the evidence for GIP effect in disease comes form preclinical testing, so direct relation to the human setting still needs to be verified. Furthermore, it is uncertain whether disturbances of GIP action are primary factors in disease etiology or secondary consequences of disease progression. Nonetheless, there is evidence for potential therapeutic use of GIP-R agonists and antagonists in a number of disease states (Fig. 2).

GIP and Diabetes

GIP, as an incretin hormone, is secreted rapidly from the gut into the bloodstream after nutrient absorption and makes an inherently important contribution to postprandial blood glucose control.[9] This incretin effect is estimated to account for up to 70% of the total insulin secreted after oral nutrient absorption in normal human subjects.[9] However, the incretin effect is markedly diminished in patients with type 2 diabetes, being less than half that observed in subjects with normal glucose tolerance.[26] Generally, the reduced incretin effect in type 2 diabetes is attributed to defective GIP action and reduced GLP-1 secretion.[16] However, in addition to effects on pancreatic beta-cells, GIP also possesses glucose-lowering extrapancreatic effects. These include inhibition of hepatic glucose production, promotion of glucose uptake in isolated muscle, increase of fatty acid synthesis, stimulation of lipoprotein lipase activity, and reduction of hepatic insulin extraction.[9] The cause of the reported GIP insulin-releasing ineffectiveness in type 2 diabetes is largely unknown but could include reduced GIP-R expression, downregulation of receptor, altered processing of GIP, defective intracellular signaling processes, or mutations of the receptor or protein.[16]

Genetic mutations of the GIP-R are rare in diabetes;[2] one Japanese study did identify two missense mutations in the GIP receptor but showed no relationship between these mutations and type 2 diabetes.[19] Furthermore, a reduced insulin secretion after intravenous glucose infusion was reported in first-degree relatives of patients with type 2 diabetes, but there was no link to decreased insulinotropic action of GIP in these patients.[22] Thus, mutations of the GIP-R as a link to development of type 2 diabetes seem unlikely. To further clarify the role of GIP and its receptor in the pathophysiology of type 2 diabetes numerous studies in rodent models have been conducted. In the hyperglycemic Vancouver diabetic fatty (VDF) rat decreased levels of pancreatic GIP-R mRNA and the GIP-R protein have been observed.[9] Furthermore, chronically elevated glucose levels are associated with downregulation of the GIP-R both *in vivo* and *in vitro*, whereas normalization of glucose levels almost completely restores GIP-R expression levels.[21] In agreement, the acutely diabetic *ob/ob* mouse on the Aston background displays severe hyperglycemia with elevated intestinal and circulating GIP levels, indicative of GIP-R downregulation.[16] However, taken in context downregulation of the GIP-R does not seem to be an inherent defect in the pathophysiology of type 2 diabetes, merely a consequence of hyperglycemia.[16] Furthermore, it is clear that the defect in insulin secretion displayed in type 2 diabetes is not limited to only GIP but it also embraces several factors including glucose and GLP-1.[16] As such, GIP-based pharmaceutics may have promise for the treatment of type 2 diabetes.

However, after release into the circulation, GIP undergoes rapid N-terminal degradation by the ubiquitous enzyme dipeptidyl peptidase IV (DPP IV).[9] DPP IV metabolism effectively eliminates the insulinotropic activity of GIP and thwarts any therapeutic potential. To circumvent this problem, a number of N-terminally modified DPP-IV resistant forms of GIP have been generated.[9,16] Furthermore, speculated abnormalities in GIP-R action can be overcome by administration of pharmacological levels of these GIP analogs in animal models of diabetes.[9,16] In addition, DPP IV inhibitors currently in use to treat human type 2 diabetic patients increase intact levels of both GLP-1 and GIP, and it is unclear to what extent the observed beneficial effects are mediated by GIP.[16] Indeed, recently, it has been shown that combined preparation of enzyme-resistant longer-acting GLP-1 and GIP peptides markedly improved glucose-lowering and insulinotropic properties in mice with type 2 diabetes when compared with either incretin mimetic given individually.[11]

The effects of amino acid modification at position Tyr^1 and Ala^2 in GIP as well as secondary modifications such as fatty acid derivatization or conjugation with polyethylene glycol (PEG) have been extensively reviewed elsewhere.[9,16] In brief, modifications at position at Tyr^1 and Ala^2 were intended to mask the DPP IV binding site of the peptide but not adversely affect biological activity. In general, Tyr^1 were more successful and exhibited complete resistance to DPP IV and enhanced bioactivity compared with the native peptide.[9] Secondary GIP modifications were anticipated to delay renal extraction of GIP by inducing plasma protein binding.[16] Surprisingly, all these secondary modified peptides

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

also displayed complete resistance to DPP IV degradation.[16] However, in a head-to-head comparison in *ob/ob* mice, the antidiabetic effectiveness of prolonged once daily injection of a primary or secondary modified GIP analog was almost identical.[16] Preclinical results to date would indicate that further investigation, either alone or in combination with established antidiabetic medications, is required to fully delineate their therapeutic promise.

GIP and Obesity

GIP levels are increased in obesity and consumption of high fat diet induces K-cell hyperplasia and increased GIP protein expression.[16] Indeed, a lipid storage action for GIP is in line with its general anabolic characteristics. There are now numerous studies linking GIP to the development of obesity resulting from chronic overconsumption of energy rich food. In keeping with this, activation of GIP-Rs on adipocytes after feeding results in efficient storage of fat.[16] Thus, when GIP-R signaling is annulled in animal models of obesity diabetes, the blockade of lipid metabolism and fat deposition encourages the use of circulating fat as the primary energy substrate. This results in decreased weight gain and improved insulin sensitivity and considerably outweighs the potential negative impact of loss of the insulin-releasing GIP component of the enteroinsular axis. Moreover, as previously stated, the insulinotropic activity of GIP is already compromised in patients with type-2 diabetes.[26] The beneficial effects of GIP-R antagonism are borne out in a number of preclinical studies using genetic knockout or chemical blockade of GIP-R signaling.[16] Thus, GIP-R$^{-/-}$ mice are resistant to high fat diet induced obesity and subchronic daily administration of the specific GIP-R antagonist, (Pro^{3})GIP, to *ob/ob* mice results in significant reduction in hyperglycemia, alleviation of insulin resistance, and restoration of glucose tolerance.[16] Other similar methodologies to inhibit GIP-R signaling such as active GIP immunization, administration of small molecular weight GIP-R antagonists, specific K-cell destruction, and dietary modification to reduce GIP secretion all result in strikingly similar metabolic effects.[16] No serious adverse effects were observed in any of the animal studies using GIP-R signaling knockdown methodologies to date.

GIP and Bone

GIP stimulates proliferation of the human osteoblastic-like cell lines, consistent with an overall anabolic effect for this hormone.[16] However, GIP-Rs have also been identified on osteoclast cells where GIP was shown to dose dependently inhibit osteoclast resorptive activity.[16] Thus, it seems that GIP may have a dual effect to increase bone formation and decrease bone resorption. In addition, GIP secreting K-cells are ideally located in the upper small intestine to efficiently coordinate the transport of ingested minerals, such as calcium and phosphate, for storage in bone. As such, the activation of GIP-Rs on bone could be extremely beneficial for the treatment of osteoporosis or other similar bone disorders. In agreement, genetic knockout of GIP-R signaling leads to decreased bone formation, increased bone resorption, and significantly lower bone mineral density.[16] Thus there is provisional optimism that longer-acting GIP-R agonists, as detailed above for potential treatment of type-2 diabetes, could also have therapeutic promise for patients with bone disorders.

GIP and Brain

The widespread expression of GIP throughout the brain would suggest an important role for this hormone in the modulation of brain function. As such, in animal models, it has been shown that GIP induces the proliferation of adult-derived hippocampal progenitor cells.[16] In keeping with this, mice that have genetic knockout of the GIP-R or overexpression of GIP peptide display characteristic detrimental and beneficial effects on cognitive function; respectively.[16] Thus, long-acting GIP-R agonists may have additional therapeutic utility for neurodegenerative diseases such as Alzheimer's. Moreover, a long-acting GIP-R agonist has already been shown to possess direct modulating effects on synaptic transmission and enhance the induction of long-term potentiation in mice, a key physiological marker of memory processes.[16] GLP-1 also appears to have similar effects in the hippocampus of animal models.[21] As with effects of GIP analogs on diabetes, obesity and bone, extrapolation of these findings to the human setting is still required.

Summary of Pathological Implications of GIP

GIP-R agonists are suggested as potential therapeutic options for type 2 diabetes, bone disorders and neurodegenerative diseases of the brain. Besides this, research now suggests that GIP-R antagonists may afford an entirely new drug class for alleviation of obesity. Thus, modulation of GIP signaling offers an array of pathophysiological targets that warrant consideration as future therapeutics. However, lack clinical data on the biological effects of GIP analogs, both agonists and antagonists, makes the effectiveness, safety, and tolerability difficult to assess at present.

From the outside it would seem that developing GIP-based drugs that can activate or block the same GIP-R for therapeutic use in disease management may seem a counterintuitive proposition. However, a complete and rational understanding of the physiological and pathophysiological roles of GIP helps explain this paradigm (Fig. 2). Thus, GIP is essentially

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

an anabolic hormone, released rapidly in response to feeding to stimulate insulin release and promote energy storage. GIP also possesses numerous insulin-like and insulin-enhancing effects in various tissue including bone and brain.[9] Under pathological conditions, such as overconsumption of energy rich diets in the Westernized World, the anabolic effect of GIP leads to adiposity, lipid deposition in tissue, and development of insulin resistance and subsequent obesity diabetes. Thus, annulment of GIP-R signaling under these circumstances promotes weight loss, improves insulin sensitivity, and counterbalances the hyperinsulinemia and beta-cell exhaust associated with obesity. Therefore, there is a clear rational for the potential use of GIP-R agonists and antagonists as therapeutic options for the treatment and management of a number of degenerative diseases (Fig. 2).

Chapter 167

Ghrelin

Theo L. Peeters

ABSTRACT

Ghrelin is the endogenous ligand for the growth hormone secretagog receptor (GHS-R), but the peptide is most abundant in the stomach, where it is produced in the endocrine cells of the oxyntic mucosa. With motilin, ghrelin forms a new gut peptide family with profound effects on gastrointestinal function. Ghrelin affects gastric acid secretion, has gastroprotective effects, modulates inflammation, and increases gastrointestinal motility by inducing the migrating motor complex and accelerates gastric emptying. These effects result from the activation of central and peripheral ghrelin receptors. Ghrelin agonists have been developed for the treatment of hypomotility syndromes (postoperative ileus, gastroparesis). Some are in phase 2 clinical trials and may soon find clinical application.

