Chapter 170

Motilin

Pierre Poitras

ABSTRACT

Motilin is released from the M cell of the duodenal mucosa into the blood circulation to help regulate the interdigestive motility of the stomach and small intestine. Motilin, as an interdigestive hormone, induces the phase III contraction of the migrating motor complex (MMC) during the fasting period. Motilin receptor stimulation is a potent pharmacological stimulus of gastric motor activity and can be used to accelerate the gastric emptying of a meal. Motilin is part of the motilin/ghrelin peptide family.

DISCOVERY OF MOTILIN

The sequence of motilin was first published in 1973 by Brown et al.[2] Inspired by observations made at the beginning of the 20th century that gastric motility was inhibited by perfusion of an acid solution into the duodenum, Brown discovered that instillation of pH 9 Tris buffer into the duodenum increased motor activity in a transplanted gastric pouch in dogs. This experiment, confirming the regulation of gastric motor activity by an endocrine factor released from the duodenum, led to the purification of this hormone. As starter material, he used a side fraction produced during the purification of porcine intestinal secretin by Victor Mutt at the Karolinska Institute. Tracing the purification steps with the *in vivo* model of a canine transplanted gastric pouch, Brown, through successive chromatographic steps on CM cellulose, Sephadex G25, and DEAE cellulose, isolated a 22-amino acid peptide with a molecular weight of 2700. He chose the name motilin "because of the original observation that it caused an increase in motor activity in pouches of gastric fundus gland area of the stomach." The structure of porcine motilin is shown in Table 1.

STRUCTURE OF MOTILIN AND RELATED PEPTIDES

Structural Heterogeneity and Species

Species heterogeneity in the structure of motilin soon became a major issue in the physiological and pharmacological exploration of the peptide; indeed, it had an impact on the detection of motilin by radioimmunoassay (RIA) and on the bioactivity of motilin on various experimental models. Biochemical characterization of motilin was, therefore, undertaken in numerous animal species. In the late 1970s, using successive chromatographies (gel, ion, and HPLC) of small intestinal extracts, and detection of motilin-like-immunoreactivity by RIA with an antiserum against porcine motilin, we purified canine motilin and found differences in 5 of its 22 amino acids (Table 1). From the mid-1980s, molecular biology techniques allowed the isolation and characterization of cDNA clones encoding motilin precursors in numerous species. Human motilin was found to be similar to the pig peptide, but differences in the amino acid sequence were subsequently identified in many species as shown in Table 1.

Mouse and Rat Motilin

Confusion certainly arose from studies in rats and mice; the 2 common laboratory animals could not be used for motilin research because motilin could not be detected in these species and was present without any biological activity. The efforts of many research teams to characterize motilin and motilin receptors in these rodents were in vain. An important step in the comprehension of this unusual situation in the field of peptide research was taken by T.L. Peeters using an "in silico" approach to identify motilin and the motilin receptor in the now elucidated rat genome. Peptide-conserved sequences were discovered, but the putative translation products contained stop codons that disable the formation of full prepromotilin peptides. A partial 1–13 fragment, which has amino acid substitutions in positions 2, 3, and 7, might eventually be formed. This fragment showed contractile activity similar to porcine motilin in the rabbit duodenum *in vitro*, confirming its motilin nature.[17] RTPCR analysis with a probe made from mouse motilin of mouse duodenum, stomach, or brain failed to reveal motilin in these organs, suggesting that motilin is not expressed in mice. Moreover, "in silico" analysis of the motilin receptor also suggested the presence of homologous regions but with many stop codons and a frame-shift making

the synthesis of the mature protein impossible. Mouse motilin, indeed, was inactive in the mouse duodenum *in vitro* or in the mouse stomach *in vivo*, suggesting that motilin receptors were absent in the mouse digestive tract. A recent study[7] confirmed that the genomes of mice and rats only contain remnants of the motilin and motilin receptor genes. Heterogeneity in the structure of motilin among species is unusual in the field of peptides.

Motilin/Ghrelin Family

Motilin was in a peculiar position because it was not identified as belonging to a family of peptides, as, for example, peptide families such as gastrin/CCK, secretin/VIP. However, ghrelin, a newly discovered peptide of the mammalian stomach, shares sufficient structural similarity with motilin to have been called motilin-related peptide.[23] Motilin and ghrelin (see the chapters on ghrelin in this Gastrointestinal Peptides Section of the book, as well as in the Brain, Endocrine, Ingestive, and Cardiovascular Peptide Sections) have a number of biological actions in common. The motor effects of ghrelin on the GI tract are indeed comparable with those observed for motilin, that is, induction of phase III of the migrating motor complex (MMC) in the fasting period and stimulation of gastric emptying during the postprandial period. In the central nervous system, motilin and ghrelin show comparable activities on the release of growth hormone (GH) or on appetite stimulation.

Not only do motilin and ghrelin show structural similarity, but their also receptors have sequence homology. Resemblance between motilin and ghrelin in the structure of the ligands and in the structure of their receptors suggests of course crossreactivity between ghrelin and motilin analogs on their receptors. However, recent studies have failed to show a significant interaction between motilin ligands and the ghrelin receptor and, vice versa, between ghrelin ligands and the motilin receptor. The significance and implication of the motilin/ghrelin peptide family have still to be identified.

GENE STRUCTURE AND POSTTRANSLATIONAL PROCESSING

The human motilin gene was mapped to the P 21.2→P 21.3 region of chromosome 6. It consists of 5 exons separated by 4 introns; the bioactive peptide structure is encoded in 2 distinct exons (exon 2 and exon 3). Nucleotide sequence analysis predicts that motilin is first synthesized as a precursor of 114–119 amino acids. A 25-amino acid signal peptide precedes the 22-amino acid sequence of the active peptide, followed by 2 lysine residues that precedes a 65-amino acid sequence that has been called motilin-associated peptide (MAP) whose biological importance remains unknown.

Northern blot analysis of human duodenal mRNA revealed a single band and suggested that the multiple forms of motilin-like immunoreactive material found by gel permeation chromatographies were produced by post-translational processing of a single motilin precursor. The importance of these promotilins, however, seems marginal; in tissues and in blood, the 22-amino acid peptide is by far the dominant molecular form encountered.

DISTRIBUTION IN THE GI TRACT

The presence of motilin in the gut of numerous animal species has been verified by RIA measurement of motilin-like-immunoreactivity (MLI) in tissue extracts, by immunostaining of motilin-containing cells or structures, and by Northern blots to detect motilin mRNA in various tissue regions of the GI tract. By far, the most prevalent region for motilin expression is the proximal gut mucosa, mainly the duodenum, and, to a minor extent, the jejunum.

Motilin is produced in a specific endocrine cell of the intestinal mucosa. The M cell is well characterized in electron microscopy by its relatively small, solid secretory granules, often of irregular shape and density. The presence of motilin in a subpopulation of 5-hydroxytryptamine-enterochromaffin cells has been initially described but remains controversial.

The presence of motilin in extramucosal structures of the GI tract is also debated. MLI was detected in extracts from gut muscle, but this could be explained by mucosal contamination during tissue preparation. Some studies, most often unconfirmed, suggested that motilin was present in the vagus nerve and in neurons of the intestinal wall. Motilin appeared as one of the rare peptides not considered as a brain–gut peptide. Motilin concentrations measured in the brain were always much lower than those found in the gut and much lower than other brain peptides such as CCK or VIP. However, motilin mRNA has been detected in specific brain regions of various animal species, including humans. Motilin receptors also seem to be present in the brain, and we must now face the concept that motilin could, indeed, like most other peptides, play a role as a neural transmitter.

RECEPTOR AND STRUCTURE ACTIVITY

Structure Activity

Nuclear magnetic resonance analysis of the 3-dimensional structure of motilin revealed that the 7 first amino acids of the N-terminal portion of the molecule are positioned in a curved fashion, whereas the C-terminal segment of the peptide displays an alpha-helix appearance (Fig. 1).

The N-terminal portion of the molecule is responsible for receptor binding and *in vitro* bioactivity. Peptide fragments containing the first 12 amino acids of the molecule

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

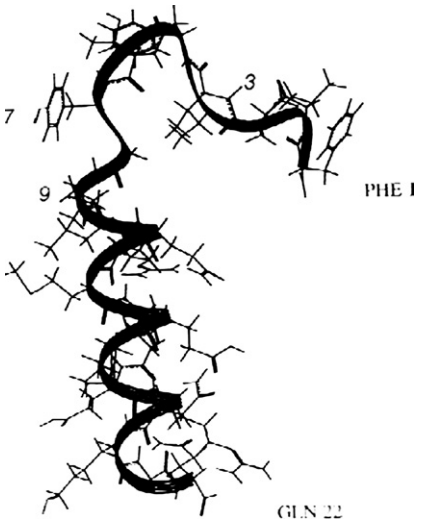

FIGURE 1 Structure of the 22-amino acid motilin peptide revealed by nuclear magnetic resonance. The N-terminal curved sequence binds to the receptor, whereas the α-helix C-terminal structure protects the molecule for *in vivo* bioactivity.

demonstrate full binding capacity and full contractile activity *in vitro*. Phe1, ILe4, and Tyr7 are key amino acids for the pharmacophore of motilin.

Interestingly, the C-terminal structure, not required for *in vitro* bioactivity, was found to be important for *in vivo* bioactivity. N-terminal fragments of 15 amino acids, fully active *in vitro*, were indeed inactive *in vivo*, whereas longer fragments with 19, 20, or 21 amino acids could mimic the motor activity of the 22-amino acid native peptide when injected into conscious dogs.[19] This is an interesting concept in the field of peptide pharmacology where the C-terminal structure seems to be important in protecting the whole molecule probably against circulating degrading enzymes. A similar observation on the protective role of the C-terminal segment *in vivo* has been made for ghrelin,[22] the other member of this peptide family.

Receptor

The motilin receptor was cloned in 1999. For years before that, all attempts to sequence the intestinal motilin receptor failed while using a goal-directed approach with a motilin probe for its recognition (of course, we now realize that strategies with mouse or rat as starting material were destined to fail due to the now documented absence of motilin receptors in these species). Researchers in the Merck Laboratories[5] followed a different strategy by first cloning and sequencing a large variety of G protein-coupled receptors from human genomic DNA libraries and then looking at the nature of the ligands for these receptors. Starting from an orphan receptor with a structure close to that of the receptor for the growth hormone secretagogue (GHS), mass screening of >500 peptide and nonpeptide molecules was performed to obtain positive results for motilin. Starting tissue for this work came from the thyroid, and the significance of this receptor localization remains an enigma.

The motilin receptor gene was mapped to human chromosome 13 q14–q21. It consists of 412 amino acids with 7 transmembrane domains and has 52% homology with the ghrelin receptor. Cloning of the motilin receptor of the rabbit and dog[14] confirmed the structural heterogeneity of motilin receptors among species, as it was suspected in earlier pharmacological studies looking at the interaction of various fragments and analogs of motilin on various tissue membranes or organs *in vitro* and *in vivo*.

In *in situ* hybridization studies,[5] motilin receptor RNA was expressed in a subset of interstitial cells mostly apparent in human duodenum, jejunum, and colon. These cells also demonstrated immunoreactivity for neuron-specific enolase and, to some extent, for nitric oxide synthase (NOS) and choline acetyltransferase. In the duodenum, motilin receptor expression was also found in a separate population of cells having an elongated appearance consistent with smooth muscle cells. In another study, motilin receptor immunoreactivity was present in muscle cells and the myenteric plexus of human GI tract.[21] In canine stomach, motilin receptor immunoreactivity was localized in neuronal cell bodies and fibers.[14]

Functional experiments in humans and in animals suggested that motilin receptors indeed exist on nerves as well as on muscles of the gut. Receptors on neurons, sensitive to antimuscarinic blockade, are activated in humans by low doses of exogenous motilin to induce phase III contraction of the MMC during the fasting period, whereas muscle receptors, insensitive to atropine, seem to be activated by higher doses of ligands to accelerate gastric emptying of a meal.[1,3] In receptor binding studies with solutions specifically enriched in muscle or in neural elements of the intestinal wall,[12] specific and distinct responses to various motilin synthetic analogs and fragments suggested the existence of structurally heterogeneous motilin receptor subtypes specific to muscle or neural elements (that we have called M and N receptor subtypes).

Motilin receptors in the brain remain an enigma. Biological responses (such as an increase in GH secretion, increase in food intake, or decrease in anxiety) to intracerebral injection of motilin were indeed observed, but, most of the time, in rats or mice, animals with a questionable contribution to motilin research. Motilin binding sites were, however, identified by autoradiographic studies of rabbit brain tissues, and receptor binding studies allowed the identification of high and low affinity binding sites for motilin on these tissues. The identification of motilin receptors in the rabbit brain and the documentation of motilin RNA in the brain of most species in which it has been investigated

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

until now suggest a role for motilin as a central neurotransmitter, a role that has still to be clarified.

BIOLOGICAL ACTIONS

Difficulties in Experimental Conditions

Motilin was discovered >30 years ago, but many questions still seem unanswered. Exploration of its biological action was difficult for various reasons: (a) Experimental subjects: rat and mouse are convenient laboratory animals for biological studies, but, as discussed previously, were of no help in motilin research. We therefore had to rely on more difficult experimental animals, including the dog that was very important in the elucidation of motilin physiology. (b) Biological actions: as discussed later, the main biological action of motilin is the induction of phase III of the MMC. Recording of this gastrointestinal contractile activity is, therefore, essential for physiological studies on motilin, but this is a complicated task; it requires, in most cases, an invasive technology (surgical implantation of recording electrodes, fluoroscopic positioning of nasally or orally introduced recording probes, etc.) that demands technical expertise from researchers as well as physical and even emotional tolerance from test subjects. Furthermore, the basal cyclical nature of the studied biological phenomenon requires prolonged and tedious experimental protocols. (c) Species heterogeneity: as discussed earlier in this chapter, species heterogeneity in the structure of motilin and of the motilin receptor, as well as in the regulatory mechanisms of the MMC, limits the possibility of extrapolating data from species to species and forces extreme caution in the transfer of information from one species to another.

Pharmacological Action

As its name implies, motilin acts on digestive motility. When administered in pharmacological doses, motilin, or motilin derivatives such as erythromycin (see later), can increase contraction of the lower esophageal sphincter, of the fundic and antral stomach, of the duodenum, of the gallbladder, and, to a lesser extent, of the sigmoid colon (this poor action of motilin on the colon is surprising considering the high number of motilin receptors in this organ). Secretions from the pancreas and from the small intestine can also be stimulated by the exogenous administration of motilin.

Stimulation of antroduodenal motility remains, however, the dominant action of the peptide. Initial *in vitro* studies with intestinal tissues from rabbits and humans revealed that motilin can stimulate smooth muscle contraction by a direct effect on muscle cells; the peptide action was seen despite the addition of all neural blockers, including tetrodotoxin. Experiments with isolated muscle cells have confirmed the presence of motilin receptors on muscle cell membranes. However, *in vivo* studies in dogs and humans clearly showed that the motor action of motilin is mediated by muscarinic transmitters.

Physiological Role

The characteristic action of motilin is the induction of phase III contraction of the migrating motor complex (MMC). The MMC is the basic organization of motor activity of the gut during the fasting interdigestive period. It lasts 80–120 minutes and consists of 3 successive phases: phase I, no signification contractions are seen for 20–60 minutes; during phase II, intermittent and irregular contractions start to occur 20–60 minutes before phase III during which strong peristaltic contractions, lasting 3–10 minutes, start from the stomach and lower esophagus to migrate distally to the duodenum, jejunum and ileum until the colon. This phase III peristaltic wave has been proposed to clean the digestive tract from bacteria or nutrients that could accumulate during the digestive period and could generate deleterious effects on the gut (e.g., bacterial overgrowth). Feeding interrupts the MMC and induces more constant motor activity of moderate amplitude to allow optimal absorption of ingested nutrients, because accelerated transit during phase III would indeed impair nutrient absorption by the small intestine.

Regulatory peptides can exert their influence via different pathways: endocrine (hormonal), neurocrine, paracrine, or autocrine. At present, we believe that the main action of motilin is to regulate MMC activity through an endocrine mechanism, that is, through variation in its plasma concentrations. Motilin is in a unique position, as a GI regulatory peptide, of being active during the interdigestive period, and being therefore not a digestive but an interdigestive hormone. Its role as an interdigestive hormone has been well identified in the dog, in which all of the Morton Grossman's criteria[4] establishing the endocrine contribution of peptides have been fulfilled:[18] (1) Regulation of the cyclical pattern of the MMC is indeed under the control of circulating factors, as shown in various experiments where MMC persists in animals when their stomach had been completed denervated. (2) Plasma motilin levels are variable during the fasting period, and there is a perfect correlation between circulating peak levels of endogenous motilin in the blood and the initiation of phase III contractions from the stomach or proximal duodenum. (3) Administration of exogenous motilin induces phase III contraction of the MMC, and this can be obtained even when motilin is given in small doses reproducing physiological plasma variations. (4) Inhibition of circulating plasma motilin by the administration of specific motilin antisera blocks phase III contractions from the upper gut. Although the situation could not be explored under such perfect experimental conditions in humans, most evidence suggests that circulating motilin also plays a key role in the regulation of phase IIIs initiated from the antrum in humans.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Release Mechanisms

Most gastrointestinal hormones are released after a meal to allow or facilitate the digestion and absorption of nutrients. Motilin is a unique hormone; it is released periodically during the interdigestive fasting period, and its cyclical release is abolished after a meal (as shown schematically in Fig. 2). Therefore, a "biological clock," still of unknown nature, somewhere in the organism periodically signals motilin cells to release the peptide into the circulation. *In vitro* preparations of intestinal mucosal cells enriched in motilin cells showed that muscarinic receptors are present on the motilin cell membrane and that protein kinase C activators are the most potent second messengers eliciting motilin release. In the *ex vivo* perfused canine intestine, bombesin has been identified as a direct stimulant of motilin release, whereas the stimulatory effect of opiates was mediated by acetylcholine. However, phenylephrine and somatostatin seem to act directly on M cell membrane receptors to block the release of the peptide. Interactions with luminal serotonin[13] as well as plasma ghrelin[25] on the release of plasma motilin have been suspected recently. Vagus nerves seem to have some influence on the release of plasma motilin because acute vagal cooling inhibited the cyclical peak increases in plasma motilin; however, vagotomized dogs displayed a normal cyclical profile of motilin plasma release.

As the stimulation of motilin cyclical peak release during the interdigestive period is incompletely understood, inhibition of this cyclical release by a meal (Fig. 2) is also incompletely understood. The situation is still more complicated by the fact that meal ingestion is followed in humans by a very early and brief increase in plasma motilin before the interdigestive release cycle is interrupted, as in the dog. This early release in humans can be mimicked experimentally by central stimulation with modified sham feeding and by distension of the gastric fundus with an air-filled balloon. The contribution of this postprandial motilin release, not present in the dog, in the process of nutrient digestion in humans remains to be characterized.

PATHOPHYSIOLOGICAL IMPLICATION

Disorder of Motilin Secretion

Some GI hormones, such as gastrin and vasointestinal polypeptide (VIP), are important to clinicians because of the disease symptoms they can generate in response to tumoral hypersecretion by gastrinomas or VIPomas. One patient with a motilinoma has been reported;[6] suffering from liver metastases from a rectal neuroendocrine tumor, the patient had an isolated increase in plasma motilin, but was without any specific clinical manifestation. Up to now, there has been no clinical phenotype attributed to motilin hypersecretion. High levels of circulating motilin have been documented, as cosecreted factors, in some patients with pancreatic tumors and Zollinger–Ellison syndrome and in patients with carcinoid tumors of the gut. Although it could be tempting to speculate on the role of motilin in the diarrhea found in these patients, its contribution to the biological alterations remains unknown.

Because motilin hypersecretion could be expected to generate GI hypermotility and hypersecretion with probable diarrhea, it is logical to expect that hypomotilinemia

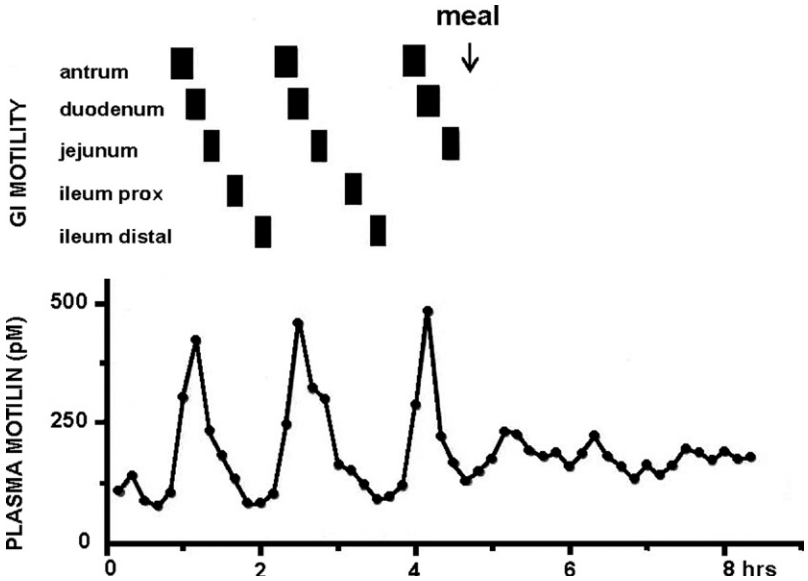

FIGURE 2 Schematic representation of canine plasma motilin variations. During the fasting interdigestive period, motilin is released cyclically every 80–120 min (lower panel) to induce the phase III contraction of the migrating motor complex (MMC) from the stomach to the ileum (indicated by the dark boxes in the upper panel). After eating, motilin cyclical peak increases are abolished for 2–8 h (depending on the content and nature of the meal) while the MMC is interrupted and the fed pattern motility profile is taking place.

would induce GI hypomotility. Some investigators have indeed reported altered levels of plasma motilin in patients with idiopathic intestinal pseudoobstruction, idiopathic or postoperative gastroparesis, or irritable bowel syndrome (IBS). To this point, however, plasma motilin measurement has not been shown to be useful for inclusion in the workup diagnoses of any clinical situations.

Motilin Receptor Agonists and Antagonists

Motilin was recently of major interest to medical clinicians because of the capacity of motilin receptor agonists to act as powerful stimulants of GI motor activity in patients with hypokinetic disorders. Zen Itoh was the first to observe that erythromycin, a macrolide antibiotic, could mimic the motor effect of motilin when injected into dogs.[8] It was soon established that erythromycin was in fact acting on motilin receptors, and Janssens et al.[9] made the capital observation that erythromycin was the most potent gastrokinetic ever tested to stimulate gastric emptying in diabetic patients with gastroparesis. Since then, erythromycin, whether administered intravenously (iv) or by mouth (po), is used by many clinicians for the treatment of patients with gastroparesis or intestinal pseudoobstruction. Motilides or motilin receptor agonist substances derived from the erythromycin macrolide and with improved gastrokinetic activity but devoid of antibiotic properties have been developed by many pharmaceutical companies.[16] At least 3 motilides have been tested in humans, but for various reasons (e.g., rapid tachyphylaxis, no significant clinical benefit, potential side effects), clinical trials with these newly derived molecules have failed to substantiate the impressive pharmacological potential seen with iv erythromycin. The motilide mitemcinal (GM-611) accelerated gastric emptying in gastroparesis patients and provided relief of symptoms attributed to gastroparesis.[11] Atilmotin (a 14-amino acid motilin analog IV administered) accelerated gastric emptying of solids and liquids in humans.[10] The small molecule compound GSK 962040 also seems to be a motilin receptor agonist with a potential therapeutic role in humans.[20]

Motilin receptor antagonists were developed recently [MA-2029,[15] TZP-201[24]]. Based on our knowledge of the contractile capacity of motilin, we could wonder if these antagonists could have a therapeutic role in relaxing the small intestine or colon in patients with IBS or the gastric fundus in patients with functional dyspepsia.

Chapter 171

Neurotensin

James M. Bugni and Charalabos Pothoulakis

ABSTRACT

Neurotensin (NT) is an enteric and brain peptide that elicits cellular signals in the gastrointestinal (GI) tract mainly on binding the 7-transmembrane G protein-coupled neurotensin receptor 1 (NTR-1). This receptor is expressed in a variety of cell types in the gut and regulates several enteric functions. NT is secreted in large quantities in the distal region of the small intestine in response to bacterial products and ingested fats and aids in the regulation of digestion, gastrointestinal secretions, and gut motility. Pathophysiologically, both NT and NTR-1 are significantly increased in expression during colitis, and signaling through this axis is important for modifying the degree of inflammation and also promoting the ensuing mucosal healing through proliferative and antiapoptotic effects. The ability of NT/NTR-1 to stimulate cell growth is usurped by neoplastic cells during cancer development, as the expression of NTR-1 is increased in colon cancer and colon cancer cell lines. This review summarizes the diverse roles of this peptide hormone in normal and diseased states in the GI tract.

DISCOVERY

The 13-amino acid peptide NT was first isolated by Carraway and Leeman from acid acetone extracts of bovine hypothalmi by column chromatography and paper electrophoresis.[7] Subsequently, high levels of the identical peptide were isolated using similar methods from calf small intestine extracts.[22] In the original report of its isolation, NT was discovered to stimulate contraction of the guinea pig ileum and contraction of the duodenum, indicating an important role for this peptide in gut motility and showing that NT is another biologically active peptide produced in both the brain and the gut.

STRUCTURE OF THE mRNA/GENE

The gene for NT (*NTS*) is located on Ch12 in humans and is about 9 kb in length. The primary transcript is processed from 4 exons to form a major mRNA species of about 1200 bp with the coding sequence for the precursor peptide spanning all 4 exons (Fig. 1A). On isolation of polyA+ RNA from canine mucosa and hybridization with probe specific to the coding region, the presence of multiple smaller mRNA species ranging in size from 500 to 980 bases are revealed.[11] These probably represent differentially spliced products. Indeed, 2 alternative splice products are predicted from the genomic sequence, one of which omits the second and another which omits the third exon. Proteins produced by these putative open reading frames (ORFs) would code for the two biologically active motifs (see below). However, the verified existence, differential expression, and functional significance of these variants have not been investigated.

PROCESSING OF THE PRECURSOR

NT is synthesized as a part of a 169- to 170-amino acid precursor polypeptide (proneurotensin/neuromedin N) that is processed to form NT and the 6-amino acid peptide neuromedin N, both located near the carboxy-terminal region of the propeptide (Fig. 1B). The amino terminal portion of the protein contains the signal peptide that targets the propeptide to the endoplasmic reticulum for secretion. The NT and neuromedin N peptides are separated by and each flanked by Lys-Arg amino acids that are recognition sequences for proteolytic processing. A homologous sequence is also present in the middle of the precursor protein, but it is not processed to a mature peptide. This internal sequence shares homology with an amphibian peptide, and thus, it probably represents and ancestral peptide. The propeptide sequence probably arose from tandem sequence duplication events and the mammalian structure is similar to the avian structure showing that the duplications occurred before the evolutionary divergence of these classes.[11]

Although NT and neuromedin N are synthesized from the same precursor peptide, they are often produced in distinct cell populations within the brain, gut, and the adrenal glands. The distinct cell type- and tissue-specific expression of either NT or neuromedin N is attributed to differential expression of prohormone convertases (PC), endopeptidases that recognize the dibasic Lys-Arg sequences that

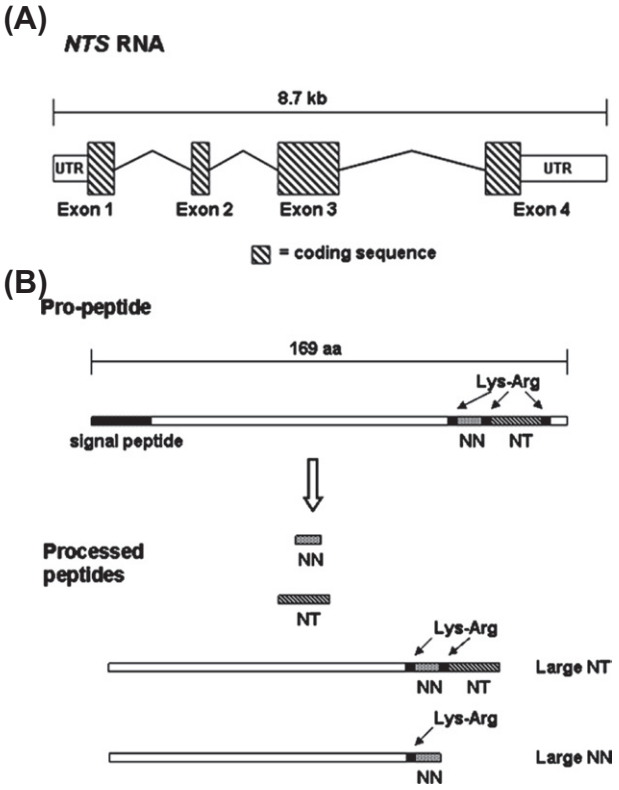

FIGURE 1 Neurotensin exon–intron and pro-peptide organization.

flank the NT and neuromedin N peptides.[21] These enzymes are discussed in detail in the Peptide Biosynthesis/Processing section of this book. Processing by the endopeptidases PC-1, PC-2, and PC-5A gives rise mainly to NT and neuromedin N in the brain, NT, and a large peptide with a C-terminal neuromedin N moiety (large NN) in the gut, and NT, large NN, and a large peptide with a C-terminal NT moiety (large NT) in the adrenals (Fig. 1B). Large NT seems to have activity as an agonist and is expressed normally in the intestine and in colon cancer cell lines. However, the full biological significance of large NT remains to be elucidated.

DISTRIBUTION OF THE PEPTIDE

Early studies showed that the GI tract is a major source of NT and that most NT in rats is localized in the intestine (~90%), whereas a much smaller percentage (~10%) is present in the brain.[22] Among the different areas of the intestine, the jejuno-ileal section expresses the highest NT concentration, although other parts of the GI tract such as esophagus, stomach, duodenum, and large intestine also express this peptide.[19] In mammals, NT-containing cells are scattered among enteroendocrine cells of the jejunal and and ileal mucosa, whereas in chicken, NT cells are more evident in the antrum.[19] NT-containing cells are abundant in the cat, dog, and human intestine and in most mammals are localized predominately on the villi, although in the canine intestine they are more numerous in the crypts. Ultrastructural analysis indicates that NT-producing neuroendocrine cells, also called N cells, contain cytoplasmic granules, predominantly in the basal portion of the cell that represent the storage site for this peptide.[19] This cellular localization facilitates rapid release of NT following specific stimuli and enables this peptide via receptor binding to target intestinal cells to modulate a variety of intestinal functions.

RECEPTORS AND SIGNALING CASCADES

Three NT receptors have been identified. The high affinity NTR1 (expressed from the NTSR1 gene) mediates most of the GI functions of NT as determined by use of specific, nonpeptide antagonists. Moreover, most NTR-2 expression is evident in the brain and other extragastrointestinal sites. The NTR3 is not of the GPCR class of receptors but belongs to the sortilin class. Expression of this receptor has been detected in colonic adenocarcinoma HT-29 cells, but the roles of NTR2 and 3 in gut physiology or pathophysiology remain uncharacterized. By contrast, NTR1 is highly conserved across mammals, and mediates several GI functions including chloride secretion, intestinal cell growth, and intestinal inflammatory and stress responses as described below.

A variety of intracellular signaling pathways are activated by neurotensin in colon cancer cell lines and in the nontransformed colonic epithelial cell line NCM460. Of the small G proteins that couple to GPCRs, NTR-1 is Gq/11 preferring, but this preference seems to be dependent on the cell type.[30] G protein activation stimulates and increases intracellular calcium and causes activation of the Pi3-kinase pathway, which mediates the NT/NTR-1-stimulated phosphorylation of the prosurvival molecule AKT. NT signaling through NTR-1 in NCM460 cells also elicits phosphorylation of insulin growth factor 1 receptor (IGF1R), which leads to NT-dependent activation of AKT and MAPK pathways.[32] Moreover, NT binding to NTR-1 causes the activation of the epidermal growth factor receptor (EGFR) and the downstream MAPK pathway by direct intracellular activation of EGFR and additionally through a mechanism that involves metalloproteinase-dependent cleavage of proTGFα in colonocytes.[34] NT-mediated activation of MAPK signaling and of the downstream transcription factor AP1 also occurs rapidly in human colorectal cancer cell lines and the pancreatic cancer PaCa-2 cells.[12] Moreover, NT stimulates activation of the small Rho-like GTPases RhoA, Rac1, and Cdc42, as well as activation of PKCδ that are, at least partially, responsible for NT-stimulated activation of the transcription factor NF-κB.[35]

BIOLOGICAL ACTIONS WITHIN THE GASTROINTESTINAL TRACT

Stimulation of NT Production and Role in Fat Absorption

Certain bacterial products and food intake particularly in the form of dietary fat are major stimuli for NT release from the GI tract. For example, consumption of a meal or administration of oleic acid dramatically increases plasma concentrations of NT.[33] Presumably, signals generated at the proximal gut after fat or meal ingestion stimulate NT production in the distal small intestine, the main source of NT.[33] In humans, infusion of emulsions of fatty acids and several other lipids into the intestine inhibits acid secretion and increases NT levels, suggesting that NT plays a causal role in inhibiting gastric secretion.[27]

NT has been also implicated as a critical mediator of bile acid cycling, both release and uptake. In support for an important role for NT in fat digestion, NT infusion into the bloodstream causes increased oleic acid translocation across the intestinal lumen into the lymph of rats.[3] Intestinal absorption of taurocholate, an important conjugated bile acid, is potently enhanced by NT administration to fasted rats.[17] NT levels seem to be responsive to bile acid concentrations suggesting a dynamic relationship between the two. Administration of intestinal bile acid during feeding increases intestinal NT mRNA expression and circulating levels of NT,[18] and treatment of rats with the NTR1 antagonist SR-48692 inhibits intestinal taurocholate TC absorption.[18] These results suggest a role for endogenous NT in enterohepatic bile acid cycling. Although the mechanism of this NT response is not entirely clear, pharmacologic evidence indicates that NT-stimulated taurocholate uptake in rat jejunum may be dependent on mast cells.[17]

NT Inhibits Motility in the Intestine While Stimulating Motility in the Colon

Tests of isolated stomach preparations showed that administration of NT inhibits spontaneous motor activity.[2] NT infusion in humans also inhibits gastric and duodenal motility and shifts the motility pattern of the duodenum and proximal jejunum from a fasting- to a fed-type.[33] These studies support the role of NT in regulating postprandial motility in the upper intestine. Apart from peripheral NT, Studies by Buéno et al. indicate that central NT might also exert inhibitory effects in gastric motility.[33] Administration of NT to normal volunteers reduces pressure of lower esophageal sphincter, suggesting that this peptide can affect esophageal function.

In contrast to its inhibitory effect in the upper GI tract, peripheral NT administration increases motility in dog and cat colon.[29] In humans, intravenous NT administration increases the duration of contractions in both the ascending colon and the rectosigmoid area and stimulates defecation. The mechanism(s) of these NT effects may be mediated by release of endogenous acetylcholine, although direct NT effects on smooth muscle cells have also been proposed. Recent results indicate that NT can induce both excitatory and inhibitory responses in motor activity of the rat or human colon, indicating the complexity of this response.[31]

NT Inhibits Gastric Acid Secretion but Stimulates Chloride Secretion in the Colon

Several studies have shown that NT functions to inhibit gastric acid secretion in mammals. Gastric acid secretion is induced in response to a variety of stimuli in humans and dogs, including exposure to pentagastrin, a test meal, or insulin hypoglycemia, and several reports have shown that administration of NT reduces this response.

NT also seems to mediate secretory responses in small intestine and colon. In an early study, Eklund et al. showed that NT stimulates fluid secretion in the cat ileum.[13] This initial report was followed by several other studies, which showed that serosal administration of NT stimulates chloride secretion in guinea pig ileum,[20] porcine jejunum, isolated rabbit colonocytes, and human colonic epithelial HT29 cell monolayers.[26] Also, NT might play a role in exacerbating several colonic diarrheal disorders. Using chamber studies show that NT induces chloride secretion in human colon and that this effect is mediated by nerve cells, adenosine, and prostaglandins.[28] Pharmacologic and immunohistochemical studies also provide evidence that NT-stimulated chloride secretion is mediated by NTR1 expressed on nerve cells of the colonic mucosa.[28] Several mechanisms have been proposed to mediate the effects of NT in gastric and small intestinal secretion and motility, including release of somatostatin, norepinephrine, and/or in the case of motility direct effects on myocytes and cells of the myenteric plexus.[1] Although a direct molecular link for participation of NT in gastric acid output and gastric and upper small intestinal motility has not been firmly established, it does not seem to involve modulation of gastrin levels.[25]

PATHOPHYSIOLOGICAL IMPLICATIONS

Role of NT and NTR1 in Intestinal Inflammation

Early investigation of NT and intestinal inflammation used an *in vivo* model of acute colitis with *Clostridium difficile* toxin A, an enterotoxin that mediates antibiotic-associated colitis in animals and humans.[16] Later chemical injury models of colitis involving intracolonic administration of

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

trinitrobenzene sulfonic acid (TNBS) or oral administration of the detergent dextran sulfate sodium (DSS) also showed an important role for NT in modulating inflammation. Examination of the causal role of NT in intestinal inflammation has been investigated mainly by the use of specific nonpeptide NTR1 antagonists and more recently with NT and NTR1 genetically deficient mice.

Injection of toxin A elicits a dramatic increase in NT and NTR1 expression in rat colonic mucosa within 4 h.[9] After exposure of ileal loops to luminal toxin A, pretreatment of rats with the NTR1 antagonist SR-48,692 significantly inhibits colonic fluid secretion, intestinal permeability, mucosal neutrophil infiltration, colonocyte damage, and mast cell activation.[9] These results strongly indicate that NT is a proinflammatory peptide in acute colonic secretion and inflammation mediated by a bacterial enterotoxin. The mechanism of the proinflammatory responses to NT may involve mast cell activation,[9] because mast cells contain NTR1 receptors that mediate histamine release in response to NT. NT signaling directly in leukocytes including neutrophils, macrophages, and lymphocytes may enhance inflammation, as NT stimulation has been shown to affect phagocytic, chemotactic, and adherence activity in these cell types.[16] NT may also affect inflammation by modulating vascular permeability through direct signaling through the NTR1 receptor expressed on endothelial cells.[16]

NT most probably also enhances inflammation indirectly by stimulating the expression of proinflammatory cytokines in human colonocytes and mesenteric preadipocytes. NTR1 is expressed in colonic epithelial cells in rat, mouse, and human colon, in the nontransformed human colonic epithelial cell line, NCM460, and in several human colonic epithelial cancer cell lines. NT-stimulated activation of NTR-1 elicits secretion of the proinflammatory cytokine interleukin-8 (IL-8), and the full response is dependent on an increase in intracellular calcium and activation of MAP kinase, NF-κB, PKC delta, and the small GTPases RhoA, Rac1, and Cdc42.[16] Mesenteric fat is another important tissue involved in colitis, particularly Crohn's disease in humans and experimental TNBS-induced colitis in animals. Levels of NT and NTR-1 increase dramatically in mouse preadipocytes in response to TNBS-induced colitis.[23] Studies using the NTR-1 antagonist SR-48629 showed that NT/NTR-1 signaling in preadipocytes causes a PKC-delta- and NF-κB-dependent increase in secretion of the proinflammatory cytokine IL-6, and causes a reduction in macrophage migration to inflamed foci in the colon. Treatment with SR-48629 also significantly ameliorates the degree of colitis in this model.[23] In the DSS model of colitis, mice deficient in NTR-1 have significantly lower total colonic expression of IL-6 and are resistant to lethality induced by DSS, although the degree of inflammation and epithelial damage is not significantly different from wild type mice.[6]

NT Promotes Cell Growth, Regeneration, and Healing of the GI Mucosa

NT is a trophic peptide able to stimulate cell growth and proliferation of epithelial cells in the gastric, small intestinal, and colonic mucosa in pathophysiologic situations where there is damage to the mucosa.[8] NT also increases cellularity and reverses mucosal hypoplasia in the intestine of rats fed an elementary diet. In rats, administration of NT accelerates the restoration of gut mucosal integrity after radiation-induced mucosal injury and small and large intestinal mucosal adaptation after colon resection.[24] NT stimulation of a proliferative response is also observed in cultured cells as NT activates growth in several colonic cancer cell lines. The positive effects of NT on cell growth seem to be usurped by cancer cells during tumor development as discussed below.

There is evidence that NT/NTR1 signaling participates in the mucosal healing phase of intestinal inflammation. Brun et al. showed that NT promotes mucosal healing in the DSS model of chronic colitis.[5] After oral administration of DSS, treatment with the NTR-1-specific antagonist SR 48692 exacerbates, whereas treatment with NT ameliorates mucosal damage, body weight loss, and neutrophil infiltration.[5] With DSS exposure, expression of NTR-1 shifts from mainly expression in the lamina propria to predominantly the epithelial layer, especially near epithelial erosions.[5] Moreover, NTR-1-mediated signals are probably important for ulcerative colitis (UC), as NTR-1 is expressed at higher levels in colonic biopsies from patients with active UC than noninvolved areas.[5] Exposure of human colonocytes to NT transactivates the EGFR, a critical receptor in colon tissue repair. Stimulation of proliferation and inhibition of apoptosis seem to be critical for epithelial expansion over eroded regions of the colon in the healing phase of colitis and NT/NTR-1 stimulation of the EGFR pathway and AKT are likely major contributors to this response.

NT Deregulation in GI Cancers

High levels of NTR-1 expression are found in human cancers from several anatomic sites including pancreatic, lung, breast, and prostate cancers as well as UC-associated colon cancer, and sporadic colorectal cancers.[14] Receptor overexpression in colon cancers can be explained, at least in part, by increased transcription of the NTR-1 gene via T cell transcription factor (TCF)/ lymphoid enhancer-binding factor (Lef)- and nuclear β-catenin-dependent pathways, as there are consensus TCF/Lef-binding sites in the NTR-1 promoter that are active in luciferase/reporter assays. Similarly, NT is also found at higher levels in colon cancers than in normal colon,[15] and *in vivo* evidence shows that neurotensin/NTR-1 signaling is causal for tumor growth. Xenograft

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

transplants of human colon cancer cell lines become larger after NT administration and smaller when treated with the NTR-1 specific antagonist SR 48692.[14] NF-κB is an important regulator of inflammation-associated colorectal cancer and functions in both cell autonomous and non-autonomous mechanisms to enhance tumor development. At least part of the mechanism for the increased growth of subcutaneous colon cancer xenografts in nude mice seems to be through NT-stimulated expression of micro-RNAs, specifically miR-21 and miR-155, in an NF-κB dependent manner.[4] These miRNAs have been implicated in cancer development by inhibiting expression of PTEN and SOCS1, which negatively regulate the prosurvival kinase AKT.

In chemical carcinogenesis models, administration of NT in depot form to rats injected with the carcinogen azoxymethane increases tumor size and invasion into the muscularis.[14] Interestingly, this pathway is important for colon tumor formation in mice genetically deficient for NTR-1. NTR-1 deficiency reduces the number of tumors that develop but does not affect tumor size in a model of sporadic cancer.[6] Although NTR-1 plays a role in modifying expression of inflammatory cytokines in the DSS model of colitis, this pathway does not affect tumor development in the azoxymethane-DSS model of inflammation-associated cancer.[6] Moreover, the positive effect of NTR-1 in promoting colon tumor development in mice does not involve NTR-1 overexpression, unlike colon cancer development in humans where NTR-1 is often expressed at higher levels in cancer than in normal colon.[6] It is still unclear whether the effect of NT is directly on the neoplastically transformed epithelial cells, for example, through stimulation of proliferation and inhibition of apoptosis, or whether indirect mechanisms such as maintenance of tumor associated macrophages are important.

NT and Colonic Stress Responses

Irritable bowel syndrome (IBS) is a common debilitating functional gastrointestinal disorder with a wide variety of symptoms known to be affected by psychological stress. Thirty minutes of immobilization stress in rats increases plasma NT concentrations and stimulates colonic mucin release, goblet cell depletion, prostaglandin E2 secretion, and mast cell activation.[10] Administration of the NTR1 antagonist SR-48692 before restraint of rats attenuates stress-mediated secretion of colonic mucin and prostaglandin E2 and activates colonic mucosa mast cells. Although the mechanism of the NT-mediated colonic effects is not entirely clear, direct NT effects on colonic epithelial cells, and mast cells, leading to mucin and mast cell mediators release, respectively, might represent a likely mechanism.[10] These results indicate that NT may mediate some of the colonic responses and symptoms in patients with IBS.

SUMMARY

The findings discussed in this review show that NT and its high affinity receptor NTR-1 play an important role in the physiology and pathophysiology of several GI functions. Important normal intestinal functions associated with this peptide include modulation of motility, enterohepatic circulation of bile acids, and GI secretions. NT also plays a role in disease or other abnormal states include colonic cancer, mucosal regeneration and healing after damage, secretory diarrhea, IBS, and inflammation induced by chemicals or a bacterial enterotoxin. Evidence indicates that NT can directly affect many intestinal cell types such as myocytes, enteric nerves, mast cells, adipocytes, and epithelial cells of the small intestine and colon via specific high affinity receptors expressed in these cells. Thus identification of the particular cells of the GI mucosa expressing NT receptors in humans and studies on the signaling cascades that are activated after exposure of the different intestinal cells to NT would facilitate an understanding of the pathways activated by this peptide. Elucidation of these NT-related pathways is critical for designing effective therapeutic strategies for possible treatment of various GI diseases using NT receptor antagonists.