DISCOVERY

Ghrelin was discovered in 1999 by Kojima et al.,[13] as the long sought ligand of what was until then known as the Growth Hormone Secretagog receptor (GHS-R) (see his chapter in the Brain Peptides section of the book). The fascinating history of the discovery of ghrelin and of the GHS-R has been reviewed many times. In relation to the effect of ghrelin on the gastrointestinal tract, it is of interest to note that 7 months before the discovery of ghrelin, a peptide with the same sequence was described, and named motilin-related peptide (MTRLP), because the authors noted a similarity with the sequence of motilin. This similarity had escaped the attention of Kojima and collaborators. Moreover, both groups overlooked the fact that their sequence had already been submitted under the name motilin homolog as part of a patent application (for a review of these developments see Ref.[24]). Because the sequences of MTRLP and motilin homolog were derived from cDNA sequences, they did not include the octanoylation of serine 3, which is an important determinant of biological activity of ghrelin. Therefore the true discovery of ghrelin was made by Kojima et al.[13] (also see his chapter of the octanoylation enzyme in the Peptide Biosynthesis/Processing section of the book).

It is now known that the desacylated ghrelin is also secreted and may have biological activities different of those of ghrelin. In more recent literature, ghrelin is therefore sometimes denoted as "acylated ghrelin," but this is a pleonasm. This review mainly concentrates on the acylated peptide, ghrelin. Des-acyl ghrelin and obestatin, another product of the ghrelin gene, are discussed in separate chapters.

STRUCTURE OF THE GENE/mRNA/PEPTIDE

The structure of the ghrelin gene, of the mature mRNA and of the processing of the translated preproghrelin(s) into the active peptide(s) is described in the section on Brain Peptides. As in most peptides, a signal peptide is first split off to produce proghrelin, which is then cleaved by a protein convertase into the active peptide and a fragment, from which obestatin is derived (see the chapter on obestatin in this section of the book).

For every step, there is a large similarity with motilin. The overall gene structure is similar, and the active peptides are encoded by two exons with the boundary between them at a corresponding residue (no. 14). The precursors of both peptides have the same arrangement and overall a large amino acid similarity. For example, to obestatin corresponds an almost identical sequence in the so-called "motilin associated peptide."

The acylation step, usually an octanoylation, is crucial in the synthesis of ghrelin. It precedes the convertase step and the enzyme for this step is named Ghrelin O-acyltransferase (GOAT).[34] In human plasma, a considerable amount of desacylated ghrelin is present, partially secreted as such, partially the result of enzymatic breakdown of ghrelin. The possible role of desacylated ghrelin has been the subject of conflicting reports. However, there is agreement that desacylated ghrelin does not activate the ghrelin receptor so that any role attributed to desacyl ghrelin assumes the existence of another as yet unknown receptor.

The amino acid sequence of ghrelin is well conserved, especially in the N-terminal part. For example, in seven mammalian species (human, monkey, cat, dog, pig, sheep,

Handbook of Biologically Active Peptides. http://dx.doi.org/10.1016/B978-0-12-385095-9.00167-6

Copyright Elsevier 2024

and cow) the first 10 residues are identical. As already noted, the sequence of ghrelin is related to the amino acid sequence of motilin where the N-terminus is also well conserved, although to a lesser extent than in ghrelin. In the same seven species, only the first six residues are identical in motilin. However, there is a paradox here. As already mentioned, a unique and crucially important feature of ghrelin is the octanoylation of serine-3. If the octanoyl group is removed, the potency drops dramatically: >2300-fold. But if the side chains of the other well-conserved amino acids are removed, the effect on potency is quite small, and the peptide can be shortened to an N-terminal fragment of only four residues without appreciable loss of biological activity. It has therefore been suggested that the evolutionary pressure may result from the enzyme responsible for the octanoylation of serine-3 requiring a large recognition site.[29] Available results do not support this hypothesis. Indeed the fact that GOAT is inhibited by a pentapeptide suggests that the recognition site is small. It may be noted that residue number 4 (Phe) of ghrelin, which aligns with residue number 5 of motilin, is identical in all species for which sequences are available.

DISTRIBUTION OF THE mRNA/PEPTIDE

As detailed in the article describing the discovery of ghrelin, the main source of ghrelin is the stomach. This applies to the peptide as well as to the mRNA. The drop in ghrelin plasma concentrations after gastrectomy and small bowel resection suggest that approximately two-thirds of the ghrelin circulating in the plasma is derived from the stomach and the remaining one-third from the small intestine.[4] Ghrelin is expressed along the whole gastrointestinal tract with decreasing concentrations from stomach to colon.[35] The distribution of ghrelin mRNA corresponds with the distribution of GOAT mRNA, suggesting that besides its endocrine effect, locally synthesized ghrelin may have paracrine effects.[17]

RECEPTORS AND SIGNALING CASCADES

The ghrelin receptor has been discussed in the section of Brain Peptides. Here, it may be noted that the ghrelin receptor belongs to a family of receptors including motilin, GPR39, neuromedin U, and neurotensin receptors, but that the motilin and ghrelin receptors are more similar to each other than to any other GPCR. Both are also encoded within two exons, with no untranslated exons, a peculiar feature. The high homology suggests a common ancestry of both receptors consistent with both sharing some GI functions. The interesting species differences in the effects of ghrelin and motolin—most remarkable are the absence of motilin effects in rodents, and the opposite motility effect of ghrelin in dog versus man (see below)—not only suggest different functional constraints acting during evolution but also question the translational value of animal models in drug development.[26]

In the ghrelin receptor, the activation domain involves transmembrane domain 2 (TM2) and TM3, and this domain has been remarkably conserved during >400 million years of evolution. Indeed, it is already present in related receptors in the pufferfish. In particular, glutamic acid residue 124 in TM2 of the GHS-R has a critical interaction with a positively charged nitrogen of ghrelin agonists.[9] In the motilin receptor, the corresponding residue may play a similar role,[32] suggesting the possibility of crossreactivity. However, no noticeable interaction between ghrelin and motilin agonists has been observed, except a weak interaction at high concentration of the motilide EM-574 with the ghrelin receptor.[26]

A peculiar feature of the ghrelin receptor is its high level of constitutional activity. It shares this property with two other members of the ghrelin receptor family, the neurotensin receptor 2 and the orphan receptor GPR39. By contrast, the motilin receptor does not have this property, which seems to be related to an aromatic cluster in the inner face of the extracellular ends of TMs VI and VII.[12] This constitutive activity of the ghrelin receptor depends on the G(q), phospholipase C pathway,[12] although ghrelin itself activates extracellular signal-regulated kinases 1/2 through a calcium-independent novel protein kinase C isoform.[16]

BIOLOGICAL ACTIONS WITHIN GASTROINTESTINAL TRACT

Gastric Acid Secretion

Because ghrelin is present in the oxyntic mucosa, a paracrine or endocrine effect on the cells present in the gastric wall and involved in the regulation of gastric acid secretion, enterochromaffin cells, parietal cells, and gastrin (G) cells, may be considered. However, although ghrelin may increase or inhibit gastric acid secretion, as yet no evidence for any direct effects within the gastrointestinal wall has been found. Instead, ghrelin's effects are vagally or centrally mediated. Indeed, the stimulation of gastric acid secretion after intravenous ghrelin is abolished by vagotomy and the inhibitory effect seen after icv administration is abolished by cysteamine, suggesting the involvement of a central somatostinergic pathway.[24] In contrast, the vagally mediated stimulatory effect involves the release of histamine and may be synergistic with the stimulatory effect of gastrin.[33]

Gastroprotection

The first report of a role of ghrelin in gastroprotection was obtained in a model of ethanol-induced gastric ulcers

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

in rats. It was confirmed in the same model and was also found in models of stress-induced ulcers. The protective effect has been observed as well after intraperitoneal, subcutaneous, or icv administration, suggesting that the mechanism can be mediated via peripheral and central ghrelin receptors.[14,24] Ghrelin released in the stomach wall may affect neighboring cells or reach them via the bloodstream. Thus, it has been shown that ghrelin acts directly on enteric neurons to produce nitric oxide (NO) and blockade of NO synthesis blocks the protective effect. The protective effect involves prostaglandin synthesis because it is reduced by indomethacin or the selective COX-2 inhibitor rofecoxib. In agreement with these observations, ghrelin does not offer protection in indomethacin-induced ulcers. Immune cells may also be involved because ghrelin reduces the expression of the proinflammatory cytokine tumor necrosis factor (TNF)-α.[14] Exogenous ghrelin, or ghrelin produced in the stomach, may also reach the central nervous system via the bloodstream (see the chapters on ingestive peptides and the blood–brain barrier later in this book), or the ghrelin signal may be conveyed to the brain via vagal afferents. However, although there seems to be agreement that sensory denervation blocks the effect of ghrelin, vagotomy blocked the effect in one study but was without effect in another. The effect of exogenous ghrelin is blocked by a ghrelin antagonist, but the role of endogenous ghrelin has not been investigated, although it has been noted that mucosal expression of ghrelin and ghrelin plasma concentrations is increased in stress- and ethanol-induced ulcers [data reviewed in Ref. 24].

Intestinal Inflammation

The gastroprotective effects mentioned above and the potent anti-inflammatory effects of ghrelin observed *in vitro* through modulation of cytokine secretion by macrophages[30] suggest a potential beneficial effect in inflammatory bowel diseases. The increased ghrelin plasma concentrations in patients with inflammatory bowel disease and with celiac disease, and the rapid increase of plasma ghrelin in response to endotoxin injection in healthy humans,[8] may also be interpreted as endogenous reactions aimed at countering the inflammatory process. Accordingly, a beneficial effect of a bolus injection of ghrelin was reported in a mouse and rat model of TNBS colitis.[11,15] However, another study found an adverse effect after prolonged administration of ghrelin. Moreover, in the same study,[7] ghrelin KO mice were less susceptible to dextran induced colitis than were normal mice. It was suggested that the treatment schedule is at the basis of the different outcomes[7] or the use of DSS versus TNBS.[5] In view of the long-term administration planned in other therapeutic areas, this should be further investigated.

Gastrointestinal Motility

Ghrelin is structurally related to motilin, the peptide known (and named) for its almost exclusive effects on gastrointestinal motility. Ghrelin is also functionally related to motilin because the two most typical effects of motilin, induction of the migrating motor complex (MMC) and acceleration of gastric emptying have also been shown for ghrelin in humans and in rodents, but not in dogs.

In view of the potential therapeutic application, the effect on gastric emptying has received the most attention and is best documented. Several studies have shown acceleration of gastric emptying by ghrelin in humans[27] and in animal models of delayed gastric emptying [for an extensive review, see Ref. 6). However, this does not necessarily mean that ghrelin plays a physiological role in the regulation of gastric emptying. Indeed in ghrelin KO mice gastric emptying is normal[6] and in humans physiological doses of ghrelin, able to stimulate growth hormone release, have no effect of gastric emptying.[3]

As for the MMC, until the discovery of ghrelin, this phenomenon was almost exclusively studied in humans and in dogs, because in small animal models, such as rats and mice, motilin is without effect. It is now known that this is because rodents are natural KOs for motilin.[25] Ghrelin has opened new perspectives for the study of the MMC, because it has also an effect on the MMC in rats. Elegant studies using various routes of administration of ghrelin and ghrelin antagonists led to the conclusion that in rats the motor effects depend on the activation of central receptors, efferent and afferent vagal pathways.[10,23] In addition, peripheral effects may also be involved. Thus, ghrelin may activate the enteric nervous system. Indeed, studies have localized the ghrelin receptor in the myenteric plexus of guinea pig ileum and in human and rat stomach and colon. *In vitro* studies provide evidence for the activation of cholinergic pathways in rat and mouse preparations.[24]

In those species in which the MMC has been classically studied, humans and dogs, results are conflicting. In humans ghrelin induces MMCs of gastric origin and not related to the release of motilin.[6] However, in dogs, ghrelin does not induce the MMC.[22] By contrast, it has an inhibitory effect via an inhibition of the release of motilin. In physiological conditions, plasma motilin peaks are followed by ghrelin peaks, with the decline of motilin and the decline of contractile activity resulting from the inhibition of motilin by ghrelin.[20] These results offer a fascinating new insight into the regulation of fasting motor activity and require confirmation and further study.

PATHOPHYSIOLOGICAL IMPLICATIONS

The mechanisms controlling the release of ghrelin are poorly understood. The most important factor seems to

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

be the nutritional state, but it is unclear as to how fasting increases ghrelin secretion and how a meal reduces it. Blood glucose may play a role and the contact of food components with the stomach wall may as well. Because of the effect of ghrelin on appetite and adiposity, ghrelin may play a role in the development of obesity. The possible role of ghrelin in obesity is discussed in the Brain Peptides and Ingestive Peptides sections.

In gastrointestinal pathophysiology plasma ghrelin has been reported to be increased in IBD, functional dyspepsia, celiac disease, after vagotomy and after Helicobacter eradication, but decreased in gastritis, gastric ulcer, gastrectomy, small bowel resection, and gastric bypass surgery.[8] However, a causal relationship between plasma ghrelin changes and the pathological condition is lacking, except that it seems logical that damage to or removal of the ghrelin producing mucosa may lead to a reduction of ghrelin production. This is what probably happens after *Helicobacter pylori* infection when expression of ghrelin and the number of ghrelin-producing cells decreases, factors that may contribute to the development of ulcers.[24] After eradication however, one study noted a rise of plasma ghrelin, but this was not confirmed in another study based on a larger group of patients. The discrepancy may be explained by the different topography (antrum or fundus, where ghrelin cells are located) and duration of the infection (reversible damage after a short infection, irreversible atrophy after long infection) in both studies. The issue may be important because it has been suggested that eradication of *H. pylori*, via its effect on plasma ghrelin, may contribute to the development of obesity and may also increase the risk of esophageal adenocarcinoma.[19]

Because ghrelin inhibits gastric accommodation[1] a possible role of ghrelin in functional dyspepsia has been explored by measuring plasma levels of ghrelin and desacyl ghrelin in patients in comparison with controls and in relation to gastric emptying, symptom score, and psychological factors. The results, recently summarized by Ogiso et al.,[21] are conflicting and contradictory. It seems safe to conclude that ghrelin does not play a major role in the pathophysiology of functional dyspepsia.

THERAPEUTIC POTENTIAL

The stimulating effects of ghrelin on gastrointestinal motility suggest a role for ghrelin agonists in the treatment of hypomotility syndromes. This potential has been confirmed in animal models of postoperative and septic ileus,[28] and in studies with patients with diabetic or idiopathic gastroparesis.[6]

Ghrelin agonists existed already before the discovery of ghrelin and were then known as Growth Hormone Secretagogues. An extensive review of the many compounds developed since the first discovery of such compounds (in 1977!) by the group of Bowers lists not fewer than 83 drug candidates or lead compounds.[18] Some of the older compounds, such as GHRP-6 and ipamorelin, are now reevaluated as prokinetics. Ipamorelin has been shown to be effective in a model of postoperative ileus and is in phase 2 development (Helsinn Pharmaceuticals). The same company lists a further unspecified compound, ST-1141, in phase 1 development for opioid-induced bowel dysfunction (http://www.helsinn.com). The most advanced seems to be ulimorelin, formerly known as TZP-101 (http://www.tranzyme.com), a molecule specifically developed as a ghrelin agonist. Promising results were obtained in a phase 2 trial with postoperative ileus patients and phase 3 trials have been initiated. Recently ulimorelin was also shown to be useful in patients with severe gastroparesis.[31] Ulimorelin has to be administered intravenously, which limits it therapeutic applications. Its successor, TZP-102 is an orally active compound developed by the same company and granted fast track status by the FDA. Ulimorelin and TZP-102 reduce symptoms, but prokinetic effects were not reported. Their benefit may therefore derive not only from enhanced motility. Therefore, ghrelin may find application in more complex conditions such as dyspepsia.[21]

Considering the high level of constitutive activity of the ghrelin receptor, inverse agonists may also find an application. Because of this phenomenon, not just ghrelin levels but also changes in the expression of the ghrelin receptor should be studied in pathological conditions.

The therapeutic target envisaged for ghrelin antagonists is the treatment of obesity. The fact these compounds delay gastric emptying only at high doses may be asset, as dysmotility side effects are unlikely to occur.[2]

Chapter 168

GLP 1/2, Enteroglucagon, Glicentin, and Oxyntomodulin

Jens Juul Holst, Carolyn F. Deacon Bolette Hartmann and Jens Pedersen

ABSTRACT

The glucagon gene is expressed not only in the pancreas but also in endocrine cells of the gut and in neurons of the brain stem. Here, the precursor, proglucagon, gives rise to the peptides glicentin, oxyntomodulin, and glucagon-like peptides 1 and 2 (GLP-1 and 2). Although the physiological role of the former is unclear, the GLPs seem to be important hormones, GLP-1 as an incretin hormone stimulating insulin release and as an enterogastrone, inhibiting appetite and gastrointestinal secretion and motility, and GLP-2 as an intestinotropic factor regulating gut mucosal growth. GLP-1 has shown great promise as a therapeutic for type 2 diabetes, and GLP-1 agonists entered the market in 2005. Inhibitors of the GLP-1-degrading enzyme, dipeptidyl peptidase-4, which increase the levels of endogenous GLP-1, are also available for diabetes therapy. GLP-2 is currently being investigated for treatment of intestinal failure (approved for short bowel syndrome in 2012), whereas oxyntomodulin seems to have appetite-reducing effects.

DISCOVERY, STRUCTURE OF THE GENE, AND PROCESSING OF THE PRECURSOR

It has been known for a long time that the gastrointestinal mucosa contains endocrine cells producing substances with glucagon-like immunoreactivity. The immunoreactivity turned out to result from two peptides containing the entire glucagon sequence of 29 amino acids. One, glicentin, consists of 69 amino acids of which residues no. 33–61 constitutes the glucagon sequence. The other, oxyntomodulin, is a fragment of glicentin, corresponding to amino acids no. 33–69, that is, glucagon + 8 additional amino acids at the C-terminus. Collectively, the two molecules were designated "enteroglucagon" or gut GLI. It was hypothesized that glicentin was part of proglucagon and in agreement with this, the N-terminal fragment corresponding to residues no 1–30 of glicentin, glicentin-related pancreatic polypeptide (GRPP), is secreted in parallel with glucagon. Proglucagon cDNA was first cloned from anglerfish islets and encoded a glucagon-containing glicentin-like peptide plus an additional glucagon-like peptide showing strong sequence homology with (anglerfish) glucagon. On cloning of the mammalian and human proglucagon genes, it was clear that they encode yet another glucagon-like sequence, glucagon-like peptide 2.[1] Further studies revealed that (1) only a single gene encodes proglucagon; (2) identical mRNAs are formed in mammalian species; (3) the gene is expressed in the gut, the pancreas and in the brain; (4) the single, identical precursor, proglucagon, is processed differentially in the different tissues so that different products are secreted from the different organs.[24] Thus, in the pancreas, proglucagon (PG), consisting of 160 amino acids, is cleaved to produce GRPP (PG 1–30), glucagon (PG 33–61) and "Major ProGlucagon Fragment" corresponding to PG 72–158. The three molecules are secreted in parallel and in equimolar amounts.[12] In the gut, the products are glicentin (PG 1–69, part of which is cleaved further to produce GRPP (PG 1–30) and oxyntomodulin (PG 33–69)) and each of the two glucagon-like peptides plus the so-called intervening peptide 2 (corresponding to PG 111–123). Human GLP-1 and 2 correspond to PG 78–107 amide (residue no 108 being lost in the amidation step) and PG 126–158, respectively.[11] In rodents, about half of the GLP-1 appears in the Gly-extended form, GLP-1 7–37. In pigs where proglucagon does not terminate in basic amino acid residues, the fully processed GLP-2 molecule corresponds to PG 126–160. Human GLP-2 corresponds to PG 126–158.[9] Gut processing is catalyzed by the prohormone convertase PC-1/3 (but PC2 in the pancreas) (see the chapters on these enzymes in the Peptide Biosynthesis/Processing section of the book). The fully processed form, now designated GLP-1 (7–36) amide or simply GLP-1, was isolated on the basis of its potent insulinotropic activity.[14] The processing pattern in the brain stem resembles that of the gut. Mutations in PC-1/3 lead to abnormalities in GLP-1 processing and secretion, associated with multiple endocrinopathies (undoubtedly because PC-1/3 is important for processing of many regulatory peptides/hormones), and mice with a