Chapter 172

Nesfatin-1

Shinsuke Oh-I, Hiroyuki Shimizu and Masatomo Mori

ABSTRACT

Nesfatin-1, an amino-terminal fragment derived from its precursor, nucleobindin-2 (NUCB2), has been identified as a novel anorexigenic molecule that is localized in adipose tissues and hypothalamic nuclei, which are involved in the feeding regulation and integrally connected with other brain areas. Nesfatin-1 is also expressed in gastrointestinal (GI) tract tissues such as the gastric mucosa, showing colocalization with ghrelin-positive granules, the duodenal mucosa, and the pancreatic β-cell cells, showing colocalization with insulin-positive granules. Peripheral injection of nesfatin-1 apparently produces anorexia in rodents, suggesting that the brain–gut axis of nesfatin-1 influences feeding behavior. Nesfatin-1 is also speculated to influence certain diseases of the central nervous system that are associated with digestive symptoms, as has been observed in some patients with a restricted type of anorexia nervosa and digestive organ diseases. However, a receptor specific to nesfatin-1 and the main tissue secreting nesfatin-1 into the peripheral blood remain to be clarified.

DISCOVERY, STRUCTURE, AND PROCESSING

Nesfatin/NEFA/nucleobindin-2 (NUCB2) was identified as a new appetite-regulating molecule by a subtraction-cloning assay used to determine genes activated by a peroxisome proliferator-activated receptor-γ activator (troglitazone) in SQ-5 cells. A computer-based program determined the signal peptides in the coding region of each of the 596 genes cloned in the assay. We performed further searches for genes expressed in both adipocytes and neuronal cells. NUCB2 is composed of a signal peptide of 24 amino acids in the N-terminal region and a protein structure containing 396 amino acids. NUCB2 is expressed in adipose and neuronal cells, and belongs to a gene family homologous to that of nucleobindin-1 (NUCB1). The functions of NUCB1 and NUCB2 as secreted proteins *in vivo* remain unknown, although both have been suggested to contribute to bone mineralization and antibody production. Nesfatin/NUCB2 may be processed by a prohormone convertase (PC) to yield nesfatin-1, nesfatin-2, and nesfatin-3. Among these fragments, only nesfatin-1, an 82-amino acid peptide located in the N-terminal region of nesfatin, is strongly anorexigenic in rodents (Fig. 1A). Nesfatin-1 is precisely present as a processing fragment in the cerebrospinal fluids of rats,[8] but our preliminary *in vitro* observations have shown that CHO cells overexpressing both NUCB2 and murine PC-1/3 or PC-2 fail to produce a fragment corresponding to nesfatin-1, suggesting the involvement of other PCs in the cleavage of NUCB2. Nesfatin-1 is distributed throughout the central nervous system and peripheral tissues, including white adipose tissues and those of the stomach, duodenum, and pancreas.[8,11] This chapter discusses the pathophysiological function of nesfatin-1 in these tissues.

CENTRAL AND PERIPHERAL SATIETY ACTION OF NESFATIN-1

Acute intracerebroventricular injection of nesfatin-1 reproducibly reduces food intake in rodents during the dark phase. In particular, acute or chronic injection of nesfatin-1 into the third ventricle of the rat brain produces decreases in body weight gain with concomitant reduction of body fat mass. It is especially interesting that the anorexigenic effect induced by nesfatin-1 is apparently independent of leptin signaling in the hypothalamus, because nesfatin-1-induced anorexia occurs in rats with a leptin receptor mutation. By contrast, previous injection of SHU9119, a melanocortin3/4 receptor (MC3/4R) antagonist, can block central nesfatin-1-induced reduction in food intake.[1] More recent studies support the notion that anorexia induced by nesfatin-1 is mediated, at least in part, by the oxytocin signaling pathway in the hypothalamic paraventricular nucleus (PVN), where urocortin and CRH_2 receptors are expressed.[4,10] The mechanisms by which nesfatin-1 act either in series or in parallel to recruit CRH_2, MC3/4R receptors, and oxytocin signal are still yet to be determined. However, these findings are interpreted as supporting the notion that a nesfatin-1-related signaling pathway is involved in the complex and integrated neurotransmission networks in the brain hypothalamus that produce anorexia.

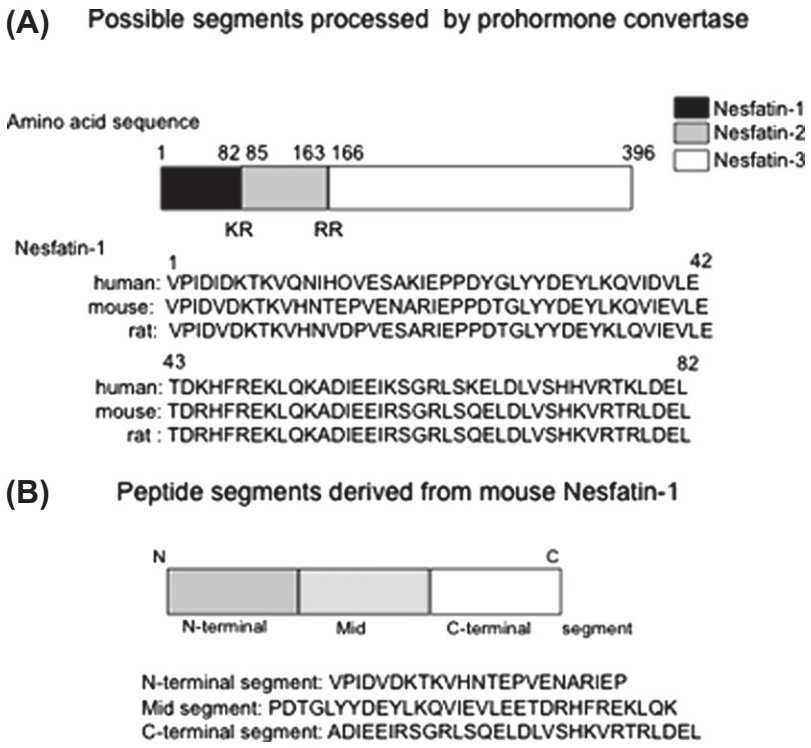

FIGURE 1 A. Structure of the precursor of nesfatin-1, NUCB2. B. Amino acid sequence of each segment derived from nesfatin-1.

Intraperitoneal injection of nesfatin-1 also produces a dose-dependent reduction in food intake in mice fed *ad libitum*. Because nesfatin-1 possesses a characteristic beta-sheet structure, three peptide segments based on the structure of the beta-sheet were artificially produced as follows: an N-terminal segment (23 amino acid residues), a midsegment (30 residues), and a C-terminal segment (29 residues). These segments correspond to the nesfatin-1 alignment of 1–23, 24–53, and 54–82 amino acid residues (Fig. 1B). Among these segments, only the midsegment (24–53 residues) showed the ability to reduce food intake. Moreover, the midsegment had an interesting structure similar to that of an activation site of agouti-related protein (AgRP), and α-melanocyte stimulating hormone (α-MSH). Intraperitoneal injection of the midsegment produces anorexigenic effects in the leptin-resistant animal models of obesity, such as genetically diabetic (*db*/*db*) mice and mice fed a high-fat diet, suggesting again that nesfatin-1-induced anorexia is independent of leptin signaling. Taken together, these findings indicate that nesfatin-1 is a new bioactive substance associated with antiobesity and that nesfatin-1 may suppress hyperphagia in obese patients with leptin resistance.

DISTRIBUTION AND BIOLOGICAL ACTION OF NESFATIN-1 IN THE GI TRACT

The fact that nesfatin-1-immuno-positive cells are selectively localized in the stomach, duodenum, and pancreas suggests that nesfatin-1 may play important roles in gastrointestinal functions similar to those observed with other satiety-regulating neuropeptides. Signal transmission from peripheral vagal afferent nerves to the neurons in the nucleus tractus solitarius (NTS) in the brain stem involves muscarinic and nicotinic cholinergic receptors. We characterized the possible role of cholinergic signals transmitted to the NTS to produce anorexia. Although atropine methyl nitrate, an antagonist for the muscarinic receptor, does not affect food intake suppression induced by peripheral injection of the midsegment of nesfatin-1, hexamethonium, a nicotinic cholinergic blocker, abolishes this suppression.[9] These results indicate that part of the anorexigenic effect of peripheral nesfatin-1 is mediated by cholinergic neurons with the nicotinic receptor.

Nesfatin-1 is expressed in the X/A-like cells of the gastric mucosa, which consists of 20–25% of the endocrine cells and contains vesicles with bioactive

substances. X/A-like cells have key roles in the regulation of gastrointestinal mobility and ghrelin secretion. Ghrelin is a stimulatory factor of growth hormone and a potent orexigenic factor (see ghrelin chapters in this and other sections of the book). Immunopositive vesicles for nesfatin-1 and ghrelin are differently recognized in X/A-like cells of the gastric oxyntic mucosa. These observations suggest that nesfatin-1 and ghrelin are released separately under different metabolic conditions. However, whether these factors coordinate food intake within the X/A-like cells remain to be clarified. Peripheral injection of some anorexigenic molecules, such as peptide YY, produces aversive effects, resulting in reduced appetite. By contrast, nesfatin-1 has no such an effect in rodents.[9] Intracerebroventricular injection of nesfatin-1 decreases food intake and inhibits gastroduodenal motility in a dose-dependent manner,[1,10] by a pathway independent of CRH receptor-2 signaling. Nesfatin-1 expressed in the gastric mucosa decreases on starvation,[11] suggesting that peripheral nesfatin-1 has significant effects on gastrointestinal function.

In rodents, nesfatin-1 is also expressed in Brenner's gland in the duodenum. Brenner's gland is located in the submucosa of the duodenum and pancreas,[15] and constitutes the hepatopancreatic sphincter (Sphincter of Oddi). This gland plays an important role in maintaining appropriate pH conditions in the duodenum by activating digestive alkalizing enzymes, thus protecting the duodenal mucosa from tissue-damaging factors such as gastric acid. Although the physiological function of nesfatin-1 in Brunner's gland *in vivo* is not clear, there is a possibility that nesfatin-1 influences exocrine function in the pancreas by stimulation of propancreatic external secretion and internal secretion.

Some of the brain–gut peptides, such as pituitary adenylate cyclase-activating polypeptide (PACAP) and ghrelin, are expressed and secreted in both the brain and pancreatic islets.[6,13] Interestingly, nesfain-1 is also synthesized and secreted by islet cells and potentiates glucose-induced insulin release in an autocrine manner by promoting Ca^{2+} influx through L-type Ca^{2+} channels in β-cells,[5] suggesting that it has insulinotropic effects.[3] The possibility of nesfatin-1 regulating glucose metabolism requires detailed clarification under diabetic conditions.

PATHOPHYSIOLOGICAL IMPLICATION

To investigate the clinical significance of nesfatin-1 in humans, we had established a sandwich-typed enzyme-linked immunosorbent assay (ELISA) system to detect human nesfatin-1 in the peripheral blood.[12] This specific and sensitive ELISA does not detect whole nesfatin/NUCB2. Exogenous administration of nesfatin-1 may be effective in improving hyperphagia in obese subjects with low blood levels of nesfatin-1. Blood levels of nesfatin-1 in patients with restricted type of anorexia nervosa are significantly higher than those of nesfatin-1 in normal controls, suggesting that nesfatin-1 is regulated by certain nutrition status and contributes to anorexia in such patients.[7] Circulating concentrations of nesfatin-1 are lower in obese subjects than in nonobese subjects, showing an inversed correlation with increased body weights.[12] Patients with newly diagnosed primary generalized epilepsy have about 120- and 160-fold higher circulating and salivary NUCB2/nesfatin-1 levels, respectively, and these are normalized after treatment.[2] These findings suggest that monitoring of nesfatin-1 in blood is useful as a biomarker not only for diagnosing illness but also for estimating responsiveness to treatment among patients with anorexia nervosa or epilepsy.

Nesfatin-1 also influences cardiac function by increasing blood pressure via its activation of the sympathetic nervous system through the MC3/4R signaling pathway in the brain,[14] suggesting that nesfatin-1 neurons are connected with MC3/4R signal and regulate the cardiovascular system.

PERSPECTIVE

Nesfatin/NUCB2 is possibly processed to nesfatin-1, which is present in a number of peripheral tissues including white adipocytes and those of the gastrointestinal tract (stomach, duodenum, and pancreas), in addition to the brain regions. In response to changes in nutrient conditions, nesfatin-1 is released to the peripheral blood. Nesfatin-1 has an important function in the brain, especially in the hypothalamic PVN and NTS, which receives directly and/or indirectly satiety signals from peripheral tissues. However, how nesfatin-1 functions to regulate the systemic energy balance remains to be elucidated (Fig. 2). One of the key means of addressing this function will be to identify a receptor specific to nesfatin-1. We have shown that nesfatin-1 activates the MC3/4R-dependent anorexigenic pathway being independent of leptin signaling in the central nervous system and that it does not directly stimulate intracellular concentrations of cyclic AMP in cells expressing MC3/4R. Although the exact intracellular signaling system remains unclear, nesfatin-1-induced suppression of food intake may be associated with a type of G protein-coupled receptor that evokes Ca^{2+} influx.

Chapter 173

Obestatin

Guillaume Gourcerol

ABSTRACT

Obestatin is a novel 23-amino acid peptide derived from the processing of the ghrelin gene. The peptide name was in keeping with its initially reported actions to inhibit food intake and gastrointestinal motility thereby opposing the stimulatory effect of ghrelin. However, subsequent reports challenged these findings because several groups hardly reproduced the original obestatin actions on satiation and gut motility and questioned the synthesis of obestatin in the stomach to further act as a gastrointestinal hormone via the bloodstream. In addition, although GPR39 has been initially considered to be the cognate receptor of obestatin, this has been recently disclaimed leaving GPR39 as an orphan receptor again. Moreover, plasma obestatin has been found to decrease postprandially, and to be negatively correlated with the body mass index, paralleling the concentration of plasma ghrelin. Hence, further investigations are warranted to ascertain the real role of obestatin as a bioactive peptide rather than as a ghrelin-gene product.

OBESTATIN DISCOVERY

In 2005, Zhang et al. from the Stanford University School of Medicine discovered a novel peptide derived from the ghrelin peptide precursor.[33] The 23-amino acid peptide was identified by a bioinformatic approach, which compared the preproghrelin sequences among 11 mammalian species and spotted a conserved region flanked by a potential cleavage site. Based on the initial reported biological actions, these authors named the newly discovered peptide "obestatin" as a contraction from the Latin verb "obedere," meaning to devour, and "statin," implying suppression. Contrary to the appetite and gastrointestinal (GI) motility-stimulating effects of ghrelin, the authors reported in their initial study that obestatin decreased food intake, body weight gain, and gastric transit. Moreover, the authors found that obestatin inhibited the ghrelin stimulatory effects on feeding and gastrointestinal contractile activity. These "*Yin and Yang* personalities of ghrelin and obestatin" were reinforced by selective binding of obestatin to the orphan receptor, G protein-coupled receptor (GPR) 39, which belongs, as well as the ghrelin receptor (GHS-R1a) and motilin receptor (GPR38), to the class A family of rhodopsin receptors. Although it was shown that one gene could encode more than one peptide, the fact that two biologically active peptides issued from the same prepropeptide antagonizes each other's actions remains a unique finding. This major breakthrough brought a novel exciting insight into the gut peptide field and triggered a flurry of investigations that, however, reported discrepant results that still fuel the debate on the real impact of obestatin on food intake and gastric motor function.

PROCESSING FROM THE GHRELIN GENE TO OBESTATIN

Obestatin is a putative 23-amino acid peptide, which derives from the ghrelin gene (GHRL),[33] located in humans in the short arm of chromosome 3 (3p25–26). The ghrelin gene consists of 4 exons that give rise to a 117-amino acid preprohormone named preproghrelin[7] (Fig. 1). Preproghrelin harbors the preproghrelin signal peptide encoded by exon 1, the 28-amino acid ghrelin peptide hormone encoded by parts of exons 1 and 2, and a 66-amino acid C-terminal peptide named C-ghrelin, encoded by the remainder of exon 2 and exons 3 and 4.[7] Although this C-terminal peptide has been detected in the human circulation, its physiological relevance remains unknown and may rather reflect changes in the transcription or the processing of preproghrelin. Finally, the ghrelin gene also encodes for an exon 3-deleted truncated C-ghrelin which further codes for ghrelin but not for obestatin.

The obestatin$_{1–23}$ sequence is identical to the residues 76–98 of the C-ghrelin, but whether obestatin is posttranslationally cleaved from C-ghrelin or is a product of alternative gene splicing remains unknown. Obestatin requires a further C-terminal amidation to be biologically active, which is a common posttranslational feature of biologically active peptides. To date, an additional isoform of obestatin, Obestatin$_{11–23}$ has also been identified in stomach extracts.[33] However, the biological role of obestatin$_{11–23}$ has not yet been established. A recent nuclear magnetic resonance study detailed the structural properties of both obestatin isoforms and identified a conserved sequence QYQQHGR

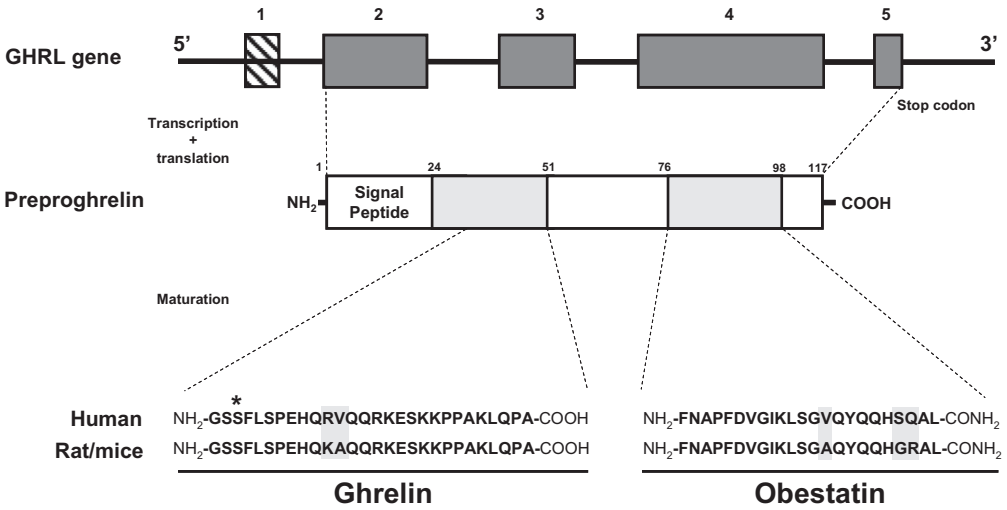

FIGURE 1 Schematic representation of the ghrelin gene and of transcriptional, translational, and posttranslational processes leading to the synthesis of ghrelin and obestatin. Note that the first exon is noncoding. The acylation of the hydroxyl group of Ser^3 indicated by asterisk (*) is required for the biological activity of ghrelin. Nonconserved amino acid are represented as shaded letters. Adapted from Gourcerol G and Taché Y. Neurogastroenterol Motil 2007;19:161–5.

with a 3-D conformation sharing similarities with neurotensin, which might indicate the ability of obestatin to bind a GPR.[26]

OBESTATIN DISTRIBUTION

Tissue Distribution

In contrast with ghrelin, which is known to be primarily synthesized in the stomach and then released into the blood circulation to act as a hormone,[7] limited studies have attempted to detect C-ghrelin-derived peptides, including obestatin, in GI tissues. In the initial report from Zhang et al., these authors used combined gel permeation chromatography and mass spectrometric analyses, and found that endogenous $obestatin_{1–23}$ and $obstestatin_{11–23}$ isoforms could be detected from rat stomach tissues.[33] To date, this has not been further investigated by the same approach, whereas subsequent reports using immunochemistry or radioimmunoassay (RIA) on stomach tissues drew divergent conclusions. For instance, obestatin immunoreactivity was found in cells of rat and human gastric mucosa,[10,16] as well as in gastric myenteric cholinergic neurons.[10] On the other hand, Chanoine et al. detected very little obestatin in rat stomach tissues.[5] Similarly, Bang et al. using combined high-performance liquid chromatography and RIA failed to detect obestatin immunoreactivity in the gastric extract from fasted rats.[3] Therefore, the biochemical identification of obestatin as a distinct and endogenous peptide in stomach remains to be confirmed. In addition to the stomach, obestatin immunoreactivity has also been found in the pancreas,[16] whereas discrepant immunoreactivity has been reported in the testis.[10,16]

Plasma Concentrations

The initial report from Zhang et al. unexpectedly pointed out that plasma obestatin, unlike ghrelin and other GI hormones involved in food intake, did not vary after a meal.[33] Although further studies in rodents led to divergent observations, with a fast inducing increased or decreased plasma obestatin, results in humans have been more consistent. Most of the reports found that plasma obestatin parallels plasma ghrelin concentration. For instance, circulating obestatin decreases after a meal in most of the studies in healthy volunteers.[7] Likewise, fasting plasma obestatin is negatively correlated with the body mass index (BMI) and plasma insulin. In parallel to ghrelin, obestatin is decreased after sham feeding or after atropine administration in healthy subjects.[7] Plasma obestatin levels are lower in patients with chronic atrophic gastritis or during *Helicobacter pylori* infection, and after gastrectomy, which suggests that circulating obestatin originates from the stomach.[7] Recently, obestatin plasma concentrations have been reinvestigated with reversed-phase high-performance liquid chromatography coupled with RIA.[22] These authors found very small amounts of obestatin that were 50- and 20-fold lower in the stomach and plasma, respectively, by comparison with ghrelin. Similarly, Bang et al. failed to detect obestatin immunoreactivity in rat blood samples.[3] This contrasts with the measured fasting plasma concentrations of obestatin in normal-weight volunteers, which range from 35 to 95 pg/mL, whereas total fasting circulating ghrelin varies from 100 to 200 pg/mL.[34] In the study by Bang et al., both ghrelin and proghrelin immunoreactivity were found in high concentrations and further decreased after feeding and an oral glucose test.[3] Moreover, specific immunoassays directed to the

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

N-terminus, C-terminus, and midregion of proghrelin all detected the same molecular species of 7000 kDa, suggesting that the only forms detected were close to the full length 66-amino acid C-ghrelin peptide.[3] Therefore, in addition to the crossreactivity with C-terminal ghrelin gene products, the release of obestatin and obestatin precursors accompanying preprandial ghrelin release might explain the parallel obestatin and ghrelin levels detected in blood samples. In addition, the variability of measured plasma obestatin concentrations might relate to the short half life of the peptide (<15 min), which suggests that obestatin may act through paracrine/autocrine pathway rather than as a GI hormone.[24]

OBESTATIN AND GPR39

GPR39 was originally cloned in 1997 and characterized to belong to the class A of the 7-transmembrane domain GPR as part of the ghrelin subfamily that also includes GHS-R1a, GPR38, neurotensin receptor 1, neurotensin receptor 2, neuromedin U receptor 1 (GPR66), and neuromedin U receptor 2.[7,20] GPR39 signals with high constitutive activity mainly through G_q and $G_{12/13}$ signaling pathways resulting in increased inositol phosphate turnover, as well as activation of the cAMP response element and serum response element transcriptional activity. The GPR39 receptor was first reported by Northern-blot analysis to be widely expressed in the human brain, while its peripheral distribution was restricted to the stomach and small intestine[20] supporting the idea that cognate ligand would exert an action within the GI tract. Because GHS-R1a and GPR38 are important receptors regulating GI motility, the influence of GPR39 on GI transit was recently shown in transgenic mice lacking GPR39. GPR39−− mice display accelerated gastric emptying and increased fecal pellet output compared with their wild-type littermates.[21] However, GPR39 knockout mice have similar body weight, adiposity, and food intake compared with their age-matched littermate controls, suggesting that GPR39 is not a major regulator of body weight at least in lean mice.[21,29] GPR39 is expressed in the endocrine pancreas, and it decreases postprandial plasma insulin concentrations in mice.[29] Zinc ions activate GPR39 signaling at micromolar concentrations.[6,17] It remains to be determined whether Zn++ is the only natural ligand for GPR39, and whether Zn++ functions as an agonist by itself or as an enhancer of GPR39 activation by another endogenous ligand, which still remains to be identified.

In 2005, Zhang et al. reported that obestatin was the cognate ligand for the orphan GPR39 receptor.[33] They observed, in a crude plasma membrane preparation of rat jejunum, that obestatin bound with high affinity to GPR39 although other members of the ghrelin subfamily did not.[33] Furthermore, obestatin displayed a high affinity to GPR39 receptors overexpressed in CHO or HEK293—T cells and also stimulated cAMP release.[33] In addition, Zhang et al., using real-time quantitative polymerase chain reaction (RT-PCR) analyses reported that the highest levels of GPR39 transcripts were expressed in the small intestine, stomach, liver, and hypothalamus, which was consistent with the results of ^{125}I-obestatin binding studies. However, later these findings were challenged by several independent groups. For instance, subsequent studies using in situ hybridization in mice and RT-PCR analysis in rats failed to detect the expression of GPR39 mRNA in the hypothalamus,[17,23] a region primarily involved in food intake regulation. In addition, Holst et al., who previously established and characterized the constitutive activity of GPR39, were unable to confirm that obestatin has agonist properties on the GPR39 receptor.[17] This was supported by the absence of obestatin signaling in GPR39 expressing cells as monitored by inositol phosphate turnover, cAMP, arrestin mobilization, as well as cAMP response element-dependent and serum response element-dependent transcriptional activity.[17] In addition, radiolabeled obestatin did not bind GPR39 in different types of GPR39 expressing cells.[17] Similarly, Lauwers et al. [19] were unable to show that obestatin elicits GPR39 signaling in transfected cells as monitored by cAMP under similar conditions of incubation as reported previously.[33] Lastly, Chartrel et al. reported in 2007 that ^{125}I-obestatin did not bind GPR39 and observed no effects of obestatin on GPR39-transfected cells using similar functional assays (cAMP production, Ca++ mobilization, and GPR39 internalization). This led the obestatin discoverers to acknowledge inconsistencies in the binding of iodinated obestatin to GPR39 resulting from impurities of iodinated obestatin. Thus, the authors disclaimed the ability of obestatin to bind GPR39 in a partial retraction.[32] More recently, however, the same research group using purified iodinated obestatin reported that obestatin was capable of binding to GPR39 in human embryonic kidney 293—T-transfected cells and observed obestatin binding to the jejunum, stomach, ileum, pituitary, and adipose tissue.[31] In addition to GPR39, Granata et al. reported that obestatin could also bind the glucagon-like peptide-1 receptor on HIT-T15 and INS-1E β-cells with low affinity.[14] However, this was later questioned by Unniappan et al., who did not observe binding of obestatin to INS-1 β-cells or HEK cells overexpressing GLP-1 receptor.[30] Altogether, although the involvement of GPR39 in GI motility has been shown by several groups, there is to date no clear evidence that GPR39 is activated by obestatin.

Biological Actions of Obestatin

Food Intake and Body Weight

Zhang et al.'s main findings in their initial report indicated that obestatin suppressed food intake for 5 h after a single intraperitoneal (ip) injection at doses ranging from 320 μg/kg

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY
Copyright Elsevier 2024

to 2.5 mg/kg (125–1000 nmol/kg) in fasted mice.[33] This was associated with a reduction in the body weight on repeated daily ip administration in lean mice. In addition, obestatin injected into the mouse lateral brain ventricle (icv) at 20 μg/kg inhibited food intake almost completely for the first hour and significantly reduced cumulative food intake for the following 5-h experimental period. The initial promise of a new regulator of appetite and body weight was curtailed by convergent studies negating these findings under a variety of conditions. To date, out of 22 studies, only 5 reproduced the anorexigenic action of obestatin whereas 17 failed to observe any effect (for a review, see Ref. 13).

Such a large discrepancy between the initial and subsequent reports is hardly explained by the different experimental protocols or species used.[13] Site and modalities of obestatin injection, either ip, subcutaneous (sc), intravenous (iv), or intracerebroventricular (icv), on acute or chronic administration, were equally ineffective in influencing food intake or decreasing body weight.[13] This was observed under conditions in which anorexigenic control substances such as cholecystokinin (CCK)-8, melanocortin-receptor agonist, MT-II, exendin, or sibutramine resulted in the expected satiety effect or body weight reduction.[13] In addition, doses of obestatin injected centrally or peripherally were in a similar or even higher range than those reported by Zhang et al. because doses up to 2.5 mg/kg, ip and 200 μg/kg, icv in mice, and doses up to 3 mg/kg, ip in rats remained ineffective in decreasing food intake.[11] Since then, Zhang et al. specified that anorexigenic effects of obestatin could only be observed under a precise experimental protocol, for example, with peptide injection performed 15 min before the chow is given to fasted animals.[32] However, negative findings were also obtained under testing conditions that mimicked those used in the initial report.[11,17,23] In addition, these discrepancies cannot be explained by the species used (rat versus mouse), nutritional status (fed versus fasted, lean versus obese animals), animal background (ghrelin-deficient versus wild-type mice) or obestatin form (humans versus rodents).[13]

Molecular approaches also resulted in contradictory findings as observed in the different functional assays. For instance, acute iv injection of obestatin induced c-fos protein expression within the nucleus of the solitary tract and the paraventricular nucleus of the hypothalamus, two key nuclei involved in the control of food intake and GI motility.[2] However, further studies failed to observe any increase in c-fos expression in these nuclei[18] or activation of gastric vagal afferent discharge[12] after peripheral injection of obestatin. In addition, the icv injection of obestatin (20 μg/kg/day for 7 days) did not influence the expression of key hypothalamic peptides regulating food intake, namely, neuropeptide Y, proopiomelanocortin, agouti-related peptide, or cocaine and amphetamine-regulated transcript.[23] Finally, the short half life of obestatin in the blood circulation and the absence of a specific transport system by endothelial cells composing the blood–brain barrier do not support the role of obestatin as a stable hormone involved in food intake and energy balance regulation.[24]

One explanation for these discrepancies might rely on the interaction between obestatin and other GI hormones influencing the satiety signal at the peripheral level. It has become increasingly recognized that different signals governing meal initiation, meal-end satiation, and intermeal satiety could modulate each other. Interaction between these signals results in a more potent satiety effect than each signal alone. Alternatively, one signal can reduce the effects of that induced by another. Therefore, obestatin and ghrelin, which both arise from posttranslational cleavage of the preproghrelin peptide, are well positioned to interact. This was highlighted in the original Zhang et al. report.[33] Both ghrelin and obestatin were coinjected ip at the same molar ratio resulting in the normalization of food intake compared with the inhibitory effect of obestatin administered alone. Conversely, repeated daily injections of obestatin prevented the body weight gain induced by ip ghrelin in lean mice over a 1-week period.[33] Although it seems unlikely that obestatin acts as an antagonist to ghrelin, interplay between ghrelin and obestatin was also reported by Zizzari et al.[35] This group observed that obestatin antagonized GH secretion and food intake induced by ghrelin only when ghrelin and obestatin were administered with equimolar quantities, whereas obestatin alone was unable to decrease GH release in different assays.[35] Subsequent studies, using central or peripheral injections of obestatin together with ghrelin, however, failed to confirm such an interaction.[23] Under conditions of chronic obestatin and ghrelin administration at the same molecular ratio, obestatin did not yield to a reduction of ghrelin-induced increased food intake and body weight gain over a 7-day treatment period in mice.[23] Furthermore, the lack of an obestatin effect to influence food intake in fasted rodents, a condition associated with the highest endogenous circulating levels of ghrelin, suggests that obestatin also does not alter the orexigenic action of endogenous ghrelin. Furthermore, another study showed that there was no interaction between obestatin and CCK-8 on food intake, gastric emptying, or gastric vagal afferent activity, while CCK-8 is known to interact synergistically with other satiety signaling hormones including leptin or bombesin.[12] Hence, these discrepancies emphasize that the originally given name of obestatin was premature because the effects of obestatin on food intake and body weight remain hardly consistent despite a growing literature on the subject.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Gastrointestinal Motility

Most of the gut peptides that display significant effects on food intake also exert biological actions on digestive motor function, especially on the upper GI. Such effects were also tested in the original report describing the anorexigenic properties of obestatin.[33] Obestatin diminished the contractile activity of jejunal muscular strips *in vitro*, whereas ghrelin displayed the opposite effects, suggesting a role for obestatin to slow down upper GI transit.[33] This was expended by *in vivo* assay where obestatin injected ip in doses ranging from 320 μg/kg to 2.5 mg/kg delayed gastric emptying of a caloric meal in mice for the 1- to 2 h period postinjection. In addition, one report detected obestatin in cholinergic myenteric plexi,[10] but the latter further questions the role of obestatin as an inhibitor of gastric emptying since these neurons enhance propulsive activity of the stomach.

Subsequently, the ability of obestatin to delay gastric emptying or gastric motor activity in the fasted state has so far not been replicated. Indeed, all five subsequent reports failed to observe an inhibition of gastric emptying in fasted rats or mice after peripheral administration of obestatin at doses ranging from 0.15 to 3 mg/kg.[4,8,9,11,12] Again, it is unlikely that divergent results between the initial and subsequent reports arise from experimental procedures. Gastric emptying was tested by different techniques, with noncaloric and caloric test meals, in both rats and mice, and with established positive controls.[13] Likewise, *in vitro* gastrointestinal contractions explored with rat and mouse jejunal, duodenal, and fundic strips were not influenced by obestatin in the presence or absence of electrical field stimulation.[4,8] Results on *in vivo* gastric and intestinal contractions are more intriguing because one study found an inhibition of antral and duodenal motor activity 30 min after iv obestatin injection in fed rats, probably recruiting a vagal and central CRF_{1-2} pathway.[2] However, two studies failed to find an inhibitory effect of iv or intracisternal obestatin on antral and intestinal motility in fasted rats at doses up to 3 mg/kg, ip.[4,11] Another study did not observe gastric relaxation after iv obestatin administration.[12] Finally, all reports failed to antagonize the ability of ghrelin with obestatin to stimulate either GI motility or gastric transit.[2,4,8,11] Hence, it seems unlikely that obestatin, by contrast with GPR39, acts as an inhibitor of gastric emptying and motility, at least in the fasted state, when plasma ghrelin peaks.

Glucose Homeostasis

As ghrelin increases blood glucose through the inhibition of insulin release by the pancreatic β-cells, much attention has been paid to the possible involvement of obestatin in glucose homeostasis and insulin secretion (for review, see Refs. 7, 14, 15, 27). This was reinforced by the detection of obestatin in the pancreas where it colocalizes with ghrelin.[16] In addition, an inverse relationship has been found between obestatin and insulin plasma levels in humans. However, discrepant results on insulin secretion and blood glucose were observed after obestatin administration in both *in vitro* and *in vivo* assays. Several reports found either little or no effect of obestatin on these parameters, although others reported a decrease and an increase in insulin release after obestatin administration.[7,14,15,27] It is currently difficult to speculate on the pathways recruited in these divergent effects of obestatin on pancreatic β-cells. Nevertheless, it was suggested that obestatin could stimulate pancreatic/duodenal homeobox-1 gene and antiapoptotic BCL2 protein expression, and promote survival of pancreatic β-cells.[15] In addition, obestatin has been shown to increase β-cell cAMP and activate extracellular signal-related kinase 1/2 and phosphatidylinositol 3-kinase/Ak[14] in pancreatic β-cells. Consequently, and comparable with food intake and GI motility, research on the effects of obestatin on glucose homeostasis and insulin secretion has generated numerous results with variable and occasionally contradictory conclusions.

Other Biological Actions

Since the original report by Zhang et al. which focused on obestatin as a regulator of food intake and GI motility, numerous and sometimes unexpected effects have been reported (for a review, see Ref. 27). As ghrelin stimulates GH release in the pituitary, obestatin was therefore investigated for its ability to inhibit GH release. Although the initial reports by Zhang et al. and Nogueiras et al. stated that obestatin did not influence GH release,[23,33] three subsequent studies have indicated that obestatin could either increase GH release or reduce the ghrelin-induced increase of GHRH release.[27] At the gut level, obestatin has been shown to increase the secretion of pancreatic-biliary juice and trypsin. In adipose tissue, obestatin could play a role in cholesterol transport, promote adipogenesis, and regulate adipocyte differentiation. Obestatin has also been suggested to increase the force of heart contractions probably through a β-adrenergic pathway, and to stimulate cell proliferation in retinal pigment epithelial cells. In the brain, obestatin has been proposed to promote sleep, improve memory, and alter thirst through a decrease in central vasopressin.[27] Most of these findings have not led so far to further investigations or confirmation and therefore require further evidence in light of the preceding controversies.

PATHOPHYSIOLOGICAL IMPLICATIONS

In the absence of pharmacological agonists and antagonist of the still unknown receptor of obestatin, limited results are available on the possible pathophysiological involvement of obestatin in diseases and rely on plasma measurement in

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

several conditions related to disturbance of food intake and glucose homeostasis.

Eating Disorders

Anorexia nervosa (AN) is a major cause of malnutrition and death in young women. In all studies to date, plasma ghrelin levels are elevated in restrictive AN. In most studies, plasma obestatin parallels ghrelin concentrations and is elevated in restrictive AN patients compared with normal-weight or BMI-matched healthy subjects (for review, see Ref. 35). However, ghrelin/obestatin ratio has been shown to be either elevated or decreased in AN.[35] Conversely, convergent studies all found decreased circulating obestatin concentrations in obese patients compared with normal-weight subjects, while the ghrelin/obestatin ratio remains unchanged.[34] In patients with bulimia nervosa, plasma obestatin has also been found to be lower than in control subjects, whereas the ghrelin/obestatin ratio is decreased.[35] As expected in this nutritional condition, plasma concentrations of ghrelin and acylated ghrelin also decrease in obese patients. Although elevated plasma ghrelin in AN patients may be interpreted as an adaptive mechanism to stimulate food intake and maintain normal blood glucose and body weight in starving situations, the elevated circulating obestatin in these patients is to date not fully understood. The same conclusion could be drawn for the decreased concentrations of circulating ghrelin and obestatin in obese patients. One explanation might rely, as mentioned above in physiological conditions, on the parallel release of ghrelin and ghrelin gene products, including obestatin. This is further supported by the elevated level of circulating obestatin observed in Prader–Willi syndrome, characterized by obesity associated with hyperghrelinemia.[7] Whether obestatin rather than ghrelin plasma level or ghrelin/obestatin ratio might represent a reliable diagnostic or prognostic marker of eating disorders remains to be further evaluated.

Insulin Resistance and Diabetes

As obestatin has been shown to be expressed in the pancreas with ghrelin to possibly regulate insulin secretion and blood glucose, a few studies have investigated obestatin plasma concentrations in patients with insulin resistance and diabetes mellitus. To date, two studies have shown that fasting concentrations of plasma obestatin, but not ghrelin, are reduced in nondiabetic subjects with insulin resistance.[1] Obestatin has even been proposed as a marker of insulin resistance in a multiple linear regression model that however did not take in account plasma ghrelin in the analysis.[25] Conversely, fasting circulating obestatin has been found either decreased or unchanged in type-2 diabetes mellitus.[25,28] Postprandial obestatin concentrations remain stable in patients with insulin resistance or in type-2 diabetes mellitus, contrasting with the decrease usually observed in control subjects.[1,28] The real significance, if confirmed, of this finding however remains not fully understood. To date, plasma obestatin levels have not been systematically measured in type-1 diabetes patients.

Other Pathophysiological Conditions

Based on the tissue expression, and preliminary reports of some organ-specific action of obestatin, several authors have suggested that obestatin could be part of the ontogeny of several disorders, and might even represent a future therapeutic target (for a review, see Ref. 27). For instance, obestatin concentrations are reduced in patients with mild to moderate high blood pressure, and are elevated in cachectic patients with congestive heart failure. In addition, obestatin has been suggested to play a role in myocardial protection after reperfusion. Although results indicating obestatin function in the renal system are lacking, obestatin concentrations are elevated in the plasma of patients with chronic kidney disease or with renal failure and normalized after hemodialysis. Obestatin has also been suggested to play a role in cancer progression. In support of this hypothesis, plasma obestatin levels have been shown to be higher in patients with ovarian cancer compared with in healthy controls, but not in prostate cancer or uterine leiomyoma. In addition, obestatin stimulates the proliferation of the KATO-III gastric cancer cell, whereas it inhibits proliferation of TT-human medullary thyroid carcinoma and BON-1 endocrine pancreatic tumor cell line. Lastly, obestatin immunoreactivity is decreased in thyroid and pancreatic tumor tissue. Hence, these preliminary and promising results on the role of obestatin as a marker or even as a therapeutic approach in heart and kidney disease, and in cancer physiopathology, require further attention and confirmation.

CONCLUSIONS

Obestatin was initially reported to reduce food intake, body weight gain, and gastric emptying and to suppress intestinal motility through an interaction with the orphan receptor GPR39. However, a number of subsequent studies undertaken in different laboratories suggest that these initial results should be interpreted with caution. To date, the obestatin receptor is yet to be discovered, and the presence of obestatin in various tissues, including the stomach still remains to be confirmed. In addition, the parallel variation of obestatin with ghrelin in the blood circulation adds another clue to the physiological functions of obestatin in regulating appetite and metabolism. The future identification of the obestatin receptor and development of more reliable assays for obestatin detection, as well as pharmacological tools, are therefore warranted to confirm and better understand the real role of obestatin as

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

a potential bioactive peptide and GI hormone rather than a ghrelin-gene product.

ACKNOWLEDGMENT

The author is grateful to Richard Medeiros, Rouen University Hospital Medical Editor, for editing the manuscript.

Chapter 174

Opioids

Catia Sternini, Celine Duraffourd and Laura Anselmi

ABSTRACT

In the gastrointestinal tract, the endogenous opioid peptides enkephalin, dynorphin, and endorphin, and their receptors, the ∂, μ, and k opioid receptors (∂OR, μOR, kOR) are localized to neurons, and endocrine and immune cells. Enkephalin and dynorphin are primarily localized to enteric neurons, whereas endorphin for the most part is found in enteroendocrine cells. Opioid receptors are predominantly localized to enteric neurons, with the ∂OR and μOR often colocalizing in subsets of neurons; μORs is also found in gut mucosal immune cells. Both ∂ORs and μORs undergo ligand-mediated endocytosis in enteric neurons, whereas μORs recycle to the cell surface, ∂ORs do not. The differential trafficking might reflect differential functions of distinct opioid receptors in the gut. μOR is the main target of opiates, potent analgesics, and mediates the opioid-bowel syndrome, a major complication of chronic opiate treatment. μOR also exerts a protective effect in intestinal inflammation.

DISCOVERY OF OPIOID PEPTIDES AND RECEPTORS

The powerful biological effects attributed to the opioid system, including analgesia, motor activity, stress response, immunity, autonomic and digestive functions, are induced by endogenous opioid peptides and opiate drugs through the activation of distinct opioid receptors,[12,28] which were originally identified on the basis of pharmacological studies with synthetic opiates. The evidence for different receptor types was originally provided by Martin et al. in 1976,[15] who named two distinct opioid receptors, the receptor μ (μ for morphine) and k (k for ketocyclazocine) after the drugs used in their studies. In 1977, the third principal type of opioid receptor, ∂ receptor (∂OR), was discovered by pharmacological analysis of opioid peptide effects on mouse vas deferens.[14] In 1992, the groups of Evans and Kieffer, using expression cloning, isolated and cloned the first opioid receptor gene, Oprd1, which encodes the ∂OR.[11] The Oprm1 and Oprk1, encoding μOR and kOR receptor, respectively, were cloned in the following 2 years.[11] The natural ligands for the opioid receptors were also discovered in the 1970s, the first being the pentapeptides, leucine-enkephalin and methionine-enkephalin, natural ligands for the ∂OR, followed by β endorphins, potent ligands for μOR and ∂OR and then dynorphins, natural ligands for kORs.[1] The cloning of cDNAs for the endogenous opioids followed shortly their isolation.[1] It is only in the 1990s that two opioid tetrapeptides, named endomorphin 1 and endomorphin 2, highly selective for μOR were isolated from the brain;[34] however, the genes for these peptides have not been identified. Opiate drugs or alkaloids, including morphine and fentanyl—the most potent analgesics widely used in humans for pain control[20]—are structurally distinct, nonpeptide ligands that activate the same receptors as native opioids.