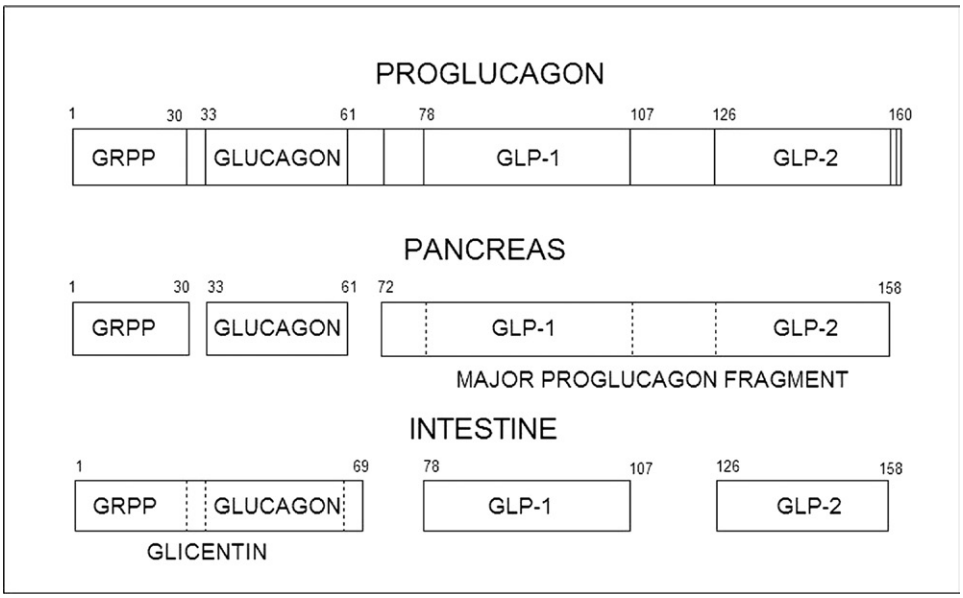

FIGURE 1 Proglucagon processing. Schematic representation of the differential processing of proglucagon as it occurs in the pancreatic islets and in the intestinal mucosa in man. The vertical lines in proglucagon (PG) indicate the positions of the cleavage sites (basic amino acids). GRPP, glicentin-related pancreatic peptide; IP-1, intervening peptide 1; IP-2, intervening peptide 2. Note that in the pancreas, the main products are glucagon itself and GRPP (inactive) and major proglucagon fragment (inactive). Small amounts of N-terminally extended GLP-1 (inactive) may also be formed. In the gut, the main products are glicentin, in which the glucagon sequence is buried (whereby glucagon-like bioactivity is lost); smaller amounts of oxyntomodulin and the same inactive N-terminal fragment as in the pancreas; GLP-1, the majority of which is amidated, whereas the rest is extended by one glycine residue; and GLP-2, which functions as a growth factor for the gut. Thus, although the precursor is the same, the differential processing gives rise to three biologically active, but completely different products in the two tissues, whereas terminal extensions inactivate the "other" active products.

targeted deletion of the PC-1/3 gene are unable to process proglucagon to GLP-2 and GLP-1. The processing is shown diagrammatically in Fig. 1.

EXPRESSION OF THE GENE/DISTRIBUTION OF THE GENE/SECRETION

Regulation of Gene Expression

At least 6 homeodomain proteins are able to interact with the glucagon gene promoter and activate its expression.[16] Thus, the transcription factor, pax6, is expressed in intestinal endocrine cells and activates proglucagon transcription. Mice with a dominant negative pax6 mutation exhibit a total absence of gut endocrine cells expressing GLP-1 or GLP-2. Disruption of the pax6 gene disrupts both islet development and selectively eliminates the endocrine cell population of the small and large bowel, including the proglucagon-producing cells. Beta-catenin, the major effector of the Wnt signaling pathway, activates proglucagon expression in intestinal cells, mediated by the transcription factor TCF-4 (now TCF7L2). Both TCF7L2 and beta-catenin bind to the proglucagon gene promoter, and a dominant negative TCF7L2 repressed proglucagon expression in an intestinal cell line that expresses proglucagon and produces GLP-1. Approximately 1250 nucleotides of the rat proglucagon gene promoter direct the expression to pancreatic islets and neurons of the brain, whereas additional upstream sequences extending to −2,250 are required for the expression of the gene in intestinal endocrine cells. However, the mechanisms regulating tissue-specific proglucagon gene expression in humans seem to differ from those described for the murine gene, and unfortunately, little is known about the regulation of the human gene. A more recent study identified conserved sequences within intron 1 of the human proglucagon gene as being important for the pancreatic expression.

The TCF7L2 mediated regulation of proglucagon expression in the gut is of considerable interest in view of the recent demonstration of a genetic association of a specific single nucleotide polymorphism (SNP), the microsatellite DG10S478 in the intron 3 of the TCF7L2 gene, and the development of type 2 diabetes. This raises the possibility that this SNP influences disease susceptibility through modulation of intestinal proglucagon gene expression and hence possibly plasma concentrations of GLP-1. However, GLP-1 levels seem to be unaffected in the high-risk group, whereas the insulinotropic actions of the incretin hormones are impaired, supporting a role of TCF7L2 for beta cell function.[28] Indeed, decreased incretin receptor levels correlate with beta cell TCF7L2 expression in diabetic models.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

The proglucagon gene in the gut is expressed in the endocrine alpha cells of the pancreatic islets and in the so-called L-cells, open-type endocrine cells of the gastrointestinal mucosa.[4] In some species (dogs, cats, and rats), there are A-like cells in the gastric mucosa, which may produce fully processed glucagon (and this probably explains the finding of glucagon-like bioactivity in stomach extracts in 1948), but such cells are rare in humans (and pigs and rats). In humans, the L-cells are lacking in the duodenum but appear with increasing frequency from the proximal jejunum toward the ileum. A large number of L-cells are also found in the colon, particularly in the cecum and the rectum. Their function in the colon is unknown. The distal L-cells also produce peptide YY, whereas the proximal GLP-1-producing cells also produce glucose-dependent insulinotropic polypeptide (GIP).[21] Most recently, Gribble and Reiman (Minkowsky lecture, EASD 2010) succeeded in isolating primary GLP-1-producing cells from mice expressing a fluorophore under the control of the proglucagon promoter.[26] Their studies clearly show coexpression and even differential coexpression of several bioactive peptides, including neurotensin, somatostatin, and cholecystokin, in the proglucagon-expressing cells. A study using diphtheria toxin-induced knockdown of cells with high expression levels of the glucagon promoter, similarly showed dramatic reductions in the expression of neurotensin, CCK, and PYY in the ileal mucosa, whereas only the expression of CCK and neurotensin are reduced in the proximal jejunum. Therefore, the endocrine cells of the intestinal mucosa show great plasticity and are capable of changing the expression pattern. Local factors may be important, and perhaps maturation and migration along the villous axis. Clearly, speaking of specific cell types, as for instance the L-cells, is no longer tenable.

Secretion

The L-cells have microvilli protruding into the intestinal lumen, and because they secrete on luminal nutrient stimulation, it is assumed that molecules in the villous membranes react to these and activate the secretory machinery.[11] Thus, in an L-cell-like cell line, glucose may activate GLP-1 secretion both in a K_{ATP}-channel-dependent manner by enhancing glucose metabolism but also after intracellular transfer via the sodium dependent glucose transporter-1 (SGLT-1). Thus, a large part of the GLP-1 response to glucose (and therefore most carbohydrates) can be blocked by the inhibitors of SGLT-1. Fructose also stimulates GLP-1 secretion, consistent with the finding that L-cells also express GLUT-5, the fructose transporter. Research using primary proglucagon-expressing cells has confirmed these results.[26] Natural L-cells are now known to express several G protein-coupled receptors that have been associated with lipid ligands including GPR 119, 120, and 131 (aka TRG5, activated by bile acids), and activation of these is associated with GLP-1 secretion both *in vitro* and *in vivo*.[26] The GPR 119 receptor can be activated by 2-monoacylglycerols, which are formed in huge quantities in the gut during normal digestion, both *in vitro* and *in vivo* in humans; this mechanism may explain a large part of the stimulatory actions of ingested lipids on GLP-1 secretion.[7] Although direct studies of L-cell products other than GLP-1 are lacking, it may be assumed that similar patterns of secretion are seen for oxyntomodulin and GLP-2. Thus a picture is emerging where these cells react to luminal factors mainly by the activation of membrane proteins, which then trigger intracellular signaling mechanisms eventually leading to exocysis of processed proglucagon products.

Because of the presence of L-cells in the upper jejunum, secretion is increased rapidly (within 10–15 min on meal ingestion) and, in agreement with the increasing density of L-cells distally, larger meals cause larger responses.[11] Likewise, the responses correlate strongly with the gastric emptying rate. Hormonal mechanisms do not seem to participate at least in pigs, where this has been studied in detail, and although secretion may be influenced by intramural enteric nervous activity, efferent vagal fibers do not stimulate secretion. The sympathetic nerve supply may inhibit secretion, and GLP-1 itself (but not the other proglucagon products) powerfully inhibits L-cell secretion, presumably by the activation of neighboring D-cells releasing somatostatin-28 that acts on the L-cells via sstr 5 receptors.[11]

ACTIVE CONFORMATION AND METABOLISM

Each of the processed products from the pancreas and gut may be found in the circulation where their concentrations reflect their rates of secretion and elimination. Elimination mainly occurs is the kidneys, which extract up to 70 % of GLP-1, greatly exceeding the amount of GLP-1 than can be cleared by glomerular filtration. Thus, the half-lives of oxyntomodulin, glucagon, and GLP-2 are around 6–7 min, whereas that of glicentin is approximately 20 min. No details are known about the metabolism of glicentin and oxyntomodulin in the circulation, but glucagon is subject to some degradation by neutral endopeptidase 24.11. GLP-1 and GLP-2 (but not glucagon) are both substrates for the ubiquitous enzyme, dipeptidyl peptidase-4 (DPP-4), which cleaves off the two N-terminal residues (His-Ala in both peptides) whereby the molecules are rendered inactive.[12] This results in a half-life for GLP-2 of 7 min as mentioned, whereas that of the metabolite, GLP-2 3–33, is around 27 min. GLP-1 is more extensively cleaved by DPP-4, with a plasma half-life of 1.5–2 min and a clearance of 6–10 L of plasma per min, that is, greatly exceeding cardiac output.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

This means that the peptide is degraded rapidly in the circulation and that a steady state is not reached. In fact, the peptide is degraded already as it leaves the endocrine organ, that is, the gut. GLP-1 is stored in the L-cells in intact form, but approximately 75% is already cleaved to GLP-1 9–36 amide as it enters the portal vein draining the gut. Because DPP-4 is localized to the endothelial surface of the capillaries, it is believed that the intact molecule on exocytosis from the L-cells diffuses across the basal lamina and into the lamina propria, where it is taken up by a capillary and degraded.[8] This means that only about 25% reaches the portal circulation in intact form. In the liver, half of the arriving GLP-1 is degraded further so that only 10–15% of that secreted makes it to the systemic circulation and thereby the pancreatic islets. The metabolite, which has a half-life around 4 min, is eliminated mainly in the kidneys. Also, GLP-1 may be degraded by neutral endopeptidase 24.11, although less extensively.

RECEPTOR EXPRESSION

The glucagon receptor is discussed in the glucagon chapter of the Ingestive Peptides section of the book. In agreement with its structure, oxyntomodulin may activate the glucagon receptor, but its potency is only approximately 1/50 of that of glucagon. GLP-1 may also interact with the glucagon receptor but with only about 1/100 of the potency of glucagon. Oxyntomodulin may also interact with the GLP-1 receptor, although less potently than GLP-1.

Glicentin has no known specific receptor and apparently does not interact with any of the other receptors of the family. The GLP-1 receptor was cloned by expression cloning[31] and is related to the glucagon receptor and to receptors for GLP-2, and to the receptors for the other members of the glucagon-secretin family of peptides.[19] It has 7 transmembrane domains, a large N-terminally extracellular domain, and a much smaller C-terminal intracellular domain. It is expressed in kidneys, lung, heart, hypothalamus, hippocampus, and of course in the β-cells in the islet of Langerhans. Interestingly, expression of the receptor has also been found in the nodose ganglion, in specific cells of the immune system, and also in the skin.