STRUCTURE OF THE mRNA/GENE AND PROCESSING OF THE PRECURSOR

Endogenous opioids are generated by three distinct genes, the proopiomelanocortin, proenkephalin, and prodynorphin genes, which generate several biologically active peptides, including beta-endorphin, enkephalin, and dynorphin, via the cleavage of precursor proteins. In addition to processing, posttranslational events also influence the final products, pharmacological profiles and selectivity that might vary in different regions of the brain or periphery.[1] The diverse effects of opioids and opiates are mediated by the activation of multiple receptors, which are classified as members of the superfamily of seven transmembrane G protein-coupled receptors.[4,11] The three major classes of receptors, ∂OR, kOR, and μOR, share about 60% similarity in their sequences. The transmembrane regions share the highest identity (~73–76%), followed by the intracellular regions with 63–66% homologies, whereas they are much more divergent in their extracellular regions with only 34–40% identity. These extracellular domains confer selectivity to the opioid receptors as to their ability to bind agonists and antagonists. Given the complex pharmacological diversity of opioid receptors based on binding sites and ligand affinities, one would have expected the identification of more

than three major ORs. Alternative splicing of the three opioid receptors has been reported, thus providing evidence for the existence of multiple opioid receptors subtypes, classified as μOR1-3, kOR1-3, and ∂OR1-2.[4] In addition, rearrangement of positioning of transmembrane domains and modulation of cytoplasmic domains in response to different agonists, as well as posttranscriptional modifications (phosphorylation, palmitoylation, or glycosylation), receptor dimerization and interactions with intracellular proteins may also account for the diversity of the opioid receptors family as suggested by earlier pharmacological studies.[4]

Opioid receptors partly overlap in their ligand affinity but maintain a certain degree of selectivity for the three families of endogenous opioids and differ in their pharmacological profiles.[4,11] Enkephalins have the highest affinity for the ∂OR, but they also have high affinity for the μOR and very low affinity for kOR. Dynorphins preferentially bind kOR and can also bind μOR and ∂OR. Endorphin binds both μOR and ∂OR with the same affinity, but it has only a low affinity for kOR. By contrast, endomorphins have a preference for μOR that is several thousand-fold that of ∂OR and kOR.[34] Similarly, opiates used clinically preferentially activate the μOR even though their ligand selectivity profiles are impaired when they accumulate at high concentrations, in which conditions they can interact with other opioid receptors.[7]

DISTRIBUTION OF THE mRNA/PEPTIDE

In the gastrointestinal tract, endogenous opioid peptides are localized to the enteric nervous system and to endocrine cells.[12,31] Specifically, in the enteric nervous system, the derivatives of proenkephalins are confined mainly to myenteric neurons projecting to the circular muscle and submucosal plexus,[6] prodynorphin-derived peptides are localized to submucosal and myenteric neurons and to fibers originating from the celiac ganglion,[30] and β endorphins are localized to myenteric ganglion cells and fibers distributed to both plexuses and the muscle.[13] Enkephalins and dynorphins colocalize with classical transmitters (for example, acetylcholine) or peptides, including substance P, vasoactive intestinal polypeptide, gastrin-releasing peptides, galanin, or nitric oxide (NO), the major transmitter from descending neuronal pathways.[6,30] Endogenous opioids are also localized to enteroendocrine and enterochromaffin cells of the stomach, intestine, and pancreas.[31] Opioid receptor binding sites have been reported throughout the mammalian gastrointestinal tract in association with different structures, whereas OR immunoreactivities with specific antibodies for the cloned opioid receptors are predominantly distributed to the enteric nervous system with different sites of expression in different species.[2,9,26,31] Most of the results on opioid receptor localization are concerned with the μOR and ∂OR, whereas results on kOR distribution are sparse. In rats, μOR neurons are more abundant in the submucosal than myenteric plexus, whereas kOR are more numerous in the myenteric than submucosal plexus.[2] μOR and kOR myenteric neurons are more abundant in the stomach and proximal colon compared with those in other regions of the GI tract, and μOR and kOR fibers are distributed to the muscle and mucosal layers. Finally, both μOR and kOR have been reported in interstitial cells of Cajal in the rat myenteric plexus,[2,8] but not in other species.[9] In the guinea pig, an animal model that has been widely used for functional studies of opioid receptors in the GI tract, μOR immunoreactivity is confined mainly to the myenteric plexus.[9,31] Myenteric μOR neuron terminals are most numerous in the small intestine, followed by the stomach and the proximal colon. μOR receptor immunoreactive fibers are dense in the muscle layer and the deep muscular plexus in close association with interstitial cells of Cajal. This distribution closely matches the pattern of enkephalin. μOR enteric neurons comprise functionally distinct populations of neurons of the ascending and descending pathways of the peristaltic reflex.[9] In human gut, μOR immunoreactivity is localized to myenteric and submucosal neurons and to immune cells of the lamina propria.[31] ∂OR immunoreactivity is located in both plexuses where it is predominant in varicose fibers, muscle, and mucosa. kOR immunoreactivity seems to be confined to the myenteric plexus and to bundles of fibers in the muscle. Gray et al. identified the cellular expression patterns of ∂, μ, and k-ORs in the rat ileum[8] and showed μ/∂OR coexpression in interstitial cells adjacent to myenteric plexus and in the submucous plexus. Punctate kOR immunoreactivity was seen broadly in nerve fibers in both plexuses, suggesting localization in varicosities. Although kOR immunoreactivity was often apposed to μOR immunoreactivity, μ/kOR colocalization was not apparent in these neurons but was detected in interstitial cells in submucous plexus ileum rat preparations.[8] Poole et al.[25] used mice in which the enhanced green fluorescent protein (eGFP) was inserted into the ∂OR gene and showed that ∂OR fluorescence is predominantly localized to enteric neurons of both plexuses with higher abundance in the small intestine compared with that in the large intestine and to fibers distributed to the muscle layer. ∂OR-eGFP is localized to secretomotor and vasomotor neurons of the submucosal plexus and to excitatory and inhibitory neurons in the myenteric plexus of the small intestine but mostly in inhibitory neurons of the colon myenteric plexus. Frequent colocalization between ∂OR-eGFP and μOR immunoreactivity is observed.[25]

RECEPTORS AND SIGNALING CASCADES

Activation of opioid receptors is translated into physiological responses via coupling to inhibitory Gi/Go proteins through a pertussis toxin-sensitive pathway resulting in activation of

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

several effectors. opioid receptors act via G proteins to inhibit adenylyl cyclase and the formation of cyclic AMP, increase potassium currents, inhibit calcium channel activity, modulate inositol triphosphate turnover, and activate mitogen-activated protein kinase.[11,28] Coupling of the opioid receptors to the effector system results in attenuation of cellular activity. Opioid receptors are G protein coupled receptors (GPCRs); thus, they follow the scheme of most GPCRs after ligand activation. Interaction of ligand with its GPCR initiates a cascade of events including phosphorylation by G protein receptor kinases (GRKs) that promote interaction with β arrestins (β-arrestins 1 and 2), which prevent further stimulation and downstream signaling pathway by uncoupling receptors from G proteins; therefore, inducing rapid acute desensitization.[3] The phosphorylated opioid receptor–ligand complex then translocates from the cell surface into the cytoplasm through a dynamin-dependent and clathrin-mediated process, undergoes intracellular sorting into endosomes, dephosphorylation and either degradation into lysosomes or recycling to the surface.[3] Phosphorylation, endocytosis, intracellular sorting, and recycling are important regulatory processes that mediate desensitization, downregulation, and resensitization, events that regulate cellular responsiveness to stimulation.

Most of the information available on opioid receptor activation, trafficking, and signaling in the gastrointestinal tract derives from studies on μOR. The presence of μOR receptor at the cell surface is essential for cellular activation, and agonist-induced receptor internalization is an important event in the regulation of cellular responsiveness because it depletes the cell surface of receptors and initiates the intracellular trafficking, thus contributing to late desensitization and to resensitization, respectively. In enteric neurons, in organotypic cultures *in vitro* and *in vivo*, ligand-induced μOR endocytosis occurs in both the soma and neuronal processes and is prevented by naloxone, an opioid receptor antagonist and by CTOP (d-Phe-Cys-Tyr-D-Trp-Orn-Thr-Pen-Thr-NH_2), a selective μOR antagonist. μOR internalization is rapid, reaches a maximum at 30 min and persists for 4–6 h. Internalized μORs recycle to the cells surface, without requiring new receptor synthesis, and internalize again.[18] Ligand-induced μOR internalization in enteric neurons is concentration dependent and ligand-selective, because it is induced by endogenous opioids with high affinity for μOR, such as enkephalins and endomorphins, by enkephalin analogs such as DAMGO ([D-Ala2,N-Me-Phe4,Gly-ol5] enkephalin) (Fig. 1) and by most opiates, including etorphine and fentanyl.[17,18,32] By contrast, morphine, the prototype of opiate drugs, which activates μOR through the same signaling pathways as other opiates and opioids, fails to induce receptor internalization under the same experimental conditions (Fig. 1), even at concentrations far in excess of those inducing maximal inhibition of electrically induced muscle contraction and inhibition of cAMP formation. Moreover, morphine partially inhibits μOR endocytosis induced by etorphine, indicating activation of the receptor.[32] Opiates with high efficiency in inducing μOR internalization (e.g. etorphine or fentanyl) have less propensity to induce tolerance than morphine, which seems to be resistant to internalization and has a higher propensity to induce tolerance.[5] This suggests that perhaps receptor internalization could serve as a mechanism to protect from tolerance, a major side effect of opiate chronic treatment that implies the need of increasing opiate doses to achieve the same analgesic effect. This ligand-selective internalization is generalized to other neurons throughout the brain. The resistance of morphine-activated μORs to undergo internalization is of interest because morphine is a drug of high clinical relevance for its widespread use for pain control and after surgery. The recruitment or upregulation of proteins mediating endocytosis, such as β-arrestin, dynamin, and the G protein-coupled receptors kinases proteins (GRKs) might be an important factor in determining agonist efficiency in inducing receptor internalization. This is supported by the observation that overexpression of GRKs or β arrestins in heterologous

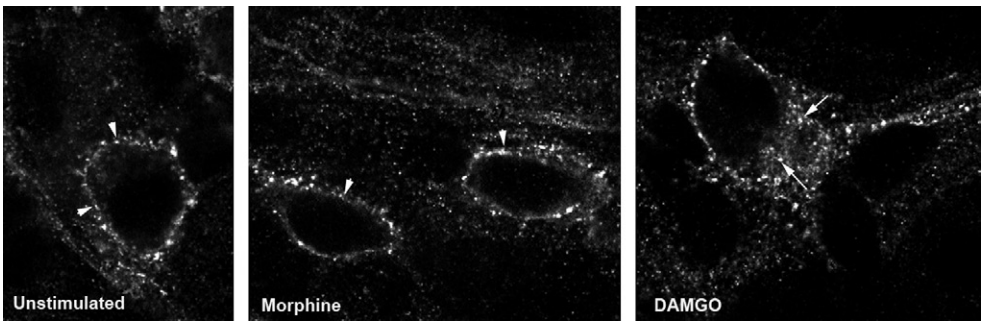

FIGURE 1 μOR immunoreactivity in enteric neurons of guinea pig ileum. μOR immunoreactivity is predominantly found at the cell surface (arrowheads) in unstimulated neurons and in neurons stimulated with morphine, a poor internalizing μOR agonist, whereas it is present in endosomes in the cytoplasm (arrows) in neurons stimulated with DAMGO, a μOR selective agonist with high endocytic efficacy. Organotypic cultures of the small intestine were incubated in medium alone (unstimulated) or containing saturating concentrations of morphine (100 μmol/L) or DAMGO (10 μmol/L) for 1 h at 40 °C to allow ligand–receptor binding, transferred to ligand-free medium at 37 °C for 30 min to allow receptor internalization, fixed, and processed for immunohistochemistry as described.[21]

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

cells increase the efficiency of morphine to induce receptor internalization.[33,35] However, it is not known whether this occurs with native receptors in highly differentiated cells as neurons. Our group has shown that morphine acquires the ability to induce pronounced μOR internalization in enteric neurons from animals rendered tolerant by chronic administration of morphine (Fig. 2). This process is accompanied by increased expression and translocation of dynamin from the intracellular pool to the membrane, whereas β-arrestin levels were not changed.[21] Morphine-induced internalization in enteric tolerant neurons is inhibited by a dynamin inhibitor that blocks coated vesicle formation, further supporting the hypothesis that the increased level and cellular location of dynamin plays a role in inducing internalization of morphine-activated μORs. DAMGO, a selective μOR agonist with high internalizing efficiency retains its ability to induce μOR internalization in tolerant neurons (Fig. 2), indicating that chronic activation of μOR does not impair receptor trafficking in enteric neurons. It is probable that different mechanisms at the receptor level and downstream of the receptor contribute to ligand-induced μOR internalization and to the regulation of opiate drug actions in the gut. These findings are of clinical relevance because μOR enteric neurons are part of the neuronal circuits controlling gastrointestinal functions including motility, which is severely impaired by chronic opiate treatment. μOR internalization also occurs *in vivo* in response to endogenously released opioids, as it occurs in stress conditions such as abdominal surgery.[22]

Like the μORs, the ∂ORs undergo ligand-mediated internalization in enteric neurons, in both the soma and neurites, which is selectively blocked by a ∂OR antagonist and is dynamin dependent. However, unlike μORs, ∂ORs do not recycle to the cell surface and are degraded in lysosomes. Replenishment of ∂ORs at the cell membrane occurs 6–16 h later and requires synthesis of new receptors. The sustained receptor downregulation might play a role in long-lasting tolerance to ∂OR agonists.[25]

BIOLOGICAL ACTIONS WITHIN THE GASTROINTESTINAL TRACT

Opioid effects are complex because they are mediated by different classes of cell-surface receptors, and they depend on different sites of action and species. Opioids and opiates affect a variety of functions within the digestive system, including motility, secretion, and electrolyte and fluid transport.[12] This is consistent with the distribution of opioid receptors in functionally distinct neuronal populations in the enteric nervous.[9] Because opioid receptors are expressed in both excitatory and inhibitory pathways within the neuronal circuits regulating gastrointestinal motility, their activation can result in the inhibition of acetylcholine or other excitatory transmitter release with consequent inhibition of peristaltic contraction; at the same time, opioid receptor activation can result in the suppression of nitric oxide or other inhibitory transmitters thus resulting in the inhibition of peristaltic distension. Thus, activation of these pathways might impair intestinal transit by changing the coordinated reflex motor activity into a segmenting and nonpropulsive motility pattern.[31] By contrast, in the guinea pig, which has been extensively used as a model for functional studies to characterize the physiological and pathophysiological effects of opioids, activation of opioid receptors on myenteric neurons inhibits nerve-mediated contraction of circular and longitudinal muscle and opiod-induced blockade of propulsion and transit is not associated with muscular spasm. Opioid neurons might also exert a modulatory influence on motor neurons subserving peristalsis and might function as a restraining mechanism in conditions of fatigues, that is, when the intestine empties against high resistance. Furthermore, the observation that μOR fibers surround interstitial cells of Cajal (ICC), which are pacemakers coordinating intestinal motor activity and are likely to be involved in neurotransmission from neurons to muscles, suggests an additional pathway through which

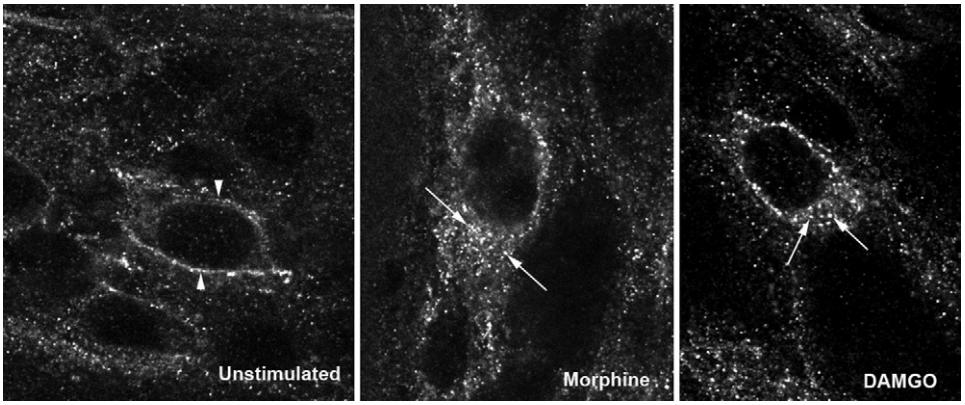

FIGURE 2 μOR immunoreactivity in enteric neurons of guinea pig ileum rendered tolerant by chronic treatment with increasing concentration of morphine for 7 days as described.[21] μOR immunoreactivity is predominantly found at the cell surface (arrowheads) in unstimulated neurons, but it translocates into endosomes in the cytoplasm (arrows) in neurons stimulated with morphine or DAMGO, as described in Fig. 1.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

OR activation might affect gastrointestinal motility.[9] opioid receptor activation might result in the inhibition of ICC activity via the reduction of transmitter release by excitatory and inhibitory neurons, which innervate ICCs. Opioids also attenuate electrolyte and water secretion and facilitate net absorption of fluids. Together, these inhibitory effects on motility and secretion induce constipation.

Even though the central administration of opiates can delay gastrointestinal transit, there is overwhelming evidence that the effects of opioids on gastrointestinal functions are mostly peripheral resulting from the direct activation of opioid receptors in the gut, which is supported by morphological and functional evidence and by the observation that opioid receptor antagonists with peripherally restricted sites of action prevent opiate-induced delay of transit and that antagonists, which do not cross the blood–brain barrier block opiate effects in the gut.

PATHOPHYSIOLOGICAL IMPLICATIONS

Opiates are sill the mainstay therapeutic approach for chronic pain. However, the prolonged use of these drugs induce a variety of side effects, including tolerance, which requires increasing doses of opiates to obtain the desired analgesic effects, which in turn aggravate tolerance thus creating a vicious cycle. Furthermore, the chronic use of opiates induces serious side effects at the level of the gastrointestinal tract resulting in the development of opioid-bowel dysfunction (OBD).[19] OBD is mediated by μOR, which is the main target of opiates and is characterized by a variety of symptoms, including decreased gastric emptying, abdominal cramping and bloating, delayed gastrointestinal transit, and constipation, which is the main and most severe symptom that can be so intolerable to induce patients to stop opiate treatment. OBD is a clinical problem affecting as many as 60–90% of patients who receive opioids for chronic metastatic malignancy or chronic noncancer pain. Currently, the best treatment available is the use of peripheral μOR antagonists, such as Alvimopan and Methylnaltrexolone to counteract the peripheral effect of opiates without affecting the central, analgesic effect.

μORs are also contribute to the worsening of postoperative ileus (POI), a transient condition that develops after abdominal or pelvic surgery.[10] POI is characterized by the delay of gastrointestinal transit with bowel distension, bloating, nausea, and vomiting. POI is caused by a combination of inflammatory, immunological, and neurogenic mechanisms, and it is aggravated by the use of opiates as postsurgery analgesics. The best results for POI treatment have been reported with the use of the selective, peripherally acting μOR antagonist, Alvimopam.

Increasing evidence supports a role of the opioid system in intestinal inflammation.[23,24] Indeed, immune cells express endogenous opioids and their receptors, μOR, kOR, and dOR, and opioid peptides are released by immune cells. *In vivo* treatment with opioids and opioid antagonists has been reported to modulate release of proinflammatory cytokines, including tumor necrosis factor (TNF) α, and opioids can sensitize T-lmphocytes and macrophages to proinflammatory stimuli. In addition, opioid antagonists have been shown to improve the inflammatory scores and quality of life of patients with Crohn's disease and to reduce inflammation in moderate experimental colitis, but not in severe colitis, probably through the activation of ∂OR, supporting a proinflammatory role of ∂OR.[16,29] By contrast, μOR seems to exert immunosuppressive effects. μOR agonists have been shown to ameliorate inflammation in animal models of acute intestinal inflammation, and μOR deficient mice have been shown to be more susceptible to colon inflammation than their littermate controls suggesting that μOR agonists might represent a novel therapeutic approach for inflammatory bowel diseases (IBD). In addition, the upregulation of μOR mRNA has been reported in intestinal inflammation and in patients with IBD. μOR has been localized on both enteric neurons and immunocytes in patients with IBD, but it is overexpressed in inflammatory cells in patients with active IBD.[23] In addition, μOR is increased by cytokines and ex vivo treatment with a selective μOR agonist reduces the expression of TNF-α in the mucosa of patient with active IBD. These results support a protective effect of μOR in intestinal inflammation and suggest that μOR agonists could be potential new therapeutic molecules for the treatment of IBD. We have shown that treatment with a selective μOR agonist, DAMGO, at concentrations that do not pass the blood–brain barrier and do not affect gastrointestinal transit, reduces the acute inflammatory processes and epithelial damage induced by intestinal ischemia/reperfusion.[27] Intestinal ischemia is a life-threatening emergency with high mortality rate that ranges from 30% to 90% depending on the etiology. It can occur in several clinical–surgical conditions, including abdominal surgery for aortic aneurysm, small bowel transplantation, cardiopulmonary bypass, strangulated hernias, and neonatal necrotizing enterocolitis. Intestinal ischemia, a consequence of reduction of tissue oxygenation, induces progressive tissue damage and necrosis, which is paradoxically aggravated by restoration of the blood flow or reperfusion. DAMGO reduction of inflammation in intestinal ischemia is accompanied by a reduction in myeloperoxidase, an index of neutrophil infiltration, and of the proinflammatory cytokines. These findings provide evidence for a protective role of μORs in intestinal inflammation induced by ischemia/reperfusion. This effect probably predominantly results from the activation of μOR in inflammatory cells and is mediated by the proinflammatory cytokine, TNF-α. These findings support the concept that peripheral μORs could be explored as possible targets for novel therapeutic approaches to ameliorate inflammation, the first acute event in intestinal injury induced by ischemia/reperfusion.

PACAP

John P. Vu, Patrizia M. Germano and Joseph R. Pisegna

ABSTRACT

Pituitary adenylate cyclase polypeptide (PACAP) is a member of the superfamily of peptide hormones that includes vasoactive intestinal polypeptide (VIP) and secretin. PAC1 is a specific receptor with a 1000-fold greater affinity for PACAP compared with VIP or secretin. PAC1 is expressed in the gastrointestinal tract where PACAP functions to regulate gastrointestinal secretion and motility. PACAP seems to play a key role in the central nervous system regulation of appetite, although its potential peripheral mechanism remains unknown. It is involved in the regulation of innate and adaptive immune responses and may have a role in inflammatory bowel diseases. In neuroendocrine tumors, both PAC1 and PACAP are expressed and seem to regulate the tumor growth and the release of other neuropeptides and biogenic amines.

INTRODUCTION

PACAP was isolated by Arimura and coworkers in 1989 by examining fractions of ovine hypothalamus capable of stimulating adenylyl cyclase (AC). PACAP is derived from a 170-amino-acid long precursor, which gives rise to two biological forms, PACAP 38 and PACAP 27, in which the first 27 N-terminal amino acids share complete identity. PACAP activity is mediated through binding to three G protein-coupled receptors:[14] the high affinity PAC1 and VPAC1/VPAC2, which bind with similar affinity to PACAP and VIP, inducing an intracellular cyclic adenosine monophosphate (cAMP) increase, and a Ca^{2+} response (only PAC1).[25] Although all the biologically active forms of PACAP can be identified in tissues, the predominant form is PACAP 38, whose structural similarity places it in the superfamily of hormones including also secretin, glucagon, glucagon-like peptides, and gastric inhibitory peptide (GIP).[14] These peptides are covered in this and other sections of the book, and specific chapters on PACAP are in the Brain, Cancer, Endocrine, and Respiratory Peptide sections.

The amino acid sequence of PACAP hormone shows interspecies mammalian similarity. Disruption of the PACAP gene has resulted in a greater understanding of the role of PACAP on lipid and carbohydrate metabolism, and thermogenesis.[12] In this murine model, the lack of PACAP expression results in inadequate heat production resulting from insufficient norepinephrine stimulation of brown adipose tissue. PACAP may play a role in the central nervous system (CNS) in the regulation of appetite/satiety by modulating leptin signaling mechanisms;[16] after blockade of endogenous central PACAP signaling with the partial PACAP antagonist, PACAP (6-38), leptin-induced hypophagia and hyperthermia are attenuated *in vivo*. In the gastrointestinal tract, PACAP expression has been identified in the esophagus, stomach, duodenum, and intestine, where its primary function is to regulate secretion and motility.[4] In intestinal warm ischemia in PACAP null mice,[7] PACAP-38 seems to have a protective role.

In intestinal smooth muscle cells, PACAP, released from the enteric nerves acts as a potent nonadrenergic, noncholinergic (NANC) transmitter, supposedly in concert with other mediators to regulate gastrointestinal smooth muscle contraction.[21] NANC inhibition of gastrointestinal smooth muscle involves several intracellular mechanisms, including increase of cyclic guanosine monophosphate (cGMP), increase of cAMP, and hyperpolarization of the cell membrane via direct or indirect activation of potassium ion (K^+) channels. PACAP-induced responses in the intestine are believed to involve intracellular mechanisms of hyperpolarization of the cell membrane, by direct or indirect activation of the apamin-sensitive potassium ion (K^+) channels, by cGMP or cAMP increase, or activation of nitric oxide.

PACAP is also a potent stimulator of cellular growth and differentiation as seen in AR-42 J cells, in which PACAP stimulates an increase of ornithine decarboxylase activity and cell proliferation,[1] and in PC-12, a pheochromocytoma cell line, in which PACAP stimulates neurite outgrowth.[6] After small bowel autotransplantation, PACAP-38 reduces small bowel oxidative stress and injury induced by cold ischemia and reperfusion, suggesting that PACAP-38 may be useful in small-bowel transplantation.[8]

PACAP has been specifically linked to some human motility disorders such as Hirschsprung's disease, in which a reduction in PACAP-immunoreactive nerve fibers is found. PACAP is expressed at high levels in neuroendocrine tumor cells where it induces intracellular signaling, release

of intracellular preformed mediators such as 5-hydroxytryptamine, and cellular proliferation.[11]

CLONING AND CHARACTERIZATION OF PAC1

Radioligand binding studies with a rat pancreatic acinar carcinoma cell line, AR42 J, as well as hypothalamic and brain cell membranes, suggested that a specific receptor for PACAP exists.[25] The AR42 J cDNA library was used for the cloning and characterization of PAC1 in 1993.[25] The receptor cDNA encodes a putative protein containing 495 amino acids with a molecular weight of approximately 50 kDa.[25] The deduced amino acid sequence of the PAC1 shows that it belongs to the family of VIP, secretin, and glucagon receptors.[14,25] Pharmacologically, PAC1 has >1000-fold greater affinity for either PACAP-27 or PACAP-38, whereas there is little to no affinity for secretin and glucagon.[25] PACAP-27, PACAP-38, and VIP have equal binding affinity for VPAC1 or VPAC2 receptors. Studies of the PAC1 gene identified that the receptor could exist in four major splice variants, which differ in the length of the third intracellular domain, each with a differential tissue expression and different signal transduction properties regarding their ability to differentially activate AC and phospholipase C (PLC).[25] A fourth splice variant occurring in the transmembrane region of PAC1 does not couple to either cyclic AMP or PLC but couples to an L-type Ca^{2+} channel.[14] A similar observation was made after the discovery of the human PAC1, wherein two exons could be differentially spliced and expressed.[25] The differential activation of PLC by the splice variants may have important consequences in the signal transduction cascades observed in the gastrointestinal tract and expressed on tumors.[10] The human PAC1 gene is localized on chromosome 7, while in the rat, it is localized on chromosome 4. Maxadilan, a peptide isolated from a sand fly salivary gland, appears to selectively bind to PAC1 but it does not share peptide homology with either PACAP or VIP.[29] Leukocyte accumulation and plasma leakage induced by maxadilan administration involves a mechanism mediated through the activation of PAC1-receptors expressed on leukocytes and endothelial cells.[29]

RECEPTOR BINDING AND INTRACELLULAR SIGNALING CHARACTERISTICS OF PAC1

Structure–function studies indicate that the N-terminal first extracellular (EC1) domain of PAC1 is the dominant region of the receptor for PACAP hormone recognition and binding.[5,32] Several domains of PACAP hormone have been recognized to be involved in the interaction with PAC1 receptor, and the presence of the helical conformation is not a sufficient feature for receptor activation.[5] PAC1 uses a similar conserved fold of Class B G-protein-coupled receptor extracellular domain for PACAP binding, indicating that there is a conserved consensus for this family of receptors.[17] Subsequent to the discovery of PACAP, Deutsch and Sun, working with the pheochromocytoma cell line PC-12 showed that PACAP is coupled to both AC and PLC.[6] These observations were confirmed in the anterior pituitary-derived somatotrophs and gonadotrophs, as well as of adrenal chromaffin cell cultures.[2] In somatotrophs, PACAP stimulates cAMP-dependent Ca^{2+} influx, whereas in gonadotrophs PACAP induced PLC-stimulated Ca^{2+} release.[2] An examination of the carboxyl-terminal region of PAC1 indicated that there are two critical amino acids (Ser and Arg) responsible for signal transduction coupling.[19] It has been hypothesized that the ability of PAC1 to signal differentially, through either the Gαs or Gαq signal transduction pathway in a tissue-specific manner, suggests a possible mechanism by which PACAP can modulate the proliferation of some tumoral cells such as the pheochromocytoma cell line, PC-12, and neuroblasts.[6,10]

PAC1 is expressed also on many tumor cell lines, including the human colon cancer HCT8 and HCT-116 cell lines[10] and BON neuroendocrine cells of pancreatic carcinoid origin as shown by immunofluorescent staining by confocal laser imaging microscopy in Fig. 1.[11] Differential coupling of PAC1 SV1 splice variant onto HCT8 and HCT-116 human colonic tumor cells induces tumor growth only when both cAMP and Ca^{2+} responses are simultaneously activated. cAMP elevation without Ca^{2+} increase does not seem to activate cell proliferation.[10]

The expression of PACAP in the suprachiasmatic nuclei of the hypothalamus, and the development of transgenic animal models, suggest that PACAP and PAC1 are involved in the regulation of circadian rhythms.[3,13] PACAP has potent neuroprotective effects not only *in vitro* on cultured astrocytes, but also in *in vivo*.[28] The expression of PAC1 in the amygdala and the demonstration of a reduced anxiety behavior suggest that PACAP may be involved in the regulation of stress responses.[15]

ROLE OF PACAP IN THE GASTROINTESTINAL TRACT

In peripheral tissues, the maximum density of PAC1 occurs in the adrenal gland[14] and also the human prostate gland and testis express high levels of PAC1.[14] In the gastrointestinal tract, PACAP is expressed in the esophagus, stomach, duodenum, as well as the small and large intestines.[4] PAC1 has been observed in the rat and mouse enterochromaffin-like cells of the stomach[24] and in gastric and colonic myenteric cells and neurons. In colonic enteric nerve fibers, PACAP and PAC1 are colocalized.[22]

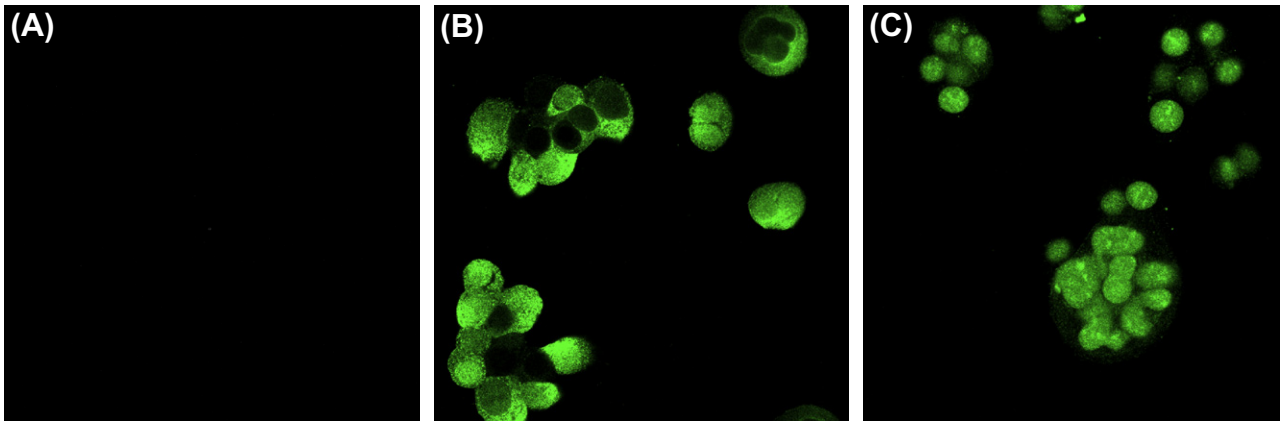

FIGURE 1 Confocal MIcrograph of BON cells stained with (B) anti-PAC1 antibody or (C) anti-PACAP antibody. See color plate 48.

In these studies, whole mount sections were stained with specific anti-PACAP and anti-PAC1 antibodies to show PACAP and PAC1 colocalization in enteric neurons and myenteric cells.[22] Other PACAP receptors as VPAC1 are expressed in the gastrointestinal tract: in the stomach VPAC1 (classical VIP receptor) are expressed on gastric D cells and on gastric chief cells.[33] These different gastric cell types are primarily involved in the secretory digestive functions of the stomach and seem to play a key role in the regulation of gastric acid secretion. In addition to being expressed on secretory cells, both VPAC1 and PAC1 seem to be expressed on gastrointestinal smooth muscle cells.

Other studies indicate that gastrointestinal lymphocytes and antigen presenting cells express VPACs and PAC1,[9] which may play a role in the regulation of gastrointestinal inflammatory responses. In the rat pancreas, PACAP is a potent stimulant of amylase release and presumably the neuropeptide is localized within nerve fibers innervating the pancreas.[26] The existence of PACAP immunoreactivity in the pancreas may implicate a role for PACAP in exocrine pancreatic function.[26] On gastrointestinal smooth muscles PACAP is a potent NANC inhibitory neurotransmitter, which is thought to act via apamin-sensitive potassium channels.[27] PACAP-containing nerve fibers are present in the small and large intestines where they are involved in motility functions. In rats, PACAP stimulates apamin sensitive K^+ channels[27] and both VIP and PACAP stimulate nitric oxide synthase (NOS), as in the porcine jejunum. Other studies show that PACAP modulates colon-inferior mesenteric ganglion (IMG) reflexes. The role of VIP and PACAP on the relaxation of the gastrointestinal smooth muscle is not clear; some results indicate that this effect would be mediated via the release of nitric oxide. In dispersed rabbit gastric muscle cells, crosscompetition by either VIP or PACAP suggests a potential interaction of both peptides with the same receptors via differential signal transduction pathways. In studies on gastric smooth muscle isolated from rabbit or guinea pig, it seems that VPAC2 is the principally expressed receptor.[31] In a guinea pig model, there is specific expression of a subclass of VPAC receptors with specificity for VIP that may represent a novel splice variant. However, the role of PAC1 has been supported by a study in a mutant mouse model showing that the effects of PACAP in mediating NANC relaxation of longitudinal muscles are mediated specifically by PAC1. Currently, it is unclear whether the discrepancy observed in these studies results from species-related differences, or whether there are multiple classes of VPAC and PAC receptors, which are intimately involved in regulating gastrointestinal motor functions. In humans, PACAP has been linked to motility disorders such as Hirschsprung's disease, in which a decrease in the number of PACAP- immunoreactive nerve fibers has been detected.

In gastric PACAP-containing enteric nerve fibers, the neuropeptide has been observed to colocalize with PAC1 receptors.[22] The physiological significance of PACAP expression in the gastric epithelium seems to be related to the gastric ECL cell stimulation of histamine release and thereby of gastric acid secretion.[18] However, PACAP activation of VPAC1 receptors, expressed on the somatostatin-containing D cells, plays an opposite effect by inhibiting gastric acid secretion.[33] The effects of PACAP stimulation of ECL cells during the nocturnal hours may account for the observed increase in gastric acid secretion that occurs in humans at approximately 0200–0400 and, therefore, may have clinical implication in the development of nocturnal gastroesophageal reflux symptoms.[33]

The isolation of pure cell populations of rat gastric ECL cells[24] has enhanced the understanding of the PAC1 receptor expression and the PACAP physiological function in the stomach. PACAP stimulation of pure populations of ECL cells results in intracellular Ca^{2+} release, cAMP stimulation, and histamine release. The use of microarray analysis has confirmed the expression profile of genes predominantly involved in the ECL secretory pathways.[24] Similarly, in

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

whole rabbit gastric glandular preparations PACAP activates intracellular Ca^{2+} release in ECL cells, and through the release of histamine stimulates parietal cell acid secretion.[33]

ROLE OF PACAP IN THERMOGENESIS, OBESITY, AND APPETITE

PACAP and PAC1 seem to play an important role in the regulation of appetite/satiety and, more recently, the development of PACAP or PAC1 deletion mouse models has allowed to better study their role in the regulation of feeding behavior. Obesity and particularly abdominal fat accumulation are associated with numerous metabolic abnormalities, including insulin resistance and type II diabetes in a significant proportion of patients. PACAP is a strong secretagog of insulin from pancreatic islets, contributing to the homeostasis of glycemia and modulation of the pathogenesis of diabetes.[26] *In vivo* and *in vitro* studies[26] suggest that PACAP has trophic effects on pancreatic beta cells and regulates both their proliferation and viability, thereby protecting against diabetes. PACAP reduces food intake and regulates energy homeostasis;[20] mRNA expression of PACAP decreases in the VMN during fasting but is increased during high fat diet. PACAP injections into the VMN inhibit food intake under normal and fasting conditions via PAC1 signaling, which may contribute to the thermogenic response of PACAP through activation of α-MSH (melanocortin system), a mediator of PACAP-induced autonomic nerve activity.[16,23] In animal models, intracerebroventricular (icv) injection of PACAP decreases food intake in vertebrates, including rodents, chick, and goldfish,[20] indicating an anorexigenic role for PACAP at the CNS level in the arcuate nucleus (ARC). In chick, PACAP and VIP icv inhibit food intake, but the coinjection of PAC1 receptor antagonist, PACAP (6–38), attenuates only the anorexigenic effect of PACAP, but not that of VIP; whereas, icv coinjection of VPACs receptor antagonist, [D-p-Cl-Phe6, Leu17]-VIP, does not alter the effects of PACAP and VIP, suggesting that PAC1 and not VPACs receptors mediate PACAP anorexigenic mechanisms in the chicken brain. PACAP, released on leptin binding to PACAP containing neurons in the nucleus arcuate, plays an anorexigenic effect through the activation of α-MSH.[23] In contrast, PACAP also stimulates the orexigenic NPY neurons in the ARC, indicating a dual and opposite central activity.

ROLE OF PACAP IN THE IMMUNE SYSTEM

PAC1 is expressed on macrophages and lymphocytes, where it seems to regulate innate and adaptive immune responses, promoting a Th1 cellular phenotype.[9] The PACAP knockout mouse model shows a hyperinflammatory effect in an autoimmune encephalomyelitis (EAE) model of multiple sclerosis, with an enhanced Th1/Th2 cytokine profile.[30] PAC1 expression has been identified on intestinal and peripheral circulating lymphocytes, where it seems to play an important role in the regulation of inflammatory cytokine gene expression.

To investigate the role of PAC1 in colonic mucosal inflammation, the DSS-colitis model was used in PAC1 -/- mice. After four days of DSS treatment, elevated inflammatory parameters are increased in PAC1-deficient mice compared with that of wild-type mice. These results suggest that the PAC1 receptor may be involved in the modulation of the pathogenetic mechanisms that underlie colonic mucosal inflammation and repair mechanisms, and that a deficiency state might increase the tissue damages, that lead to the evolution of inflammatory bowel disease (IBD).

CONCLUSIONS

The discovery of PACAP and its receptor PAC1 has resulted in a new era of understanding the role of neuropeptides in the regulation of physiological processes. PACAP and its receptors are expressed throughout the body, and especially in the central nervous system, where they play an important role in the embryological development of the brain, induce a neurotrophic effect, are involved in the regulation of circadian rhythms, act as anxiolytic agents, and control feeding behavior. In the gastrointestinal tract, the neuronal and mucosal cell expression of this peptide suggests that PACAP is one of the key regulators of the neuroenteric nervous system. PACAP seems to stimulate secretion from the stomach through its actions on the PAC1 receptor,[18] whereas it clearly has a regulatory function in inhibiting gastric acid secretion through the VPAC1 receptor expressed on the gastric D cells.[33] In the intestine, PACAP acting at either via PAC1 or VPAC1 seems to be a regulator of gut motility and responsible for smooth muscle relaxation. In the pancreas, PACAP acts as a trophic factor and is involved in the stimulation of insulin secretion at the exocrine pancreas level.[26] PACAP and PAC1 are potential therapeutic targets for future clinical development.

Chapter 176

Pancreatic Polypeptide

Tricia M. Tan and Stephen R. Bloom

ABSTRACT

Pancreatic polypeptide (PP) is a 36-amino acid, C-terminally amidated peptide, and is a member of the PP-fold peptide family. It is produced and secreted by the PP cells of the islets of Langerhans. PP secretion is stimulated by food intake proportional to calorie intake under the control of the vagus nerve. Its physiological functions include actions as a satiety hormone, suppression of exocrine pancreatic secretion and possibly in slowing gastric emptying. The PP cognate receptor is the neuropeptide Y4 receptor, and key anatomical structures expressing this receptor are the brainstem (area postrema, dorsal vagal complex), hypothalamus and the small and large intestines. There is evidence of a distinct PP receptor in the liver, but this is not as well characterized as yet.

DISCOVERY

PP was originally discovered as a contaminant of insulin preparations from chicken pancreas by Kimmel et al.,[19] and bovine pancreas by Lin and Chance.[24]

STRUCTURE OF THE GENE AND PROTEIN

The *Homo sapiens* gene encoding the precursor preproPP (HGNC name: *PPY*) is located on chromosome 17, adjacent to the gene encoding the precursor of peptide YY (HGNC name: *PYY*). Evolutionarily, *PPY* seems to have arisen as a tandem duplication of the *PYY* gene with or just before the emergence of tetrapods. In a second evolutionary event, the *PYY-PPY* gene cluster has been duplicated in the primate and ungulate lineages, after the divergence of the rodents, to create a *PYY2-PPY2* cluster on chromosome 17. The *PPY2* gene seems to be a pseudogene as there is a point mutation introducing a premature stop codon in the signal peptide region, and the gene does not encode a functional protein.[13]

The cDNA for *PPY*, first isolated and sequenced by Boel et al.,[10] consists of 4 exons, all constitutively spliced together. Exon 1 contains the sequence of the 5′ untranslated region (45 nt long). Exons 2–4 contain the coding sequences. Notably, exon 2 contains the signal peptide and most of the functional domain of PP with the exception of the C-terminal Tyr^{36}. Exon 3 encodes the Tyr^{36} residue and the C-terminal PP "icosapeptide." Exon 4 encodes the C-terminal heptapeptide and the 3′ end of exon 4 contains a 3′ untranslated region of 124 nt.

PP is a 36-amino acid, C-terminally amidated peptide (Fig. 1). It is a member of the so-called PP-fold peptide family. This family encompasses neuropeptide Y (NPY), peptide YY (PYY), and PP. These peptides contain a common structural motif, the PP-fold, which consists of two antiparallel helices, a type 2 proline helix and an alpha helix, connected by a type 2 beta turn. The two helices interact via hydrophobic residues, stabilizing the fold.[35]

The sequences of human and bovine PP are closely related and differ only by two residues.[10] A sequence comparison between the PP orthologs isolated from mammals, avians, and reptiles identifies 8 conserved (and presumably key) residues, namely, Pro^5, Pro^8, Gly^9, Ala^{12}, Leu^{24}, Tyr^{27}, Arg^{33}, and Arg^{35}.[14]

PROCESSING OF PREPROPP AND PP

The precursor preproPP (Fig. 2) is a 95-amino acid peptide, which is processed to PP (residues 30–65 of preproPP). The N-terminal signal peptide is cleaved in the endoplasmic reticulum (preproPP residues 1–29) to release proPP (residues 30–95). Residues 66–68 (Gly-Lys-Arg—"GKR") represent the cleavage and amidation signal.[11] Residues 69–87 encode the PP icosapeptide, which is followed by the C-terminal heptapeptide (residues 88–95).

ProPP is believed to be first cleaved at the "dibasic cleavage site" Lys-Arg (residues 67,68) to release PP and the proPP C-terminal peptide. The proPP C-terminal peptide is subsequently processed at the "monobasic cleavage site" to release the PP icosapeptide and the C-terminal heptapeptide.

Although multiple forms of PP immmunoreactivity separable by gel filtration chromatography are found in circulation, normal pancreatic tissue only produces one form of PP that is indistinguishable from the pure PP peptide.[2] Therefore, the circulating forms probably represent incompletely cleaved or breakdown products.

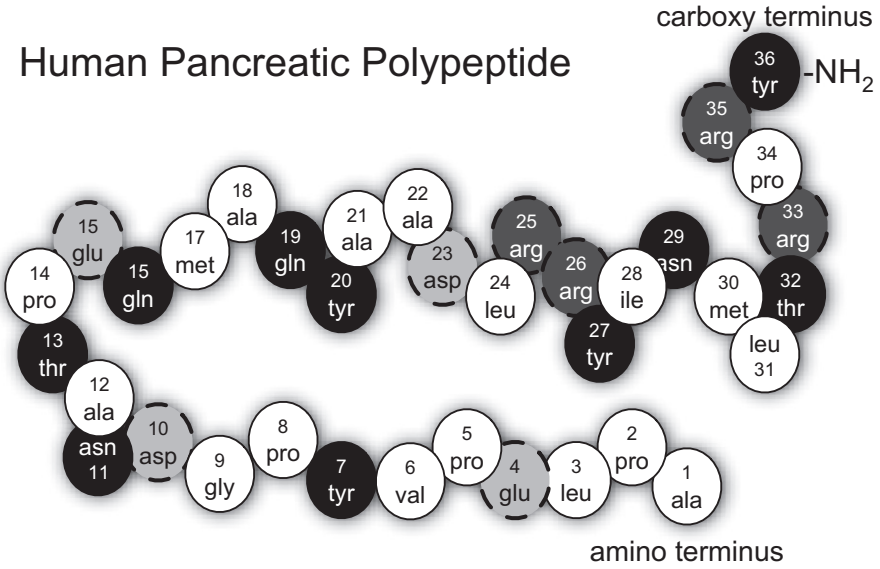

FIGURE 1 Primary sequence of human pancreatic polypeptide. Amino acid residues are abbreviated as follows: Ala = alanine, Pro = proline, Leu = leucine, Glu = glutamic acid, Val = valine, Tyr = tyrosine, Gly = glycine, Asp = aspartic acid, Asn = asparagine, Thr = threonine, Gln = glutamine, Met = methionine, Arg = arginine, Ile = isoleucine. NH_2 = carboxy terminal amide group. Dashed line, dark gray = positively charged side chains; Dashed line, light gray = negatively charged side chains, Black = polar uncharged side chains; Solid line, white = hydrophobic side chains. Numbers denote the residue numbers from the amino terminus.

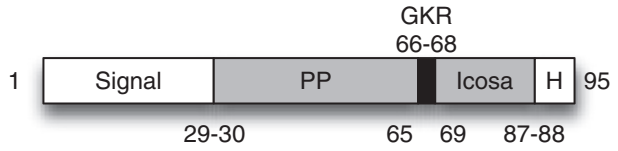

FIGURE 2 Structure of preproPP peptide. Key: Signal = signal peptide; GKR = Gly-Lys-Arg cleavage and amidation signal; Icosa = Icosapeptide; H = C-terminal heptapeptide.

Pharmacokinetic studies with bovine PP infusions into human volunteers reveal that PP is rapidly broken down, with an apparent terminal elimination half life of 6.9 ± 0.3 min, a metabolic clearance rate of 5.1 ± 0.2 ml/kg/min and an apparent volume of distribution of 51 ± 3 ml/kg.[4] This rapid breakdown is mediated by endogenous peptidases such as neprilysin (neutral endopeptidase 24.11) and dipeptidyl peptidase IV.

DISTRIBUTION AND SECRETION OF PP

PP is secreted by PP cells of the islets of Langerhans. The PP cells are localized more in the periphery of the islets. PP cells tend to be found in greater quantity in the islets in the head of the pancreas rather than the tail. In primates, 93% is found in the pancreas, but PP is also found in smaller quantities in the distal gut. The mean fasting plasma level of PP in normal volunteers is 31.2 ± 6.2 pmol/L.[2]

Food intake stimulates PP secretion, for example, a "normal" hospital lunch caused a postprandial increase in PP levels to 164 ± 46.2 pmol/L. The postprandial secretion seems to be biphasic, incorporating an acute peak of secretion at 0–60 min and a more sustained peak from 60 to at least 360 min.[1] Postprandial PP secretion is proportional to the size of the meal eaten. Postprandial PP secretion seems to be under the control of the vagus nerve, such that vagotomy or atropine treatment markedly reduce secretion.[32]

PP release is not stimulated by parenteral infusions of glucose, amino acids, or fat. Insulin-induced hypoglycemia induces a sharp increase in PP secretion from the pancreas.[1]

Other influences on PP secretion include the following:

- *Cholecystokinin* (*CCK*): Adrian et al. showed that an infusion of caerulein, a CCK analog, in humans stimulates PP release,[1] and this is also true of the CCK peptides found in humans.
- *Secretin*, *Gastric Inhibitory Peptide* (*GIP*): Secretin and GIP are gut hormones that are related in sequence. Secretin stimulates PP release in human volunteers.[1] Similarly, a bolus injection of GIP has been shown to stimulate PP release by 2- to 3-fold in volunteers.[6]
- *Somatostatin*: Studies with an isolated perfused human pancreas preparation show that there seems to be no direct effect of somatostatin-14 infusion on PP secretion. There was also no effect of immunoneutralization of intraislet somatostatin on PP secretion.[20] However, infusion of somatostatin into human volunteers does suppress PP secretion, suggesting that the effects of somatostatin may be indirectly mediated.[27]
- *Ghrelin and related peptides*: The octanoylated form of ghrelin and obestatin (an alternative product of the processing of the proghrelin precursor) seem to inhibit the secretion of PP by isolated rodent islets.[30]

RECEPTORS AND SIGNALING CASCADES

PP-fold peptides bind to the neuropeptide Y family of seven-transmembrane-domain receptors, Y1, Y2, Y4, and Y5, all of which are expressed in the hypothalamus and in the periphery.[9]

PP binds with highest affinity to the Y4 receptor with a K_D of 13.8 pM, and also to Y1 and Y5 with lesser affinity. The Y4 receptor is distributed widely, with expression in the small and large intestines and testis (in the rat).[9] It is distributed widely in the CNS, particularly in the hypothalamus, area postrema, the dorsal vagal complex and a subregion of the nucleus tractus solitarus called the subnucleus gelatinosus.[34] Y4 receptor exists in the membrane as homodimers, but these dissociate on binding PP. The activated Y4 receptor inhibits adenylyl cyclase via the G_i G-protein, therefore reducing intracellular cyclic AMP levels.[25] Y4 also activates G_q, inositol triphosphate release, and intracellular Ca^{2+} release.[28]

The key residues of PP involved in binding of PP to Y4 appear to be Pro^2, Pro^3, Arg^{33}, Arg^{35}, Tyr^{36}. Deletion of the C-terminal amide substantially reduces binding, indicating its key importance.[16]

A specific PP-binding receptor activity has been found in the liver that binds PP with a higher K_D of 3.4–4.6 nM.[29] Y4 receptor is not known to be expressed in the liver, implying that the hepatic PP receptor is a distinct receptor type, the exact nature of which is as yet unknown.

BIOLOGICAL ACTIONS

Effects of PP on Appetite, Energy Expenditure, and Energy Balance

A major physiological action of PP seems to be as a postprandial satiety hormone. PP was originally shown to reduce food intake when administered peripherally to mice in 1977.[26] Batterham et al. showed that an iv infusion of PP at a dose of 10 pmol/kg/min for 90 min reduced food intake in lean human volunteers by 21.8 ± 5.7%, as assessed by consumption of a buffet lunch. There was a significant inhibition of cumulative food intake during 24 h of 25.3 ± 5.8%. During the infusion, PP levels increased from a baseline of 15.5 ± 4.4 to 258.5 ± 21.4 pmol/L, a supraphysiological concentration. Although PP is known to slow gastric emptying in other studies,[31] at this dose, there was no detectable effect on gastric emptying.[8]

Schmidt et al. also infused PP at lower doses of up to 2.25 pmol/kg/min in lean human volunteers.[31] Interestingly, this lower-dose infusion achieved peak levels of 299 ± 23.7 pmol/L, higher than those reported by Batterham et al., and three times normal postprandial levels. The study did not focus on food intake as an endpoint, but it was noted that PP infusion was not associated with significant reductions in hunger and appetite as assessed by visual analog scales.

The exact site of action of PP's anorexigenic (appetite-reducing) action is not completely known. Possible sites of action include the area postrema as Y4 receptors are particularly rich in this area, and also visceral vagal nerve afferents to the brainstem as vagotomy abolishes the anorectic effect of PP.[21] Indeed, intraperitoneal PP activates the area postrema and nucleus tractus solitarius as assessed by staining for the neuronal activation marker c-*fos* (Fig. 3).[23]

The hypothalamus is also another possible site of action, circulating PP perhaps diffusing to the hypothalamus through the incomplete blood–brain barrier at the median eminence. Intraperitoneal PP also activates c-*fos* expression in the arcuate nucleus of the hypothalamus and, more specifically, the anorexigenic neuronal group that expresses alpha-MSH (Fig. 3, POMC/CART). The importance of alpha-MSH signaling in mediating the anorexigenic action of PP is underlined by the observation that knockout of the alpha-MSH receptor, MC4, abolishes the anorexigenic effect of PP. Moreover, a conditional knockout of the Y4 receptor in the hypothalamus abolishes the activation of the alpha-MSH neurons by intraperitoneal PP, suggesting that the principal site of action is indeed in the hypothalamus.[23] In addition to its action on food intake, repeated intraperitoneal injections of PP also stimulate sympathetic activity and oxygen consumption, perhaps causing an increased energy expenditure that would tend to augment weight loss.[7]

Effects of PP on Pancreatic Secretion and Gall Bladder Function

PP inhibits the exocrine secretion from the pancreas and the motor function of the biliary tree and gall bladder. This was assessed by measurement of trypsin and bilirubin output, respectively, from duodenal juice samples in volunteers undergoing infusion of secretin and caerulein to stimulate pancreatic secretion and gall bladder contraction: infusion of bovine PP to achieve typical postprandial PP levels inhibited trypsin output four-fold and suppressed bilirubin secretion almost completely.[17] Extrinsic denervation of the pancreas does not affect PP inhibitory activity, which suggests that intrinsic mechanisms are involved.[15]

Gastric Effects of PP

Bovine PP does not seem to have any significant effects on gastric emptying nor on gastric secretion in humans when given at doses to achieve circulating PP levels equivalent to the postprandial state.[5] By contrast, Schmidt et al. infused human PP (as opposed to bovine PP) into volunteers eating a radioactively labeled meal, and they showed PP is able to slow gastric emptying of solid food but not water. However, they used a dose that was sufficient to increase circulating levels to approximately 3-fold normal postprandial levels,

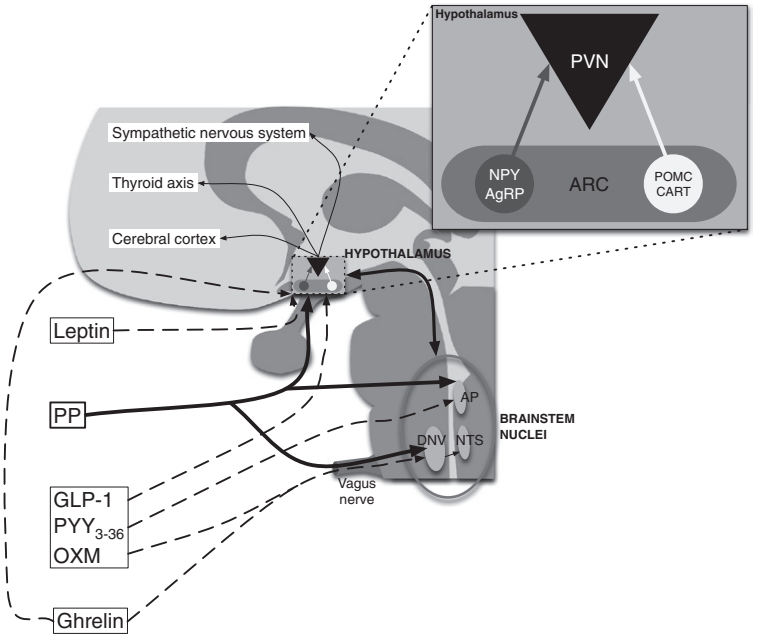

FIGURE 3 Appetite regulatory centers of the CNS. The two main centers in the CNS that regulate appetite, the brainstem nuclei (DNV—Dorsal Nucleus of the Vagus; NTS—Nucleus Tractus Solitarius; AP—Area Postrema) and the hypothalamus (ARC—arcuate nucleus; PVN—paraventricular nucleus) are indicated. These two centers enjoy extensive reciprocal connections with each other. Within the ARC, there exist two antagonistic sets of neurons projecting to the PVN: orexigenic neurons expressing neuropeptide Y (NPY) and Agouti gene Related Peptide (AgRP), and anorexigenic neurons expressing pro-opiomelanocortin (POMC) and Cocaine-Amphetamine Regulated Transcript protein (CART). POMC is processed to alpha-MSH (top right hand of the figure). The regulation of food intake and weight is determined by the balance of activities between these two sets of neurons, and their influence on the PVN. The PVN in turn influences higher centers in the cerebral cortex (to regulate food-seeking behavior), the thyroid axis and sympathetic nervous system (to regulate basal metabolism). Some peripheral influences on the brainstem nuclei and the hypothalamus are indicated (leptin, GLP-1, $PYY_{3–36}$, oxyntomodulin (OXM), Ghrelin—the dashed arrows indicate likely mechanisms of action). In particular, PP is believed to exert its effects by (1) diffusion through areas where the blood–brain barrier is incomplete with activation of Y4 NPY receptors at the AP and perhaps the median eminence of the hypothalamus and (2) activating visceral vagal nerve afferents.

and so the physiological relevance of this observation may be questioned.[31]

Metabolic Effects of PP

The infusion of bovine PP does not affect the basal nor the postprandial secretion of insulin.[3] Similarly, an infusion of human PP does not affect the basal secretion of insulin.[8] Both studies show no significant effects of PP infusion on the secretion of glucagon, gastrin, GIP, secretin, oxyntomodulin (enteroglucagon), peptide YY, glucagon-like peptide-1 (GLP-1), ghrelin, or leptin.[3,8] Schmidt et al. did show a slight delay to the peak of postprandial insulin secretion by about 16 min at the highest dose of human PP used, together with a sustained postprandial increase in glucose. This may be explained by the delay in gastric emptying of solid food that they observed and therefore may not represent a direct effect of PP.[31]

Can PP influence insulin sensitivity? This question was studied in patients with chronic pancreatitis, which exhibit PP deficiency and a blunted response to insulin in terms of suppression of hepatic glucose output during euglycemic–hyperinsulinemic clamp studies, that is, evidence of insulin resistance. Brunicardi et al. showed that an 8-h bovine PP infusion restores insulin sensitivity. PP reduced patients' mean glucose levels in response to an oral glucose challenge in two of the five patients studied, indicating that this change in insulin sensitivity has some influence on glucose tolerance in these patients.[12] It is unclear, however, if PP significantly influences insulin sensitivity in healthy humans.

PATHOPHYSIOLOGICAL IMPLICATIONS

High concentrations of plasma PP are frequently observed in patients with pancreatic neuroendocrine tumors (PNET). Some cases of this phenomenon result from PP cell hyperplasia in the normal islets surrounding a PNET that may be secreting other hormones (insulin, VIP, glucagon), and some result from incorporation of PP-secreting cells within the tumor itself. More rarely, some cases are because of a primary PP-secreting PNET, that is, a "PPoma."

PPomas are generally diagnosed during the investigation of abdominal pain, hepatomegaly, liver metastases, obstructive jaundice, pancreatitis, or gastrointestinal hemorrhage (either resulting from direct erosion of blood vessels or resulting from portal hypertension as a consequence

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

of portal vein thrombosis). Although watery diarrhea was initially believed to be part of the tumor syndrome, it is now evident that this occurs only in one-third of patients. Weight loss can occur as a presenting symptom, consistent with PP's satiety-inducing action. In contrast to other varieties of PNETs, metastatic/malignant PPomas are relatively uncommon, but not unknown.[22]

Given its postprandial release and postulated role in reducing appetite after food intake, it may be conjectured that obesity may result, at least partially, from a reduction in PP secretion, therefore decreasing the feedback inhibition of food intake. Some studies have shown that the fasting and postprandial levels of PP are lower in obese subjects compared with that in lean subjects. Conversely, other studies have found that there are no significant differences in PP levels (fasting or postprandial) between lean and obese subjects. Thus, there remains some controversy as to the exact relationship between circulating PP levels and obesity. This may perhaps be because there are marked variations in PP secretion, influenced by diurnal variation, by age (where increasing age is associated with increased PP levels), and by large interindividual variations.[18]

Finally, given the actions of PP as a satiety hormone, it represents an attractive therapeutic target for an antiobesity drug. Longer-lasting analogs of PP and other Y4 agonists are currently in trial for this purpose.[33]

Chapter 177

Paneth Cell α-Defensins

André J. Ouellette and Michael E. Selsted

ABSTRACT

Enteric α-defensins are constituents of dense core granules that Paneth cells secrete from small intestinal crypts into the lumen in response to cholinergic or bacterial stimuli. The molecular signature of the ~4.5 kDa α-defensins consists of six Cys residues which form an invariant pattern of disulfide pairings. The tridisulfide array establishes a conserved backbone topology and protects against proteolysis, enabling the peptides to function in the environment of the intestinal lumen. α-Defensins are broad-spectrum microbicides that constitute the majority of bactericidal peptide activity released by Paneth cells. Enteric α-defensins modulate the composition of the small intestinal microbiota, and they confer immunity to experimental infection by orally-administered *Salmonella enterica* serovar Typhimurium. Mutations that disrupt Paneth cell homeostasis may cause defective α-defensin secretion or reduce the solubility of secreted granules, diminishing luminal Paneth cell α-defensin levels, impairing innate immunity, and contributing to immunopathologies.

DISCOVERY OF PANETH CELL α-DEFENSINS

The defensins are one of two major antimicrobial peptide (AMP) families in mammals and were among the first AMPs to be identified and characterized.[26] They comprise three cationic, Cys-rich subfamilies, termed α-, β-, and θ-defensins, all of which have broad-spectrum antimicrobial activities.[28] The α-defensins are ~4.5 kDa and contain six Cys residues positioned in a pattern that facilitates the formation of invariant Cys^{I}–Cys^{VI}, Cys^{II}–Cys^{IV}, Cys^{III}–Cys^{V} disulfide bond pairings that define the α-defensins (Fig. 1).

Paneth cell α-defensins were found as abundant small intestinal mRNAs expressed in adults but not in fetal mouse small bowel, which coded for α-defensin precursors as inferred from the spacing of six Cys residues in the C-terminal region of the deduced mRNA products. Prepro-α-defensin mRNAs were abundant only in small intestine and localized by in situ hybridization to Paneth cells at the base of the crypts of Lieberkühn. The mouse α-defensin peptides were termed "cryptdins" (Crps) for "crypt defensin."[16] α-Defensin mRNAs were soon identified in human Paneth cells with oligonucleotide probes based on sequences conserved in known α-defensin cDNAs and genes.[10] Cloning of mouse crypt α-defensin cDNAs showed that mouse Paneth cells express numerous α-defensin variants, many with very similar primary structures, and genomic studies confirmed that the peptide isoforms were coded by individual, closely linked genes. By immunohistochemical analysis, Crp1 was localized exclusively to the cytoplasm of small bowel Paneth cells and subsequently to their dense core secretory granules (Fig. 2). The bactericidal activities predicted for Paneth cell α-defensins were confirmed with the purification mouse enteric α-defensin peptides and the demonstration of their potent microbicidal activities.[27]

DEFENSIN GENE AND PRECURSOR STRUCTURES

The determinants regulating α-defensin gene transcription and peptide abundance are poorly understood. Paneth cell defensin genes are closely linked at chromosomal loci along with the myeloid α-defensin genes. Genes that encode HD5 and HD6, the two human Paneth cell α-defensins, map to 8p21-8pter and are the syntenic with mouse genes located in the proximal region of chromosome 8.[1,17,30] α-Defensin gene expression is tissue-restricted, with major sites of expression in promyelocytes of the bone marrow and Paneth cells of the small intestine. The fidelity and Paneth cell specificity of HD5 transgene expression of *DEFA5*-transgenic (+/+) mice suggests that *cis*-acting β-catenin/TCF-4 sites in the human Paneth cell HD5 gene are conserved and sufficient to direct transgene gene transcription with accuracy.[21]

Most myeloid α-defensin genes consist of three exons, and genes expressed in Paneth cells have a two-exon structure.[28] Most myeloid α-defensin genes, as well as the related θ-defensin genes in primates, have an additional intron ranging from 1 to 6.5 kb that interrupts the 5′-untranslated region (Fig. 3). Whether α-defensin genes consist of

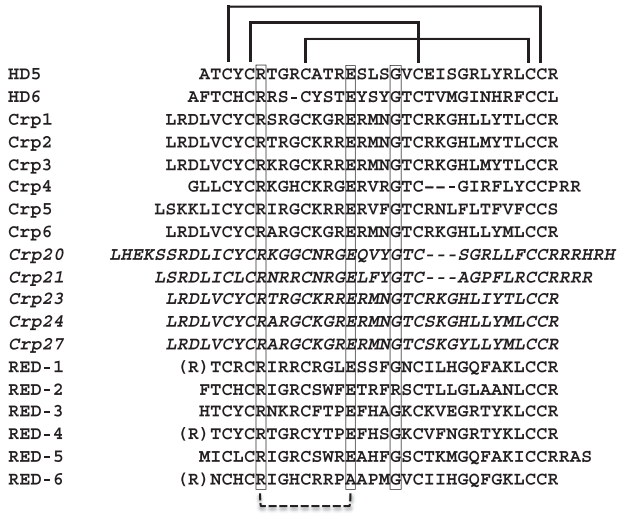

FIGURE 1 Primary structures and canonical features of representative Paneth cell α-defensins. The single letter notation amino acid sequences of human Paneth cell α-defensins HD-5 and HD-6, mouse Crps 1-6, 20, 21, 23, 24, and 27, and rhesus macaque enteric α-defensins REDs 1-6, respectively, were positioned manually to align canonical Cys residue positions. Crps 20, 21, 23, 24, and 27, identified only in the C57BL/6 strain to date [Ref. 29], are shown in italicized font. The canonical Arg, Glu, and Gly residue positions are identified within boxes, and the conserved Arg-Glu salt bridge is depicted by the dotted bracket below the RED-6 sequence. Dash characters denote spaces introduced to maintain the alignment of conserved Cys residues and the disulfide array. The tridisulfide array that defines the α-defensin peptide family is shown above the HD5 sequence.

two- or three-exons, the distal 3′-exon codes for the mature α-defensin peptide. To date, no single α-defensin gene has been reported to be expressed in both bone marrow and in Paneth cells, irrespective of gene organization. In macaques, however, the RED-1 and RED-6 Paneth cell α-defensin genes, which have characteristic 3-exon myeloid gene structures and are closely related to rhesus myeloid α-defensin 4 (RMAD-4), are not transcribed in bone marrow (R.A. Llenado and A.J. Ouellette, unpublished).

The α-defensin gene loci appear to be inherently unstable, as judged by extensive genomic and proteomic differences between species and even between inbred strains of mice.[1,29] Detailed annotations of defensin gene loci are not available for most mammalian species, but rhesus macaques, mice and horses express numerous, diverse enteric α-defensin genes based on cloning studies. In the mouse, comparisons of the α-defensin gene loci of the NIH C57BL/6 and Celera mixed strain genome assemblies revealed extensive genomic and proteomic differences between inbred strains.[1,29] For example, the C57BL/6 genome contains five strain-specific α-defensins (Crps 20, 21, 23, 24, 27 in Fig. 1), a repeated multigene cassette found only in that assembly, and several non-defensin coding genes within the locus that are oriented differently in the two assemblies.[29] In addition, the five most abundant C57BL/6 strain α-defensins have not been reported in other inbred strains of mice and differ from those identified previously in mice. Instability of the gene locus in mice is illustrated further by the existence of α-defensin-related subfamilies of cysteine-rich sequence (CRS) peptides found only in mice. CRS1C and CRS4C are coded by linked two-exon genes whose second exons diverge markedly from the α-defensin genes, coding for peptides with 11 or 9 Cys residues that occur in a series of [C]-[X]-[Y] triplet repeats. Phylogenetically, CRS1C and CRS4C genes are more closely related to the rat enteric α-defensin genes than to any known mouse defensin gene, showing that they are evolutionarily distinct from mouse α-defensin genes.[29] Also, although mice lack neutrophil α-defensins,[5] both mouse genome assemblies contain over twenty α-defensin ancestral rat myeloid α-defensin pseudogenes.

α-Defensin Precursors

The bactericidal activity of Paneth cell α-defensins requires proteolytic removal of inhibitory proregion acidic amino acids from the precursor to enable membrane disruptive activity of the mature peptide. Paneth cell α-defensins derive from ~10 kDa prepropeptides that contain canonical signal sequences, usually acidic proregions, and a ~4.5 kDa mature α-defensin peptide in the C-terminal portion of the precursor (Fig. 3). In nearly all pro-α-defensins, the electropositive charge of the α-defensin component, essential for bactericidal peptide activity, is balanced or neutralized by anionic amino acid residues in the prosegment. Pro-α-defensins lack bactericidal activity and have reduced ability to bind to and permeabilize model membrane systems until activated proteolytically by specific converting proteinases.

The details of posttranslational Paneth cell α-defensin precursor processing differ in humans and mice. For example, human Paneth cells store and release unprocessed α-defensin precursors, e.g., proHD5, which are processed by trypsin isoforms during or after secretion to generate the mature, activated HD5 molecules.[8] By contrast, mouse Paneth cell pro-α-defensin processing is mediated intracellularly by matrix metalloproteinase-7 (MMP7), which cleaves at conserved sites in the proregion of the precursor, including at the junction of the propeptide and the α-defensin moiety of the proform.[6] In studies of mouse Paneth cell pro-α-defensin proCrp4$^{20–92}$ activation *in vitro*, the cleavage step at Ser43↓Ile44 removes nine acidic amino acids that collectively block the membrane disruptive behavior of the Crp4 moiety of the precursor.[6,33] Further mutagenesis studies showed that the four acidic residues near the proCrp4 amino terminus, at residue positions D20, D26, E27, E28, are primarily responsible for inhibition of Crp4-mediated membrane disruption in the precursor. Also, analyses of proCrp4 variants with proregion truncations showed that, as measured along the polypeptide backbone, decreasing the

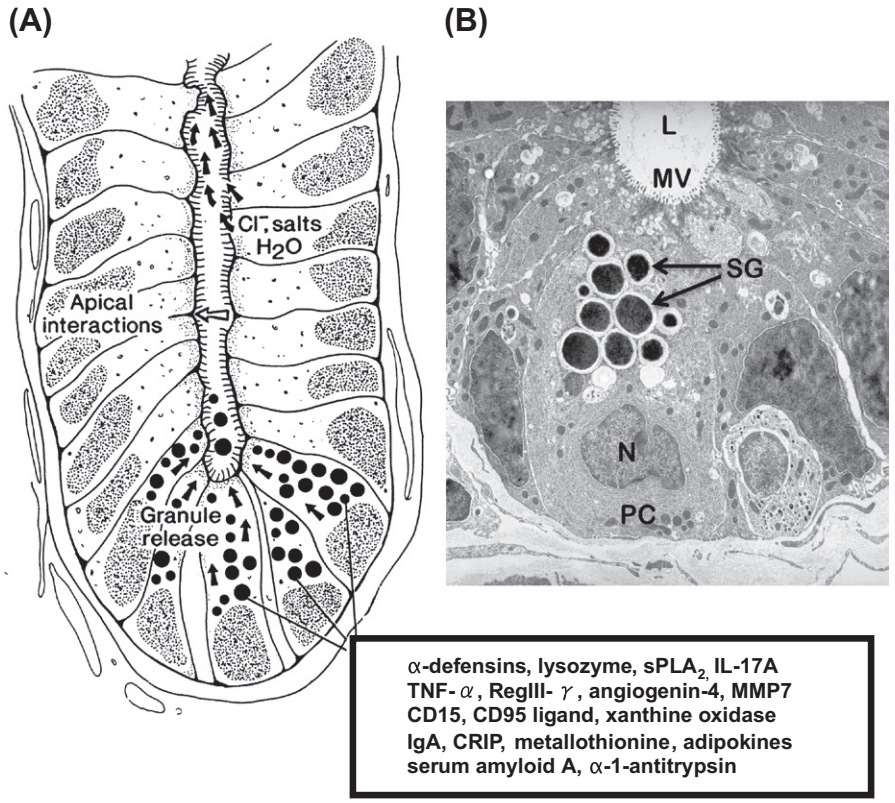

FIGURE 2 Paneth cell release of α-defensins in dense core secretory granules. In A, the apical release of α-defensin-containing dense core granules and additional constituents into the crypt lumen is illustrated. Solubilized α-defensins inhibit microbial colonization and shape the composition of the microbiota. Because mouse Paneth cell α-defensin cryptdin-3 stimulates the release of chloride ion from T84 cells [Ref. 11], certain secretory components may provide a luminal clearance mechanism by drawing water into the crypt lumen. In B, large, electron-dense secretory granules (SG) are shown for a single Paneth cell. SGs are clustered at the apical cell surface with its stubby microvilli (MV) in proximity of the crypt lumen (L). The basolaterally-oriented nucleus (N), characteristic of this lineage also is indicated. The electron micrograph was provided by Dr. Susan J. Hagen, Beth Israel Deaconess Medical Center, Boston, MA.

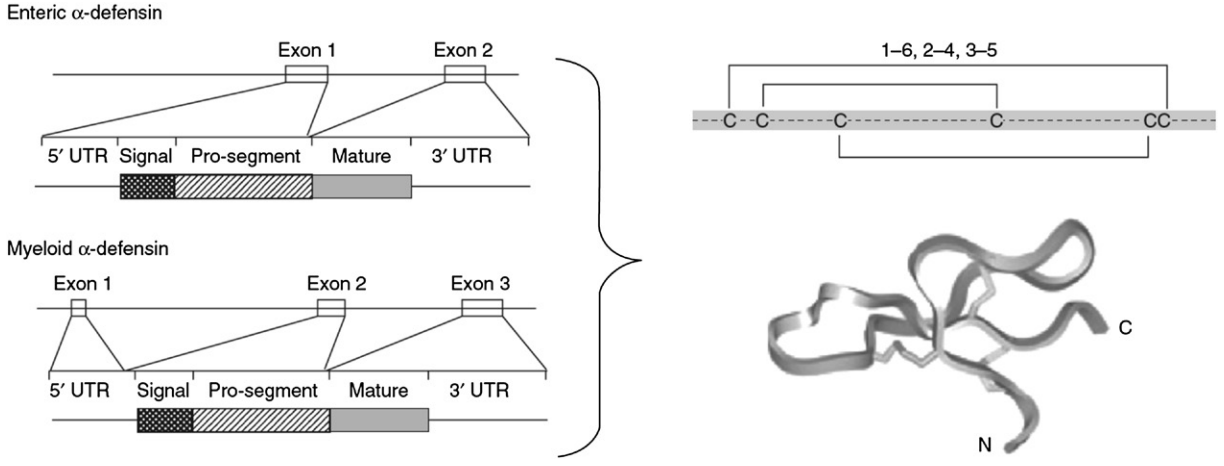

FIGURE 3 α-Defensin gene and precursor structures. Schematics of the myeloid and Paneth cell α-defensin genes and precursors are aligned at left. The signal peptide and proregions are crosshatched differentially, and the gray C-terminal region of the precursors denote the residues that constitute the mature α-defensin peptide. At right, the conserved spacing and disulfide connectivities of the α-defensin peptide family is illustrated at top, and the three-dimensional structure shown below is that of rabbit α-defensin RK-1. length of the linear proregion is not structurally important for maintaining proCrp4 in an inhibited state. MMP7 gene disruption ablates proCrp processing, creating a deficiency of activated Crp peptides. The resulting MMP7-null mice have impaired innate immunity to oral bacterial infection and their small bowel microbiota differ from wild-type littermate controls.[22,34]

Distribution of α-defensins in the GI Tract

The major site of enteric α-defensin biosynthesis is in Paneth cells, which normally are restricted to the crypts of Lieberkühn of the small intestine and secrete dense core granules apically into the lumen.[18] As components of a regulated secretory pathway, the granules dissolve rapidly to deliver a complex mixture of host defense peptides and proteins to the crypt lumen (Fig. 2). In addition to α-defensin, Paneth cell granules contain secretory phospholipase A2 (Pla2g2a), lysozyme, lipopolysaccharide-binding protein, RegIII-γ, xanthine oxidase, matrix metalloproteinase 7 (MMP7), CD95 ligand, IgA, and CD1d as granule constituents.[18] Paneth cells also produce diverse proinflammatory mediators that include IL-17A, TNF-α, IL-1β, and adipokines.[4]

Mechanisms that regulate Paneth cell differentiation and maturation provide understanding into the distribution of enteric α-defensins. The epithelial cell lineages of the small intestine are specified by transcription factors that are controlled by the Wnt and Notch signaling pathways.[32] Paneth cell α-defensin genes are Wnt targets, and their transcription is mediated in part by β-catenin/TCF-4 (TCF7L2) along with additional tissue specific transcription factors, including Cdx2.[32] In addition to their distinctive role in enteric innate immunity, Paneth cells also provide key signals for maintenance of the crypt stem cell niche, Lgr5+ stem cell survival, and crypt homeostasis.[23]

In health, small intestinal Paneth cells are the sole source of enteric α-defensins, yet microbicidal α-defensins of Paneth cell origin are abundant in mouse distal colonic lumen.[13] The colonic epithelium does not express α-defensins, but the peptides accumulate in colonic luminal contents as a result of their proximal secretion in the small intestine and inherent resistance to proteolysis. The peptides recovered from the colonic lumen have bactericidal peptide activities equivalent to native α-defensins extracted from ileum.[13] Because the colonic microbial burden is several orders of magnitude greater than that of the small bowel, α-defensins may affect the colonic microbiota by means other than direct peptide-mediated cell killing. For example, at low peptide concentrations, certain defensins inhibit bacterial peptidoglycan synthesis by lipid II binding,[25] and we speculate that α-defensins may use a lipid II binding mechanism to exert selective antimicrobial effects on the microbiota of the colon. Although it remains speculative, α-defensin inhibition of bacterial peptidoglycan biosynthesis by lipid II binding could provide a mechanism for low α-defensin peptide levels to influence the colonic microbiota.

Structures of Paneth Cell α-defensins

Several α-defensin structures have been determined by NMR and X-ray crystallographic techniques.[28] The three-dimensional structures contain a canonical triple-stranded antiparallel β-sheet motif (Figs. 3 and 4) constrained by the C^{I}–C^{VI}, C^{II}–C^{IV}, C^{III}–C^{V} α-defensin tridisulfide array. The crystal structure of the human neutrophil α-defensin HNP-3 is a non-covalent, amphipathic dimer[9] as are the crystal structures of all human α-defensin peptides.[31] On the other hand, α-defensins from rabbit neutrophils, mouse Paneth cells, and rabbit kidney are monomeric in solution.[15,28] (Fig. 4).

Four structural features are conserved in the α-defensin peptide family (Figs. 1 and 4). Numbering residue positions from the N-terminus of the mouse Crp4 mature peptide, the conserved features are: (1) the disulfide array, (2) a salt bridge formed by Arg^{7}-Glu^{15} hydrogen bonds, (3) a conserved Gly at residue position 19, and (4) a high Arg:Lys molar ratio. In most instances, site-directed mutagenesis at these conserved positions does not alter *in vitro* bactericidal peptide activities.[15] For example, disulfide-null α-defensins are as bactericidal as the native molecules; however, the disulfide array is essential in conferring protection against proteolysis. Peptide mutants of the Arg^{7}-Glu^{15} salt bridge fold inefficiently and are sensitive to proteolysis, but, once folded and oxidized, their bactericidal activities are equivalent to those of the native molecules.[19,20] Perhaps, rather than having been selected to optimize bactericidal activity, these conserved features evolved to enable or facilitate efficient peptide folding, interactions with chaperone proteins, trafficking in the ER, and thereby mimimize unfolded protein responses. Effects of complete Lys-for-Arg replacements on bactericidal peptide activity vary with peptide primary structure, in that they attenuated HNP-1 and Crp4 activity but improved the activity of RMAD-4.[12,35] In both Lys substituted Crp4 and RMAD-4, complete Lys-for-Arg substitutions increased the sensitivity of the peptides to inhibition by NaCl, suggesting that Arg may be under selection as the electropositive α-defensin amino acid to confer improved bactericidal peptide activity under conditions of higher ionic strength.

Receptor Expression and Regulation

α-Defensins are microbicidal against gram-positive and gram-negative bacteria, certain fungi, spirochetes, protozoa, and certain viruses,[28] but those activities are not mediated by receptor-based mechanisms. In phagocytes, diverse AMPs are stored in azurophilic granules and mediate non-oxidative microbial cell killing following phagolysosomal fusion by permeabilizing the outer and inner membranes of *E. coli*, inducing the formation of ion channels in lipid

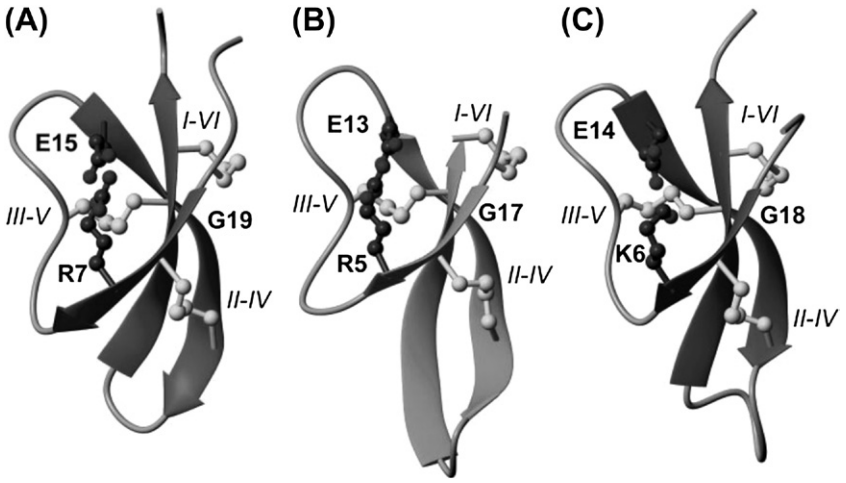

FIGURE 4 Ribbon diagrams of the NMR solution structure of Crp4 (A), the crystal structure of the HNP3 monomer (B) (Protein Data Bank code 1DFN), and the NMR solution structure of rabbit kidney α-defensin RK-1 [Ref. 22] (C) (Protein Data Bank code 1EWS) are displayed. Disulfide bonds are shown in *ball-and-stick* representation, illustrating the cross-braced central β-sheet. The main structural differences occur in the hairpin loop formed between Cys^{IV} and Cys^{V} resulting from the number of residues between the disulfide pairs, 6, 8, and 9 residues in Crp4, RK-1, and HNP3, respectively. The side chains of the conserved Arg and Glu residue positions form a tight electrostatic interaction in all three structures. Note that the rare R6K substitution in the natural RK-1 peptide retains the capability of forming a salt bridge with Glu^{35} in that peptide. The N and C termini are flexible in all peptides as evident from their disorder in the Crp4 and RK-1 structures and from the lack of density for the terminal residues in the X-ray analysis of HNP3. Reprinted from Rosengren, K.J., Daly, N.L., Fornander, L.M., Jönsson, L.M.H., Shirafuji, Y., Qu, X., Vogel, H.J., Ouellette, A.J., and Craik, D.J.: Structural and functional characterization of the conserved salt-bridge in mammalian Paneth cell α-defensins: Solution structures of mouse cryptdin-4 and (E15D)-cryptdin-4. bilayers. Both peptide-elicited effects are influenced by membrane energetics and are selective for membranes that mimic the composition of electronegative bacterial cell membranes. Certain α-defensins have distinct membrane disruptive mechanisms even though their overall topologies are very similar. For example, human neutrophil α-defensin HNP-2 dimers form stable, 20 Å multimeric pores after insertion into model membranes, but the monomeric rabbit NP-1 peptide permeabilizes the membrane by creating large, short-lived defects in model phospholipid bilayers. High-resolution synchrotron small-angle X-ray scattering studies of defensin interactions with heterogeneous membranes show that α-defensins selectively generate saddle-splay, or "negative Gaussian," membrane curvature in model membranes of bacterial phospholipid composition, consistent with vesicle leakage assays.[24]

Biological Actions within Gastrointestinal Tract

Paneth cells in mouse small intestinal crypts secrete granules rich in microbicidal peptides when exposed to bacteria or bacterial lipopolysaccharide, lipoteichoic acid, lipid A, and muramyl dipeptide, or when stimulated pharmacologically with cholinergic agonists.[2] Paneth cell secretion is modulated by the Ca^{2+}-activated intermediate conductance K^+ channel KCa3.1 (also known as mIKCa1 and KCNN4), and highly selective blockers of KCa3.1 block Paneth cell secretion by 50–60%.[3] In *ex vivo* crypt preparations, mouse Paneth cells respond equivalently to purified bacterial cell envelope glycolipids, regardless of acyl chain modifications associated with attenuation or virulence in human infections. Total secreted protein, secreted lysozyme, and the bactericidal activities of collected secretions are independent of glycolipid acyl chain modifications of the glycolipid agonists associated with virulence. In an oral challenge mouse model of *Toxoplasma gondii* infection, Tlr9 mRNA levels were induced, as was type I IFN mRNA, and Crp3 and Crp5 α-defensin gene expression was elevated.[7] The *T. ondii* effects are mediated by Tlr9-dependent production of type I IFNs, because IFN-β replicated the responses in Tlr9 -/- mice, and responses were abrogated in IFNAR -/- mice.

The contribution of Paneth cell α-defensins to enteric mucosal immunity is evident from the phenotype of mice that are transgenic for the human Paneth cell α-defensin, HD5 (*DEFA5*-transgenic (+/+)).[21] *DEFA5*-transgenic (+/+) mice express a 3 kb HD5 minigene encompassing the peptide-coding exons only in Paneth cells and at levels that are similar to those encoded by endogenous mouse Paneth cell α-defensin genes. When orally challenged with *Salmonella enterica* serovar Typhimurium, *DEFA5*-transgenic (+/+) mice are highly resistant to infection.[21] Thus, addition of a single new α-defensin to Paneth cell secretions of *DEFA5*-transgenic (+/+) mice is sufficient to confer immunity to the lethal effects of this virulent pathogenic bacterium.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

As the *DEFA5*-transgenic (+/+) mouse phenotype illustrates, differential sensitivities of bacterial species to particular α-defensins suggests that peptide diversity may confer selective advantage against certain enteric pathogens.

α-Defensins secreted by Paneth cells shape the composition of the mouse small intestinal microbiota, apparently by selecting for peptide-tolerant resident microbial species *in vivo*.[22] For example, in the distal ileum of individual *DEFA5*-transgenic (+/+) mice, Firmicutes constituted 25% of bacterial species compared to 59% in FvB mice, the reference strain for the *DEFA5* (+/+) transgenic animals. Also, Bacteroidetes made up 69% of bacterial species in *DEFA5* (+/+) transgenic ileum, but in FvB controls only 35% of species were in the Bacteroidetes group.[22] Thus, the ileal microflora of mice secreting one additional exogenous α-defensin was markedly different and genotype-dependent. Also in the same study, the distinct repertoire of C57BL/6 mouse Paneth cell α-defensins (Fig. 1) appears to influence the ileal microbiota, because significant differences were found in the percent distribution of the Firmicutes and Tenericutes groups in C57BL/6 and FVB mice.[22]

Pathophysiological Implications

Paneth cell α-defensins contribute to enteric innate immunity to infection and also determine the composition of the small intestinal microbiota.[21,22] As noted above, *DEFA5*-transgenic (+/+) mice are immune to oral challenge with wildtype *S. enterica* serovar Typhimurium, and the composition of their resident ileal microbiota differs profoundly from that of controls.[21,22] Because a resident microflora is essential in IBD pathogenesis, the quantity and/or the repertoire of Paneth cell α-defensins and other gene products may influence gastrointestinal inflammation by shaping a healthy microbiota or one that promotes disease in genetically predisposed individuals. Thus, a reduction in luminal α-defensins resulting from disrupted Paneth cell homeostasis or Paneth cell deficiency could skew the resident microbiota toward more a proinflammatory composition and thereby contribute to disease.

Necrotizing enterocolitis (NEC) is a leading cause of morbidity and mortality in neonatal intensive care units, and many predisposing factors have been associated with NEC pathogenesis, including deficits or changes in Paneth cell function. By *in situ* hybridization, HD5 and HD6 mRNA levels appear to be 2-3 fold greater in NEC patients than in atresia or meconium ileus controls, yet immunohistochemical analyses showed that levels of HD5 peptide were equivalent in NEC and the control groups. These findings have led to the proposal that Paneth cells of NEC patients may be hypersecretory and thus accumulate reduced levels of mature α-defensin. We speculate that this may be the result of disrupted Paneth cell homeostasis resulting from induced autophagy or ER stress responses in NEC. The finding of reduced lysozyme immunostaining in Paneth cells of NEC patients is consistent with a diminished level of host defense protein production in the Paneth cell lineage in NEC individuals.

Mucosal immunity could be compromised by deficient α-defensin levels, defects in crypt homeostasis that impair Paneth cell delivery of secretory granules, or impaired solubility of α-defensins and secreted proteins following release into the crypt microenvironment.[14] Because Paneth cell α-defensins modulate the composition of the mouse small intestinal microbiota,[22] a reduction in luminal α-defensins could contribute to disease by skewing the composition of resident microorganisms toward more a proinflammatory microbial population. Disruptions to Paneth cell homeostasis induced by varied genetic defects may lead to induced autophagy, ER stress, unfolded protein responses, and apoptosis leading to ileitis and enhanced sensitivity to colitis.[14]

Chapter 178

PYY

Louise Purtell and Herbert Herzog

ABSTRACT

Peptide YY (PYY) is produced as a 36 amino acid peptide hormone within the distal gastrointestinal tract and the pancreas where it acts in a para- and endocrine fashion. It circulates in two biologically active forms, which act upon Y receptors to exert digestive, absorptive, antisecretory and satiety effects. PYY is implicated in a number of gastrointestinal diseases and has been proposed as a putative anti-obesity therapy.