In vitro studies have shown that the receptor is desensitized by phosphorylations of serine residues on the cytoplasmatic tail, which also leads to internalization of the receptor. However, in rats, there is no reduction in GLP-1-mediated responses after 1 week of treatment with a GLP-1r agonist, and in humans with type 2 diabetes, the antihyperglycemic effect is unimpaired after 7 days of continuous intravenous infusion or 6 weeks' continuous subcutaneous infusion, indicating that GLP-1 receptor desensitization is of little physiological relevance. Mutagenesis based screening studies reveal that the third intracellular loop of the receptor is involved with coupling of the hetero-trimeric G protein and the coupling with both $G_s\alpha$ and $G_i\alpha$ has later been confirmed with the use of isolated cell membranes. Further *in vitro* studies established a coupling between GLP-1r and $G_q\alpha$. GLP-1r signaling is partly mediated by coupling to β-arrestin-1, and this coupling does not seems to mediate desensitization or internalization of the receptor. Augmentation of glucose-induced insulin secretion subsequent to the activation of the GLP-1r is mediated by cAMP/PKA and cAMP/EPAC2 pathways. Inhibition of apoptosis is mediated by PKA and PI3 K pathways; for instance, tacrolimus-induced cell death in isolated human islets is inhibited by GLP-1 signaling through PI3 K/PKB pathways. Further studies involving cultures of isolated human islets in monolayer have shown that GLP-1-induced cell proliferation is dependent on PKA, PI3 K and mitogen-activated kinases. Song et al. reported that phosphorylation of snapin is an essential step in downstream actions of PKA activation.

The GLP-1 receptor is also expressed in the alpha cells, but "how much" is a highly controversial issue, although the subject is important in view of the powerful and clinically highly relevant inhibitory effect of GLP-1 on glucagon secretion. The receptor is also expressed in the gastric mucosa, perhaps particularly by the parietal cells, and in the lungs where type II pneumocytes have a dense expression. Hepatocytes do not normally express GLP-1 receptors but may do so during development and under pathological conditions, and other cells, perhaps associated with the portal vessels also express the GLP-1 receptor. GLP-1-R (and GLP-2R) mRNA occurs in cells of the nodose ganglion, suggesting that sensory vagal neurons may express the GLP-1 receptors. Receptors have also been localized in the subfornical organ and in the area postrema, areas with leaks of the blood–brain barrier, and GLP-1 injected into the peripheral circulation can access these circumventricular organs suggesting that peripherally secreted GLP-1 may influence the CNS via this pathway. Quantification by the highly sensitive multiple-time regression analysis of blood to brain influx indicates entry into brain parenchyma elsewhere as well.

The GLP-2 receptor (GLP-2R) was cloned in 1999, and is related to the GLP-1 receptor.[22] It is expressed throughout the gastrointestinal tract[22] and in pancreatic alpha cells. The localization in the gut, however, is highly controversial, with some studies showing expression in enteroendocrine cells throughout the gastrointestinal tract, whereas other studies showed immunoreactivity in subepithelial myofibroblasts (SEM) just beneath the basement membrane.[23] In addition, different groups have reported that the receptor is localized to neurons in both Auerbach and Meissner's plexus of the intestine. Expression analysis of isolated epithelium, mucosa, external muscle coat, and enteric ganglia from rat jejunum was negative in the epithelium, but the receptor

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

was apparently expressed in enteric ganglia. Expression has also been noted in the nodose ganglion and scattered in the epithelium of a human cervical adenocarcinoma.

Like other class II 7 transmembrane receptors, the GLP-2R undergoes desensitization and internalization on stimulation. The physiological relevance of desensitization and internalization is unclear, however; thus, increased cellularity of the intestine occurs after 7 days of GLP-2 stimulation, and the effect is sustained after another 11 days of stimulation. The GLP-2-mediated effects are reversed 11 days after cessation of GLP-2 stimulation. In people with GLP-2 producing tumors, a growth effect on the small intestine continues until intestinal obstruction develops.

Downstream signaling from the GLP-2R involves accumulation of $[cAMP]_i$ and thereby activation of PKA.[22] However, GLP-2 seems to counteract induced apoptosis by the inhibition of caspases 3, 8, and 9 in a cAMP dependent but PKA and PI3 K independent manner in transfected BHK cells. Phosphorylation of MAPK ERK1/2 is seen after GLP-2R activation in different *in vitro* cell models but not in BHK cells. In primary intestinal cell cultures phosphorylation of ERK1/2 is not induced by GLP-2 stimulation, but jejunum isolated from GLP-2 stimulated mice shows induction of ERK1/2. GLP-2R stimulation was coupled to $G_i\alpha$ in Hela cells. In agreement with this, the cAMP accumulation after GLP-2 stimulation of primary cultures of rat small intestine shows a polynomial appearance, indicating that cAMP induction is inhibited at higher concentration of GLP-2. *In vivo*, parenterally fed piglets infused with GLP-2 dose dependently show activation of protein kinase B (PKB) and inactivation of proapoptotic glycogen-synthase kinase 3 and caspase 3, and upregulation of the prosurvival gene B-cell CLL lymphoma 2 (Bcl2). Stimulation of mice with GLP-2 induces epidermal growth factor receptor family (ErbB) ligands, while effects of GLP-2 are blocked by a pan-ErbB antagonist.[35]

BIOLOGICAL ACTIONS

Glicentin has been reported to influence gastric acid secretion and single reports on growth effects and other effects have been published, but most investigators have found the peptide to be inactive. Thus, in unpublished studies from the authors' laboratory, synthetic glicentin is without effects on gastric acid secretion and insulin secretion in humans. Oxyntomodulin mimics most of the actions of glucagon but is less potent and probably does not act as a glucagon-like agonist physiologically. Like glucagon, it inhibits gastric acid secretion, but by an action that seems to be mediated by GLP-1 receptors (although their exact location is uncertain). However, it is doubtful whether the circulating concentrations of oxyntomodulin under normal circumstances reach sufficient levels to activate the receptors. Intracerebrovascular administration of oxyntomodulin powerfully inhibits food intake in rats by actions that do not seem to be mediated via the GLP-1 receptor. In agreement with the gut-like processing pattern of proglucagon in the proglucagon-producing neurons in the nucleus of the solitary tract,[17] it is possible that oxyntomodulin released from the fibers arising from the proglucagon-producing neurons in the nucleus of the solitary tract may contribute to the inhibitory effect on appetite and food intake apparently resulting from the activation of these neurons, together with GLP-1 and GLP-2. Administration of oxyntomodulin to humans is associated with strong inhibition of appetite and food intake and associated with weight loss. Studies of chimeric proteins with both GLP-1 and glucagon activity show dramatic efficacy in terms of inhibiting appetite and food intake without upsetting blood glucose regulation.[2] Therefore such "dual-agonists" and/or oxyntomodulin-like peptides are currently studied intensely. As dealt with elsewhere, glucagon itself is a surprisingly potent appetite suppressant (see the glucagon chapter: in Ingestive Peptides Section of the book).

ACTIONS OF GLP-1

The most conspicuous effect of GLP-1 is the stimulation of glucose-induced insulin secretion.[11] GLP-1 one of the incretin hormones, the gut hormones that augment insulin secretion on oral as opposed to intravenous administration of glucose. Together, GLP-1 and GIP are responsible for the incretin effect, which may account for as much as 70% of the insulin secreted after carbohydrate intake. Indeed, glucose tolerance and insulin secretion are impaired in mice with the deletions of both the GLP-1 and the GIP receptor and more so in animals with knockout of both receptors. However, GLP-1 has numerous other actions, and its physiologically most important role may be to act as an enterogastrone hormone, inhibiting gastrointestinal motility and secretion, reducing appetite and food intake, and to enhance peripheral deposition of already absorbed nutrients by stimulating insulin secretion.

Effects on the Islets

GLP-1 is strongly insulinotropic and mice with a targeted deletion of the GLP-1 receptor become glucose intolerant and may develop fasting hyperglycaemia.[29] In humans, administration of the GLP-1 receptor antagonist, exendin 9–39, reduces the insulin responses to enteral glucose.[22] The insulinotropic activity of GLP-1, which is strictly glucose-dependent, is exerted via interaction with the GLP-1 receptor located on the cell membrane of the ß-cells.[19] GLP-1 stimulates all steps of insulin biosynthesis and insulin gene transcription, thereby providing continued and augmented supplies of insulin for secretion. Activation of PDX-1, a key

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

regulator of islet growth and insulin gene transcription may be involved. In addition, GLP-1 upregulates the genes for the cellular machinery involved in insulin secretion, such as the glucokinase and GLUT-2 genes. GLP-1 also has trophic effects on ß-cells. Not only does it stimulate ß-cell proliferation but it also enhances the differentiation of new ß-cells from progenitor cells in the pancreatic duct epithelium. In addition, GLP-1 is capable of inhibiting apoptosis of beta cells including human beta cells. The complicated intracellular mechanisms whereby GLP-1 may exert these effects on the beta cells are reviewed elsewhere.[5]

GLP-1 also strongly inhibits glucagon secretion from the alpha cells. The mechanism is still unclear but may involve interaction with the alpha cells directly (although in isolated alpha cells secretion has been reported to be stimulated by GLP-1) or a paracrine action by neighboring D-cells whose secretion of somatostatin-14 is potently stimulated by GLP-1. The intraislet hypothesis states that it is GLP-1 stimulated insulin that inhibits glucagon secretion in a paracrine manner. This hypothesis fails to explain the powerful inhibitory actions of GLP-1 in C-peptide negative patients with type 1 diabetes.

Effects on the Gastrointestinal Tract

GLP-1 inhibits gastrointestinal secretion and motility, notably gastric emptying. Physiologically, these effects of GLP-1 may be more important than the insulinotropic activity. When GLP-1 is infused intravenously during ingestion of a meal, the insulin responses are diminished dose dependently, rather than being enhanced. At the same time, gastric emptying is progressively retarded, so that the explanation of the reduced insulin secretion is the reduced gastric emptying of and reduced subsequent absorption of insulinotropic nutrients. Thus, the physiological role of GLP-1 may be to adjust the delivery of chyme to the digestive and absorptive capacity of the gut by retarding propulsion and digestion of the gastric contents. Thus, the GLP-1 receptor antagonist, exendin 9–39 increases fasting antral motility and meal-induced gastric and duodenal motility and decreases pyloric tone. This strongly suggests that endogenous GLP-1 is a physiological regulator of antroduodenal motility. Studies using the same antagonist confirm the physiological nature of the inhibitory effect of postprandial GLP-1 secretion on gastric emptying. The mechanism whereby GLP-1 exerts these actions seems to involve the nervous system. As described above, GLP-1 is degraded extensively in the gut before it reaches the systemic circulation. This has led to the hypothesis that GLP-1 must act locally in the lamina propria before it gets degraded. Thus, on its way to the capillary, while still in the intact form, GLP-1 may interact with afferent sensory nerve fibers arising from the nodose ganglion, causing them to send impulses to the nucleus of the solitary tract. From here, motor nuclei of the vagus or fibers projecting to brain, notably in the hypothalamus, may be activated directly. Exogenous GLP-1 may increase impulse activity in afferent vagus. These impulses may be reflexively transmitted to the pancreas. Studies with ganglionic blockers show that even the insulin response to intraportal administration of GLP-1 and glucose may be reduced to that elicited by glucose alone after ganglionic blockade. Thus, regarding the mechanism of GLP-1 stimulated insulin secretion under physiological circumstances, the neural pathway may be more important than the endocrine route. However, the concentration of intact GLP-1 does increase after meal intake and increases the larger the meal is. Thus, it is possible that the endocrine route becomes more prominent after extensive L-cell stimulation. Also, this inhibition of gastric motility, acid secretion, and emptying seems to involve regulation of efferent vagal activity subsequent to activation of vagal sensory afferents.