DISCOVERY

PYY is a 36 amino acid, straight-chain polypeptide. It shares structural similarity with pancreatic polypeptide (PP) and neuropeptide Y (NPY); all three peptides have tyrosine residues at the C-terminal which is also amidated. PYY has also a tyrosine at the N-terminus, designated in peptide nomenclature as Y, which gives PYY its name.[1] PYY was first isolated from porcine small intestine by Takemoto et al in 1980, and in 1988 its protein sequence was determined in humans.[28,29]

STRUCTURE OF GENE

The PYY gene has been cloned and sequenced from a large number of species. It comprises four exons and three introns, with each of the exons encoding a different functional domain of the mRNA[7,15] (Fig. 1). The human PYY gene is located in a cluster with PP on chromosome 17q.21.1 and spans approximately 1.2 kbp. There is significant conservation of gene, sequence and protein structure between PYY, NPY, and PP, indicating that these genes arose from a common ancestor by gene duplication. In higher mammals additional gene duplication events lead to the generation of other PYY-like genes which in at least one species, bovine, lead to the production of the active peptide, seminalplasmin.[8]

PROCESSING OF THE PRECURSOR

Transcription and translation of the PYY gene produces a 98 amino acid prepropeptide. A signal peptide is followed by the 36 amino acid PYY sequence and the cleavage and amidation sequence Gly-Lys-Arg, with a 31 amino acid flanking peptide at the carboxy terminal[7] (Fig. 1).

There are two biologically active forms of endogenous PYY: $PYY_{1\text{-}36}$ and $PYY_{3\text{-}36}$, which have different affinities for the Y receptors. Dipeptidyl peptidase IV (DPP-IV) cleaves the tyrosine and proline residues from the N-terminal end of the full-length peptide ($PYY_{1\text{-}36}$) to form the truncated peptide ($PYY_{3\text{-}36}$).[21,22] DPP-IV, a short-acting, abundantly-expressed cell surface enzyme, also acts to metabolize GLP-1 to its inactive form. Approximately 40% of total PYY released is converted to $PYY_{3\text{-}36}$[10] (Fig. 1). The half-live time of the peptides in the serum is approximately 8 min[17] and proteases such as kallikreins specifically remove amino acids 36 and 35 and thereby render the peptide inactive.

DISTRIBUTION IN THE GASTROINTESTINAL TRACT

PYY is produced by the endocrine L-cells of the epithelial mucosa (Fig. 2). PYY is abundantly expressed in the colon, terminal ileum, and rectum, and produced to a lesser extent in the esophagus, duodenum, proximal jejunum, and stomach.[18] Furthermore, in the pancreas specific PYY expressing cells surround the insulin producing cells in the islets of Langerhans (Fig. 3). PYY is colocalized in the gastrointestinal tract with proglucagon, glicentin, glucagon-like peptide 1 (GLP-1), and GLP-2 and, upon arrival of food in the duodenum, co-released from the same secretory granules.[2] The level of PYY expression increases from the proximal end to the distal end of the gastrointestinal tract. PYY-expressing neurons can be found in the central nervous system and in specific gastric neurons in some species.

REGULATION OF SECRETION

PYY release from the endocrine L-cells in the gut can be triggered by a number of mechanisms. Circulating levels rise within 15 min of ingestion of a meal, reaching a peak at approximately 60–120 min postprandially (Fig. 4). PYY

plasma concentrations can remain elevated for as long as 6 h, depending on the calorie load of the meal ingested. Meal components shown to stimulate PYY secretion include glucose, bile salts, lipids, short-chain fatty acids, and amino acids. Of these, dietary lipids are the most potent stimulant of secretion.[11] The sustained postprandial production of PYY is consistent with the hypothesis that the L-cells of the distal bowel and colon detect levels of these macronutrients and release PYY in response. Upon meal ingestion, plasma PYY concentrations become elevated before nutrients reach the distal gastrointestinal tract. This suggests that the initial postprandial PYY release may be modulated by indirect neural or humoral pathways, such as the vagus nerve.[2] The presence of regulatory peptides such as cholecystokinin (CCK) and vasoactive intestinal polypeptide (VIP) may also stimulate PYY release in the absence of a meal cue.[2] PYY secretion has been further shown to be stimulated by exercise, both long-term and after only a single session of high intensity exercise.[16]

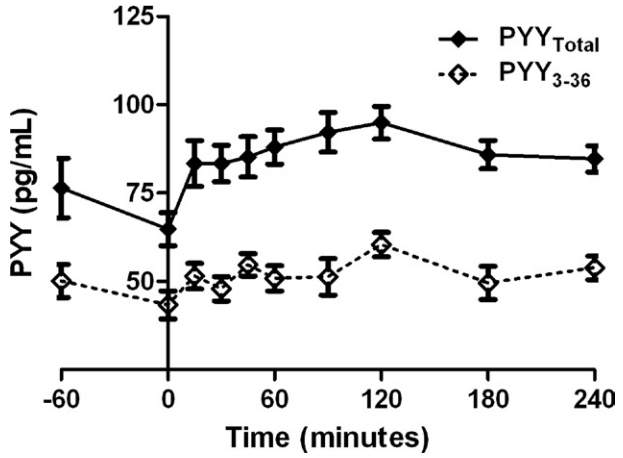

FIGURE 4 Plasma levels of PYY_{Total} and PYY_{3-36} in response to an oral mixed meal in lean adults ($n = 10$). Circulating PYY is elevated postprandially with a peak at 120 minutes. (Adapted from Purtell L, Sze L, Loughnan G, Smith E, Herzog H, Sainsbury A, et al. In adults with Prader–Willi syndrome, elevated ghrelin levels are more consistemt with hyperphagia than high PYY and GLP-1 levels. *Neuropeptides* 2011;**45**:301–7.)

RECEPTORS AND SIGNALING CASCADES

PYY, NPY and PP exert their physiological actions through at least five G-protein coupled receptors: Y1, Y2, Y4, Y5, and y6. These belong to the guanine nucleotide binding regulatory protein (G-protein) coupled receptors superfamily. Upon activation of the receptor, the G_{ialpha}-subunit is released from the receptor/G-protein complex, inhibiting the production of second messenger cyclic AMP through the inhibition of adenylyl cyclase.[35] In addition, the Y-receptors alter neuronal excitability and neurotransmitter release through inhibition of voltage-gated K^+ channels and stimulation of Ca^{2+} channels.[35] PYY and NPY have indistinguishable affinities for all Y-receptors with a rank order of ligand-binding affinities of Y2 > Y1 > Y5 > Y6 >> Y4; this is reversed for PP, which binds with greatest affinity to Y4 > Y6 >> Y2 > Y5 > Y1. Despite some structural and functional similarities, the Y-receptors have differential distribution profiles. In humans, the Y1 receptor is localized in the proliferative zone of the colonic epithelium and the mucosal nerves, as well as centrally where it is involved in appetite regulation and anxiety.[9] The Y1 receptor has been found to have a role in regulating the proliferation of gut epithelial cells.[20] The Y2 receptor has been found in the human small intestine, as well as in rat jejunum and colon mucosa. In the brain, it has been shown to be expressed in mouse hippocampus, hypothalamus and amygdale. Like the Y1 receptor, it binds PYY and NPY in preference to PP; however unlike Y1 it also shows considerable affinity for C-terminal PYY and NPY fragments such as PYY_{3-36}. Postprandial suppression of gastric motility, and the subsequent satiety, is mediated in part through PYY's action on the Y2 receptor. Y4 receptors are localized in both small and large intestine in humans, as well as the pancreas; they are also expressed in the brain, with the hypothalamus being the region of highest expression. Upon binding of PP to the Y4 receptor, increases in colonic muscle contraction and fecal output is triggered in mice.[24] The Y5 receptor shows overlapping expression with Y1 receptors in the brain where it is also involved in appetite and energy homeostasis regulation.[14] PP is thought to also act as a ligand for the y6 receptor. While functional in mouse and rabbit, this Y-receptor is truncated in the human genome.[6] The truncated y6 receptor is present in a number of human tissues, including the small and large intestine; however, a specific physiological role has not yet been found for it. In mice, the expression of y6 in the suprachiasmatic nuclei of the hypothalamus suggests involvement in the circadian regulation of energy homeostasis.

TABLE 1 Physiological Actions of Peptide YY

Organ	Physiological action
Pancreas	• Inhibits pancreatic exocrine secretion • Inhibits insulin secretion (mouse, dog) • Inhibits insulinotropic effects of GRP and GIP (dogs)
Stomach	• Slows gastric motility • Inhibits gastric acid secretion
Small intestine & colon	• Inhibits Cl^- secretion • Promotes electrolyte absorption • Lengthens mouth to cecum transit time
Kidney	• Suppresses glomerular filtration rate, renin and aldosterone • Promotes sodium secretion
Appetite & food intake	• Increases appetite and promotes weight gain (PYY1-36) • Inhibits appetite and promotes weight loss (PYY3-36)
Vascular	• Promotes vasoconstriction • Increases systolic and diastolic blood pressure
Growth	May facilitate GI growth and development
Bone	Inhibits osteoblast activity

BIOLOGICAL ACTIONS WITHIN GASTROINTESTINAL TRACT

PYY is a key player in a number of physiological processes acting in an autocrine, paracrine, and endocrine fashion. Its main action in the gastrointestinal tract is to enhance nutrient absorption by suppressing gastric motility and inhibiting electrolyte secretion in the small intestine and colon. It also has an important role in the regulation of appetite and food intake (Table 1).

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Motor Effects

When nutrients, particularly lipids, are present in the lumen of the ileum, the "ileal brake" mechanism takes effect. This acts on the upper gut to slow gastric emptying and is probably mediated by PYY. The ileal brake has been found in humans, where infusion of lipids into the ileum exerted inhibitory feedback on gastric motility.[27] Studies in dogs show that ileal lipid infusions increase the interval between jejunal migrating motor complexes.[33] PYY's effects on gastrointestinal motility may act vasovagally. Witte et al compared the effects on gastric motility of PYY_{1-36} and PYY_{3-36} in humans and found the latter to be significantly more potent, both in half emptying time and gastric emptying rate.[34]

Gastric Secretion

PYY acts as a physiological enterogastrone in a number of species, including human. Gastric acid secretion in the stomach is stimulated by the parasympathetic nervous system via the vagal nerve, as well as by hormones, primarily gastrin. The presence of lipids in the lumen of the ileum causes PYY release, which in turn inhibits gastric acid secretion. In studies of dogs, PYY to inhibits pentagastrin- and histamine-stimulated, but not bethanecol-stimulated gastric acid secretion.[12] Further, it can abolish cephalic stage secretion, which is mediated by the vagus. This may be because of an inhibition of acetylcholine release from vagal nerve fibers.

Pancreatic Exocrine Secretion

PYY inhibits pancreatic secretion. Exogenous and endogenous CCK, secretin, intraduodenal amino acids and neurotensin stimulate secretion of pancreatic juice, bicarbonate ions and pancreatic enzymes (Fig. 3). PYY acts to counter these stimulatory effects through the Y2 receptor in rats. PYY also inhibits postprandial nutrient-stimulated pancreatic secretion. Further, treatment with anti-PYY serum causes enhanced pancreatic secretion, demonstrating PYY's importance in this feedback mechanism. As yet there is no consensus as to the mechanism by which PYY regulates pancreatic secretion. Dog studies suggest that the mechanism is independent of the vagus, and is instead mediated by adrenergic pathways. Others suggest that the feedback effects are modulated by the CCK pathway.

Pancreatic Endocrine Secretion

Animal studies strongly support a role for PYY in the inhibition of pancreatic endocrine secretion, but this evidence is not borne out by clinical studies. While no effect of intravenous PYY on plasma insulin was seen in mice, it significantly reduced circulating insulin levels in dogs (Fig. 3). Both mouse and dog studies show a glucose-dependent inhibition of insulin by PYY in the postprandial state. These effects were mirrored in *in vitro* studies: PYY dose-dependently inhibit insulin production in the presence of glucose, but not under basal conditions. Knockout mouse models also implicate PYY in pancreatic endocrine regulation and suggest that its actions are mediated by the Y1 receptors. PYY may also have indirect effects on the enteroinsular axis, as it inhibited the insuliotropic effects of gastrin releasing peptide (GRP) and gastric inhibitory peptide (GIP) in dogs. However, these insulin-inhibitory effects of PYY have not been replicated in clinical studies. Intravenous administration of PYY has not been found to influence insulin secretion in humans, either basally or under glucose-dependent conditions.

Small Intestinal and Colonic Secretion

PYY has an antisecretory action in the small intestine and colon, acting to increase fluid and electrolyte absorption. VIP modulates secretion of water and chloride ions in the small intestine through stimulation of intracellular cAMP production. PYY reduces this VIP-mediated secretion through mucosal Y1, Y2 and Y4 receptors.[5,9] PYY can also exert this effect on basal or prostaglandin-stimulated cAMP production. High postprandial PYY levels ensure that electrolytes are optimally absorbed at the intestinal mucosa; in the fasted state the relative absence of this feedback allows secretory hormones to maintain fluid homeostasis.

Appetite and Food Intake

PYY is an important modulator of appetite, feeding behavior, and body weight homeostasis. Importantly, the two circulating forms of PYY, PYY_{1-36} and PYY_{3-36}, can both act through the Y2 receptor to induce satiety. Thus, the extent and rate that DPP-IV converts PYY_{1-36} to PYY_{3-36} is not critical for the satiety action of PYY. However, conversion of PYY_{1-36} to PYY_{3-36} reduces the action on the Y1 receptor, which in general has inhibitory functions in many peripheral tissues such as fat and bone.

Renal Function

PYY's influence on renal function has been studied in humans. PYY, when infused at concentrations mimicking normal postprandial levels, decreases glomerular filtration rate by 10%. Sodium secretion increased by 30%, while rennin and aldosterone is significantly suppressed. Infusion with a high dose mimicking levels in pathological conditions, shows, in addition to these changes, reduced renal plasma flow. The mechanism behind these changes is not yet clear, but, whether directly or indirectly, PYY appears to have a major role in modulating postprandial natriuresis.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Vascular Effects

PYY plays a role in vasoconstriction, reducing blood flow to, in particular, the intestine through predominantly Y1 mediated actions.[19] In humans, PYY infusion is associated with increased systolic and diastolic blood pressure.

Growth and Development

PYY is one of the earliest gut peptides to be expressed in the fetal development of mice, suggesting a role in gastrointestinal growth and differentiation. *In vitro* studies indicate that these effects are mediated by the Y1 receptor. High levels of PYY or NPY during embryonic development is lethal because of the failure of midline formation.

PATHOPHYSIOLOGICAL IMPLICATIONS

The secretion pattern of PYY is altered in, and may contribute to, a number of gastrointestinal and systemic disorders.

Anorexia Nervosa

Anorexia nervosa (AN) is a condition in which patients deliberately suppress their food intake in order to reduce body weight. Whether this decreased food intake is modulated by endocrine cues has long been debated. Adolescent girls with AN have higher fasting PYY concentrations than healthy controls.[23] Interestingly, another study observed that PYY levels in women with AN are strongly correlated with bone mineral density (BMD), suggesting that PYY may contribute to the bone loss often seen in this condition via over-stimulating the inhibitory Y1 receptor on bone forming cells.[30]

Prediabetes

Low circulating PYY may not only be a function of type 2 diabetes (T2D), but also a predictor. A 2008 study investigated postprandial PYY response in healthy individuals with and without a family history of T2D. The authors found that the family history positive group have a blunted PYY secretory response, a defect that could precede insulin resistance and adiposity on the path to T2D in genetically susceptible individuals.[31]

Gastrointestinal Diseases

Many diseases involving the gastrointestinal tract are characterized by altered patterns of PYY secretion. Malabsorptive disorders are often accompanied by elevated PYY concentrations. Celiac disease, or sprue, is an autoimmune disorder involving severe small intestinal malabsorption of nutrients because of villous atrophy. It is caused by an allergic response to the gluten protein gliadin. Tropical sprue causes a similar malabsorptive state, but has an unknown infectious origin. In both types of sprue, PYY concentrations are greatly elevated in both basal and postprandial states. Circulating PYY is also high in patients with other forms of gastric malabsorption, such as chronic pancreatitis, infective diarrhea, and the inflammatory bowel diseases Crohn's disease and ulcerative colitis.[3]

PYY's involvement in malabsorptive gastrointestinal disorders is consistent with its ileal brake role. Ingested nutrients are primarily absorbed in the proximal small intestine in healthy individuals. When there is a defect in intestinal absorption, such as in these conditions, unabsorbed nutrients reach the distal ileum and colon, triggering PYY release in an adaptive attempt to slow gastric emptying and thus increase mucosal contact time.

Gastrointestinal Surgery

PYY concentrations increase after significant bowel resection.[3] This is an adaptive response to the shortening of the gastrointestinal tract and some subsequent loss of absorptive capability. Thus PYY secretion is not elevated after resection of small bowel segments, as in this case absorptive power is not greatly altered. Significant colon resection, however, can produce the opposite effect—decreased PYY levels.[3] This reflects the fact that the colonic mucosa is where a large proportion of PYY-expressing cells are localized. Removal of colon segments reduces the ability to produce and release PYY.

Bariatric Surgery

The purpose of bariatric surgery is to promote weight loss through restrictive or maladaptive means. Candidates for these types of surgery are generally morbidly obese, with the low fasting and postprandial PYY levels associated with obesity. In general, bariatric surgery tends to increase circulating PYY, reflecting both decreased nutrient intake (after restrictive surgery such as vertical banded gastroplasty) and reduced nutrient absorption (malabsorption operations such as jejuno-ileal bypass).[13] Surgery which combines both restrictive and malabsorption elements, such as Roux-en-Y gastric bypass, undoubtedly reaps the benefit of both mechanisms. Despite bariatric surgery's stimulatory effects on PYY, post-surgery patients rarely attain levels equivalent to those of healthy individuals. This may be because many postoperative patients are still overweight, if not obese.

Pancreatitis

In addition to neuroendocrine actions, a role for PYY has been found in immune function. A 2007 study found that therapeutic PYY confers significant survival benefits on mice with ethionine-induced necrotizing pancreatitis.[32] The

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

same group observed *in vitro* that these effects are mediated by a PYY-dependent suppression of amylase and cytokine secretion.

Obesity

There has been much research into PYY's role in obesity, and particular interest has been given to potential therapeutic uses. Basal PYY concentrations are lower in obese individuals than in lean, in both adults and children.[25,26] An inverse linear relationship between PYY and BMI had been suggested; however, this does not hold true in the case of morbid obesity. PYY release is similarly blunted in obese individuals after mixed meal ingestion. This difference disappears, however, when the mixed meal is replaced with an oral glucose load. It may be that obese patients respond appropriately to glucose but develop resistance to fat-stimulated PYY secretion. PYY has been widely proposed as a possible anti-obesity drug because of its inhibitory effects on appetite. Batterham et al conducted a placebo-controlled study in which healthy individuals were peripherally infused with $PYY_{3\text{-}36}$ to achieve postprandial concentrations. Participants reduced their *ad libitum* calorie intake by 36% in a meal 2 h after the infusion, and 24 h calorie intake was reduced by 33%.[4] There was a comparable reduction in caloric intake when the experiment was repeated with obese participants, showing that obese and lean individuals have a similar sensitivity to peripheral PYY.

Chapter 179

Secretin

Laurence J. Miller

ABSTRACT

Secretin is a linear 27-residue amidated peptide that is prototypic of natural peptide ligands that bind to and activate family B G protein-coupled receptors. All these peptides have diffuse pharmacophoric domains, with important determinants for high affinity binding spread throughout their length and with key determinants for biological activity at their amino terminus. Recent insights provide an evolving understanding of the structural basis of secretin binding to its receptor and stimulation of receptor signaling. The structure of the gene encoding secretin, its primary transcripts, and the processing of products of translation are well described. Physiological functions of this hormone include stimulation of secretion of biliary and pancreatic bicarbonate-rich fluid and inhibition of gastric secretion and gastric emptying. There are clinical pathological states of both elevation and deficiency in the levels of secretin, as well as clinical diagnostic utility for secretin infusion in testing pancreatic exocrine function and provocative testing for gastrinoma.

DISCOVERY

Secretin and its receptor hold unique and important roles in history, with the peptide representing the first hormone and giving birth to the field of endocrinology,[1] and the receptor representing the first member of the B family of G protein-coupled receptors.[17] Secretin was identified in 1902 by Bayliss and Starling[1] when they observed that the infusion of acid into a denervated loop of canine jejunum resulted in the stimulation of pancreatic exocrine secretion. The response was believed to be mediated by a blood-borne transmitter that they called a hormone, based on the Greek word meaning "I arose to activity." Indeed, secretin is one of the many gastrointestinal peptide hormones that have subsequently been isolated from the intestine, purified, structurally characterized, and ultimately synthesized and used to reproduce their physiological effects by Jorpes and Mutt.[23] Because the source of secretin and other gastrointestinal hormones are isolated enteroendocrine cells scattered throughout the intestinal mucosa, making them much more difficult to study than the classical solid endocrine organs, the field of endocrinology moved ahead quite quickly working on the classical endocrine organs, although it took many years to assemble the cast of mediators comprising the gastrointestinal endocrine system and to develop tools and reagents to characterize them.

The secretin receptor cDNA was cloned using the expression cloning technique in which a pool of genes from the NG108-15 neuroblastoma-glioma hybrid cell line in a mammalian expression vector was used to transfect COS cells that were then screened for secretin radioligand binding.[17] The primary sequence of the secretin receptor included seven hydrophobic segments likely to represent the seven transmembrane helical segments typical of the G protein-coupled receptors (GPCRs) known at that time, yet the classical signature sequences known to be present in family A GPCRs were absent in this receptor. Within a short time, the calcitonin and parathyroid hormone receptor sequences were also reported, and it became clear that a new and unique family (family B GPCRs) had been identified. Although this family has similar predicted heptahelical transmembrane topology and the ability to couple with heterotrimeric G proteins to that of family A GPCRs, clear structural differences from family A and coherence in themes have defined this as a unique family within the GPCR superfamily.[30]

STRUCTURE OF THE mRNA/GENE

The porcine secretin gene was first cloned in 1990[18] and found to include four exons and three introns spanning 813 bp.[19] Similar organization is present in genes subsequently cloned from rats, pigs, and humans (Fig. 1). All these include an untranslated region and coding regions for a signal peptide, an amino-terminal peptide that can be part of a biologically active form of secretin, and a long carboxyl-terminal extension peptide of unknown biological significance. The organization of the secretin gene is similar to that of several other peptides in this family, including glucagon, pituitary adenylate cyclase–activating polypeptide, and vasoactive intestinal polypeptide, with all having the mature hormonal peptides encoded by a single exon. FIGURE 1 Genomic organization of the porcine secretin gene. Shown is the general organization of the genomic sequence encoding secretin, including four exons (E1–E4) and intervening introns. The mature transcript for this hormone includes a signal peptide (SP) and amino terminal-coding region (N-term) that comes from the first exon and the 5′-end of the second exon. The classical mature peptide hormone (SCT) is encoded by the second exon. A carboxyl-terminal extension (C-term) is encoded by portions of the third and fourth exons.

FIGURE 2 Amino acid sequence of secretin from various animal species. Shown are the amino acid sequences of secretin from multiple species with the one-letter code. These sequences in multiple mammalian species are highly conserved, and the biologically critical amino-terminal sequence is also most conserved in an avian species as well. Identical amino acids are shown as (-), whereas amino acid replacements are directly identified.

this family, such as glucose-dependent insulinotropic peptide and growth hormone-releasing hormone, have the hormone-coding region spanning two exons. Although there is only a single copy of the secretin sequence within its gene in these species, glucagon and vasoactive intestinal polypeptide genes that have been cloned to date do include duplications such as glucagon-like peptides 1 and 2 and peptide histidine-methionine (PHM).

PROCESSING OF THE PRECURSOR

Mature secretin peptides are highly conserved in multiple mammalian species (Fig. 2). To date, one avian species, from *Gallus gallus* (chicken) has been reported (Fig. 2) and found to retain most of the amino-terminal sequence that is so important for the biological activity of this hormone. In addition to the mature, carboxyl-terminally-amidated form of secretin, various proforms of this hormone have been isolated. These are analogous to those of several other family members. These include a nine amino acid amino-terminally-extended form (N-prosecretin), glycine-extended forms believed to be in various stages of processing (secretin-Gly and secretin-Gly-Lys-Arg), and carboxyl-terminally-extended precursor forms of unknown significance.[2,9] The carboxyl-terminal peptides predicted from mRNA molecules isolated from rats and pigs are 72 residues in length, although these peptides are minimally conserved and far more divergent than the sequences of the coding regions of the mature peptides. Of interest, the first precursor form characterized to include portions of this sequence represented secretin plus 41 residues at its carboxyl terminus, although it did not include the first 32 residues of the predicted carboxyl-terminal peptide that had been replaced with an Arg residue.[10] Other precursors were ultimately characterized, including one with the full length predicted carboxyl-terminal peptide and one with a shortened form of this peptide.[19] The Gly-Lys-Arg sequence that is present immediately after the carboxyl-terminal Val residue in the mature porcine and human secretin peptides provides the classical site for dipeptidyl-peptidase cleavage, as well as the amino group that is donated during α-amidation of peptides that occurs as an important part of the posttranslational processing of the hormone precursor.

DISTRIBUTION OF THE mRNA/PEPTIDE

Secretin-secreting S cells are scattered in the small intestinal mucosa, particularly in the villus region, throughout the length of the small intestine of most species, with a gradient decreasing in frequency from proximal to distal. Consistent with this, secretin-like immunoreactivity is the highest in the duodenum where secretin-containing cells can represent six per one thousand cells,[16] and the frequency of these cells is found to progressively decrease to very low levels of immunoreactivity in the ileum. There are some differences among species, with rats having less of a proximal-to-distal gradient and pigs extending the presence of secretin into the colon, but these species seem to represent exceptions. The presence of secretin-like immunoreactivity in tissues outside of the intestine has been inconsistent and somewhat confusing, with some studies reporting its presence and others failing to find it in the same tissue. Tissues following this theme include the gastric antrum, pancreatic islets, and various regions of the central nervous system.

Although the identification of the cDNA encoding secretin and the ability to determine the presence of secretin mRNA could help clarify the distribution of this hormone, the apparent lack of correlation of the amount of mRNA with the amount of secretin peptide provides challenges. Clearly, the predominant site of secretin mRNA is in the intestine, but, of interest, it seems to be present in the highest concentration in the distal small intestine and is also present in the colon, sites that typically contain little mature peptide. Similarly, Northern blotting has failed to detect secretin mRNA in the stomach, pancreas, and many brain regions, probably because of levels that are too low to detect by this technique, whereas the very sensitive polymerase chain reaction amplification shows the presence of this mRNA in these tissues. It is of interest to note that polymerase chain reaction has provided positive results for the amplification of secretin transcripts present in first-strand cDNA prepared from the heart, lung, kidney, and testis.[25] The significance of the latter observations is unclear, particularly with no immunoreactive secretin peptide being identified in these tissues.

Secretin has been identified during the late stages of fetal development in the intestine and pancreas, remaining at high levels in the early postnatal period and then falling to adult levels.[19] This pattern of temporal expression is quite distinct from that of other gastrointestinal peptides such as cholecystokinin, which increase after feeding begins. It has been suggested that the prenatal expression of secretin could relate to the trophic action of this hormone in stimulating pancreatic growth and development.

RECEPTORS AND SIGNALING CASCADES

The secretin receptor is a family B guanine nucleotide-binding protein (G protein)-coupled receptor (GPCR). It was the first member of this family to be cloned[17] and has turned out to be prototypic of all peptide-binding members of this family[30] (Fig. 3). Although these receptors have the seven transmembrane topology and G protein coupling typical of all other GPCRs, the family B GPCRs are quite distinct in relation to their signature sequences, missing the key conserved amino acids present in the much larger and more extensively studied family A group. All the crystal structures for GPCRs that have been published to date are family A receptors,[28] and even the helical bundle region of those receptors that has been most conserved among them is predicted to be distinct in family B.[6] The most characteristic feature of the family B GPCRs is the relatively long extracellular amino-terminal tail region (>125 residues) that includes six conserved cysteine residues that contribute to three intradomain disulfide bonds.[12] Recently, a series of members of this family have had the structures of their amino-terminal tail regions solved using either NMR or X-ray crystallography. This has resulted in the characterization of a highly conserved structure that includes a highly conserved core with two antiparallel β-sheet regions, three disulfide bonds, and multiple loop regions with variable presence of an amino-terminal α-helix.[27] This structure also includes a conserved hydrophobic peptide-binding cleft above the stable core and between the helix and loop region.

The carboxyl-terminal portion of secretin, like other natural ligands for receptors in this family, assumes an alpha-helical conformation and occupies this peptide-binding cleft in the receptor amino terminus (Fig. 3). At the end of this helical segment, there is a helix N-capping motif that is believed to stabilize the important helical conformation and to direct the biologically critical peptide amino-terminal segment toward the core of the receptor[24] (Fig. 3). Although the details of the docking of the peptide amino terminus are not clear, this interaction is key for the biological activity of the natural hormonal ligand. Because the amino-terminal tail domain of the receptor is only covalently linked with the helical bundle core domain through the peptide backbone (carboxyl-terminal end of the amino-terminal tail region to the top of transmembrane segment one), the tethering process mediated by the bound natural agonist ligand is believed to be very important to induce the conformational change in the helical bundle that exposes the G protein-coupling site at the cytosolic face of the receptor. It is probable that these processes are conserved in this family, based on the similarity of peptide ligand and receptor structures and structure–activity considerations for both molecules.

In addition to its binding and activation of the secretin receptor, secretin is also capable of binding and activating another family B GPCR, the VPAC1 receptor.[13] This receptor binds secretin with low affinity, yet high concentrations

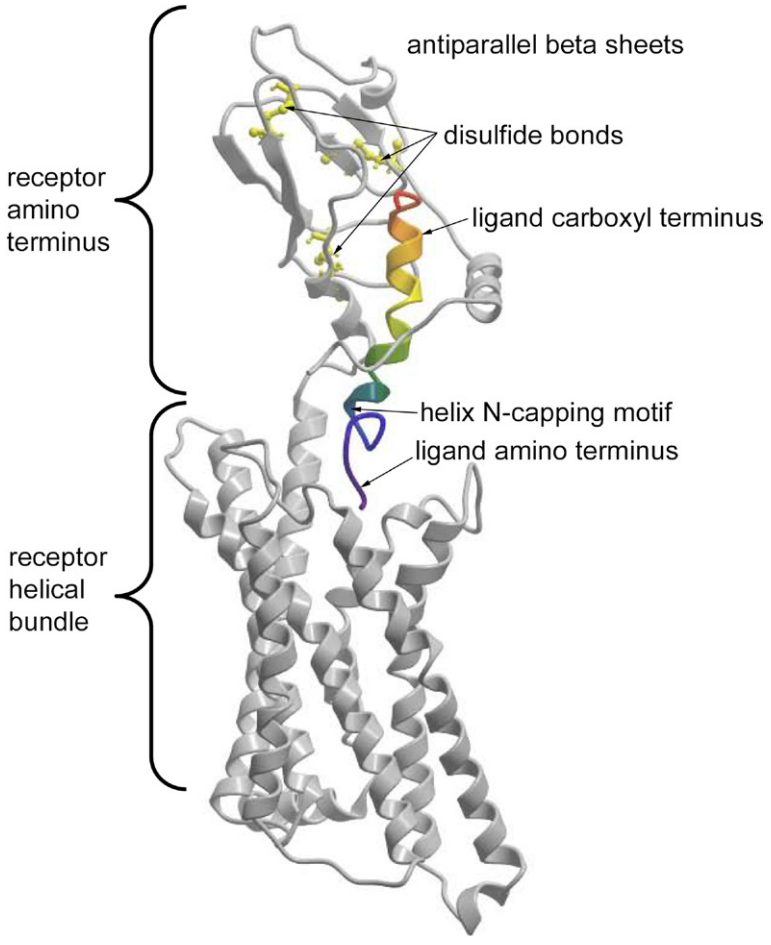

FIGURE 3 Illustration of the structure of the secretin receptor. Shown is a prototypic family B GPCR in gray, with the extracellular amino-terminal domain above the intramembranous helical bundle domain. Within the amino terminus are three highly conserved disulfide bonds (yellow), two antiparallel beta sheet regions, and several loop and helical structures. The peptide ligand is shown colored from purple-to-red, representing amino-to-carboxyl-terminal regions. The carboxyl terminus is illustrated in the typical alpha helix conformation ending in the conserved helix N-capping motif and the biologically important amino terminus directed toward the helical bundle. See color plate 50.

of secretin are capable of stimulating a full biological response. This is fully consistent with the common themes for structures and mode of binding and activation of these receptors. The carboxyl-terminal ends of the peptide ligands provide considerable binding energy but without a high degree of specificity. The amino-terminal ends of the peptide ligands provide the biological activity with a higher degree of specificity, while also adding binding energy to form the productive ligand–receptor complex.

Another interesting feature of secretin activation of its receptor is an evolving theme of receptor dimerization. There is a relatively recent appreciation that GPCRs can associate with themselves and with each other to form oligomers, although the presence of such higher-order complexes and their functional implications vary substantially across the superfamily.[7] For family C GPCRs, dimerization is quite common and even necessary to achieve some types of responsiveness to particular ligands. For family A GPCRs, oligomeric complexes can form for select members, with the implications varying substantially, from disrupting preformed complexes to stabilizing and stimulating the formation of such complexes, and ranging from no functional effects to substantial effects on ligand affinity, specificity, and signaling. For family B GPCRs, the secretin receptor has been studied more extensively than any other member[11] and seems to be prototypic of the typical behavior of members of this receptor family. Secretin receptors form structurally specific homodimeric complexes along the lipid-facing surface of TM4. This complex is key for the high affinity G protein-coupled state of this receptor. This complex is also critical for the negative cooperativity of binding observed for this receptor and other members of this receptor family.[11]

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Like other GPCRs, the secretin receptor is regulated by both biochemical and cellular mechanisms. The major biochemical regulatory mechanism involves receptor phosphorylation.[26] This occurs via signaling kinases such as protein kinase A and protein kinase C, and via G protein-coupled receptor kinases.[29] Phosphorylation is believed to mediate arrestin association with the receptor and uncoupling of the receptor from its G protein. The major cellular mechanism for regulation involves receptor internalization to move the peptide-binding site off the cell surface to a protected environment. This can be reversed by receptor recycling back to the cell surface or by new receptor biosynthesis.

BIOLOGICAL ACTIONS WITHIN THE GASTROINTESTINAL TRACT

The major physiological actions of secretin in the gastrointestinal tract provide a critical mechanism that contributes to nutritional homeostasis.[3] This relates to the ability of secretin to stimulate alkaline secretions from the pancreatic and biliary ductular systems. It is noteworthy that secretin is secreted from its intestinal S cells in response to acidic chyme in the lumen, with this requiring neutralization by the alkaline secretions to achieve an optimal pH environment for the actions of many digestive enzymes required for the breakdown of complex nutrients into absorbable forms. The components of intestinal chyme described to stimulate secretion of secretin include gastric acid and products of fat digestion (long chain fatty acids) and protein digestion (oligopeptides and amino acids), bile acids, and certain herbal extracts (curcuma longa and licorice root). The gastric acid delivered to the duodenum seems to be the most quantitatively important stimulant, with the pH threshold for secretin secretion of about 4.5 (release of hormone at pH levels below this threshold). Of interest, a secretin-releasing peptide has been postulated to exist,[22] mediating this effect of the luminal acid and providing still another level of potential feedback inhibition.

Secretin is also known to stimulate gastric secretion of mucus and pepsinogen, duodenal Brunner's gland secretion, pancreatic islet cell secretion of insulin, glucagon, pancreatic polypeptide, and somatostatin, and pancreatic growth. It can also inhibit the secretion of gastric acid and inhibit motility and transit in the esophagus, stomach, small intestine, and colon.

Another coherent set of responses to secretin have become clear in studies with knockout animal models.[5] These relate to body fluid homeostasis, where central nervous system effects of secretin can stimulate drinking and vasopressin release into the circulation; renal effects can result in water retention in the kidney particularly through effects on aquaporins, and effects of cardiovascular osmoregulatory neurons to regulate blood volume.[4] Indeed, insights into these effects may provide therapeutic opportunities for secretin receptor–active drugs in the future.

The actions of secretin are known to be synergistic with other gastrointestinal hormones such as cholecystokinin, with both acting together to stimulate the release and delivery of enzyme-rich pancreatic secretions into the duodenum. Additional interactions have been described for neurotensin and insulin with secretin. How this might affect normal human physiology is not yet clear. Interactions with nerves and neuronal actions are also prominent for secretin, being particularly affected by the integrity of the vagus nerve and with cholinergic potentiation of some effects of this hormone.

PATHOPHYSIOLOGICAL IMPLICATIONS

Clinical situations have been described in which levels of circulating secretin are elevated. These include gastric hypersecretory syndromes such as peptic ulcer and Zollinger–Ellison (gastrinoma) syndrome, renal failure with inadequate clearance of secreted peptide, and even a rare secretin-secreting islet cell tumor. Reduced levels of secretin have been observed in patients with achlorhydria and celiac disease, probably reflecting the absence of physiological stimulation or reduced S cell mass.

Secretin is also administered in diagnostic testing as a means of stimulating secretion in the pancreatic and biliary ductular systems, particularly together with imaging of these ducts, and as a provocative test for Zollinger–Ellison (gastrinoma) syndrome.[8] Most islet cell tumors responsible for this syndrome have excess secretin receptors on their cell surface and respond with a substantial elevation of serum gastrin during this provocative test, although rare tumors with excessive misspliced forms of this receptor do not respond.[20]

To date, there have not been any reports of abnormal or variant secretin molecules with recognized clinical presentations. There had been some excitement about an early report suggesting a role for secretin as a therapeutic for autism,[15] but further studies have failed to confirm the utility of this approach.[21]

Misspliced forms of the secretin receptor have been described in the setting of neoplasia.[20] This includes both islet cell tumors, such as the unresponsive gastrinoma described above, and pancreatic ductal adenocarcinomas. The dominant negative action of the variant splice form can actually have an inhibitory effect on the growth inhibitory role of this hormone, thereby stimulating the growth of such tumors.[14]

Chapter 180

Somatostatin

Vicente Martinez

ABSTRACT

Somatostatin is a tetradecapeptide isolated in the early 1970s from sheep hypothalami. It has been found in virtually every organ of the body, and it is particularly abundant in the gastrointestinal tract. Somatostatin exerts an inhibitory action on numerous physiological functions, acting as a classical endocrine hormone, a local (paracrine) regulator, or a neurotransmitter. Somatostatin actions are mediated through five distinct receptor subtypes (sst_{1-5}). sst_2 and sst_5 are the main mediators of the gastrointestinal effects of the peptide. Within the gastrointestinal tract, somatostatin exerts a broad range of physiological and pharmacological effects, mostly inhibitory, of which suppression of gastric acid secretion is a landmark response. Several diseases of the gastrointestinal tract imply disturbances in the somatostatin production or an altered expression of somatostatin receptors. The development of selective somatostatin agonists and antagonists has been critical in understanding the physiological and pathophysiological functions of somatostatin within the gastrointestinal tract.

Somatostatin was discovered in 1973 in sheep hypothalamic extracts and named originally hypothalamic growth hormone inhibiting factor.[2] Since then, the peptide has been found throughout virtually every organ of the body. Apart from its numerous endocrine and central nervous actions, it was quite clear that somatostatin has extensive gastrointestinal actions, acting mostly as an inhibitory mediator. During the last four decades, continued scientific interest resulted in the cloning and characterization of a family of five somatostatin receptors, the identification of three related neuropeptides, namely, coststatin, thrittene, and neuronostatin, and the development of numerous synthetic somatostatin analogs, some of them with clinical applications.

DISCOVERY

On searching for soluble factors involved in the inhibition of growth hormone secretion, a hypothalamic peptide consisting of 14 amino acids was isolated, identified as an inhibitor of growth hormone release, and named hypothalamic growth hormone inhibiting factor or somatostatin.[2] A few years later, a second biologically active, amino-terminally extended form of 28 residues, called somatostatin-28, was isolated from the porcine gut.[24] Both forms of somatostatin exhibit a disulfide bridge that allows a cyclic structure. Somatostatin peptides of 25 and 20 amino acids have also been purified from sheep hypothalamus and porcine intestine, respectively. However, the possibility that these peptides result from the proteolytic cleavage of somatostatin-28 during the isolation process has not been excluded.[3]

Both, somatostatin-14 and somatostatin-28 have a cyclic structure and derive from a single precursor, preprosomatostatin, a product of the somatostatin 1 gene, through tissue-specific posttranslational processing.[12,30] Somatostatin is a phylogenetically ancient peptide that is widely distributed throughout the body. The somatostatin-14 sequence is totally conserved across species, whereas there is only a 40–66% homology between somatostatin-28 and its counterparts in fish. In mammals, somatostatin-28 contains the somatostatin-14 moiety, responsible for the biological activity, at its carboxyl-terminal end. The processing machinery required for its synthesis is present in almost all tissues, with different relative activities. This leads to different tissue-specific types of synthesis and release of somatostatin-14 and somatostatin-28. Somatostatin-14 is the predominant form in the CNS and in most peripheral organs, including the gastrointestinal tract. By contrast, somatostatin-28 is mainly produced by intestinal enteroendocrine cells.[3,20]

During the previous years, the somatostatin family of regulatory peptides has expanded with the identification in mammals of three additional somatostatin-related peptides, namely, cortistatin, thrittene, and neuronostatin.

Cortistatin was identified in rats as a neuropeptide with strong homology to somatostatin. Like somatostatin, cortistatin has a short (cortistatin-17 in humans and cortistatin-14 in rats) and a long form (cortistatin-29 in rats and in humans). Rat cortistatin-14 shares 11 of its 14 amino acids with somatostatin-14, including the FWKT tetramer believed to be responsible for somatostatin's receptor interactions and the pair of cysteine residues that probably render the peptides cyclic. Unlike the broad tissue expression of the somatostatin-1 gene, the cortistatin

Copyright Elsevier 2024

gene has a more restricted expression pattern, mainly in the cortex and hippocampus.[7,8,28]

Recent studies using unique polyclonal antisera and a strain of somatostatin-deficient mice showed the existence of an additional somatostatin-like gastrointestinal peptide that has been named thrittene. Thrittene is homologous with the 13 residues of the proximal region of somatostatin-28 (somatostatin-$28_{(1–13)}$) but is not derived from the somatostatin-1 gene or the cortistatin gene.[10]

Bioinformatic analyses of evolutionarily conserved sequences predicted the existence of a novel somatostatin-related peptide within the prosomatostatin molecule. After this, a 13-residue amidated product of the prosomatostatin, named neuronostatin, was purified from porcine pancreas. Unlike somatostatin-14, somatostatin-28 and the cortistatins, neuronostatin is not a cyclic polypeptide.[25] Although derived from the same preproprotein as somatostin, the processing of neuronostatin and somatostatin could be differentially regulated. Moreover, because of the need for the amidation of neuronostatin, but not somatostatin, expression of amidation enzymes in cells expressing somatostatin transcripts could determine neuronostatin levels.

The physiological role of these somatostatin-related peptides is still unclear.

STRUCTURE OF THE mRNA/GENE

The abundant expression of somatostatin in anglefish pancreatic islets was vital for the initial cloning of a somatostatin cDNA encoding the full amino acid sequence of preprosomatostatin in 1980.[13,14] Subsequently, cDNAs encoding preprosomatostatin of numerous species have been isolated and shown to have virtually complete homology in the region encoding somatostatin-28 and somatostatin-14.[30]

Somatostatin is encoded by a single gene, the somatostatin 1 gene, which, in humans, maps to the long arm of the chromosome 3. In the rat, the gene spans 1.2kb and is interrupted within the coding sequence of preprosomatostatin, the 116-amino-acid precursor of somatostatin-14 and somatostatin-28, by a single intron of 630 bases. The somatostatin 1 gene is present in all vertebrate classes, showing a virtually complete homology in the region encoding both forms of the peptide.[12,30] A single promoter directs transcription of the gene in all tissues, and there are no known alternative mRNA splicing events.

Cortistatin is the product of a second somatostatin gene present in most mammals (somatostatin 2/costistatin gene).[12,30] A revised evolutionary concept of the somatostatin gene family suggests that a primordial gene underwent duplication during or before the advent of chordates and that the two resulting genes underwent differing rates of mutation to produce the distinct preprosomatostatin (somatostatin 1) and preprocortistatin (somatostatin 2/cortistatin) genes in mammals. A second gene duplication event from the ancestral somatostatin gene occurred in teleosts to generate the so-called somatostatin 3 and somatostatin 4 genes.[12,30]

Therefore, so far, there is evidence for the existence of at least four distinct somatostatin genes in vertebrates: (i) the somatostatin 1 gene, encoding for somatostatin-14 and somatostatin-28 and representing the ancestral gene of the family; (ii) the somatostatin 2/cortistatin gene, encoding for cortistatin; (iii) the somatostatin 3 gene, encoding for several somatostatin-like peptides in teleosts; and (iv) the somatostatin 4 gene, encoding for somatostatin-like peptides in ostariophysi.