Effects on Appetite and Food Intake

Nutrients in the ileum have a satiating effect, curtailing food intake and also cause a release of GLP-1. Infusions of slightly supraphysiological amounts of GLP-1 significantly enhance satiety and reduce food intake in both normal subjects, obese subjects as well as in subjects with type 2 diabetes. Intraperitoneal administration of the GLP-1 antagonist, exendin 9–39 significantly augments food intake, and also strongly reduces the inhibitory effect of a preload of food.[33] A new small molecule antagonist of GLP-1 that can be used more chronically reduces food intake and leads to an increase in weight in a week-long study in rats, indicating that also endogenous GLP-1 regulates food intake. Direct injections of GLP-1 into the cerebral ventricles also inhibit food intake. Here, the peptide presumably interacts with cerebral GLP-1-receptors that are targets for GLP-1 released from nerve fibers ascending from cell bodies in the nucleus of the solitary tract in the brain stem. The question arises whether these neurons are linked to meal-induced satiety. Williams et al.[33] showed with either central (icv) or peripheral (ip) administration of GLP-1 with or without exendin 9–39 that the peripheral effect of GLP-1 is uninfluenced by a central antagonist, while the icv effects of GLP-1 are the same after peripheral blockade. The peripheral and the central GLP-1 systems, therefore, do not seem to require interaction with each other. The mechanism whereby peripheral (intestinal) GLP-1 reduces food intake remains unsettled, but studies indicate that transmission occurs via both vagal sensory afferents and pathways involving central nervous structures, perhaps including the area postrema.[25] Although GLP-1 receptor knockout mice do not become obese,[29] this may reflect the redundancy of the appetite regulating mechanisms rather than ineffectiveness of the signal.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Other Actions

The cardiovascular effects of GLP-1 were recently reviewed.[30] Intracerebroventricular GLP-1 administration is associated with improved learning in rats and also displays neuroprotective effects. The neuroprotective effects of GLP-1 were recently reviewed.[13] The functions of GLP-1 in the lungs are unclear, although it has been reported to increase the secretion of macromolecules from the neuroendocrine cells.

ACTIONS OF GLP-2

These remained elusive for some time until Drucker et al.[6] observed mucosal hypertrophy in mice carrying proglucagon-producing tumors with an intestinal processing pattern. In subsequent studies of the effects of injected proglucagon products, GLP-2 was found to be capable of producing a similar mucosal growth. GLP-2 presumably activates its receptor on either neuronal cells or subepithelial myofibroblast which in turn produce growth factors that cause mucosal growth. GLP-2 enhances enterocyte proliferation and inhibits enterocyte apoptosis and thereby produces a pronounced growth of the epithelium. In addition, it may increase the expression of nutrient transporters and thereby augment the absorptive capacity of the gut. GLP-2 is currently believed to be an important regulatory factor for an adaptive intestinal growth as illustrated by the blunted intestinal adaptation to refeeding after prolonged fasting in the GLP-2 receptor knockout mouse. Further, modulation of endogenous GLP-2 signaling by immunoneutralization attenuates the adaptive growth of rest ileum after a 75% midsmall intestinal resection and reanastomosis, and immunoneutralization of GLP-2 in streptozotocin treated rats impairs intestinal growth after streptozotocin treatment. GLP-2 also powerfully increases intestinal blood flow. The mechanism is unknown, but it may be related to an increased intestinal metabolic rate. GLP-2 may also act as an enterogastrone hormone. Thus, GLP-2 inhibits sham-feeding induced acid secretion and may inhibit gastric emptying, but it is not as potent as GLP-1. GLP-2 treatment attenuates the inflammatory response in rats after chemically induced colitis by a pathway involving VIP positive enteric neurons, and the anti-inflammatory effects of GLP-2 are reproduced in interleukin 10 knockout mice, a model of chronic colitis. The gastrointestinal effects of GLP-2 have potential in the treatment of patients suffering from intestinal failure, and patients with short bowel syndrome benefit from treatment with GLP-2. Finally, GLP-2 may be one of the possibly several intestinal signals responsible for meal-induced regulation of bone resorption. In studies, where bone resorption was monitored by measurements of cross-linked fragments of collagen-1, the secretion of GLP-1 and 2 was well correlated to meal-induced inhibition of resorption, and upon subcutaneous administration GLP-2 caused a similar reduction of bone resorption.

The GLP-2R knockout (GLP-2R$^{-/-}$) mouse has a blunted intestinal adaptive response to refeeding after fasting for 24 hours. In addition GLP-2R$^{-/-}$ has impaired bone metabolism. The glucose metabolism of GLP-2R$^{-/-}$ and wild-type mice is similar, and weight gains on both high fat and chow diets are also similar. However GLP-2R$^{-/-}$ mice crossed into *ob/ob* mice have, compared with *ob/ob* mice, increased fasting plasma glucose, increased fasting levels of glucagon, and paradoxically improved oral glucose tolerance.

ACTIONS OF OXYNTOMODULIN AND GLICENTIN

Oxyntomodulin is a dual agonist of both the GLP-1r and the glucagon receptor. In humans, oxyntomodulin inhibits both appetite and food intake and induces a significant weight loss in humans.[34] In diet-induced obese mice, treatment with a long-acting oxyntomodulin analog results in weight loss and intraperitoneal glucose tolerance was improved as well. Glicentin probably functions as a precursor of oxyntomodulin, but administration of glicentin to rats was reported to stimulate intestinal growth.[6] A specific receptor or mechanism has not been identified.

PATHOPHYSIOLOGICAL IMPLICATIONS

Disturbances in L-cell Secretion

The secretion of GLP-1 is often decreased in patients with type 2 diabetes, and this may contribute to the severely impaired incretin effect seen in these patients and thereby also to their impaired insulin secretion. The finding is not constant, and the variation probably results from the differences with respect to body mass index, insulin resistance, duration and severity of type 2 diabetes mellitus, gall bladder emptying rates, gastric emptying rates, and importantly antidiabetic therapies, where, for example, metformin increases GLP-1 secretion. In patients with morbid obesity, GLP-1 responses to meal ingestion may be almost eliminated. Because GLP-1 inhibits appetite, the impaired secretion may contribute to or aggravate the development of obesity.

As discussed above, GLP-1 secretion is related to gastric emptying rate, and in patients with accelerated gastric emptying, GLP-1 secretion may be excessive and may be responsible for the occurrence of postprandial reactive hypoglycemia in such patients.[32] Thus, accelerated gastric emptying causes high postprandial glucose concentrations coinciding with high GLP-1 concentrations resulting in exaggerated insulin secretion, which in turn causes hypoglycemia. Inhibition of glucagon secretion may contribute.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Exaggerated GLP-1 secretion may also be responsible for the cases of hypoglycemia sometimes observed after gastric bypass operations for obesity.[20]

One of the most effective therapies for obesity is gastric bypass operations, which often leads to rapid (within days) remission of diabetes if present. The patients have extremely exaggerated (often around 10-fold) GLP-1 (and GLP-2) responses to meal ingestion, presumably resulting from an accelerated exposure to nutrients in the distal small intestine in which the density of L-cells is much higher than in the bypassed upper small intestine. Note that digestion does not occur until the secretions from the secretory limb are mixed with the contents from the alimentary limb in the distal jejunum, and that the mechanism of nutrient stimulated GLP-1 secretion involves interaction with L-cell membrane proteins, including Na^+/glucose cotransporters, Na^+/H^+-peptone cotransporters and many specific G protein-coupled receptors in the apical membrane.

Tumors producing proglucagon products generally exhibit a pancreatic processing pattern, and the resulting glucagonoma syndrome is caused by the excessive secretion of glucagon. However, in some cases, an intestinal processing pattern is observed, and in these patients, the most dramatic clinical symptoms (intestinal obstruction) are because of intestinal mucosal hyperplasia. This is probably a consequence of increased secretion of GLP-2.

Therapeutic Application of Proglucagon-Derived Peptides

The actions of GLP-1 have attracted great interest, because almost all of them are beneficial in the context of treatment of type 2 diabetes. Infusions of GLP-1 completely normalize fasting blood glucose concentrations in virtually all patients with type 2 diabetes investigated and in clinical studies involving subchronic (6 weeks) continuous subcutaneous infusion, blood glucose levels are greatly reduced, blood lipids improved, body weight reduced, and beta cell secretory capacity and insulin sensitivity increased. Single subcutaneous injections, however, are ineffective because of rapid degradation of the peptide by DPP-IV. To exploit the effects of GLP-1 receptor activation, several pharmaceutical companies have developed resistant analogs of GLP-1 or activators of the receptor. One of these is exendin-4, a peptide of 39 amino acids isolated from the salivary secretions of the lizard, *Heloderma Suspectum*, which is 53% homologous with GLP-1 (with respect to the sequence of the first 30 amino acids) and is a full agonist of the GLP-1 receptor. This peptide is resistant to the actions of DPP-4 and is cleared by the kidneys by glomerular filtration, resulting in a plasma half-life of about 30 min. Single subcutaneous injections, therefore, result in plasma exposure lasting 5–6 h. The peptide that is designated exenatide in its synthetic form has been available for diabetes treatment since 2005 under the name of Byetta. The most conspicuous effects are a sustained reduction of levels of glycated hemoglobinA1c (a measure of the average blood glucose levels) and a weight loss of 7–8 kg that is maintained for >3 years in individuals completing the protocol. A formulation of exenatide with similar clinical effects, which provides continued exposure for several weeks and therefore is useful for once-weekly administration, has been approved in 2012.