The gene encoding for thrittene, which is not derived from either the somatostatin-1 or the somatostatin 2/cortistatin genes, remains elusive.

PROCESSING OF THE PRECURSOR

As mentioned, both forms of mammalian somatostatin (14 and 28) are derived post-translationally from a common preprohormone (116-amino-acid) by the action of specific proprotein convertases (PCs). For instance, genetic studies indicate a primary role for PC2 in the generation of somatostatin-14[17] (see the PC2 chapter in Peptides Biosynthesis/Processing section of this book).

The processing machinery required for the synthesis of somatostatins is present in almost all tissues, including some that ordinarily do not synthesize the peptide, with different relative activities.[3] This leads to different tissue-specific types of synthesis and release of somatostatin-14 and somatostatin-28. Depending on the tissue considered, the somatostatin precursor is processed to somatostatin-14 or to both somatostatin-14 and somatostatin-28, with no processing intermediates and with no evidence of conversion of somatostatin-28 to somatostatin-14. However, the detection of fragments somatostatin-$28_{1–12}$ (the amino terminal fragment after somatostatin-28 cleavage) in tissues producing somatostatin-14 suggests the possible production of this form of the peptide from somatostatin-28.[3]

Somatostatin-14 is the predominant form in the CNS and in most peripheral organs, including the gastrointestinal tract, where it can be found in the stomach, duodenum, colon, and pancreas. By contrast, somatostatin-28 is produced mainly by intestinal enteroendocrine cells and represents >50% of the somatostatin content in the small intestine.[20]

DISTRIBUTION AND RELEASE

The central nervous system, gastrointestinal tract, and endocrine glands are the major sites of production and action of somatostatin. In the rat, the gastrointestinal tract accounts

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

for approximately 65% of the total body somatostatin, the pancreas for approximately 5%, the brain for approximately 25%, and the remaining organs for approximately 5%.[20] Somatostatin mRNA is distributed throughout the gastrointestinal tract, being present in both enteroendocrine cells and neurons. The gastrointestinal tract is the main source for the picomolar concentration of somatostatin measured in the circulation. Somatostatin, however, degrades rapidly in the circulation, with a half-life of <3min. Although the shorter somatostatin-14 form is mainly synthesized in the stomach, colon, and pancreas, the longer somatostatin-28 form is mainly found in the small intestine, in particular in its proximal part.[3,20]

Distribution of Somatostatin and Somatostatin-like Peptides in the Gastrointestinal Tract

In mammals, somatostatin is found mainly in the mucosal layer of the gastrointestinal tract. For instance, >90% of immunoreactive somatostatin in extracts of human gastrointestinal tissue is measured in the mucosa, in particular in the stomach, the duodenum, and the jejunum; <10% occurs in the muscle layers. Within the mucosa, somatostatin is localized in epithelial endocrine cells termed D cells, found preferentially in the upper gastrointestinal tract. In the stomach, D cells are localized both in the antral and the fundic mucosa. They have a characteristic morphology, with cytoplasmatic processes that terminate in close proximity to the target cells. Such morphology supports the concept of a paracrine/local mode of action of somatostatin in the gastric mucosa. In the fundic mucosa, D cells are of a "closed type," without luminal contact, whereas in the antrum, they are of an "open type," with their apical membrane exposed to the gastric lumen. This organization correlates with functional responses to different stimuli.[3,20]

Endocrine D cells are also found in the intestinal mucosa and pancreas. Intestinal D cells are "flask-shaped" cells, with their apical membranes open to the lumen, and, therefore, respond to luminal stimuli. In the pancreas, endocrine D cells are a functional component of the pancreatic islets, participating in the local endocrine control.[3,20]

Although gastric somatostatin is mainly of endocrine origin, intestinal somatostatin is mostly present in neurons of the submucosal and myenteric plexus, throughout the whole gastrointestinal tract, with the lowest levels observed in the colon. Most neuronal somatostatin-like immunoreactivity is present in the intrinsic innervation of the gut. For instance, 20% of the cell bodies in the submucous plexus of the small intestine of guinea pigs contain somatostatin-like immunoreactivity, corresponding to cholinergic secretomotor neurons. Pancreatic ganglia and nerves also contain significant amounts of somatostatin.[3,20]

Cortistatin mRNA is expressed in the same gastrointestinal tissues as somatostatin mRNA but at levels significantly lower than those of somatostatin. Besides regions of the central nervous system (cortex and hippocampus), selective expression of cortistatin is only found in cells of the immune system, where it was proposed to function as the main endogenous somatostatin receptor ligand.[7,8]

Thrittene has been localized in enteroendocrine cells of the stomach and the distal small intestine, and in the enteric nervous system.[10] Neuronostatin has been localized in parietal cells of the gastric mucosa and in pancreatic islets, probably acting as a local regulator of gastric acid secretion and pancreatic endocrine function, although this needs to be confirmed.[25]

Regulation of Somatostatin Release in the Gastrointestinal Tract

Somatostatin is secreted mostly in a paracrine/neurocrine fashion, and, therefore, circulating levels are relatively low and might not reflect release at local sites. Moreover, to avoid spreading of actions, somatostatin is rapidly degraded by plasma enzymes, having a relatively short half-live in circulation, about 3min. These factors complicate the study of somatostin release and regulation *in vivo*. Somatostatin release in the gastroenteropancreatic system is regulated by intraluminal, neural, and endocrine factors in a complex network.

Release by Intraluminal Stimuli

Nutritional factors and acid (low pH) are the main intraluminal stimulants of somatostatin release. These factors, and in particular luminal acid, are key regulators of somatostatin release from open-type endocrine D cells in the antral region of the stomach. Similarly, the presence of nutrients and acid in the duodenum stimulates the release of gastric somatostatin, an effect probably mediated through the combined release of intestinal enterogastrone(s) and the activation of neural reflexes targeting antral D cells.[3,18,20] Because somatostatin is a potent inhibitor of gastric acid secretion, stimulation of its release by intraluminal acid represents a physiologically significant negative feedback regulatory loop. Physiological postprandial changes of somatostatin levels in the peripheral or portal circulation derive from gastric and intestinal somatostatin release. Other sources of somatostatin do not contribute significantly to the peripheral plasma levels of the peptide.[3]

Release by Neural Mechanism

The sympathetic and parasympathetic nervous systems have opposite effects on somatostatin release. Adrenergic agonists, through β-adrenergic receptors, stimulate gastric somatostatin release. On the other hand, muscarinic cholinergic agents inhibit somatostatin release in *in vitro* conditions. However,

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

in vivo, there is evidence for vagal-dependent enhancement and inhibition of somatostatin release, an effect that has been explained by the existence of vagal nonadrenergic stimulatory pathways. Cholinergic agonists directly inhibit fundic D cells. Therefore, cholinergic effects *in vivo* may lead to a stimulation of acid secretion by direct action on parietal cells and also by inhibition of fundic somatostatin release. Moreover, the contribution of intrinsic peptidergic nerves targeting antral and fundic D cells needs to be taken into consideration.[3,20,22,35]

Release by Gut Regulatory Peptides

Several regulatory peptides, acting as classical hormones or as neuropeptides, modulate gastrointestinal somatostatin release. These can be categorized as stimulatory and inhibitory agents. The most important stimulants of somatostatin release are gastrin and cholecystokinin (CCK). Peptides of the secretin family, bombesin/gastrin-releasing peptide (GRP), oxyntomodulin, glucagon-like peptide-1 (GLP-1), and calcitonin gene-related peptide (CGRP), which consistently inhibit gastric acid secretion, may function by stimulating somatostatin release. On the contrary, substance P, insulin, glucagon, pancreatic polypeptide, and opioids are potent inhibitors of somatostatin release. The exact signaling pathways by which these stimuli trigger somatostatin release from D cells are complex and not completely understood. They involve mucosal cells and afferent and efferent vagal nerves.[3,20]

RECEPTORS AND SIGNALING CASCADES

Somatostatin Receptors

Somatostatin acts on its target cells through a family of rhodopsin-like G protein-coupled receptors (GPCR) with seven transmembrane domains, of which five subtypes (sst_1–sst_5) have been cloned and characterized from various species.[15] In addition, two splice variants of the sst_2, sst_{2A}, and sst_{2B}, which differ in length and composition of their intracellular carboxy termini, have been cloned in the mouse and in the rat. Sequence homology is 39–57% among the five subtypes, being highly conserved across species. For instance, there is an 80–99% homology among the human, rat, and mouse isoforms. The nearest relatives of the somatostatin receptors are the opioid receptors, sharing about 37% sequence similarity to that of the mouse sst_1. According to structural and functional characteristics, the somatostatin receptors are divided into two groups: group 1, including sst_2, sst_3, and sst_5 and group 2 that comprises sst_1 and sst_4.

In humans, somatostatin receptors are encoded by five nonallelic genes, mapped to chromosomes 14, 17, 22, 20, and 16, respectively. Genes coding for sst_1, sst_3, sst_4, and sst_5 are intronless; however, the gene for sst_2 contains three introns, which result in the generations of the unspliced sst_{2A} and the spliced sst_{2B} variants mentioned above. Recently, the existence of truncated sst_5 variants in humans, pigs, mice, and rats that lack one or more transmembrane domains has been reported. These truncated forms are formed by noncanonical splicing and show characteristic molecular and functional properties. They show a broad distribution in normal and tumoral tissues. However, their functional involvement, if any, in somatostatin (or cortistatin) actions remains to be elucidated.[4]

An increasing body of evidence suggests that in many instances somatostatin receptors do not function as monomers but that they associate with other receptors to form homodimers and heterodimers whose binding, pharmacological and signal properties can diverge significantly from those of the corresponding single receptor. However, these potential interactions have not been shown in native cells, and their relevance for receptor physiology is not clear.[9]

Signaling of Somatostatin Receptors

The binding of somatostatin to its receptors triggers a complex set of signaling events, initiated by the interaction of the activated receptors with a large number of different protein partners (Table 1). The interactions occurring between the activated receptor and its effectors determine the subsequent intracellular signaling events and, ultimately, the associated biological responses. For review on the subject see Refs. 16, 27.

Signaling of somatostatin receptors involves the activation of heterotrimeric G proteins. All somatostatin receptors decrease adenylyl cyclase activity, reducing the concentration of intracellular cAMP, via the pertussis-sensitive G protein family G_i/G_o, leading, further down, to the stimulation of a vanadate-sensitive phosphotyrosine phosphatase (PTP), the modulation of mitogen-activated protein kinases (MAPKs), as well as the stimulation of phospholipase C. Further, some somatostatin receptors activate inwardly rectifying K^+ channels and/or inhibit voltage-dependent Ca^{2+} channels. The net effect of coupling to these membrane channels is the hyperpolarization of the membrane potential leading to an inhibitory effect on secretion. Moreover, somatostatin receptors can act via pertussis toxin-independent mechanisms, via the activation of G proteins such as G_{12} or G_{14}. In some instances, a direct interaction between somatostatin receptors and phosphatases or kinases might happen.

The lowering of intracellular cAMP and Ca^{2+} are the most relevant mechanisms for the inhibition of hormone secretion from endocrine cells, whereas activation of PTP and MAPK are postulated to play a role in the antiproliferative effect of on tumor cells.

In addition, a different series of agonist-triggered events lead to somatostatin receptor desensitization and internalization. Somatostatin binding to sst_1, sst_{2A}, and sst_3 results in the activation of kinases and the subsequent receptor

phosphorylation. This results in a receptor subtype-specific recruitment of arrestins, thus stopping all G protein-mediated signaling and starting the receptor internalization process.

Somatostatin Receptor Localization in the Gastrointestinal Tract

All somatostatin receptor subtypes are present in the gastrointestinal tract; however, their exact localization is still a matter of debate. This results from the complex physiology of somatostatin (and cortistatin), the existence of numerous species-specific differences in receptor distribution, and discrepancies depending on whether the receptors are estimated at the mRNA or protein level (Table 1).

At the transcriptional level, mRNAs for all somatostatin receptor subtypes, have been detected throughout the whole rat gastrointestinal tract in the epithelium and the lamina propria of the mucosa, the submucosa, the smooth muscle layers, and the submucosal and myenteric nerve plexus. In humans, mRNAs for the various somatostatin receptor subtypes were found in the stomach, in the small intestine, and in the epithelium and lamina propria of the colon.

In the stomach, sst_2 is the predominant receptor subtype, with both splice variants (sst_{2A} and sst_{2B}) being present, as shown by *in situ* hybridization studies and RT-PCR techniques. This was further confirmed at the protein level with immunohistochemical studies using antipeptide antibodies specific for the sst_{2A} and sst_{2B} isoforms. These studies showed that sst_{2B} is mainly present in parietal cells and, in high concentration, in enterochromaffin-like (ECL) cells. On the other hand, sst_{2A} seems to be restricted to a small population of ECL cells. So far, no somatostatin receptors have been found in other cellular types of the gastric mucosa. Sst_{2A} has also been localized in nerve fibers arising from the enteric nervous system and innervating the mucosa, with fibers running parallel to the epithelia. Many of these fibers are in close proximity to D cells of the gastric mucosa. This distribution supports the view that sst_{2A}

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

receptors might mediate somatostatin effects in the gastrointestinal tract via neuronal and paracrine pathways.[18,20,31]

In situ hybridization studies have identified all five receptor subtypes in the epithelium, submucosal plexus, and muscle layers of the rat small intestine and colon. However, only sst_1, sst_2, and sst_3 are found in the myenteric plexus. The main receptor subtype found in the intestine is the sst_2 form. Imunohistochemical studies showed the presence of sst_{2A} receptors in the myenteric and submucosal plexuses and in nerve fibers innervating the muscle, mucosa, and vasculature, thus suggesting an important role for this receptor subtype in the regulation of intestinal motor and secretory functions. Sst_{2A} receptors have been described also in interstitial cells of Cajal, indicative of other target cells for somatostatin to regulate smooth muscle activity.[20,31]

Within the pancreas, early autoradiographic studies showed the presence of somatostatin binding sites in alpha and beta cells. Subsequent molecular studies showed that rat islets contain mRNA for all five receptor subtypes, although this does not imply the presence of functional receptors. In humans, immunohistochemical studies showed a predominant expression of sst_2 and sst_5, with a cell-specific distribution pattern: beta and delta cells contain sst_5, while alpha cells contain mostly sst_2. In the exocrine pancreas, sst_2 has been detected in rodent, but not human, acinar cells.[23]

In addition to normal tissues, a vast majority of human tumors, either benign or malignant, express somatostatin receptors in high concentrations, frequently featuring more than one isotype.[6,29] In particular, somatostatin receptors are present in almost all neuroendocrine enteropancreatic tumors. The expression patterns seem to be tumor specific, with a general profile of $sst_2 > sst_1 > sst_3 > sst_4 > sst_5$. For instance, sst_2 predominance is found in about 90% of carcinoid tumors and 80% of endocrine pancreatic tumors.[20]

Cortistatin Receptors

It has been suggested that human MrgX2 and the GH secretagog receptor 1a (GHS-R1a) might function as cortistatin receptors. However, there is no convincing evidence supporting this view. First, cortistatin has up to 1000-fold higher affinities for the classical somatostatin receptors than it has for MrgX2 or GHS-R1a. Moreover, there is a major discrepancy between receptors and peptide distribution; with MrgX2 (actually the complete Mrgx family) being absent in rodents, where cortistatin was discovered. Therefore, as of today, cortistatin and somatostatin share the same receptors.[28] Functional differences reported to distinguish cortistatin and somatostatin may relate to ligand-driven transductional selectivity and/or other factors such as receptor dimerization and/or the influence of accessory proteins.

BIOLOGICAL ACTIONS WITHIN THE GASTROINTESTINAL TRACT

Somatostatin, acting in a paracrine fashion, as a classical hormone or as a neurotransmitter, mediates a broad range of physiological actions, mostly inhibitory, in the gastrointestinal tract (Table 2). Biological actions of somatostatin-related peptides are not yet fully investigated.

TABLE 2 Receptor Selectivity of Somatostatin Actions in the Gastrointestinal Tract

Somatostatin action	Receptor subtype	Localization
Inhibition of acid secretion	sst_2	Parietal cells
Inhibition of histamine release	sst_2	Enterochromaffin-like cells
Inhibition of gastric emptying	sst_2/other undetermined	Myenteric plexus
Modulation of intestinal motility	sst_2	Interstitial cells of Cajal
Modulation of the peristaltic reflex	sst_2/other undetermined	Myenteric plexus
Modulation of epithelial function and blood flow	sst_2/other undetermined	Submucous plexus
Stimulation of ion transport	sst_2	Colonic epithelial cells
Inhibition of chloride secretion	sst_2	Colonic epithelial cells
Inhibition of pancreatic amylase release	sst_5	Pancreatic acinar cells
Inhibition of insulin secretion	sst_5/sst_1 (sst_2 in humans)	Pancreatic beta cells
Inhibition of glucagon secretion	sst_2	Pancreatic alpha cells
Inhibition of cell proliferation	sst_1/sst_2/sst_3/sst_4/sst_5	Tumor cells

Somatostatin Actions in the Stomach

Gastric acid secretion reflects a complex balance between stimulatory and inhibitory factors. Somatostatin is a potent inhibitor of gastric acid secretion and probably the main inhibitory regulator during the cephalic, gastric, and intestinal phases of secretion.

The somatostatin-dependent regulation of gastric acid secretion involves gastric somatostatin produced by fundic antral endocrine D cells, acting locally through paracrine, rather than endocrine, mechanisms. Fundic D cells are stimulated by gastrin and acetylcholine, as well as by other neuropeptides; they are closely associated with parietal cells and ECL cells through cytoplasmic extensions. Antral D cells respond to changes in gastric luminal acidity and are closely associated with their target cells, that is, G cells, resulting in the local release of somatostatin, which in turn, inhibits gastrin synthesis and release from G cells. During the cephalic and gastric phases of a meal, gastric acid secretion is stimulated through the release of gastrin. Attenuation of excessive acid secretion can be attributed to the local release of somatostatin, regulating (inhibiting) the activity of G cells, parietal cells and ECL cells. In addition, *in vivo* and *in vitro* observations suggest that somatostatin also controls basal gastric acid secretion during the interdigestive phases, acting as a tonic restraint on acid secretion.[3,18,20]

Several *in vivo* and *in vitro* studies in rats, mice, dogs, and humans using different relatively selective agonists and antagonists of somatostatin receptors established that sst_2 mediates the inhibitory effects of somatostatin on gastric acid secretion.[18–22] The most conclusive evidence for the involvement of sst_2 receptors in the control of gastric acid secretion comes from functional studies in mice with targeted disruption of the sst_{2A} receptor gene (sst_2–/–).[18–22,34] Because the sst_{2B} variant is a spliced product of the sst_{2A}, these animals lack both forms of the receptor; therefore, none of the splice variants is expressed, and no information about the isoform mediating somatostatin action on acid secretion can be derived.

Several gut regulatory peptides [i.e., amylin, adrenomedullin, CGRP, bombesin, glucose-dependent insulinotropic polypeptide, GLP-1, and pituitary adenylate cyclase-activating polypeptide (PACAP)] inhibit gastric acid secretion through the release of somatostatin or have somatostatin-dependent mechanisms of action. Moreover, receptors for several of these neuropeptides have been localized in gastric D cells. These observations suggest that gastric D cells function as an integrator of inhibitory signals controlling gastric acid secretion. Activation of D cells translates into the release of somatostatin, the activation of sst_2 receptors in parietal and ECL cells and the subsequent inhibition of acid output (Fig. 1).[18,20–22,35]

Against that expected, sst_2–/– mice have normal levels of circulating gastrin and unchanged basal acid output,[19,35] thus suggesting the existence of alternate compensatory mechanisms that can replace the integrative role of D cells and somatostatin in the inhibitory control of acid secretion. Indeed, it has been shown that the genetic ablation of the paracrine somatostatin/sst_2-dependent inhibitory control of acid secretion in sst_2–/– mice leads to (i) a shift toward a galanin-neuroendocrine-dependent control of ECL activity and (ii) an enhancement of the direct action of gastrin and vagal cholinergic pathways on parietal cells.[35] Overall, this plasticity of the gastric neuroendocrine control is able to maintain similar basal acid secretion and postprandial stimulated secretion in sst_2–/– and wild-type mice.

As it relates to gastric motor functions, somatostatin inhibits the normal reflex response to volume increase, slows down the emptying of a meal, and decreases the perception of fullness.[5,11,31] The receptors mediating these effects are not fully identified although the expression of sst_2 receptors in the enteric nervous system points toward this receptor subtype. Nonetheless, gastric emptying was normal in sst_2–/– mice.

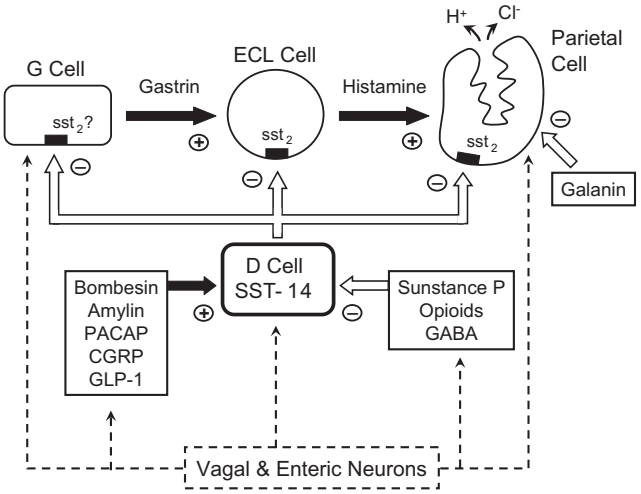

FIGURE 1 Basic mechanisms controlling gastric acid secretion. Somatostatin secreted from gastric D cells modulates the gastrin-enterochromaffin-like (ECL) cell–parietal cell axis. Gastrin, secreted from G cells, stimulates the release of histamine from ECL cells, which is the major stimulant of acid from gastric parietal cells. Somatostatin, acting through sst_2, inhibits secretion from each of these cell types, although the predominant actions seem to be on ECL and parietal cells. The activity of these cells is also modulated by neural signals from the vagus and the enteric nervous system. In fact, D cells might function as a common integrator center for the action of neuropeptides that either stimulate or inhibit somatostatin release and, through this mechanism, inhibit or stimulate gastric acid secretion, respectively. Some neuropeptides, such as galanin, might function as alternative somatostin-independent pathways controlling acid production and might be upregulated when the somatostin-sst_2-dependent control is altered, as during the targeted disruption of the sst_2 in mice. The pathways illustrated are not all-inclusive but represent many of the key regulatory steps.

Somatostatin Actions in the Small Intestine

Within the small intestine, somatostatin acts as an important neurotransmitter, acting through somatostatin receptors located in the submucosal and myenteric nervous plexus of the enteric nervous system. The physiological implications of these actions are complex because of the broad spectrum of functions modulated by the enteric nervous system (i.e., motility, exocrine and endocrine secretions, absorption of nutrients, microcirculation, or the local immune system). In the small intestine, neuronal somatostatin is released locally by intestinal distension, and it participates, as a neuromodulator, in the coordination of the peristaltic reflex. Pharmacological studies and the use of sst_2−/− mice support the notion that sst_2 in enteric ganglia is involved in the regulation of peristalsis; however the implication of other receptor subtypes cannot be ruled out.[1,5,31,34] The presence of sst_2 receptors in interstitial cells of Cajal further supports a role for somatostatin modulating intestinal motility.

Expression of sst_2 receptors in submucosal ganglia suggests an involvement in the regulation of mucosal function and blood flow. Indeed, somatostatin decreases intestinal fluid secretion, stimulates the absorption of water and electrolytes, and reduces collateral splanchnic blood flow up to 30%, without causing adverse systemic effects. Comparable effects can also be detected in humans on the application of somatostatin analogs such as octreotide.

Somatostatin Actions in the Colon

In humans, somatostatin has been reported to modulate colonic motor and sensory functions. As in the small intestine, somatostatin participates in colonic peristaltic activity, decreases postprandial colonic tone, increases the threshold for visceral sensory perception, prolongs transit, and modulates epithelial function. Motor and sensory effects of somatostatin are probably mediated through sst_1 and sst_2 receptors, with sst_1 located in the longitudinal colonic smooth muscle and sst_2 in the circular.[5]

Somatostatin Actions in the Pancreas

Somatostatin affects both endocrine and exocrine pancreatic secretion, acting through paracrine and endocrine mechanisms. Although the pancreas contains mRNA for all somatostatin receptor subtypes, pharmacological studies in normal and sst_2−/− mice have shown that pancreatic actions of somatostatin are mediated through sst_1, sst_2, and sst_5 receptors.[20,32–34]

In mice, intraislet somatostatin, acting locally through sst_1 and sst_5 receptors, exerts a tonic inhibitory effect on insulin secretion. Similar effects, although exerted through sst_2 receptors, are observed on glucagon-secretory alpha cells. In this sense, somatostatin not only exerts a tonic inhibitory effect on stimulus-induced glucagon secretion but also regulates the suppression of glucagon secretion by glucose. Conversely, a recent study with human pancreatic islets indicated that sst_2 mainly mediates the somatostatin inhibition of insulin release, suggesting the existence of potential species differences.

In the rat, somatostatin acts directly on acinar cells to inhibit pancreatic enzyme and bicarbonate secretion. Pharmacological studies identified sst_5 as the main receptor subtype inhibiting pancreatic amylase release in rats. In humans, circulating somatostatin-14 and somatostatin-28 are equally potent inhibiting basal and CCK-stimulated exocrine enzyme secretion. However, no somatostatin receptors have been identified in the human exocrine pancreas so far.

PATHOPHYSIOLOGICAL IMPLICATIONS

Disturbances of the somatostatin system have been observed in pathologic human gastrointestinal tissues, both neoplastic and nonneoplastic. They include disturbances of somatostatin production and of somatostatin receptor expression. There have been no reported cases of heritable genetic syndromes caused by reduced or absent expression of either somatostatin or any of its receptors. A number of polymorphisms have been identified in the somatostatin 1, sst_2, and sst_5 genes, but no linkage has been found between particular alleles and specific disease states.

A clear pathophysiological role of somatostatin has been shown only in cases with somatostatin-producing tumors (somatostatinomas). Somatostatinomas are rare neuroendocrine tumors that arise typically from transformed D cells in the pancreatic islets or duodenum. The clinical syndrome of somatostatin hypersecretion is characterized by malabsorption, steatorrhea, cholelithiasis, diabetes, and pancreatic insufficiency.

Alterations in the responsiveness and number of gastric D cells might be related to the hypersecretory states observed in patients with nonatrophic gastritis associated with *Helicobacter pylori* infection and in patients with duodenal or gastric ulcers. Because of its medical interest, the relationship between chronic *H. pylori* infection and reduced gastric somatostatin has been actively investigated.[5] *H. pylori* infection induces a gastric inflammation with release of several cytokines that induce a decrease in both D cell mass and somatostatin secretion, leading to elevated gastrin levels and increased gastric acid output. The eradication of *H. pylori* infection is followed by structural and functional restoration of endocrine D cells. Animal models of human *H. pylori* infection suggest that somatostatin may play a role in the disease not only by interacting with acid regulation but also by influencing the inflammatory status.

Somatostatin Receptor Expression in Neoplastic Disease

Of much greater importance and clinical impact than the production of somatostatin is the expression of somatostatin receptors in neoplasms. A very high incidence, and often a high density, of somatostatin receptors have been found in the gastroenteropancreatic endocrine tumors with receptor autoradiography and by *in situ* hybridization methods. They include endocrine neoplasms of the pancreas and the intestinal tract that express predominantly sst_2, with or without other subtypes.[6,29]

Somatostatin Analogs and their Clinical Applications in Gastrointestinal Disease

The natural somatostatins are very potent molecules, produced locally and degraded very rapidly, thus limiting their clinical use. Therefore, extensive pharmaceutical discovery programs have been ongoing to synthesize somatostatin analogs with receptor subtype selectivity (or pan-activity, as the natural ligands), improved pharmacokinetics and oral bioavailability. As a result, stable somatostatin agonist analogs, such as octreotide, have been developed not only for diagnostic and therapeutic applications but also to elucidate the physiological role and mechanism of actions of the native hormones. In addition, more recently, nonpeptidergic, receptor subtype selective, agonists, and antagonists have been synthesized (Table 1).

Diagnostic Applications with Radioactively Labeled Somatostatin

Somatostatin receptors were the first peptide receptors to exemplify the principle of *in vivo* targeting of human cancers expressing a high receptor density. Radioactively labeled synthetic somatostatin analogs are now used diagnostically for *in vivo* scintigraphy of primary neoplasms overexpressing somatostatin receptors and their metastases, in particular gastroenteropancreatic cancers.[6]

Therapeutic Applications

Targeting of the overexpressed somatostatin receptors by synthetic somatostatin analogs in diseased tissues can be used therapeutically in several ways: (i) as radioactive and nonradioactive cytotoxic analogs for tumor radiotherapy, and (ii) as nonradioactive noncytotoxic analogs for symptomatic tumor therapy or therapy of nonneoplastic diseases.

i. *Tumor therapy with somatostatin analogs*—Because sst_2 seems to be the main receptor subtype in many human tumors, several somatostatin analogs with a particularly high sst_2 affinity have been developed for tumor therapy.[6] Some potent chemotherapeutic agents, such as camptothecin, methotrexate, paclitaxel, and doxorubicin, have been coupled to sst_2-preferential somatostatin analogs to generate selective cytotoxic agents.[26] In these conjugates, the ability of the peptide portion to bind the receptor specifically is preserved and the cytotoxicity of the attached radical is retained, thus displaying significant selective antitumor abilities in many different types of tumors. The clinical efficacy of these compounds has not been assessed. (see the Somatostatin chapter in the Cancer/Anticancer Peptides section of this book).

ii. *Nonradioactive noncytotoxic somatostatin analogs*—Stable somatostatin analogs can be used for the symptomatic treatment of a variety of neoplastic and nonneoplastic diseases of the gastrointestinal tract. Somatostatin and its stable analog octreotide have been consistently used in the treatment of esophageal variceal bleeding, pathological states of the exocrine pancreas, and neuroendocrine enteropancreatic tumors.

Long-acting somatostatin analogs can be administered to treat symptoms caused by the oversecretion of hormones from gastroenteropancreatic endocrine tumors. Octreotide can, for example, alleviate hypokalemia, dehydration, and diarrhea in patients with vasoactive intestinal polypeptide-secreting tumors (VIPomas) and can reduce peptic ulcers and necrolytic skin lesions in patients with gastrin- or glucagon-producing tumors, respectively. Although somatostatin seems to have an inhibitory effect on cell growth and proliferation, a true antiproliferative effect of somatostatin analogs in these tumors is, however, modest.

Somatostatin and octreotide reduce intestinal secretion and have, therefore, been used to treat diarrhea. Somatostatin was originally shown to be effective in treating diarrhea caused by VIPomas. It has since been recognized that somatostatin analogs are also effective in treating other diarrheal conditions. Octreotide improves secretory diarrhea, prolonging gastrointestinal transit time, decreasing endogenous fluid secretion, and stimulating the absorption of water and electrolytes. Moreover, octreotide has been shown to improve diarrhea associated with irritable bowel syndrome by slowing intestinal transit time and to increase the rectal perception threshold for discomfort, an effects probably mediated via the inhibition of exaggerated release of serotonin from enteroendocrine cells.

Chapter 181

Tachykinins

Peter Holzer

ABSTRACT

Within the gastrointestinal tract, the tachykinins substance P and neurokinin A occur in neurons of the enteric nervous system, in fibers of extrinsic afferent neurons, and in enterochromaffin and immune cells of the mucosa. Their biological actions are mediated by three different types of G protein-coupled receptors, termed NK1, NK2, and NK3 and are involved in the regulation of gastrointestinal motility, secretion, vascular permeability, and pain sensitivity. Pathophysiologically, tachykinins seem to be involved in inflammation-induced disturbances of gut function such as dysmotility, secretory diarrhea, inflammation, and hyperalgesia. Expressed in a cell-specific manner, tachykinin receptors thus represent an attractive target for novel therapeutic strategies in gastroenterology. Indeed, NK1 receptor antagonists have proved beneficial in vagus nerve-mediated nausea and vomiting, and a combined NK1, NK2, and NK3 receptor antagonist shows promise in the treatment of irritable bowel syndrome.

DISCOVERY OF TACHYKININS IN THE GUT

The biological activity of substance P (SP) was discovered in 1931 when Ulf S. von Euler and John H. Gaddum reported that both the intestine and the brain contained a substance that caused contraction of gastrointestinal (GI) smooth muscle, the substance being different from any of the endogenous compounds known at that time. In the early 1950s, Bengt Pernow realized the wide distribution of SP in the GI tract, and in the 1960s, Fred Lembeck and others found that SP causes copious salivary secretion in rats and dogs. This biological effect was the lead bioassay whereby Susan E. Leeman and the workers in her laboratory identified SP as an undekapeptide in 1970. SP turned out to be the mammalian counterpart of a family of amphibian and nonvertebrate peptides named tachykinins by Vittorio Erspamer, because they caused fast contraction of GI smooth muscle (see the chapters on tachykinins in the Invertebrate, Amphibian/Skin, and Brain Peptides sections of this book). This breakthrough was followed by the discovery of another tachykinin, neurokinin A (NKA), in the mammalian gut, the identification of three tachykinin receptors labeled as NK1, NK2, and NK3, and the development of highly selective nonpeptide antagonists for all three tachykinin receptors. As a result, the distribution, biological actions, and pathophysiological implications of tachykinins in the mammalian gut have been thoroughly investigated, and tachykinin receptor antagonists have been explored for their utility in the treatment of inflammatory bowel disease (IBD), irritable bowel syndrome (IBS) and other GI disorders.[8,9,10,16,31] NK1 receptor antagonists have proved to be effective in preventing nausea and emesis caused by GI and other emetic stimuli.[6]

DISTRIBUTION OF TACHYKININ mRNAs AND PEPTIDES IN THE GI TRACT

The structures of the 3 known tachykinin genes (TAC1, TAC3, TAC4) and their protein products are discussed in the chapter of N.M. Page in the Brain Peptide section. SP and NKA, the major tachykinins in the GI tract, are derived from the TAC1 gene (previously called PPT-A or PPT-I for preprotachykinin A or I, respectively). The primary RNA transcript of TAC1 is alternatively spliced to produce 4 different types of mRNA (α-TAC1, β-TAC1, γ-TAC1, δ-TAC1), which all encode SP, whereas β-TAC1 and γ-TAC1 also encode NKA and some N-terminally extended forms of NKA such as neuropeptide K (derived from β-TAC1) and neuropeptide γ (derived from γ-TAC1).[27] The TAC3 (PPT-B or PPT-II) gene can be transcribed to 3 mRNA isoforms (α-TAC3, β-TAC3, γ-TAC3), of which only the α-TAC3 and β-TAC3 mRNA are translated into NKB.[8,16,27] The tachykinins and tachykinin gene-related peptides encoded by TAC4 vary considerably among mammalian species.[27] The human TAC4 (PPT-C) gene can be transcribed to 4 mRNA forms to yield endokinin A (α-TAC4v1), endokinin B (α-TAC4v2, β-TAC4, γ-TAC4, δ-TAC4), endokinin C (α-TAC4v1, α-TAC4v2), or endokinin D (β-TAC4), while the mouse and rat TAC4 gene encodes hemokinin 1.[27]

In the human colon, the expression of TAC1 mRNA is particularly abundant in the muscle layer, whereas the expression of TAC3 mRNA is low or negligible.[18] Because

TAC1 mRNA prevails in the gut, SP and NKA are the predominant tachykinins in this organ system, whereas NKB has proved difficult to be detected in the bowel.[8] Expression of TAC4 has been shown to occur in the human stomach, small intestine, and colon.[18,27] The levels of TAC4 mRNA are similar in the muscle and mucosa layers of the human colon,[18] but the precise cellular distribution of TAC4 gene products in the GI tract has not yet been mapped in detail.

Although some SP is contained in enterochromaffin and immune cells of the GI mucosa, the major source of tachykinins in the gut is the enteric nervous system (ENS).[8,9,31] This predominantly neural expression of SP and NKA is conserved across mammalian species, yet there are both regional and species differences in the quantitative distribution of tachykinins to different classes of enteric neurons.[8,9,25,31] In the guinea pig intestine, SP is typically present in intrinsic primary afferent neurons (IPANs) of the myenteric and submucosal plexus and, within the myenteric plexus, in ascending interneurons, as well as in excitatory motoneurons to the longitudinal and circular muscle (Fig. 1). Most enteric neurons containing SP are cholinergic as they coexpress choline acetyltransferase. The tachykininergic enteric neurons can be further subgrouped by their content of calbindin/calretinin, neurofilament protein triplet, and dynorphin/enkephalin-like immunoreactivity (Fig. 1). Primary afferent neurons that originate from dorsal root ganglia and reach the gut via sympathetic and sacral parasympathetic nerves also contribute to the tachykinin content of the gut. The peripheral fibers of these extrinsic sensory neurons project primarily to submucosal arterioles and also supply the mucosa and enteric nerve plexuses (Fig. 1).

TACHYKININ RECEPTOR SUBTYPES, SIGNALING, AND DISTRIBUTION IN THE GI TRACT

The biological actions of tachykinins in the GI tract are mediated by 3 tachykinin receptors,[8,16,31] termed NK1, NK2, and NK3, and encoded by 3 different genes, TACR1, TACR2, and TACR3. Although SP, NKA, and NKB are full agonists at all 3 tachykinin receptors, the potency order of tachykinins is SP > NKA > NKB for NK1 receptors, NKA > NKB > SP for NK2 receptors, and NKB > NKA > SP for NK3 receptors.[31] Rat and mouse hemokinin 1 is a preferential NK1 receptor agonist.[27] As outlined in the chapter by N.M. Page, the membrane topology of tachykinin receptors is typical of metabotropic receptors with seven transmembrane domains. Being associated with the pertussis toxin-insensitive G proteins Gq/G11, tachykinin receptors use the phospholipase C/inositol trisphosphate/diacylglycerol/protein kinase C system as major transduction pathway.[28,31] In addition, tachykinin receptors can couple to the G proteins Gs and Gi, resulting in adenylyl cyclase activation and inhibition, respectively.[28,31]

The pharmacology of tachykinins is one of the most advanced among neuropeptides. By modification of the amino acid sequence of endogenous tachykinins, selective agonists for all three tachykinin receptor types have been obtained, and this advance has been complemented by the design of potent and receptor-selective nonpeptide antagonists for NK1, NK2, and NK3 receptors.[8,31] It is important to note, however, that the potency of nonpeptide tachykinin receptor antagonists can greatly vary among different species, one typical example being that a number NK1 receptor antagonists with high affinity for the human NK1 receptor has only moderate affinity for the rat NK1 receptor.[31]

The distribution of tachykinin NK1, NK2, and NK3 receptors to GI neurons and effector cells (Fig. 2) enables tachykinins to modify GI motility, secretory activity, vascular diameter, vascular permeability, immune function, gut sensitivity, and nociception.[8,9,10,22] Although all 3 receptor types are expressed in the human colon, mRNA for TACR2-α, the gene encoding the functional NK2 receptor, is more abundant than TACR1 and TACR3 mRNA.[12,18] NK1 receptors have been localized to the muscularis mucose, the media of submucosal blood vessels (Fig. 2), and some immune cells of the human GI tract.[8] In the rodent gut, NK1 receptors occur on longitudinal and circular muscle cells, interstitial cells of Cajal (ICCs), IPANs, excitatory and inhibitory motoneurons, secretomotor neurons, epithelial cells, and granulocytes.[8,31] NK2 receptors are typically expressed by the longitudinal muscle, circular muscle, and muscularis mucose of the rodent GI tract and, in addition, are present on epithelial cells and enteric nerve endings (Fig. 2). NK2 receptors also abound in the smooth muscle of the human intestine[16] but in addition are expressed by a majority of myenteric neurons in the human colon, these neurons sending varicose fibers to the longitudinal and circular muscle.[13] NK3 receptors are largely confined to enteric neurons; in the rodent intestine, these NK3 receptor-bearing neurons comprise IPANs, ascending and descending interneurons, excitatory and inhibitory motoneurons, as well as secretomotor neurons (Fig. 2).

BIOLOGICAL ACTIONS OF TACHYKININS IN THE GUT

Transmitter Function in the Enteric Nervous System

SP and NKA are cotransmitters of intrinsic enteric and extrinsic afferent neurons, which is consistent with their vesicular localization and calcium-dependent release upon nerve stimulation.[8,9,10,16,22,31] Within the ENS, tachykinins mediate slow postsynaptic excitation, a process in which both NK1 and NK3 receptors are involved. Slow postsynaptic excitation contributes to the communication among IPANs (mediated primarily by NK3 receptors), between IPANs and ascending as well as descending interneurons (mediated by NK3 receptors), between ascending interneurons and excitatory motoneurons (mediated by NK3 receptors), as well as between IPANs and inhibitory motoneurons

(mediated by NK1 receptors).[8,9,31] The activation of after hyperpolarization-type myenteric neurons by electrical stimulation of the guinea pig small intestinal mucosa is primarily mediated by NK1 receptors.[5] Apart from neuro-neuronal transmission, tachykinins also participate in excitatory neuromuscular transmission (mediated by NK2 and to some extent NK1 receptors), in which they share this role with the principal transmitter acetylcholine.[8,22,31]

Motor Activity

Tachykinins can both stimulate and inhibit GI motility, the net response depending on the type and site of tachykinin receptors that are activated.[8,9,16,22,31] Facilitation of GI motor activity is typically brought about by the activation of NK1 receptors on IPANs, ICCs, and muscle cells, NK2 receptors on muscle cells, and NK3 receptors on IPANs, cholinergic interneurons, and cholinergic motoneurons (Fig. 2). The stimulation of NK1 receptors on ICCs enforces motility by prolonging the duration of the slow waves generated by these cells.[8] Tachykinin-induced muscle contraction in the human gut *in vitro* is prominently mediated by muscular NK2 receptors,[16] and in the circular muscle of the isolated human sigmoids, it seems as if tachykinins acting via NK2 receptors are the main excitatory neurotransmitters released by nerve stimulation.[16] NK2 receptors also make an important contribution to the effects of SP and NKA to stimulate motility in the human small intestine *in vivo* and to replace the regular pattern of interdigestive motor activity by a pattern of irregular activity.[16] The contractile response to NK3 receptor stimulation in the guinea pig intestine is predominantly mediated by cholinergic neurons.[8]

NK1 and NK3 receptors on inhibitory motor pathways within the ENS enable tachykinins to depress motor activity via release of nitric oxide and adenosine triphosphate.[8]

Despite the high pharmacological potency of tachykinins to modify GI motility, NK1, NK2, and NK3 tachykinin receptor antagonists have, overall, little effect on GI motor performance in the guinea pig and human gut under physiological conditions both *in vitro* and *in vivo*. NK1 receptor antagonists cause a minor stimulation of peristaltic motility in the guinea pig isolated small intestine.[8] This activity profile is consistent with the failure of the NK1 receptor antagonist aprepitant to change gastric retention, gastric emptying, as well as small and large intestinal transit in humans,[21] although cases of mild diarrhea have been reported.[8] Likewise, NK2 receptor antagonists do not alter small intestinal motility in humans and in the long-term fail to modify bowel habits,[16] but lead to a minute inhibition of peristalsis in the guinea pig small bowel.[8] Only when the overwhelming cholinergic component in the neural activation of smooth muscle has been compromised, does blockade of tachykinin receptors impair peristalsis in the guinea pig small intestine. SP and NKA thus function as a backup system in the cholinergic activation of GI muscle during small intestinal peristalsis, a role that in the guinea pig small intestine is brought about by NK1 and NK2 receptors but in the human intestine is primarily mediated by NK2 receptors.[8,16]

In the colon of the guinea pig and mouse, however, tachykinins seem to play a more prominent role in the regulation of peristalsis than in the small intestine. Thus, when all 3 tachykinin receptors are blocked simultaneously, peristalsis in the guinea pig distal colon is significantly depressed even without concomitant blockade of cholinergic transmission.[8] Similarly, propulsion of fecal pellets in the mouse isolated colon is inhibited by both NK1 and NK2 receptor antagonists in the absence of acetylcholine receptor antagonists.[2] From these findings it seems as if tachykinins regulate motility primarily in the colon. Furthermore, multi- or pan-tachykinin receptor antagonists would seem to be more efficacious than mono-receptor antagonists in modifying GI motor activity and, eventually, GI motor disorders.[8]

Secretory Activity

Tachykinins modify endocrine and exocrine secretory processes in the GI tract including the stomach and pancreas.[8,10] Electrolyte and fluid output in the rodent intestine can be stimulated through activation of tachykinin NK1 and NK3 receptors on cholinergic and noncholinergic secretomotor neurons in the submucosal plexus as well as NK1 and NK2 receptors on epithelial cells. Mucosal ion transport in the isolated human colon is enhanced by both NK1 and NK2 receptor activation and subsequent stimulation of enteric neurons.