An acylated analog of human GLP-1, liraglutid with a half-life of 12–13 h after sc injection has been available since 2010 and has similar or may be even slightly better effects on body weight and HgbA1c. Both exenatide and liraglutid are as effective as insulin therapy but pose very little risk of causing hypoglycemia; their use is therefore recommended in patients with failure of the first oral agent (typically metformin). In addition, both agents function very well in combination with basal insulin therapy, where 70–80% of patients may reach target values of HbA1c (7.0%) without causing weight gain or hypoglycemia, making this combination the most effective therapy for type 2 diabetes to date. The clinical application of GLP-1 agonists for diabetes therapy is reviewed elsewhere.[18]

An alternative approach is inhibition of the enzyme DPP-IV. Unlike the GLP-1 agonists or analogs, DPP-IV inhibitors are small molecules that are orally available. DPP-IV inhibition increases the levels of intact GLP-1 and thereby amplify the actions of the endogenous hormone presumably both with respect to insulin and glucagon secretion. DPP-IV inhibitors have been marketed since 2006, where sitagliptin was launched. The inhibitors elevate the concentrations of both GLP-1 and GIP in their active forms and improve glucose-induced insulin secretion (same secretion elicited at lower plasma glucose concentrations) and lower plasma glucagon concentrations. The fall in HbA1c is about 0.5–1.0 %, but there is no effect on body weight. Unlike the agonists, the inhibitors do not cause gastrointestinal adverse effects (nausea) and are remarkably free from any other adverse effects. They perform well in combination with other oral antidiabetic agents, in particular metformin. One of the ways by which metformin acts is to increase the secretion of GLP-1; with a combined therapy, one therefore obtains stimulation of secretion with one and enhanced survival of GLP-1 with the other, and this may be the explanation for the particular efficacy of this combination. The clinical use of DPP-4 inhibitors is reviewed elsewhere.[3]

Because of its intestinotrophic activities, GLP-2 is currently being investigated as a therapy for intestinal insufficiency. Because of its much slower metabolism compared with that of GLP-1, GLP-2 can be used in its natural form and can enhance intestinal absorption and increase lean body weight in patients with short bowel syndrome in the course of a 5-week study with two daily subcutaneous

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

injections. In a subsequent study, patients with short bowel syndrome were treated with native GLP-2 for 1 year, resulting in a reduction in fecal weight of 1000 g/d and enabling patients to maintain their intestinal fluid and electrolyte absorption at lower oral intake. A DPP-IV resistant analog (Teduglutide) may be produced by the substitution of amino acid residue no 2 (with Gly) and has similar, but prolonged effects. Tedoglutide was approved for short bowel syndrome treatment in 2012. Studies in experimental animals show that GLP-2 may also be effective in the therapy of intestinal atrophy after parenteral nutrition, and in intestinal failure after experimental enteritis and after radiation and chemotherapy. GLP-2 is also currently investigated as a therapy for osteoporosis, and is able to strongly reduce the nightly increase in bone resorption in postmenopausal women. In subchronic clinical studies (120 days), GLP-2 administration significantly improves bone mineral density in postmenopausal women.[10] The biology and clinical use of GLP-2 are reviewed elsewhere.[15]

Chapter 169

Leptin

Sandra Guilmeau, Robert Ducroc and André Bado

ABSTRACT

The initial view that leptin, a 16-kDa polypeptide encoded by the ob gene, is an adipocyte-derived signal has been modified by the identification of other producing tissues, such as the stomach. The discovery of stomach-derived leptin, mainly secreted in the lumen, has initiated several investigations leading to the suggested clues: (1) gut leptin may act locally within the gastrointestinal tract to regulate intestinal functions such as nutrient absorption; (2) leptin may integrate meal-related signals from the gut and thus participate in the short-term regulation of energy balance, and (3) leptin secretion may have pathophysiological implications.

INTRODUCTION

Leptin, secreted primarily from white adipose tissue,[35] has been recognized as an adipostatic signal. Thus, leptin administrated peripherally in rodents with genetic or diet-induced obesity decreases body weight and adiposity and improves metabolic control by central nervous system (CNS)-mediated mechanisms.

The leptin receptor Ob-R, encoded by the *db* gene,[32] is a member of the gp130 family of cytokine receptors. It occurs in several isoforms resulting from the alternative splicing of the *db* gene.[19] Only the long isoform, Ob-Rb, can activate the signal transducers and activators of transcription (STAT) pathways, whereas both Ob-Rb and one of the short isoforms (Ob-Ra) can transduce signals through insulin receptor substrates (IRS) and mitogen-activated protein kinase (MAP kinase) pathways.[31]

Leptin is now considered to be involved in a wide range of biological processes. Leptin not only regulates food intake and energy expenditure but it also participates in the regulation of the hypothalamus–pituitary axis, angiogenesis, the immune system and inflammatory response, cell proliferation and apoptosis, and nutrient absorption. This multifunctional role of leptin is consistent with the production of this hormone by various tissues and organs, including the stomach.[2]

This review will focus on stomach-derived leptin and its implication in the physiology of the gastrointestinal tract.

THE STOMACH PRODUCES LEPTIN

The stomach serves as a reservoir in which ingested food accumulates and undergoes chemical and enzymatic primodigestion. The gastric mucosa consists of several types of secretory epithelial cells. Among these cells are endocrine cells secreting hormones, the mucous cells secreting alkaline mucus that protects the epithelium, parietal cells secreting gastric acid, and chief cells secreting pepsinogen, a proteolytic enzyme. The leptin-secreting cells were initially identified as pepsinogen-secreting chief cells in rodents and humans. Subsequent studies have detected leptin in the secretory granules of endocrine P cells in addition to chief cells.[8] Further, ultrastructural studies showed that leptin protein is present along the rough endoplasmic reticulum–Golgi-granule secretory pathways in both chief and endocrine cells.[7]

During development, leptin production in the stomach starts at the onset of suckling in neonatal rats and markedly increases during the transition from liquid to solid food intake.[23,26] This observation underlies the physiological importance of stomach-secreted leptin and the potential role that it could play in the control of gut-derived regulation of food intake in neonates.

Leptin secretion in the stomach is regulated by the nutritional status, acetylcholine-released by the vagus nerve, and intestinal hormones, that is, cholecystokinin and secretin.[14] In addition, gastric leptin shows diurnal variations influenced by food intake rhythms, and the changes occurring just before the beginning of the feeding period are opposite to those of the appetite stimulating peptide ghrelin.[27] Gut-derived leptin can be distinguished from fat-derived leptin by its rapidly increased secretion induced by a meal and its main secretion into the gastric lumen suggesting different functions for these two pools of leptin.

GASTRIC LEPTIN IS A NEUROENDOCRINE MOLECULE FOR SATIETY

One of the first questions raised by gastric leptin is whether it can act locally in the stomach to generate signals

contributing to meal-induced termination of food intake, namely, on the vagus nerve conveying those signals to the CNS. This implies, however, the expression of leptin receptors on the vagus nerve. Interestingly, mRNA and protein for leptin receptors have been localized in the nodose ganglion.[5] The vagal afferent neurons possess functionally active leptin receptors proteins and leptin may activate intracellular STAT3 in these neurons.[5] Moreover, leptin receptors have been also described on the intestinal vagal mechanoreceptors. These vagal receptors are responsive to leptin directly delivered in the stomach, as evidenced by the increase of the tonic activity of gastric-related neurons in the NTS.[33] These results correlate well with those initially obtained from *in vitro* gastric vagus rat stomach preparation in which electrophysiological studies identified two types (1 and 2) of leptin-responsive gastric vagal afferent fibers.[34] Pretreatment of cholecystokinin-8 (CCK-8) fibers is required to increase the sensitivity for leptin of the type 2 fibers.[34] This clearly provides a basis for the reported leptin-CCK potentiating effects to increase the firing frequency of gastric vagal terminals,[34] neuronal activity in the nucleus tractus solitarius (NTS), and to reduce food intake[3] and body weight.[20]

Altogether, the vagus nerve seems to be the primary target of leptin produced by and secreted into the stomach. This leptin acts from the luminal side via a neurocrine mode of action through the vagal leptin receptors. The molecular basis of this neurocrine action of leptin remains to be elucidated.

GASTRIC LEPTIN ENTERS THE INTESTINE

Some of the stomach-derived leptin is not fully degraded by proteolysis, reaching the intestine in an active form to initiate biological functions. Thus, high amounts of free leptin and leptin bound to high molecular weight proteins are present in duodenal lumen in rats.[15] Such leptin-binding proteins were reported as the soluble leptin receptor in the blood and also identified as clusterin, also termed apolipoprotein J, a protein whose function has not yet been defined. Interestingly, in the rat colonic lumen, leptin can only be detected as free leptin.[15] Although the significance and the precise nature of these high molecular weight leptin-binding proteins in the intestinal juices needs further investigation, they may have physiological implications in the bioavailability of leptin in the gut lumen. Notably, the amount of leptin in the duodenum is greater than that expected from the stomach, suggesting contribution from other leptin-producing sites. In addition to gastric secretions, the duodenum receives hepatobiliary and exocrine pancreatic secretions and the liver also produces leptin.[17] Thus, the liver can contribute to the levels of leptin trafficking in the intestinal lumen by direct hepatic synthesis of leptin and/or by increasing the release of free leptin from the hepatic stores of the complexes of leptin bound to OB-Re.[17] More precise quantification of leptin and additional molecular studies are needed to ascertain the respective contribution of the different parts of the digestive system to leptin in the intestinal lumen. In addition to the presence of leptin in the gut lumen, leptin receptors occur at both the apical and basolateral sides of the enterocytes all along the small and large intestine, supporting the contention that leptin, acting from the luminal side, affects biological functions of the intestinal epithelium.[10]

LEPTIN REGULATES INTESTINAL ENDOCRINE SECRETIONS

CCK-1 receptor antagonists can both prevent peripheral leptin-induced inhibition of food intake[3] and the stimulation of pancreatic exocrine secretions.[14,22] In addition, intraduodenal leptin also stimulates pancreatic enzyme secretion in a CCK-1 receptor-dependent manner, probably through the activation of duodeno-pancreatic reflexes.[22] These results suggest that endogenously released CCK may be involved in those leptin actions. Circulating leptin (mainly reflecting adipocyte leptin) and, more importantly duodenal leptin, increases plasma CCK at levels comparable with those induced by feeding.[15] This action of duodenal leptin is probably relayed via a direct activation on the CCK-producing endocrine I cells. Finally, the leptin-induced release of CCK determines a positive feedback loop, because CCK can stimulate the release of gastric leptin.[2] CCK is one of the meal-generated molecules inducing satiety signals that are conveyed by the viscerosensitive vagal afferent neurons to the NTS, and then to the hypothalamus. Thus, leptin stimulation of duodenal CCK secretion suggests that under physiological conditions both peptides may potentiate their own actions by cross-stimulating their secretions. This is in accordance with the reported dampening of CCK or leptin inhibitory action on food intake when either peptide is absent or their receptors functionally inactive.[3]

Leptin can also stimulate the secretion of glucagon-like peptide-1 (GLP-1), another satiety signal, *in vitro* in enteroendocrine L cells and *in vivo* in rodents[1] providing evidence for the existence of an adipoenteroendocrine axis involved in the regulation of nutrient homeostasis.