The neurogenic actions of tachykinins to elicit electrolyte and fluid secretion in the intestine are consistent with a role of SP and NKA as transmitters of enteric secretory reflexes. The implication of tachykinins in these reflexes can be threefold.[8] First, tachykinins released from IPANs or interneurons can activate cholinergic and noncholinergic secretomotor neurons. Second, SP can be released from axon collaterals of IPANs close to the epithelial effector cells and elicit chloride secretion via a mechanism resembling an axon reflex. Third, tachykinins released from extrinsic sensory nerve endings in response to capsaicin, *Clostridium difficile* toxin A, or distention can stimulate enteric secretomotor neurons through activation of NK1 and NK3 receptors.[8]

Proinflammatory Function

Tachykinins, particularly SP, are vasoactive peptides that can induce dilation or constriction of blood vessels in the digestive tract, the type of action depending on the vascular bed and species under study.[8,10] The tachykinin-evoked

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

vasodilation in the intestines of cat, dog, and guinea pig is mediated by NK1 receptors. Both SP and NKA enhance blood flow in the proximal small intestine of humans, probably through activation of NK1 receptors which have been localized to the media of submucosal blood vessels. Conversely, blood flow in the rat gastric mucosa is diminished by tachykinins via constriction of collecting venules, a mechanism which may depend on the release of proteases from mast cells.[8]

Another effect of substance P acting via endothelial NK1 receptors is to increase venular permeability in the intestine and, thereby, to facilitate the extravasation of plasma proteins and leukocytes.[8] In addition, tachykinins can influence the activity of various immune cells in the gut. Thus, NK1 and NK2 receptors have been localized to monocytes/macrophages, granulocytes, lymphoid cells, and eosinophils, and stimulation of tachykinin receptors can lead to recruitment and activation of granulocytes as well as mast cells in the GI tract.[8,10]

PATHOPHYSIOLOGICAL IMPLICATIONS OF TACHYKININS IN THE GI TRACT

Implications of Tachykinins in GI Motor Disturbances

In view of the motor effects of SP and NKA and their apparent involvement in the regulation of GI motor activity, particularly in the colon, there is accumulating evidence that pathological alterations of GI motility are related to a disturbed function of the tachykinin system.[8,9,16,31] Experimental support for this hypothesis comes from the findings that certain GI diseases are associated with (i) changes in the expression of tachykinins and/or tachykinin receptors, (ii) changes in the functionality of tachykinin receptors and, consequently, in the motor effects of tachykinins, and/or (iii) a beneficial effect of tachykinin receptor antagonists.[8] For instance, slow-transit constipation in some pediatric patients is accompanied by a decrease in the density of nerve fibers containing substance P in the colon.[15] In line with this finding, neuromuscular transmission to the circular muscle via NK2 receptors is impaired in pediatric patients with slow-transit constipation.[33] In adult patients with slow-transit constipation, the responsiveness of the colonic circular muscle to NK1 or NK2 receptor agonists is either enhanced or decreased,[19,23] whereas in ulcerative colitis, Crohn's disease, and diverticular disease the contractile response of the colonic circular muscle to an NK2 receptor agonist is decreased.[23] Similarly, the responsiveness of the colonic musculature to tachykinin receptor agonists is depressed in rats and rabbits with trinitrobenzene sulfonic acid (TNBSA)-induced colitis, whereas in ricin-evoked ileitis of the rabbit tachykinin-mediated neurogenic contractions are amplified.[8]

Tachykinin receptor antagonists are able to correct various types of experimentally disturbed motility in the gut.[8,9,16,31] Thus, NK1 receptor antagonists inhibit stress-induced defecation and correct the hypomotility and muscular hyporesponsiveness caused by anaphylaxis, inflammation, and pain. Postoperative and peritonitis-induced ileus is ameliorated by NK1 and NK2 receptor antagonists, while the giant colonic contractions associated with inflammatory diarrhea are effectively suppressed by NK2 receptor antagonists.[8] Although the usefulness of NK3 receptor antagonists remains to be explored, it seems as if NK1 receptor antagonists are particularly efficacious in alleviating GI motor inhibition. NK2 receptor antagonists seem to be beneficial in attenuating pathological hypermotility without causing constipation.[8]

Apart from acting on mast cells, enteric neurons and muscle cells, tachykinin receptor antagonists may correct GI dysmotility by interfering with the function of extrinsic afferents which can contribute to GI motor dysregulation in two ways.[8] First, they participate in autonomic intestino-intestinal reflexes in which SP and NKA, released from the central endings of sensory neurons in the spinal cord, mediate transmission to the efferent reflex arc. Second, tachykinins released from sensory nerve endings in the gut can disturb GI motility, an instance that may be reflected by the ability of NK1 receptor antagonists to ameliorate dysmotility caused by esophageal acidification, anaphylaxis, and inflammation.[8]

Implications of Tachykinins in GI Inflammation, Hypersecretion, and Cancer

Many studies have shown that GI infection, inflammation, and mucosal injury are associated with time-related changes in the expression and release of tachykinins as well as with alterations in the expression and function of tachykinin receptors in the gut. However, the alterations in SP and NKA expression are variable, given that the GI tachykinin levels in patients with gastritis, IBD or diverticular disease have been reported to be decreased, increased, or unchanged.[8,10,18] The expression of TAC4 mRNA is enhanced in IBD, particularly in the mucosa of patients with ulcerative colitis.[18] Whole-mount analysis of the myenteric plexus has revealed that the chemical coding of enteric neurons in ulcerative colitis is shifted in as much as the ratio of SP-positive versus SP-negative cholinergic neurons is significantly enhanced. Animal studies have shown that experimental infection and inflammation in the alimentary canal also cause changes in the tachykinin levels, which mirror those seen in human diseases to a variable degree.[4,8,10]

By contrast, there is more consistent evidence that IBD and experimentally induced infection or inflammation in the gut are accompanied by an increased expression of NK1 and NK2 receptors in the inflamed and noninflamed regions

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

of the small and large intestines.[4,8,24] The upregulation and ectopic occurrence of SP binding sites in pseudomembranous colitis resulting from *C. difficile* infection has been reproduced by treatment of rats with *C. difficile* toxin A.[8]

There is ample evidence that, in addition to alterations in the expression of SP, NKA, and their receptors, disturbances of the GI tachykinin system contribute to the manifestations of IBD and functional GI disorders.[8] For example, the secretory response to SP is blunted in mucosal tissues isolated from patients with Crohn's disease or ulcerative colitis, and tachykinin receptor antagonists display beneficial effects in various models of experimental GI infection, GI inflammation, GI injury, diarrhea, and pancreatitis.[8] A search through the contemporary literature shows that, in rodents, esophagitis evoked by chronic acid reflux, colitis induced by TNBSA, dinitrobenzene sulfonic acid, dinitrofluorobenzene, dextran sulfate sodium, zymosan, or injection of T cells in SCID mice, and pancreatitis elicited by cerulein are blunted by an NK1 receptor antagonist.

Tachykinins play a particular role in the inflammation (granulocyte, mast cell, and macrophage activation) and hypersecretion evoked by *C. difficile* toxin A, which involves activation of capsaicin-sensitive extrinsic afferent neurons, release of SP, and activation of NK1 receptors on enteric neurons. Many other types of GI hypersecretion involve tachykinin receptors, which is exemplified by the observations that the intestinal hypersecretion evoked by *Cholera* toxin and the diarrhea caused by castor oil in rats are inhibited by NK1 and NK2 receptor antagonists.[8,10]

Of further relevance is the question whether tachykinins play a role in the initiation and/or maintenance of GI hypersecretion and inflammation. Experimental results indicate that SP and NKA participate primarily in the initial stage of TNBSA- and acetic acid-induced colitis.[8] If so, tachykinin receptor antagonists may be more beneficial in the initiation or reactivation of inflammation than in the suppression of an ongoing inflammatory process. The effect of SP to increase vascular permeability in the GI tract is amplified in the inflamed tissue because inflammation leads to downregulation of neutral endopeptidase which in the normal tissue maintains low levels of SP in the extracellular fluid and, thus, limits its proinflammatory effects.[8]

Preclinical studies suggest that various immune cells in the gut are under the influence of SP and NKA. The tachykinin-responsive cells include mast cells, lymphocytes, and granulocytes.[8] Furthermore, immune cells are not only targets of tachykinin actions but under pathological conditions can themselves be induced to synthesize and release tachykinins. This is true for macrophages in the mucosa of the rat ileum exposed to *C. difficile* toxin A and for eosinophils from the mucosa of IBD patients.[8]

Tachykinins may play a role in GI tumor biology. Tachykinin-like immunoreactivity is synthesized in and released from carcinoid tumor cells, and circulating levels of tachykinin-like immunoreactivity are significantly correlated with symptoms of flush and diarrhea in patients with metastasizing ileocecal serotonin-producing carcinoid tumors.[1] Substance P promotes colitis-associated cancer and acts as a mitogen on cell lines derived from human gastric and colonic adenocarcinomas, these effects being prevented by NK1 receptor antagonists.[26,29]

Implications of Tachykinins in GI Hyperalgesia, Pain, and Irritable Bowel Syndrome

The majority of spinal afferents supplying the rodent GI tract contain SP and NKA; and NK1, NK2, as well as NK3 receptors are expressed at many levels of the gut–brain axis. It is in keeping with these circumstances that a plethora of preclinical studies attests to a role of tachykinin receptors in visceral pain and hyperalgesia.[8,30] For instance, genetic deletion of NK1 receptors in mice prevents intracolonic acetic acid and capsaicin from eliciting pseudoaffective pain responses, from inducing primary mechanical hyperalgesia in the colon, and from causing referred mechanical hyperalgesia in abdominal skin.[8] Experimental studies with selective tachykinin receptor antagonists indicate that all 3 tachykinin receptors play a role in visceral nociception and inflammation-induced hyperalgesia, although to a different degree.[8] Thus, the visceromotor pain response to acute gastric and colorectal distention in the rat is inhibited by NK2 and NK3 receptor antagonists but left unaltered by NK1 receptor antagonists.[8] The infection-, inflammation-, or stress-induced hypersensitivity to distention in the rabbit, rat, gerbil, and guinea pig jejunum or colon is likewise reduced by either NK1 or NK2 receptor antagonists.[8,14] Results in the contemporary literature indicate that pancreatitis-evoked abdominal hyperalgesia in rodents is likewise blunted by NK1 and NK3 receptor antagonists.[20]

Tachykinin receptor antagonists may target multiple relays in the nociceptive pathways from the periphery to the brain. One site of action is within the spinal cord where tachykininergic transmission from primary afferents is interrupted. This seems to be true for the antihyperalgesic effect of NK1 receptor antagonists in the rabbit, guinea pig, and rat. Intrathecal administration of NK1 and NK3 receptor antagonists abrogates the abdominal hyperalgesia associated with experimental pancreatitis,[20] inhibits the visceromotor pain response to colorectal distention, and counteracts the GI hypersensitivity caused by repeated distention or experimental GI inflammation.[8] Further consistent with a central site of the antinociceptive action of NK1 receptor antagonists is the finding that experimental colitis or cystitis in the rat leads to an upregulation and de novo expression of NK1 receptors in the dorsal horn of the spinal cord.[8]

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Apart from blocking tachykininergic transmission in the spinal cord, NK1, NK2, and NK3 receptor antagonists may be antihyperalgesic by a peripheral site of action.[8,30] Although the expression of tachykinin receptors by primary afferent nerve fibers remains to be clarified, the NK2 receptor antagonist nepadutant has been observed to inhibit the enhanced firing that lumbosacral afferent neurons exhibit after distention of the experimentally inflamed rat colon.[8] Because the activity in pelvic and somatic afferent neurons is not affected, nepadutant has been proposed to be antihyperalgesic by a peripheral action on hypersensitive afferents supplying the colon. A similar conclusion has been reached for the brain-impermeable NK3 receptor antagonist SB-235375 which is able to inhibit the visceromotor reaction to painful colorectal distention in rats.[30] Because colonic motility and compliance are little affected and mechanonociception in the skin is not altered, it has been inferred that NK3 receptor antagonists exhibit intestine-specific antinociceptive activity. Part of the antinociceptive action of tachykinin receptor antagonists in the periphery may be indirect and result from their ability to blunt hyperexcitability in the enteric nervous system, to normalize aberrant GI motility and secretion, and to dampen inflammatory processes.[8,30]

Taking all preclinical studies together, it would seem that tachykinin receptor antagonists have considerable potential for the treatment of visceral pain and functional GI disorders.[8] By correcting hyper- or hypomotility, hypersecretion, and inflammation, tachykinin receptor antagonists may reduce the sensory gain of extrinsic afferents in the GI tract and, in addition, block tachykininergic transmission in the spinal cord. Furthermore, the effects of brain-penetrant NK1 receptor antagonists at the level of the gut and afferent system may favorably combine with their inhibitory actions on emesis, anxiety, depression, and stress reactions in the brain.[8] In clinical studies, however, this therapeutic promise of tachykinin receptor antagonists has thus far been borne out only to a limited extent.

For instance, when esophageal pain was studied in healthy volunteers, a NK1 receptor antagonist proved ineffective in altering pain thresholds to electrical stimulation both at baseline and following acid-induced esophageal allodynia.[34] The NK3 receptor antagonist talnetant was likewise without effect on sensory function and compliance in the colon of healthy volunteers.[11] In addition, talnetant was unable to provide any benefit to IBS patients as revealed in a phase II trial.[3] Tested in a small group of patients with IBS, the NK1 receptor antagonist ezlozipant also failed to modify the sensory response to rectosigmoid distention, but attenuated the associated emotional response.[17] It thus seems as if selective mono-tachykinin receptor antagonists are unable to alter GI pain and hyperalgesia in IBS patients.

The situation seems to be different, however, when nonselective multi-receptor antagonists with activity at 2 or all 3 tachykinin receptors are used. DNK333, an antagonist with affinity for NK1, NK2, and NK3 receptors has been reported to increase the rate of satisfactory relief from abdominal discomfort and pain and to reduce global IBS symptoms in women with diarrhea-predominant IBS.[35] It follows that pan-tachykinin receptor antagonists may hold therapeutic potential, although their efficacy and safety remain to be thoroughly tested.

Nausea and Vomiting

Preclinical studies have revealed that NK1 receptor antagonists inhibit vomiting caused by a variety of factors including the anticancer agent cisplatin, irradiation, copper sulfate, morphine, apomorphine, and motion.[6] This broad-spectrum profile of activity against peripherally and centrally acting emetogenic stimuli and the requirement for brain penetration show that NK1 receptor antagonists interrupt the emetic reflex at a central site of action within the brainstem, close to the nucleus of the solitary tract and the Bötzinger complex. The experimental observation that NK1 receptor antagonists block both the acute and delayed phase of cisplatin-induced emesis has been confirmed in clinical trials. The NK1 receptor antagonists aprepitant and casopitant add significantly to the antiemetic efficacy of 5-HT3 receptor antagonists and dexamethasone in humans and, in this combination, provide significant control over both the acute and delayed phase of chemotherapy-induced nausea and emesis.[6,7] Both aprepitant and casopitant have also been shown to enhance the antiemetic effect of 5-HT3 receptor antagonists in preventing postoperative nausea and vomiting.[6,32] Like casopitant mesylate, fosaprepitant (a prodrug bioequivalent to aprepitant) can be administered by intravenous injection, which is of benefit to patients who do not tolerate oral medication.

ACKNOWLEDGMENTS

The artistry of Evelin Painsipp in preparing the figures is greatly appreciated. Work in the author's laboratory is supported by the Austrian Science Funds, the Jubilee Funds of the Austrian National Bank, the Austrian Federal Ministry of Science and Research, and the Zukunftsfonds Steiermark.

Chapter 182

TFF Peptides

Werner Hoffmann

ABSTRACT

The trefoil factor family (TFF) domain is a cysteine-rich shuffled module forming the basic unit for the TFF peptides (in short, TFFs). TFFs are typically secreted by mucin-producing cells of the gastrointestinal tract and other epithelia. Furthermore, they are synthesized in the brain and some other organs. The three mammalian TFFs consist of one (TFF1, TFF3) or two TFF domains (TFF2). In amphibia, the pattern differs remarkably. The biosynthesis of mammalian TFFs is rather complex. TFF1 and TFF3 form disulfide-linked heteromers with gastrokine-2 and IgG Fc binding protein, respectively. TFFs play a key role in the maintenance of the surface integrity of mucous epithelia in health and disease. Their multiple molecular functions include (1) formation of the mucus barrier, (2) enhancement of mucosal repair (restitution) on different levels, (3) modulation of mucosal differentiation processes, and (4) modulation of the immune response. Of special note, TFFs are also connected with oncogenic pathways.

DISCOVERY

Secretory trefoil factor family peptides (in short, TFFs; for reviews, see Refs. 4, 10, 13, 28, 29, 31, 34) share a common structural motif: the TFF domain (formerly: P-domain or trefoil-domain). This unique ancient shuffled module arose well before amphibian evolution and contains six conserved cysteine residues. TFF domains are also present in mosaic proteins associated with mucous surfaces (for review, see Ref. 10). The actual nomenclature of TFF peptides is based on an agreement reached in 1997 at the *Conférence Philippe Laudat* to avoid the term "trefoil" because of its multiple meanings.

Historically, the discovery of the three mammalian and various amphibian TFFs was the result of four groups working in different fields (for review, see Ref. 10). Mammalian TFFs consist of one (TFF1, TFF3) or two TFF domains (TFF2). The amino acid sequence of human TFF1 (formerly: pS2/BCEI/pNR-2/pNR-105/Md2) was deduced in 1984 and the primary structure of porcine TFF2 (formerly: [pancreatic] spasmolytic polypeptide/[P] SP) was reported in 1985. However, the high similarity between TFF1 and TFF2 was first recognized in 1988 by the analysis of TFF domains from the frog integumentary mucin FIM-A.1 (formerly: spasmolysin). Human TFF2 was first described in 1990. TFF3 (formerly: intestinal trefoil factor/ITF/P1.B) was detected in 1991 in rats and in 1993 in humans.

The first amphibian TFFs have been characterized in 1991 (for review, see Ref. 10). Typical of the *Xenopus laevis* gastrointestinal (GI) tract are xP1 (single TFF domain), xP4.1, and xP4.2 (four TFF domains).

STRUCTURE OF THE mRNA/GENE

The three human and the three mouse TFF genes as well as part of the amphibian TFF genes have been characterized (for review, see Ref. 10). All three human TFF genes are clustered on chromosome 21q22.3 in a head-to-tail arrangement within 54.5 kb in the order tel-TFF1-TFF2-TFF3-cen. Transcription of all three genes is directed toward the centromere (Fig. 1). A syntenic 40kb region was characterized in the mouse genome on chromosome 17q. This locus also encodes an antisense TFF1-related transcript.

All TFF genes analyzed thus far share common structural features. Most notably, TFF domains are typical shuffled modules always encoded by a single exon belonging to the class 1-1. Consequently, the TFF1 and the TFF3 genes consist of three exons; whereas the TFF2 gene contains four exons (Fig. 1).

The situation in amphibia is rather complex (for review, see Ref. 10) because additional TFF genes exist for which no mammalian ortholog is known (e.g., xP2 expressed in the skin and xP1-L in the tadpole stomach). Whether these genes form a cluster as in mammals is not yet known.

The expression of the clustered mammalian TFF genes is coordinatedly regulated (for reviews, see Refs. 4, 10, 13). This has been observed also in various TFF-deficient mice. There are numerous studies characterizing the promoter regions of the mammalian and amphibian TFF genes and their complex transcriptional regulation by various stimuli such as estrogen, cytokines, gastrin, transforming growth factor-α, prostaglandins, peroxisome

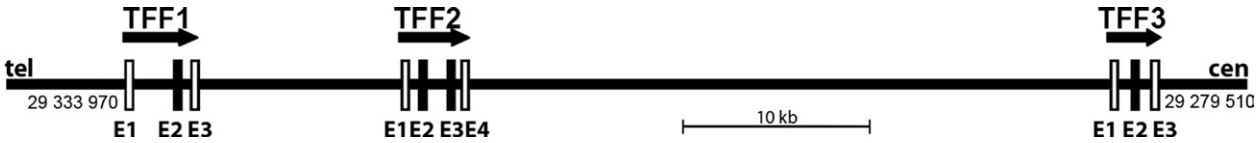

FIGURE 1 Chromosomal localization of the human TFF genes. Illustrated is the TFF cluster on chromosome 21q22.3. Indicated also are the orientation of the telomere and the centromere as well as the nucleotide positions. The exons (E) encoding the TFF domains are shown in black. Each of the first exons (E1) encodes the signal sequences typical of precursors of secretory proteins.

proliferator-activated receptors (PPARs), osmotic stress, and hypoxia (for reviews, see Refs. 2, 4, 10, 13, 28). Pathologically relevant are the induction of TFF expression by hypoxia and its modulation by nitric oxide[20] as well as the regulation of TFF1 by Ras/ERK signaling and TFF3 by STAT1/3 (for reviews, see Refs. 2, 13). Furthermore, TFF1 and TFF2 expression is regulated by gastrin,[2,32] whereas TFF3 expression is inducible by Toll-like receptor activation.[21]

PROCESSING OF THE PRECURSOR

All TFF peptides are synthesized via precursors containing a cleavable N-terminal signal sequence typical of secretory proteins. A hallmark of the unique TFF modules (comprising about 42 amino acid residues; for compilation, see Refs. 10, 29) are six conserved cysteine residues which form intramolecular disulfide bridges in the order C^1–C^5, C^2–C^4, C^3–C^6 (for review, see Ref. 29), creating three characteristic loop structures (L1–L3). A planar projection of this structure resembles a trefoil (Fig. 2). The complex pattern of disulfide bridges is probably one reason for the remarkable resistance of TFFs against proteolytic degradation particularly in the stomach.[13,29] However, shortened forms of TFF3 are found in the human gastric juice[16] and intestine.[1]

In the human GI tract, all TFFs are capable of forming heteromers with different partner proteins (Fig. 2). Gastric TFF1 forms a disulfide-linked heterodimer with gastrokine-2 (GKN2; formerly: GDDR, TFIZ1) via C^7,[15,18] and intestinal TFF3 is disulfide-linked to IgG Fc binding protein (FCGBP) via C^7.[1] Furthermore, gastric TFF2 mainly exists as a high molecular weight complex associated with an unknown partner protein.[15] By contrast, porcine pancreatic TFF2 has been reported to exist as a monomer that is stabilized by an additional intramolecular disulfide bridge between cysteine residues outside the TFF domains (Fig. 2).[29] Taken together, the differences concerning their partner proteins point to highly specialized functions for TFF1, TFF2, and TFF3.

Besides the heteromeric forms, also monomeric and homodimeric forms of TFF1 and TFF3 were detectable *in vivo*.[1,15,16] For example, about 15–20% of colonic TFF3 exist mainly in a monomeric form, which could be released from the TFF3–FCGBP heteromer *in vivo* by reduction with exogenous hydrogen sulfide (H_2S) because of high H_2S concentrations particularly in the lumen of the colon.[1] Of special note, TFF3 liberated in this manner could be posttranslationally modified by H_2S, that is, by S-sulfhydration.[1] Alternatively, TFF3 could also be released from the TFF3–FCGBP heteromer by a disulfide isomerase activity, may be as TFF3 homodimer,[1] which is detectable, for example, in the gastric juice.[16]

The N-terminal glutamic acid residues of human TFF1 and human TFF3 as well as recombinant human TFF2 produced in yeast are not cyclized to form a pyroglutamic acid residue.[1,29] By contrast, porcine pancreatic TFF2 contains an N-terminal pyroglutamic acid residue formed by cyclization of a glutamine residue in the precursor.

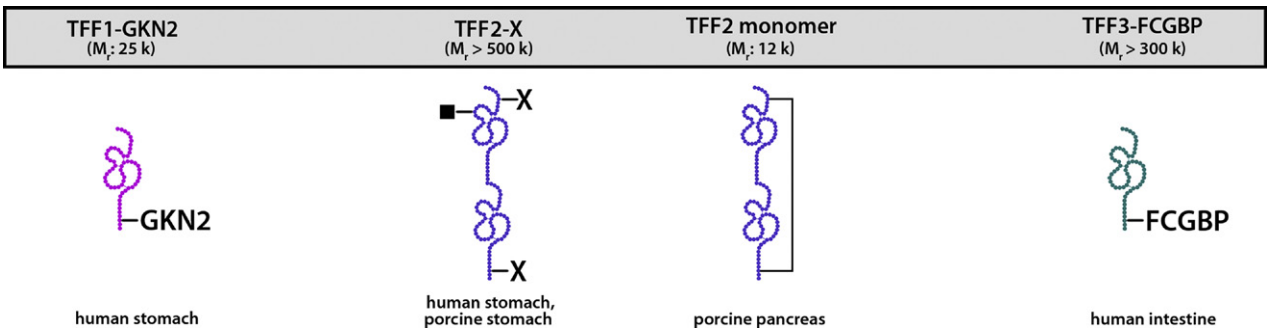

FIGURE 2 TFF forms in the mammalian GI tract. Schematically represented are the TFF1–GKN2 heteromer, the monomeric form of TFF2 (including the additional disulfide bridge), the high molecular weight complex of TFF2 (partner X is not known thus far), and the TFF3–FCGBP heteromer. The TFF1 and TFF3 heteromers are disulfide-linked. Also indicated is the N-glycosylation site of human gastric TFF2 (rectangular knob). See color plate 51.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Additionally, most of human gastric TFF2 (in contrast to porcine and murine TFF2) is posttranslationally modified by N-glycosylation. Here the unusual fucosylated N,N′-diacetyllactosediamine (LacdiNac) oligosaccharide was identified (Hanisch et al., *Glycobiology*, in press). Interestingly, the ratio of glycosylated to nonglycosylated TFF2 in the gastric juice showed diurnal variations and is modulated by food intake.[27]

The three-dimensional structures of porcine pancreatic TFF2 and recombinant human TFF1 (monomer and homodimer) and TFF3 (homodimer) were determined (for reviews, see Refs. 10, 29). A hydrophobic cleft between loops L2 and L3 is a characteristic feature of all TFF domains, and all the conserved amino acid residues are located here. Particularly, the tryptophan residue just before C^6 is probably of great importance.

DISTRIBUTION OF THE mRNA/PEPTIDE

TFF peptides are characteristic exocrine products of mucous epithelia and in particular of the GI tract (for reviews, see Refs. 10, 13, 34). Here, they are often synthesized together with secretory mucins (Table 1). However, this does not imply that expression of TFFs and mucins is regulated together; for example, expression of TFF3 and MUC2 shows a marked divergence along the rat intestine. Furthermore, TFFs are found in the human serum, and they are also typical neuropeptides (for review, see Ref. 10).

There are remarkable species differences concerning TFF expression in the GI tract. The focus will be put here on the human GI tract. TFF expression on the protein level often does not parallel the corresponding mRNA levels.[14,16] Similar results were reported for expression of mucins. The reason for this may be mRNA instability.[16] Furthermore, particularly TFF2 mRNA and protein expression is not congruent in the murine and human stomach corpus because of differentiation and migration processes of precursor cells.[14,23]

Expression in the Human Alimentary Tract

TFFs are secreted from all parts of the normal human alimentary tract but in variable amounts (Table 1). TFF3 seems to represent the "standard" TFF peptide, which is found in all GI organs (and in other regions of the human body), whereas TFF1 and TFF2 are predominantly expressed in the stomach.

The synthesis of TFFs starts in the oral cavity where TFF1, TFF2, and TFF3 are detectable in the submandibular and labial salivary glands. TFF3 is the major TFF secreted (submandibular glands), and it represents an important constituent of the saliva.

The normal esophagus is also a site of TFF peptide synthesis. Here, TFF3 is a typical secretory product of the submucosal glands.

The most complex TFF expression pattern of the whole body is present in the stomach. Only here, are all three TFF

TABLE 1 TFF Peptides Synthesized in the Normal Human Alimentary Tract. Scarce TFF Peptide Levels are Indicated by Parentheses. Also Shown are the Secretory Mucins Coexpressed

Organ	Cell	TFF peptide	Secretory mucin
Salivary glands	Submandibular glands	(TFF1, TFF2), TFF3	MUC5B, MUC7, MUC19
	Labial glands (mucous acini)	(TFF1, TFF2), TFF3	MUC5B, MUC7, MUC19
Esophagus	Submucosal glands	TFF3	MUC5B
Stomach	Cardiac and antral SMCs	TFF1, TFF3	MUC5AC
	Corpus SMCs	TFF1	MUC5AC
	Mucous neck cells	TFF2	MUC6
	Antral glands	TFF2	MUC6
Intestine	Brunner's glands	TFF2, TFF3	MUC6
	Goblet cells	TFF3	MUC2
Vater's ampulla	Goblet cells	TFF3	MUC5AC, MUC5B
Pancreas	(Duct epithelium), islets	(TFF1), TFF3	(MUC6)
Liver	LBDs, SBDs, PBGs	TFF1, (TFF2), TFF3	MUC6
Gall bladder	Epithelial cells	(TFF1), (TFF2), TFF3	MUC5B, MUC6

SMC, surface mucous cell; LBD, large biliary duct; SBD, small biliary duct; PBG, peribiliary gland.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

peptides synthesized in relatively large amounts.[14] TFF1 peptide predominates in the surface mucous cells (SMCs), whereas TFF2 peptide is detectable in mucous neck cells (MNCs) and antral gland cells. Of special note, TFF2 mRNA and protein expression is not congruent as shown for the murine and human stomach corpus.[14,23] TFF2 mRNA is typically observed in precursor cells, whereas TFF2 protein appears in mature MNCs only. Gastric TFF3 expression has been neglected for a long time. However, there is significant synthesis at the gastric border zones, that is, at the cardia and the antrum[14,16] where TFF3 peptide is detectable in early SMCs located close to the isthmus (by contrast, TFF1 peptide occurs primarily in superficial, late SMCs).

All three TFFs are also present in the gastric juice with great individual variations. Here, a shortened form of TFF3 is found that is probably the result of a peptic cleavage at the N-terminal region.[16] Remarkably, the concentration of TFF2 in the gastric juice is subject to diurnal variations.[27]

There is an abrupt change of the TFF expression pattern at the antroduodenal transitional zone. TFF1 is absent at the protein level in the intestine, whereas TFF2 is secreted from duodenal Brunner's glands. TFF3 is found in Brunner's glands and in goblet cells of the small and large intestine. Furthermore, significant amounts of TFF3 can be detected in the meconium of human infants as early as 12 weeks of gestation.

TFF2 expression in the pancreas is rather scarce, and there is little TFF1 synthesis in ductal cells. Only recently has abundant TFF3 immunoreactivity been reported in the pancreatic islets colocalized with insulin indicating endocrine secretion (for reference, see Ref. 5).

Synthesis of TFFs also occurs in the biliary system (for review, see Ref. 26). Here, mainly TFF1 and TFF3 are occasionally detectable in large and rarely in small bile ducts, and TFFs are also secreted from the gall bladder. Furthermore, TFF3 was identified in goblet cells of the hepatopancreatic ampulla, also known as the ampulla of Vater, where it is localized together with MUC5AC, MUC5B, and MUC6.

Expression in the Alimentary Tract of Other Mammals

Remarkable species differences have been observed in the TFF expression patterns. These variations also affect the respiratory tract.[8] However, currently, information from other mammals is mainly restricted to the porcine, murine, and rat.

Considerable differences exist for TFF2 expression in the pancreas. In contrast to the situation in humans, the pancreas is the major source for porcine TFF2 (acinar cells). Relatively high TFF2 expression levels are also found in the mouse and rat pancreas. Furthermore, in the murine liver (and kidney) an antisense TFF1-related transcript has been identified, which is not detectable in humans.

Expression in the Amphibian Alimentary Tract

The situation in amphibia is quite different from that in mammals (for review, see Ref. 10). There are differences in the histology of the GI organs and in the structure of the TFFs. Limited information is available only for the South African toad *Xenopus laevis* (GI TFFs: xP1, xP4.1, xP4.2; xP1-L).

xP1, the amphibian ortholog of TFF1, is detectable in gastric SMCs with a decreasing gradient from the corpus toward the antrum, whereas the pronounced amphibian gastric MNCs are completely devoid of xP1. Of note, expression of the homologous xP1-L gene was detected in larval SMCs only.

xP4.1 is N-glycosylated and comprises four TFF domains. It is localized together with mucins in the characteristic MNCs and less in SMCs in all parts of the stomach. Based on its expression pattern, xP4.1 is considered as a functional equivalent of TFF2. xP4.2 is very similar to xP4.1 (89.7% identity), but it lacks the N-glycosylation site. This peptide is mainly expressed in a distinct population of esophageal goblet cells and in MNCs of the gastric fundus and corpus but not the antrum.

RECEPTORS AND SIGNALING CASCADES

Many of the multiple biological functions of TFFs are expected to be triggered by receptor ligation. However, there are no molecular data published unambiguously describing TFF binding molecules with the classical characteristics of high affinity receptors in spite of circumstantial evidence for their existence on the basolateral side of mucous epithelia (for reviews, see Refs. 4, 9, 13). For example, injected TFF1 and TFF3 have been shown to bind predominantly to TFF2-positive MNCs of the stomach (for references, see Ref. 13). Furthermore, the β-subunit of the fibronectin receptor (i.e., a β-integrin) and a transmembrane protein with similarity to CRP-ductin/DMBT1 were identified from porcine stomach because of their TFF2-binding capacity (for review, see Ref. 13). Only lately has the chemokine receptor CXCR4 been described as a low affinity receptor for TFF2 (for review, see Ref. 9). This receptor, together with its predominant physiological ligand CXCL12 plays a key role for various chemotactic processes. However, there are considerable differences *in vitro* between TFF2 and CXCL12 concerning signaling cascades involved, and the biological role of a TFF2-CXCR4 ligation is not clear thus far (for review, see Ref. 9).

There are only limited studies identifying the signaling cascades triggered by TFFs (for reviews, see Refs. 4, 7) including ERK1/2, JNK, Akt, and NF-κB.[6,12] Generally, the recombinant TFFs and porcine TFF2 used for these studies showed only relatively weak effects. Of note, TFF1 and TFF3 differ in their ability to induce activation of STAT3. Reports on TFF-triggered gene expression are also rare.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Possible target genes include decay-accelerating factor, NOS2, COX2, MMP1, 3, 13, and TFFs themselves[25] (for review, see Ref. 7). TFFs have occasionally been claimed to trigger phosphorylation of the EGF receptor in certain cell lines (for review, see Refs. 4, 7). However, TFFs do not bind directly to the EGF receptor,[28] but they show synergistic effects with EGF (for review, see Ref. 7). For example, TFF2 and EGF synergistically enhance haptotactic migration but trigger different signaling cascades.[7]

BIOLOGICAL ACTIONS WITHIN THE GASTROINTESTINAL TRACT

Protective and Healing Effects in Animal Models

There are numerous *in vivo* studies indicating protective and healing effects of all three recombinant TFFs after various damages to the rodent GI tract[22,33] (for reviews, see Refs. 10, 13). Recombinant TFFs were applied via different routes, that is, luminally or systemically, or transgenic mice overexpressing TFFs were investigated. GI damage was induced chemically, by restraint, hypoxia, or radiation. Generally, only TFF2 and the dimeric forms of TFF1 and TFF3 were active but not the monomeric forms. The beneficial effect of TFFs was correlated with reductions in VCAM-1, IL-6, and TNF-α expression. Also, a synergistic protective effect with EGF was reported.

Detailed comparative studies with recombinant TFF2 and TFF3 clearly documented that luminal application is superior over systemic delivery.[22] Surprisingly, systemic TFFs (in particular the TFF3/monomer) even aggravated colitis scores.[22] Furthermore, induction of colitis was effectively prevented after intragastric administration of TFFs by genetically modified *Lactococcus lactis*.[33] This also points to biological activity after luminal application.

In agreement with the observed protective role of TFFs, all transgenic TFF-deficient mice show abnormalities in the GI tract. TFF1-deficient mice fail to develop a functional gastric mucosa and develop obligatory antroplyloric adenomas, 30% of which progressed to carcinomas (for review, see Ref. 31). TFF2-deficient animals show a modulation of crucial genes involved in innate and adaptive immunity,[3] and they have an altered gastric surface pH regulation after damage.[35] TFF3-deficient mice show a decreased resistance to colonic injury, they are particularly sensitive to chemotherapy and radiation-induced mucosal injury (for review, see Ref. 28) and have a reduced body mass when compared with the wild-type animals.

There is evidence now that TFFs support a variety of different mucosal defense and repair mechanisms to various extents. These mechanisms synergistically enhance the surface integrity of the GI mucosa. The multiple molecular functions include (1) formation of the mucus barrier, (2) enhancement of mucosal repair (restitution) on different levels, (3) modulation of mucosal differentiation processes, and (4) modulation of the immune response.

TFFs are Integral Constituents of the Mucus Barrier

All three TFF peptides appear as constituents of laminated mucous gels when localized by immunohistochemistry[16] (for review, see Ref. 10). The hydrated mucus also contains, for example, different oligomeric mucins, FCGBP, soluble forms of DMBT1, and immunoglobulins. Remarkably, the mode of association differs for each TFF peptide. In this context, it is also interesting to note that TFF domains are integral constituents of the frog integumentary mucins FIM-A.1 and FIM-C.1 and other mosaic proteins associated with mucous surfaces (for review, see Ref. 10). Furthermore, a pH-dependent, lectin-like activity has been reported for both TFF1 and TFF3.[24]

Gastric TFF1 is cosecreted with the mucin MUC5AC and has been reported also to interact with MUC5AC (for review, see Ref. 10). However, the majority of the TFF1-GKN2 heterodimer does not associate with the mucin fraction after size exclusion chromatography; only a small proportion (<0.1%) appeared together with mucins.[15] The TFF1–GKN2 heteromer may have a role in the complex oligomerization and/or packaging of MUC5A during the secretory pathway in gastric surface mucous cells. This view is supported by the observation that TFF1-deficient mice have an altered gastric mucus layer and show activation of the "unfolded protein response."[31]

In contrast, gastric TFF2 mainly exists as a high molecular weight complex associated with the mucin fraction even after size exclusion chromatography.[15] Thus, TFF2 could act as "link peptide" crosslinking an unknown partner protein (Fig. 2). One candidate would be the mucin MUC6, which is cosecreted with TFF2. Furthermore, porcine pancreatic TFF2 monomer has been shown to interact noncovalently with a gastric DMBT1 isoform (porcine CRP-ductin; for review, see Ref. 13) and recombinant TFF2 changed specifically the viscoelastic properties of mucous gels.[30] Of note, this effect is characteristic of TFF2 and is not observed for TFF1 or TFF3.[13,30]

Recent results showed that TFF3 also is mucus-associated by forming a disulfide-linked heteromer with FCGBP in the intestine.[1] The cysteine-rich repetitive glycoprotein FCGBP (Mr > 300 k) is a typical constituent of mucus in various organs. It is autocatalytically cleaved, and in the intestine parts are covalently attached to the mucin MUC2 (for references, see Ref. 1). Thus, it is tempting to speculate that the mucus-associated TFF3-FCGBP heteromer might serve as a reservoir for

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

biologically active, modified TFF3 monomers (and probably also dimers) upon release.

TFFs Enhance Mucosal Restitution and Modulate Apoptosis and Angiogenesis

Migration of epithelial cells is particularly observed in the gastric and intestinal mucosa after superficial injury. This rapid repair is called "restitution" and starts within minutes of damage and well before extensive inflammatory processes and proliferation occur. TFFs have been shown in a number of *in vitro* models to influence different stages of this multistep process (for reviews, see Refs. 7, 10). Generally, TFFs are believed to act from the luminal side reaching their basolateral receptors only when the epithelial integrity is lost, that is, after local mucosal damage. This view is strongly supported by systematic protection studies *in vivo*.[22]

The first step in mucosal restitution is the reduction of cell–cell contacts directly at the borders of the injured area, followed by acquisition of these cells into a migratory phenotype. There are reports that TFF3 modulates adherens and tight junctions.[19] This would be in line with the observation that recombinant TFF3 changes the migration pattern of epithelial cells *in vitro*.

Furthermore, TFFs have been shown to speed up migration of epithelial cells and also immune cells in different *in vitro* model systems (motogenic effect; for reviews, see Refs. 7, 10). This effect is critically dependent on activation of ERK1/2.[6]

Restitution is also supported by the antiapoptotic effect of TFFs [12] (for reviews, see Refs. 4, 7, 28, 31). This effect is in line with the motogenic effect of TFFs because both cell migration and apoptosis are linked by common signaling mechanisms, for example, Rac1/XIAP. Of special note, under inflammatory conditions recombinant TFF3 has been reported to have a proapoptotic effect and has also increased the expression of matrix metalloproteinases.[25]

Restitution *in vivo* is also dependent on uninterrupted mucosal blood flow. Consequently, the pro-angiogenic activity of TFFs (for reviews, see Refs. 4, 7) supports particularly the final period of restitution, that is, remodeling, which is overlooked often and can take months.

TFF1 and TFF3 Modulate Mucosal Differentiation Processes

Continuous regeneration of the GI mucosa via proliferation and differentiation from stem cells followed by directed migration is an essential mechanism for maintaining its surface integrity.[14] A role of TFFs for differentiation processes of gastric and respiratory epithelial cells has been demonstrated (for reviews, see Refs. 8, 31). For example, TFF1-deficient mice show an increased number of SMCs, whereas the number of parietal cell is decreased.[31] This effect is explained by altered differentiation from prepit to preparietal cells. Furthermore, the amplification of mucous progenitor cells is even more changed in the pyloric antrum of TFF1-deficient mice leading gradually to dysregulated differentiation and the development of adenomas and carcinomas.[11]

Furthermore, SMCs in the human gastric corpus and the antrum are generated via different differentiation programs.[14,16] There are indications that TFF3 plays a role for the stepwise maturation of antral SMCs and that this process is also responsible for the higher turnover rate of the antral mucosa when compared with the body mucosa.

However, cell proliferation is not enhanced by TFFs.[13,28] Only in the presence of EGF has TFF3 been reported to stimulate β-cell replication.[5] There are rather reports on an antiproliferative effect of TFFs (for reviews, see Refs. 4, 13, 28, 31).

TFF2 Modulates the Immune Response

There is increasing evidence that particularly TFF2 is involved in immune responses and inflammatory processes (for review, see Ref. 3). For example, TFF2 and TFF3 are expressed in lymphoid tissues such as spleen, thymus, lymph nodes, and bone marrow, and they stimulate migration of monocytes. Thus, TFF2 expression is not only limited to the gastric mucosa but is also present in macrophages and lymphocytes.[17] TFF2-deficient mice show altered expression particularly of genes involved in innate and adaptive immunity[3] and these animals have also an increased susceptibility to *Helicobacter felis*-induced gastritis.[17] Furthermore, $TFF2^{-/-}$ cells were hyperresponsive to interleukin 1β stimulation suggesting TFF2 as a negative regulator of gastrointestinal inflammation and immune cell cytokine response.[17] In addition, the tumor necrosis factor-α-induced secretion of IL-6 and IL-8 is enhanced by TFF2 and TFF3 *in vitro* pointing to a possible function in the recruitment of leukocytes during mucosal inflammation.[6]

TFFs Probably Differ in Their Biological Actions

Based on the observation that TFFs are capable of forming heteromers or high molecular weight complexes with different partner proteins (Fig. 2), one might expect different biological functions also. It is still an open question whether the various TFF heteromers represent the functional forms or they are storage forms of TFFs or TFFs have just a structural function in these heteromers. Generally, TFF monomers can be released from the heteromers by reduction of disulfide linkages. During this process also

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

posttranslationally modified monomers could be generated. These modifications could be essential for TFF ligation to specific high affinity receptors and thus could alter dramatically the biological activity of TFFs. Unfortunately, the functional results are limited thus far because mainly recombinant TFF monomers and homodimers have been tested, which showed only weak biological activities. Taken together, the following picture appears concerning the multiple biological actions of TFFs in the GI tract.

TFF1 forms a heterodimer with GKN2, which could act as a motogen by triggering a specific receptor. Here, GKN2 could synergistically support the motogenic activity of TFF1. This hypothesis is strengthened by the report that the closely related peptide GKN1 has both mitogenic and motogenic activities. Furthermore, TFF1 could also have a function for the complex oligomerization and/or packaging of MUC5AC.

TFF2 could act as "link peptide" crosslinking a yet unknown high molecular weight component of the gastric mucus, for example, MUC6. By acting as a structural component of mucus, it could influence the rheological properties of this barrier dramatically. Furthermore, monomeric TFF2 could also activate a specific receptor, such as CXCR4.

TFF3 could have a motogenic effect by triggering a specific receptor after its release as a modified monomer or a homodimer from the TFF3-FCGBP heteromer.

However, the precise molecular mechanisms of TFFs still await their full elucidation.

PATHOPHYSIOLOGICAL IMPLICATIONS

Generally, TFF expression is dysregulated in inflammatory diseases and many neoplastic conditions (for reviews, see Refs. 4, 13, 31, 34). Furthermore, the unusual TFF plasma levels are indicative for the progression of certain cancers and can improve, for example, gastric cancer screening. TFFs are also important factors affecting the bacterial microbiota and progression of diseases of the alimentary/GI tract.

For example, *Helicobacter pylori* infection induces TFF expression and TFF1 (and to a lesser extent TFF3) enhances the efficient colonization of the gastric mucosa with *H. pylori* because these peptides interact in a lectin-like fashion specifically with *H. pylori* core oligosaccharide portion of lipopolysaccharide.[24] This TFF-sugar interaction is pH-dependent. It would be interesting to extend such studies to the gastric and intestinal microbiota.