GUT LEPTIN AND INTESTINAL ABSORPTION OF NUTRIENTS

The small intestinal lining contains functionally and morphologically polarized enterocytes that play a central role in the absorption of nutrients after digestion. In the intestine, the chyme undergoes hydrolysis by proteolytic enzymes from pancreatic, bile, and the intestinal juices, pursuing

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

the primodigestion started in the stomach. Nutrients thus degraded in smaller molecules cross the intestinal brush-border by active transport, passive diffusion, or facilitated processes. The arrival of the meal in the intestine stimulates the release of gastrointestinal hormones that control the absorption of nutrients and are also signals for induction of postprandial satiety. Thus, it is conceivable that gut leptin rapidly secreted in the lumen after a meal (in contrast to adipocyte leptin) is a key molecule controlling intestinal absorption of nutriments.

Jejunal Absorption of Proteins

Under physiological conditions, dietary proteins are degraded in a series of steps by hydrolytic enzymes originating from the stomach, pancreas, and small intestine. This results in a mixture of free amino acids and small peptides that are efficiently absorbed by enterocytes. These small peptides are cleared from the intestinal lumen by the brush-border transporter PepT-1, which cotransports dipeptides and tripeptides with protons. Luminal but not basolateral leptin increases the absorption of dipeptides through PepT-1 in the enterocyte-like Caco2 cells *in vitro*.[4] These results were confirmed *in vivo* in the rat in which the direct administration of leptin in the jejunum (mimicking gastric leptin) rapidly increases the absorption of dipeptides.[4] The mechanism of this short-term action involves increased recruitment of membrane PepT-1 molecules from an intracellular preformed pool to the apical membrane. From a physiological point of view, the facilitation of protein absorption through PepT-l activation by gut leptin is consistent with the reports of a satiety effect of dietary proteins and is in line with the aminostatic hypothesis.

Jejunal Absorption of Fats

A major function of intestinal cells is to absorb a large amount of dietary lipids. After a digestive phase, the free fatty acids (FAs) lipolytic products are absorbed by the enterocytes, in which sequential events result in their packaging as chylomicrons. The formation and secretion of these intestinal lipoproteins are key steps in the transport of dietary fats. The assembly of triglyceride (TG) rich lipoproteins within the enterocytes, involves multiple pathways including (1) the uptake of FA by several specific carriers, such as Fatty Acid Transporter FAT/ and its human homolog CD36; (2) their translocation from the brush-border membrane to the endoplasmic reticulum by intestinal and liver Fatty Acid Binding Proteins (I- and L-FABPs); (3) their esterification in TG and subsequent assembly with apolipoprotein (apoB, apoA-IV) to form lipoprotein particles. Leptin seems to play a role in regulating the synthesis of apolipoproteins. Leptin administrated to fat-loaded *ob/ob* mice induces STAT5 DNA binding, and reduces apolipoprotein transcript levels in the mice jejunum.[21] Leptin is also involved in the regulation of circulating apo-AIV by suppressing apo-AIV synthesis in the small intestine.[9] Moreover, leptin can regulate the expression of microsomial triglyceride transfer protein (MTP) in mouse enterocytes through intestinal melanocortins and MC4-receptors.[18] Such an enterocyte-specific regulatory mechanism may provide additional peripheral control of fat mobilization independently of that determined by central nervous leptin signaling. It remains unknown however whether these leptin functions are assumed by leptin trafficking in the lumen of the intestine.

In the enterocyte-like Caco2 cells, leptin reduces the output of *de novo*-synthesized apolipoprotein ApoB-100 and ApoB-48 as well as that of newly formed chylomicrons and of low-density lipoproteins, supporting a role for leptin in the reduction of intestinal TG secretion into the circulation. Moreover, I-FABP expression is decreased by leptin in Caco2 cells. These effects of leptin on FA uptake and assembly in the enterocyte are probably involved in the regulation of energy homeostasis.

Jejunal Absorption of Sugars

Dietary carbohydrates are digested in the intestine through the action of amylase and intestinal brush-border membrane disaccharides into monosaccharides, D-glucose, D-galactose, and D-fructose. Sodium-dependent glucose cotransporter-1 (SGLT-1) is the specific transporter for D-glucose and D-galactose, whereas D-fructose is transported into the enterocytes by the pentose transporter GLUT-5. After accumulation in the enterocytes, the monosaccharides exit the cell across the basolateral membrane by the Na+-independent transporter GLUT-2. In the jejunum, leptin can inhibit the active absorption of galactose mediated by SGLT-1 without affecting the passive component of the absorption.[10] This leptin inhibition of galactose absorption *in vitro* probably involves leptin–receptor coupled activation of protein kinase C and A. In contrast, systemic leptin administration to rats after massive small bowel resection (MSBR) leads to an increase in the amount of GLUT-5 protein with no change in the levels of SGLT-1.[24]

Gut leptin also retains the ability to modulate the absorption of glucose-galactose in the rat jejunum. Indeed, luminal addition of leptin on rat jejunum, isolated in Ussing chambers, rapidly and dramatically decreases active glucose transport.[10] This rapid inhibition of glucose entry into the enterocyte by luminal leptin involves a reduced recruitment of SGLT-1 from an intracellular preformed pool to the apical membrane. The inhibition of active glucose transport by serosal leptin is however slower and probably involves the release of CCK as a relay molecule. This leptin regulation

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

of active glucose absorption has been extended to GLUT-2 mediating the passive component of glucose absorption and to GLUT-5 mediated fructose transport. These studies clearly show that introduction of leptin into intestinal lumen results in the upregulation of both GLUT-2 and GLUT-5 transport activities through mechanisms critically dependent on the catalytic α_2 subunit of 5′ adenosine-monophosphate-activated protein kinase.[29] Because the small intestine is now recognized as an insulin-sensitive organ, a better understanding of the mechanisms by which leptin affects the intestinal absorption of monosaccharides may have physiological relevance in the management of diabetes, in particular non-insulin-dependent diabetes mellitus.

Importantly, the increased activity of the fructose GLUT-5 transporter is associated with a concurrent increase of blood glucose and liver fructose. This latter effect is accompanied by hypertriglyceridemia, suppression of intestinal and hepatocyte Fasting-induced adipocyte factor (Fiaf) expression, and by the induction of hepatic sterol regulatory element-binding protein transcription factor, targeting genes in the fatty acid biosynthesis pathway. Finally, a positive regulatory control loop between gut leptin and fructose has been identified in which fructose triggers the release of gastric leptin which in turn upregulates GLUT-2/GLUT-5 leading to increased fructose absorption and changes in some metabolic functions in the liver.[29]

Jejunal Absorption of Amino Acids

L-Glutamine is the primary metabolic fuel for enterocytes. Glutamine from the diet is transported into the absorptive cells by two sodium-dependent neutral amino acid transporters present at the apical membrane: ASCT2/SLC1A5 and B^0AT1/SLC6A19. The capacity of luminal leptin to control Na^+-dependent transport of glucose led to the question of leptin action on Na(+)-dependent glutamine absorption. Thus, mucosal leptin inhibits the uptake of glutamine and phenylalanine (substrate of B^0AT1) in everted intestinal rings.[15] In Ussing chambers, glutamine and phenylalanine absorption follows as Na+-induced short-circuit current is inhibited by leptin in a dose-dependent manner. The mechanisms of leptin regulation of the active entry of neutral amino acids involve a reduction of both B^0AT1 and ASCT2 proteins traffic to the apical plasma membrane and modulation of their gene expression.[11]

Colonic Absorption of Short Chain Fatty Acid

Butyrate, a short chain fatty acid (SCFA), is one of the products of the microbial digestion of carbohydrates and dietary fibers in the large bowel, which represents a dominant energy source for the colonocytes. Gut leptin is involved in the regulation of butyrate uptake by the intestinal epithelial cells through the proton-linked monocarboxylate transporter type 1 (MCT-1).[6] Indeed, in the human intestinal Caco2 cells, luminal leptin increases butyrate uptake by increasing MCT-1 mRNA levels and the amounts of MCT-1 protein on the apical membrane.[6] Such a control of MCT-1 activity by leptin which affects the availability of SCFA in the mucosa probably modulates the intracellular events regulating normal differentiation and proliferation in the colonic mucosa. Along this line, it has been reported that *in vitro* leptin promotes colon cancer HT-29 cell survival on butyrate challenge by counteracting the apoptotic programs initiated by this short chain fatty acid,[25] suggesting potential implications for the diseased colon (see the leptin chapter in Cancer/Anticancer section of the book). More investigations are needed to establish the relevance of these current results in the pathophysiology of colon cancer.

LEPTIN AND GUT PATHOLOGIES

Leptin is involved in maintaining gastric epithelial cell integrity and gastroprotection. In rats, systemic leptin is effective in attenuating both ethanol- and aspirin-induced damage to the gastric mucosa. This is correlated with an increase of leptin production by the stomach during experimentally-induced gastric damage in rats and during H pylori infection in humans. This gastric cytoprotective effect of leptin involves an increase in blood flow, local production of nitric oxide and prostaglandin E_2, and vagus nerve-dependent mechanisms.

One of the important functions of leptin is its role in the regulation of inflammatory processes. There is indeed a large body of evidence that leptin-mediated signal pathways play an active role in innate and adaptive immunity through alteration of various target genes transcription.[13] Interestingly, leptin-deficient *ob/ob* mice are resistant to colonic inflammation induced by oral dextran sulfate sodium or trinitrobenzene sulfonic acid and replacement of leptin converts their resistance to disease into susceptibility.[28] The mechanisms responsible for such an action largely involve T cell activation capacity of leptin.[13] Human inflamed colonic cells exhibit a strong leptin-immunoreactivity that is concentrated at subapical part of the colonic cells, whereas normal colonic epithelial cells do not show this.[30] This supports the idea that fat- and gut-derived leptin may be a key component in the control of intestinal inflammation processes. Whether the aberrant expression of leptin is a cause or consequence of inflammation in colon mucosa or whether leptin acting from the luminal side contributes to the progression and maintenance of the chronicity of the inflammation, remains to be further investigated.

Beside this proinflammatory action of leptin acting in the intestinal mucosa, leptin signaling can be important in the mucosal defense against enteric infection. Thus, a mutation

of leptin receptor is associated with increased susceptibility to *Entamoeba histolytica* infection with greater levels of mucosal destruction in children.[12] In mice with deleted intestinal leptin receptors, leptin signaling in the intestinal epithelium mediates resistance to enteric infection by *Entamoeba histolytica* through the STAT3 and protein–tyrosine phosphatase SHP2/ERK pathways.[16]

CONCLUSIONS

The gastrointestinal epithelial cells are in contact with submucosal immune cells that are tightly and finely controlled by the enteric nervous system. There is increasing evidence pointing out the importance of leptin at the interface between the immune, endocrine, and enteric nervous systems, and the epithelial barrier within the gut. These results make leptin, a hormone and a cytokine, a good candidate to link neuroendocrine and immune systems to metabolic status. A better understanding of the role of gut leptin in the physiology of gastrointestinal functions will provide a basis for the determination of its relevance in several disease states such as obesity, diabetes, and IBD.