There is a vast literature on the ectopic expression of TFFs during inflammatory diseases of the GI tract (such as gastroesophageal reflux disease, gastric ulcerations, ulcerative duodenitis and colitis, Crohn's disease, hepatolithiasis, cholecystitis, and pancreatitis; (for reviews, see Refs. 10, 13, 34)). Under these conditions, a unique glandular structure known as the ulcer-associated cell lineage (UACL) is a prominent site of TFF synthesis. The UACL is thought to represent a natural repair kit activated after mucosal damage.[34] Interestingly, a selective reduction in TFF3 expression has been reported in untreated celiac disease.

Inflammation is a critical component of tumor progression. Pathological TFF expression is also observed in premalignant conditions, such as Barrett's metaplasia and metaplastic polyps and TFF3 is a promising biomarker for Barrett's esophagus nowadays. Biosynthesis of TFFs is also dysregulated in many epithelial tumors (e.g., of the esophagus, stomach, biliary tract, pancreas, and intestine), suggesting a role for TFFs in cancer progression (for reviews, see Refs. 4, 10, 31). Particularly, TFF3 is a marker for bad prognosis of both stomach and colon carcinomas. Of particular interest, coexpression of TFF1 and GKN2, which normally form a heterodimer, is deregulated in gastric cancer.[18] Furthermore, there are also indications that formation of the TFF3–FCGBP heteromer is deregulated during colon carcinogenesis.

TFF1 and TFF3 are believed to represent key players in the different responses of the stomach and the intestine to inflammation. TFF1 and TFF3 expression is differentially regulated by SHP2/ERK and STAT3 signaling, respectively. Cancer develops in the stomach, and inflammatory bowel disease hits the intestine when this critical gp130-regulated balance is disrupted (for reviews, see Refs. 2, 13). Consequently, reduced TFF1 expression and increased TFF3 synthesis have been observed in many gastric cancers indicating a clear shift toward STAT3 signaling in gastric neoplasia.

Interestingly, TFF2 arises also in a metaplastic lineage of the gastric fundus and corpus called "spasmolytic polypeptide-expressing metaplasia." This cell type probably arises in part through trans-differentiation of chief cells and is at least as strongly associated with the development of cancer as intestinal metaplasia.[23]

Deregulation of TFFs is also observed after incisional wounds of GI tissue, in various induced gastric ulcerations, and after irradiation and chemotherapy. Particularly, the late and sustained TFF1 and TFF3 responses are indicative for a role in late-stage repair processes (for review, see Ref. 10).

Taken together, TFFs are expected to play important roles in physiological wound healing and in inflammatory processes, carcinogenesis, and metastasis.

Chapter 183

Urocortins

Vincent Wu, Pu-Qing Yuan, Muriel Larauche, Lixin Wang and Mulugeta Million

ABSTRACT

Urocortins (Ucn 1, Ucn 2, and Ucn 3) are members of the corticotropin-releasing hormone (CRH) family of peptides with ancient evolutionary lineage. In mammals, Ucns and CRH make up the four known CRH paralogous peptides. The mature Ucn peptides have comparable amino acid length, 38–40 amino acids, and share significant sequence homology. Ucns are distributed throughout the neuraxis and peripheral tissues including the epithelial, neuronal, and immune cells of the gastrointestinal tract. They exert biological actions by activating two related class B G protein–coupled CRH receptors, CRH_1 and CRH_2. Ucn 1 binds to both CRH_1 and CRH_2, whereas Ucn 2 and Ucn 3 bind selectively to CRH_2. In mammals, Ucns administered peripherally exert profound effects on food intake and on the gastrointestinal secretomotor, mucosal barrier, inflammation, and visceral pain responses. The identification of Ucns-like peptides throughout evolution, their distribution, and their biological actions support their critical role in gastrointestinal tract homeostasis during metabolic demands and/or in stress-related gut pathophysiologies.

DISCOVERY OF UROCORTINS

The identification of urocortins followed the earlier discoveries of corticotropin-releasing hormone (CRH) and the nonmammalian CRH-related peptides; urotensins, and sauvagine (see the CRH/Urocortins chapter in the Brain Peptides section of the book). CRH was isolated from the ovine hypothalamus, urotensins from the caudal spinal cord/neurosecretory organ (urophysis) of teleost fishes, and sauvagine from the skin of frog *Phyllomedusa sauvageii*. The differential responses of tissues to CRH and the nonmammalian peptides and their differential affinities to CRH receptors provided impetus to search for other CRH-related peptides in mammals. This resulted in the discovery of the first of the three urocortins from rat brain named urocortin, now renamed urocortin 1 (Ucn 1).[1,11,33] The discovery of Ucn 1, using antisera against the suckerfish urotensin-I, and the phylogeny of the then known CRH-related peptides led Lovejoy and Balment[21] to further suggest the existence of at least 4 CRH-like peptides in the vertebrate genome (see Lovejoy's chapter in the Brain Peptides section of the book). This and the lack of a pervasive Ucn 1 projection to CRH receptor type 2 (CRH_2)-expressing cells guided studies and increased the plausibility for the existence of other CRH peptides that are endogenous ligands for CRH_2. Consistent with this contention, the use of the public genome database, bioinformatic analysis, and molecular cloning, resulted in the identification of two new peptides named urocortin 2 (Ucn 2)/stresscopin-related peptide (SRP), and urocortin 3 (Ucn 3)/stresscopin (SCP) in humans and mice by two independent groups.[12,18,28] The two CRH/Ucns-related peptides share significant sequence homology with the mammalian CRH and Ucn 1. Furthermore, the sequence homology of the human Ucn 2 and Ucn 3 and that of the mouse mature Ucn 2 and Ucn 3 peptides is 76% and 90%, respectively.[18,28] Phylogenetically, the mammalian Ucns are part of the superfamily of neuropeptides that includes CRH, urotensin-I, sauvagine, and the insects diuretic peptides I and II (see the Diuretic/Antidiuretic chapter in the Invertebrate Peptides section of the book). The orthologous peptides are believed to have evolved through species divergence whereas the mammalian paralogs have evolved as a result of two gene duplications.[21] The discovery of Ucns and their functions have thus strengthened the long held thoughts and predictions that the CRH peptides are one of the oldest peptide lineages that are conserved throughout the species and confer biological actions that are critical for survival.

UROCORTIN GENES AND PRECURSOR STRUCTURES

The CRH/UCN gene family members share similar genomic organization and sequence homology. Like CRH, all the three UCN genes contain two exons and a single intron varying greatly in size from 200 to 8000 bp in human UCNs and their rodent orthologs (Table 1). Unspliced and alternatively spliced transcripts have been found in Ucn 1 and Ucn 3. However, the presence of the intron or alternative splicing would not affect the coding sequence of preproUcns since the preferred start codon is located downstream on the second exon.

TABLE 1 Chromosomal Location and Physical Size of Intron and Exons of UCN genes. The Annotations are Based on the Latest Assemblies of Human GRCh37, Rat RGSC3.4, and Mouse NCBIM37 Genome

		DNA (bp)			Protein (aa)	
	Chromosome	Exon 1	Intron	Exon 2	Precursor	Mature peptide
Human						
UCN1	2p23-p21	286	509	251	124	40
UCN2	3p21.3	71	1410	566	112	38, 43
UCN3	10p15.1	222	492	8484	161	38, 40
Rat						
UCN1	6q14	35	535	261	122	40
UCN2	8q32	71	651	655	109	38
UCN3	17q12.3	511	922	3119	164	38, 41
Mouse						
UCN1	5B1	33	471	263	122	40
UCN2	9F2	74	1002	715	113	38
UCN3	13A1	509	969	3184	164	38, 41

The retained intron may contain regulatory sequences or form secondary structure to affect cell-specific mRNA processing (e.g. RNA splicing, antisense RNA) and protein translation.

Ucn 1

The human urocortin 1 (hUcn 1) is a 40-amino acid (aa) peptide. It has been identified in other mammalian species including in rats and mice. The human, mouse, and rat Ucn 1 share a highly conserved sequence (83–95%).[5,33] In addition, human and rat Ucn 1 display 44–63% sequence identity with the urotensin-I identified in various fish species, 45% identity with rat/human (r/h)CRH, and only 33% and 35% identity, respectively, with frog sauvagine.[5,33] The human Ucn 1 precursor is a 124 polypeptide encoded by the UCN1 gene (on chromosome 2p23-p21). The precursor is processed by a cleavage of paired dibasic arginine (R) by proprotein convertase subtilisin/kexin type enzyme and removal of carboxy-terminal lysine (K) by carboxypeptidase E, followed by amidation of the eventual valine (V) residue by peptidylglycine alpha-amidating monooxygenase (PAM) resulting in the generation of the intermediate Ucn-57 amide (with N-term 17 aa extension) and the mature Ucn1-40 amide (see the Peptide Biosynthesis/Processing section of the book). Outside the brain, Ucn 1 mRNA is expressed in diverse visceral organs including the heart and GI organs, more prominently in the stomach, colon, pancreas, and intestinal barrier/lining, and secretory epithelium.

Ucn 2

Human Ucn 2, also known as stresscopin-related peptide, is a 38–43 aa peptide processed from a 112 aa polypeptide precursor encoded by human gene UCN2 (on chromosome 3p21.3). In rodents, Ucn 2 has a conserved carboxy-terminal tripeptide GRR sequence and, therefore, can be amidated at the proximal Val after dibasic residue removal by carboxypeptidase E and α-amidation from Gly donor by the PAM enzyme complex. Posttranslational processing of human prohUcn 2 is not yet fully characterized. Human Ucn 2, with its unique C-terminal tripeptide GHC sequence, may require a different strategy to use carboxypeptidases or prohormone-converting enzymes to generate a mature amidated peptide. However, amidated hUcn 2 peptides with predicted 38–43 residues possess full agonist activity. In rodents, Ucn 2 is expressed in the brain, esophagus, heart, skin, and many other tissues.[12,28]

Ucn 3

Human Ucn 3, originally named stresscopin to implicate its stress-coping activity, is a 38 or 40 aa carboxy-terminal amidated peptide processed from the 161 aa polypeptide precursor encoded by UCN3 gene on chromosome 10p15.1. In rodents, posttranslational processing of 164 aa proUcn 3 yields mature peptides with predicted 38 or 41 residues (Ucn3-41 amide and Ucn3-38 amide) with full agonist activity. Ucn 3 is expressed in the brain, pancreas, cardiovascular, endocrine, intestinal epithelium barrier/lining, and several other tissues.[12,18]

RECEPTORS AND SIGNALING CASCADES

Previous studies showed that binding and biological actions of urocortins are mediated by two class B G protein-coupled receptors (GPCR), referred to as CRH_1 and CRH_2. Ucn 1 binds to both receptor subtypes with equally high affinity and thus is considered as a nonselective agonist. Ucn 2 and Ucn 3, however, bind selectively with high affinity to CRH_2 receptors while showing little or no affinity or activity toward CRH_1. Thus, they have been implicated as the cognate ligands of ubiquitously expressed CRH_2 in the periphery. The molecular basis for ligand selectivity involves a single amino acid difference in the N-terminal extracellular domains (ECDs) of the receptors (CRH_1 Glu104/ $CRH_2\alpha$ Pro-100) at a site proximate to peptide residue 35 (Arg in CRH/Ucn 1, Ala in Ucn 2/3).[27] As members of the class B1 GPCR, CRH receptors are primarily coupled to Gαs, the hallmark feature known to this GPCR subfamily. On ligand stimulation, GTP binding and dissociation of Gαsβγ heterotrimer complex activates adenylyl cyclase, which in turn elevates second messenger cAMP production. Increased intracellular cAMP concentrations would lead to several cAMP-dependent signaling cascades, including PKA and EPAC, which have multiple effects on cytoplasmic and nuclear events, in particular, CREB-regulated gene activation.[9]

Cell Signaling Events Mediated by Ucn 1-Activated CRH_1 Receptor

More detailed studies of G protein coupling to transfected CRH_1[9] show that the type 1 receptors are capable of interacting with other Gq, Gi/o subunits to activate additional cell signaling pathways such as PKC, MAPK (ERK1/2), and AKT relevant to the CRH/Ucn actions. Furthermore, identification of multiple CRH_1 isoforms expressed in human and rodents may expand the role of CRH_1 in coordinating ligand and cell type-specific cell signaling.[35]

Emerging Cell Signaling Events Mediated by Ucns-Activated CRH_2 Receptor

More recent studies on CRH_2-mediated cell signaling show more subdued responses to CRH and Ucn 1. Lack of a robust response to CRH is not surprising because CRH has a much lower affinity to CRH_2. Given that Ucns are considered as endogenous ligands of CRH_2 and that CRH_2 has been considered to primarily couple with Gαs and activate a cAMP-dependent pathway, the subdued response to Ucns was surprising. However, although Ucns elicit relatively weaker cell response in cAMP production and ERK activation,[35] they trigger elevated inhibitory response in nitric oxide (NO) and cell apoptosis. Ucn 2 has also been implicated in calcium channel activation via CRH_2,[9] although the underlying mechanism is not yet clear. As shown in the case of CRH_1, current[35] and future identification of additional CRH_2 isoforms that are coupled to multiple G-proteins other than Gαs shall provide a better understanding of Ucns-activated CRH_2 signaling.

DISTRIBUTION OF UROCORTINS IN THE GI TRACT

Morphological and molecular studies show that Ucns are distributed throughout the neuraxis and the peripheral tissues.[7] Although, abundant data established the expression of Ucns in specific and distinct brain regions that control the stress response and energy balance,[2] convergent evidence show that Ucns are expressed in the gastrointestinal tract. The distribution of Ucn 1, Ucn 2, and Ucn 3 mRNA in the GI tract was first detected by in situ hybridization and reverse transcription polymerase chain reaction (RT-PCR).[4,12] Thereafter, immunohistochemical techniques provided an insight into their cellular localizations.[2,16] Most of the reports on Ucn distribution are related to Ucn 1 and less on Ucn 2 and Ucn 3, primarily because of the lack of specific Ucn 2 and Ucn 3 antibodies. Differences in sensitivity between the techniques used or the specificity of the molecular and immunological reagents used also account for some of the discrepancies in the reports on the distribution of Ucns. Nonetheless, the expression of Ucns and their receptors in the GI tract suggests a local autocrine and/or paracrine action of Ucns in the modulation of GI functions.

Urocortin 1

Stomach

After the initial report of Ucn 1 immunoreactivity (IR) in rat duodenal extracts,[33] Ucn 1 IR was later detected throughout the gastrointestinal tract of rats[14] and in the human gastric tissue.[4] Specifically, Ucn 1 IR is present in the gastric mucosa parietal cells of both human and rats.[2] Similarly Ucn 1 IR is detected in fibers of the gastric submucosal and myenteric plexi colocalized with tyrosine hydroxylase (TH) and in serotonin (5-HT)-immunoreactive (IR) enterochromaffin cells of the rat stomach.[2]

Small intestine

Ucn 1 mRNA-expressing cells are exclusively localized to the submucosal and myenteric plexi in the rat small intestine.[7] Ucn 1 immunoreactivity, on the other hand, is shown in TH positive fibers of the enteric nervous system primarily in fibers near the Lieberkühn crypts but not in enteric neuronal cell bodies.[2,14,16] Whether Ucn 1 protein is present in the small intestinal enteric neuron cell bodies that are not

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

TH positive is yet to be determined. These results suggest that Ucn 1 may play an important role in the regulation of intestinal secretomotor function.

Colon

Ucn 1 in the rat colon is expressed in different cell types. The majority (70–80%) of rat colonic submucosal and myenteric neurons express Ucn 1.[29] The Ucn 1 positive colonic myenteric neurons are mainly cholinergic and serotonergic neurons. Ucn 1 is expressed in very few cells of colonic mucosa.[2,16] By contrast in the human colon, Ucn1 mRNA and peptide are primarily expressed in mucosal immune cells, specifically in the lamina propria macrophages and isolated lamina propria mononuclear cells. Human studies further show that Ucn 1 peptide expression is detected as early as three months of age but not before birth or in neonates. These data suggest that Ucn 1 synthesis may be subject to diet and luminal factors and that Ucn 1 may play a role in modulating local inflammation through an autocrine/paracrine effect on mucosal immune cells.[2,16] The presence of the local effects of neuronal Ucn 1 in the human colon is yet to be established, as results in support of the expression of Ucn 1 in rodents[30] but lack of expression in human are reported.[26]

Urocortin 2

Stomach

Ucn 2 expression in the stomach has only been described at the mRNA level, but it is present in the mouse, rat, and human.[2] A comparison with other peripheral tissues in the mouse reveals that gastric expression of Ucn 2 is low.[2]

Small intestine

Ucn 2 mRNA is detected in both the rat and mouse small intestine.[2,16] Throughout the rat small intestine, Ucn 2 mRNA is detected in the epithelium, lamina propria immune cells, and the enteric plexuses with the highest expression in the jejunum.[3] In human small intestine, Ucn 2 mRNA is absent. The cellular location of Ucn 2 peptide in the stomach and small intestine is still unknown.

Colon

Ucn 2 mRNA is not detected in the human colon, expressed at a very low level in the murine colon, but is abundantly expressed in the rat colon.[3,12] The location of Ucn 2 IR in the small and large intestines of rats include epithelial cells, the lamina propria immune cells, and enteric neurons.[3] The protein levels of Ucn2 in the rat colon are however lower than that in the jejunum. Ucn 2 IR in Peyer's patches, although faint, is reported.[3] The Ucn 2 mRNA distribution on the other hand shows antergorade gradient in that the highest level is found in the distal colon, followed by the proximal colon and the terminal ileum.[3]

Urocortin 3

In rats, the GI tract contains a relatively high level of Ucn 3 mRNA compared with other peripheral organs/tissues.[12] Significant levels of Ucn 3 mRNA are found in the colon, the small intestine and stomach, but not in the ileocecal region, cecum, and esophagus.[12] Immunohistochemical studies detected specific Ucn 3 signals in the muscularis mucosae of the small intestine of the mouse.[12] In humans, Ucn 3 mRNA is in the stomach and all regions of the small intestine, except for the ileocecal area.[12] Both immunohistochemistry and in situ hybridization techniques show Ucn 3 expression in the myenteric and submucosal plexus, in vascular endothelial cells, and vascular smooth muscle cells of blood vessels in subserosa and in smooth muscle layers. Immunohistochemical analysis reveals the expression of Ucn 3 in serotonergic enterochromaffin cells and the epithelium, albeit at a rather low level. Immunohistochemical results further show Ucn 3 localized in both enteric neurons and S-100-ir enteric glial cells. The signal is the strongest in the myenteric plexus. In contrast to Ucn 1, Ucn 3 is hardly detected in the lamina propria inflammatory cells in colonic mucosa. Ucn 3 peptide is also detected in the large intestine by RIA, with high concentrations in the rectum and sigmoid colon.[2] In addition, Ucn 3 is expressed in the pancreatic islets.[15] All these findings suggest that Ucn 3 has the potential to play physiological or pathological roles in the modulation of gastrointestinal functions during stressful conditions. Overall, the distribution of Ucns and their receptors in the gut is compatible with a local role in the GI response to stress and metabolic demand.

BIOLOGICAL ACTIONS WITHIN THE GASTROINTESTINAL TRACT

The biological actions of urocortins on the gastrointestinal functions are primarily derived from experimental *in vivo* injections or *in vitro* applications of physiological or pharmacological doses of urocortins. These studies show that Ucns exert a profound effect on gut tissue contractility, secretion, mucosal barrier function, transit, visceral pain, inflammatory responses, and food intake.[7,23]

Gastrointestinal Motility and Transit

Stomach

Intraperitoneal (ip) or intravenous (iv) injection of Ucn 1 and Ucn 2 exert an inhibitory action on gastric motility and emptying. In rats and mice, the peripheral actions of Ucn 1

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

and Ucn 2 are prevented by either nonselective CRH_1 and CRH_2 antagonist, a selective CRH_2 antagonist, astressin$_2$-B, but not by a selective CRH_1 antagonist suggesting the primary role of CRH_2 in the responses.[23] Overall, peripherally injected CRH and Ucns-induced inhibition of gastric motility and emptying are fairly consistent across the species and involve inhibition of gastric contractility and/or gastroduodenal coordination.

Colon

In rodents, peripherally injected Ucn 1 (iv or ip) mimics the central effects of Ucn 1 in that it stimulates colonic transit and contractility.[22,23] Direct application of Ucn 1 to enteric neurons of rats and guinea-pigs activates neurons through CRH_1 and not CRH_2.[20] By contrast, peripherally injected Ucn 2 reduces stress-induced colonic motor activity and fecal pellet output that are known to be mediated through CRH_1.[8] These results suggest that the CRH_1 and CRH_2 receptors may play different roles in the colonic response to CRH peptides and stress.

Gastrointestinal Secretion

Gastrointestinal secretory function is an active process that plays an important role in digestion as well as in the protection of the mucosal surface. The regulation of GI secretions is effected through humoral and neural factors. Studies on peripheral Ucn effect on the gastric and small intestinal secretory responses are scant. However, earlier studies show that iv injected CRH decreases pentagastrin-stimulated gastric acid secretion in dogs and rats[32] and duodenal bicarbonate secretion in rats.[17] It is, thus, likely that peripheral Ucns modulate gastric and intestinal secretions.

In the lower gut, restraint stress or iv CRH-induced colonic mucin secretion is prevented by CRH receptor antagonists suggesting the role of CRH signaling in stress-related colonic mucin secretion. Intraperitoneal administration of CRH, Ucn 1, or sauvagine mimic stress-induced watery diarrhea, reminiscent of intestinal secretion, through a CRH_1-dependent pathway.[22] The intestinal capacity for high ion and water secretion is a defense mechanism against pathogens, which is commonly observed as the phenomenon of diarrhea. The passive movement of water at the epithelial level is assured by an active ion transport across the tissue, whose changes can be measured in Ussing chambers by modifications of the short circuit current (I_{sc}). Chronic peripheral administration of Ucn 3 increases basal colonic I_{sc}, suggesting a role for CRH_2 receptors in ion secretion.[16] Although direct evidence on the role of Ucns on intestinal secretion proper is scarce, given that Ucns and CRH act on the same receptors, it is plausible that results with CRH also apply to Ucns. For instance, in rats, treated with antagonists and selective agonists, CRH_1 receptors are involved in the increased basal colonic Isc and diarrhea occurring with rapid onset after peripheral and central CRH administration.[16] Although both CRH receptors are involved in ion secretion, the maximal epithelial I_{sc} responses in rat colonic tissue obtained with sauvagine administered *in vitro*, at doses 200–1000 fold lower than CRH, suggest a predominant CRH_2 effect in the modulation of secretory epithelial functions in the rat colon.[16]

Emerging evidence show that Ucn 1 stimulates pancreatic exocrine secretion in the rat through a CRH_1 receptor–mediated mechanism.[10] These actions are exerted indirectly and seem to involve cholinergic intrapancreatic neurons. Exogenous Ucn 3 also increases glucagon and insulin levels through CRH_2.[19] The results suggest that both CRH_1 and CRH_2 receptors may play a role in the Ucn-induced pancreatic secretions.

Intestinal Permeability

The gastrointestinal mucosal barrier function is ensured primarily by the continuous and compact epithelial cell layer that is held together by tight junctions. Trafficking of molecules through the intestinal epithelial barrier occurs via two routes: paracellular (between cells) controlling ion selectivity, nutrients, and solute permeability and/or transcellular (through cells) allowing for transport of large molecules (antigens, immunoglobulins). Stress or exogenous CRH alter barrier function. Chronic systemic administration of Ucn 3, in rats increases both paracellular and transcellular colonic permeability. By contrast, chronic peripheral administration to rats of the selective CRH_1 ligand stressin-1 only increases paracellular permeability.[16] In human colonic biopsies mounted in Ussing chambers, CRH serosal application induces increased transcellular permeability via activation of both CRH_1 and CRH_2, but does not affect paracellular permeability.[16] This result contrasts with the increase in both paracellular and transcellular permeability observed in rat colonic tissue after exposure to CRH and sauvagine *in vitro*, suggesting a role for both CRH_1 and CRH_2.[16] Together with mast cells, alterations in paracellular permeability are mediated by adrenergic and nicotinic nerves, whereas cholinergic, adrenergic, and nicotinic nerves participate in the alterations of transcellular permeability.[16]

Visceral Pain

The modulatory effect of the CRH peptides on visceral pain is primarily evidenced through the use of CRH and CRH receptor antagonists. Much evidence shows that CRH exerts pronociceptive action via CRH_1 receptors at both central and peripheral levels.[16,31] Very few studies have addressed the role of urocortins in the modulation of visceral pain response. The presence of Ucn 1 and

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Ucn 3 immunoreactive nerve terminals in association with CRH_2 receptors in the dorsal root ganglia and periaqueductal gray suggests, however, a modulatory influence of these receptors in visceral pain. In rats, iv injection of hUcn 2 reduces colorectal distension (CRD)-induced visceral hyperalgesia, and ip administration also has a similar antinociceptive effect in a model of duodenal distension-induced visceral pain. The Ucn 2 antinociceptive effects are blocked by peripheral administration of selective CRH_2 peptide antagonists, astressin$_2$-B and antisauvagine-30, suggesting CRH_2 mediation. Peripheral antinociceptive effects of hUcn 2 has been associated with the inhibition of splanchnic afferent spike activity, as observed in an *in vitro* colonic preparation and the phosphorylation process of ERK in the dorsal horn of the spinal cord.[24] Preliminary evidence, so far, is consistent with the activation of peripheral CRH_2 receptors exerting an antinociceptive modulatory effect while activation of CRH_1 receptors enhancing nociception. The detailed mechanisms as to how urocortins are released during stress and how CRH receptors are recruited to modulate visceral sensitivity require further studies.

Intestinal Inflammation

The modulatory role of CRH and Ucns in intestinal inflammation is shown by the fact that glucocorticoids are the mainstay of therapy against colitis. In the periphery, increased CRH immunoreactivity and mRNA expression in the mucosal biopsy of ulcerative colitis (UC) patients suggest that colonic CRH plays a role in colitis.[13] Ucn 1 IR increases in the colonic mucosa of UC patients that is reduced by glucocorticoid therapy.[30] There is also increased expression of Ucn 2 in colonic biopsies of both UC and CD patients.[25] In the upper gut, the upregulation of Ucn 1 but not CRH is reported in the biopsies of patients with *Helicobacter pylori*-induced gastritis.[4] That Ucns have a modulatory role in the gastrointestinal inflammation is now documented. However, the specific role they play in the prevention, maintenance, and/or recovery of inflammation is yet to be determined. For instance, local deletion of CRH, but not Ucn 2, ameliorates *Clostridium deficile* toxin-induced ileal inflammation. On the other hand, Ucn 2 enhances proinflammatory markers in human colonic epithelial cells, whereas CRH, Ucn 1, and Ucn 2 exert an anti-inflammatory effect in freshly isolated LPS-activated primary murine macrophages and macrophage cell line through Cox2 and PGE_2 pathways[2]

Food Intake

Ucns induce anorexic effect, in experimental animals, when injected peripherally (ip or iv). Intraperitoneally injected Ucns in mice and rats induce inhibitory effect on food intake and activate brain regions implicated in appetite regulation.[34] Differences in potency, however, exist between the CRH peptides. For instance, in rodents, peripherally injected Ucn 1 is more potent than CRH, Ucn 2, or Ucn 3 in appetite suppression. Likewise, although ip administration of Ucn 1 or Ucn 2 inhibits food intake, Ucn 2 does so without inducing malaise while Ucn 1 shows conditioned taste aversion and interoceptive stress with increased corticosterone levels in rats.[6] Mechanisms through which Ucns exert differential effects on food intake are not yet fully known. However, evidence exists supporting peripherally initiated effects through direct modulation of afferent vagal pathways and/or modulation of appetite- and energy balance-regulatory hormones such as ghrelin, insulin, and PYY exists. For instance, in humans, iv infusion of Ucn 1 blocks the increase of ghrelin in the circulation during a fast. Given that ghrelin is mainly secreted by gastric mucosa and has been implicated in the regulation of eating behavior, the results suggest that peripheral Ucn inhibitory effect on food intake may involve a local modulation of gastric ghrelin production. Similarly, Ucn 3 and CRH_2 are abundantly expressed in the pancreatic islets and regulate insulin release, which affects energy metabolism.[15,19]

PATHOPHYSIOLOGICAL IMPLICATIONS

As outlined above, preclinical and clinical evidence suggests that the activation of peripheral Ucn signaling exerts a profound effect on the gastrointestinal functions in health and diseases. The inhibitory effects of Ucns on upper gut secretomotor responses are mediated primarily by peripheral CRH_2, whereas stimulation of the lower gut secretomotor function involves CRH_1. Results mainly from CRH and also from Ucn studies show that Ucns modulate mucosal barrier function through both CRH_1 and CRH_2. The effect of Ucns on gut inflammation is now well documented although a full understanding of the specific effects awaits future studies. Finally, CRH and Ucn 1 enhance stress-related colonic distention-induced pain primarily through CRH_1, whereas CRH_2 exerts antihyperalgesic effects. These results clearly show that Ucns and their receptors are positioned to play a role in the gut secretomotor, mucosal barrier, inflammation, and visceral pain pathophysiology. Overall, available evidence suggests that CRH and Ucn 1, by acting on CRH_1, mediate most of the stress responses. Although not yet conclusive, Ucn 2 and perhaps Ucn 3 by acting on CRH_2 dampen the lower gut responses to stress. The relevance of Ucns in gut pathophysiology is exemplified by the ongoing clinical trials involving selective CRH_1 antagonists against irritable bowel syndrome, a condition known to be highly associated with stressful life events.

Chapter 184

VIP

Karnam S. Murthy and John R. Grider

ABSTRACT

Relaxation of smooth muscle of the gastrointestinal tract reflects the interplay of nitric oxide (NO), and peptide transmitters, mainly vasoactive intestinal peptide (VIP) and its homolog, pituitary adenylyl cyclase-activating polypeptide (PACAP). The role of VIP is most evident as mediator of the relaxation component of the peristaltic reflex. In smooth muscle cells, VIP and PACAP interact with cognate seven-transmembrane $VPAC_2$ receptors to generate cAMP and with the single-transmembrane NPR-C to generate NO and cGMP. Concurrent generation of cAMP and cGMP, and activation of cAMP-dependent protein kinase (PKA) and cGMP-dependent protein kinase (PKG), respectively, is the physiological norm. Both PKA and PKG act on various downstream targets to inhibit Ca^{2+} mobilization and MLC_{20} phosphorylation and thus induce muscle relaxation.

DISCOVERY

Sami Said, who was investigating the vasodilating substance responsible for systemic hypotension in acute respiratory syndrome and massive pulmonary embolism, joined Viktor Mutt, a well-known peptide biochemist, at the Karolinska Institute to isolate the substance from lung extracts.[29] Although a peptide extract with vasodilator activity was identified from the extracts from porcine lung, purification was hindered because of the paucity of a sufficient quantity of fresh tissue from the slaughterhouses in Stockholm. Based on the vasodilatory actions, a vasoactive peptide was isolated from pig small intestine, an organ that develops from the same embryonic bud as the lungs. As they were not sure about the existence of the peptide outside the intestine, it was named "vasoactive intestinal peptide," and initially classified as a gut hormone. Further studies using immunohistochemical and radioimmunoassy have shown that VIP has a widespread distribution, and the predominant localization of VIP in central and peripheral neurons led to the identification of neurotransmitter or neuromodulator functions. Said and Mutt characterized the 28 amino acids sequence of VIP, and this led to the synthesis of this peptide by Miklos Bodansky. The synthetic peptide was equipotent with VIP and had similar biological activities. The amino acid composition of VIP reveals that it is related to the secretin family of peptides, which includes pituitary adenylyl cyclase-activating peptide (PACAP), secretin, glucagon, helodermin, peptide with histidine and isoleucine in the N-terminal, and C-terminal respectively [peptide histidine isoleucine (PHI) and its human homolog peptide histidine methionine (PHM)], gastric inhibitory peptide (GIP), growth-hormone releasing hormone (GHRH), and glucagon-like peptides 1 and 2 (GLP-1 and GLP-2).[29] VIP is a more basic peptide than secretin and glucagon. The sequence of VIP is highly conserved between species including human and in terms of structure, cellular signaling, and function, VIP is most closely related to PACAP.[14]

STRUCTURE OF THE GENE AND PROCESSING OF THE PRECURSOR

The human VIP gene was cloned in 1985 by Gozes using synthetic oligodexoynucleotides based on human VIP-cDNA sequence. Further studies showed that the intron–exon organization of the VIP gene is similar to the genes of VIP-related peptides.[29] The human VIP gene contains seven exons and six introns. Each exon encodes a distinct functional domain of the VIP precursor or its mRNA: 5′ untranslated regions of the mRNA (exon I), signal peptide of preproVIP (exon II), N-terminal peptide (exon III), PHM (exon IV), VIP (exon V), and C-terminal of preproVIP (exon VI), and 3′ untranslated region of the mRNA (exon VII). The peptides VIP and PHI/PHM, which share 48% amino acid sequence identity are located on two adjacent exons. The sequence around VIP-coding and PHM-coding exons and their adjacent introns are highly conserved. The rodent VIP gene is similar in organization to human VIP gene with seven exons and six introns. Using chromosomal mapping and *in situ* hybridization, the human VIP gene was localized to chromosome 6 region 25. Using RNA blot hybridization, S1-nuclease analysis and cDNA cloning, VIP-gene transcripts were characterized. The rate of transcription of the VIP gene is regulated by many transcription factors such

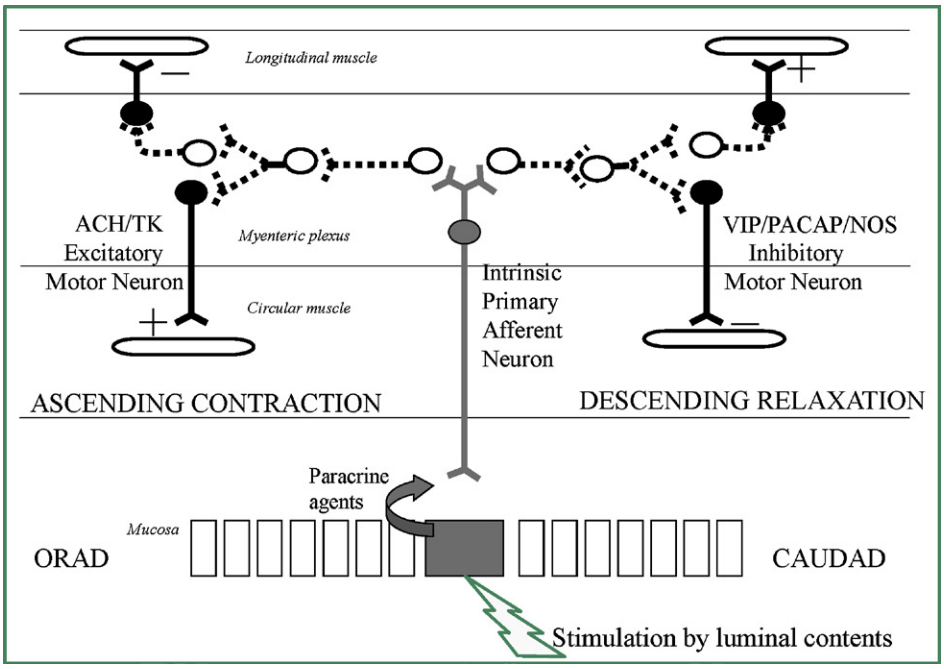

FIGURE 1 Model of peristaltic reflex underlying propulsive peristalsis. Components of chyme or mucosal mechanical stimulation activate specialized enteroendocrine cells (gray square) of the mucosa, which release paracrine agents such as serotonin (5-HT). The paracrine agent then activates intrinsic calcitonin-gene-related peptide containing intrinsic primary afferent neurons (IPAN) (gray neuron) to initiate the reflex. The IPAN activates chains of ascending and descending interneurons (open-dashed neurons), which release a variety of neuropeptides including somatostatin, enkephalin, and vasoactive intestinal peptide (VIP). The ascending interneurons terminate on excitatory motor neurons (solid neurons) that release acetylcholine (ACH) and tachykinins (TK) causing contraction of circular muscle (ascending contraction) orad to the site of stimulation. The descending interneurons terminate on inhibitory motor neurons (solid neurons) that release VIP, pituitary adenylate cyclase-activating peptide (PACAP), and nitric oxide (NO) causing relaxation of circular muscle (descending relaxation) caudad to the site of stimulation. Longitudinal muscle relaxes during ascending contraction and contacts during descending relaxation in a reciprocal manner to circular muscle (see Ref. 10 for details). Plus sign (+) indicates contraction and minus sign (–) indicates relaxation.

as CREB (cAMP response element binding protein). Translation of mRNA of human VIP gene transcription yields a 170-amino-acid precursor, preproVIP, and the posttranslational processing of the precursor yields the 28-amino-acid VIP and 27-amino-acid PHI in rodents and PHM in humans. VIP and PHI are present in a 1:1 molar ratio and released in roughly equimolar amounts. PreproVIP is also processed to preproVIP22–179, preproVIP111–122 and preproVIP156–170. All these preproVIP-derived peptides have been identified albeit with unequal amounts in human gastrointestinal tract and in VIP-producing cell lines.[29] Differences in the posttranslational processing of preproVIP exist in subpopulations of neurons in the gastrointestinal tract.

DISTRIBUTION IN THE GASTROINTESTINAL TRACT

In the gastrointestinal tract, VIP is localized in different populations of enteric neurons with different projections and is colocalized with different combinations of transmitters. The enteric nervous system is composed of two ganglionated plexuses: the myenteric plexus, which is present between the muscle layers and the submucosal plexus, which lies in the submucosa.[6] In the submucosal plexus, VIP is present in secretomotor neurons where it acts to stimulate secretion. In the myenteric plexus, VIP is present in about 25% of enteric neurons, which typically project in a caudad direction to innervate other neurons or smooth muscle cells of the circular muscle layer.[3,6] These neurons typically also contain the homologous peptides PACAP, PHI in animals or PHM in humans, and neuronal nitric oxide synthase (nNOS), an enzyme responsible for generation of nitric oxide (NO) (see the chapters by the discoverers of these peptides elsewhere in this book). Although single enteric neurons contain a variety of transmitters, VIP neurons never contain the tachykinin contractile transmitters, and thus these two peptides mark distinct, nonoverlapping populations of neurons.[3,6,7]

RECEPTORS AND THEIR SIGNALING PATHWAYS

The biological actions of VIP and PACAP are mediated by a family of G-protein-coupled receptors, which are designated $VPAC_1$, $VPAC_2$, and PAC_1 receptors.[14,17] These receptors belong to family B of the G-protein-coupled receptors also known as the secretin receptor family, which includes

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

receptors for secretin, GIP, glucagon, glucagon-like peptide 1, calcitonin, parathyroid hormone, GHRH, and corticotrophin-releasing hormone. The PAC_1 receptors exhibit high affinity for PACAP and low affinity for VIP, whereas $VPAC_1$ and $VPAC_2$ receptors exhibit equal affinity for VIP and PACAP. Although $VPAC_1$, $VPAC_2$, and PAC_1 are expressed throughout the gastrointestinal tract, the various VIP/PACAP receptor subtypes exhibit differential expression patterns. $VPAC_1$ receptors are expressed in the mucosa and myenteric neurons; $VPAC_2$ receptors are expressed in neuroendocrine cells, blood vessels, and smooth muscle; and PAC_1 receptors are expressed in myenteric neurons.[14,17] Neural VIP/PACAP receptors are present in two locations: on nerve terminals where they act as autoinhibitory receptors to suppress further neurotransmitter release and on cholinergic/tachykinin neurons that innervate the longitudinal muscle layer. Activation of these receptors by VIP/PACAP released from myenteric neurons stimulates the release of ACh and tachykinins and induces contraction of longitudinal muscle.[10]

In gastrointestinal smooth muscle, VIP and PACAP interact with two distinct classes of receptors: a cognate $VPAC_2$ receptor coupled via G_s and stimulation of adenylyl cyclase V/VI resulting in cAMP formation and activation of cAMP-dependent protein kinase (PKA), and a single-transmembrane natriuretic peptide clearance receptor (NPR-C) coupled via G_{i1}/G_{i2} and stimulation of Ca^{2+} influx and sequential activation of Ca^{2+}/calmodulin-dependent eNOS and NO-dependent soluble guanylyl cyclase[23,24] (Fig. 2). In the smooth muscle of the gut, NPR-C is coexpressed with NPR-B but not NPR-A. Unlike NPR-A and NPR-B, NPR-C is devoid of intracellular cyclase-activating domain and consists of a short 37-amino acid sequence capable of activating pertussis toxin-sensitive G_{i1} and G_{i2}.[24] Using receptor-derived synthetic peptides, a 17-amino-acid G-protein-activating sequence has been identified in the intracellular domain of NPR-C; the sequence (^{469}RRNHQEESNIGKHREL^{485}R) is characterized by two NH_2-termial basic residues and a COOH-terminal motif BBXXB, where B and X represent basic and non-basic residues, respectively[24] (Fig. 2). Similar sequences have been identified in other G-protein-coupled seven-transmembrane receptors such as muscarinic and adrenergic receptors.[26]

In gastrointestinal smooth muscle, $VPAC_2$ receptors are desensitized and internalized by a mechanism distinct from those used by $VPAC_1$ or secretin receptors. $VPAC_2$ receptors are phosphorylated by G-protein-coupled receptor kinase 2 (GRK2) resulting in desensitization and internalization of receptors. GRK2 is phosphorylated by PKA at Ser^{685} and this phosphorylation greatly augments the ability of GRK2 to phosphorylate the receptor and induce receptor internalization.[25] $VPAC_1$ receptor phosphorylation, internalization, and desensitization are inhibited by concomitant activation

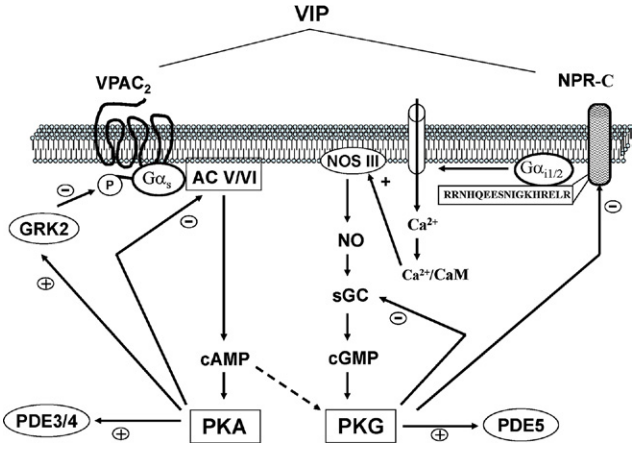

FIGURE 2 Signaling pathways initiated by VIP in gastrointestinal smooth muscle. In gastrointestinal smooth muscle, VIP activates cognate seven-transmembrane $VPAC_2$ receptors coupled via G_s to adenylyl cyclase V/VI, cAMP generation and activation of cAMP-dependent protein kinase (PKA). They also activate a single-transmembrane natriuretic peptide receptor C (NPR-C) coupled via $G\alpha_{i1}$ and $G\alpha_{i2}$ to Ca^{2+} influx and Ca^{2+}/calmodulin activation of NOS III expressed in smooth muscle cells, leading to NO-dependent activation of soluble guanylyl cyclase (sGC), cGMP generation and activation of cGMP-dependent protein kinase (PKG). Activation of $G\alpha_{i1/2}$ is mediated by a 17-amino-acid sequence in the middle region of the intracellular domain of NPR-C (inset). cAMP activates PKA and cGMP activates PKG, but in the presence of cGMP, cAMP crossactivates PKG also. Both PKA and PKG act separately upstream to induce desensitization of $VPAC_2$ and NPR-C receptors, inhibition adenylyl cyclase and soluble guanylyl cyclase, and activation of cAMP-specific PDE3A and PDE4 and cGMP-specific PDE5. Stimulation (+); inhibition (−).

of Gq-coupled muscarinic m_3 receptors. The mechanism involves phosphorylation of RKIP (Raf kinase inhibitory protein) by PKC and subsequent dissociation of RKIP from Raf-1 and association with GRK2 and inhibition of GRK2 activity.[16] The functional significant of this crossregulation may reside when there is overlap in the release of both Gq-coupled excitatory transmitters with the VIP.

In gastric and intestinal smooth muscle cells, $VPAC_2$ receptors exhibit equal affinity for both VIP and PACAP. In tenia coli smooth muscle cells, however, VIP and PACAP interact with distinct receptors.[15] These cells express a VIP-specific receptor that does not recognize PACAP and a PACAP-specific receptor that does not recognize VIP. The VIP-specific receptor, but not the PACAP-specific receptor, is coupled to activation of adenylyl cyclase. The PACAP-specific receptor, but not the VIP-specific receptor, is coupled to the activation of apamin-sensitive K^+ channels.

The cDNA of the VIP-specific receptor cloned from guinea pig tenia coli encodes a 437-amino-acid protein with a calculated molecular weight of 49,560 Da.[35] All amino acid residues required for VIP binding including aspartate, tryptophan, and glycine residues (corresponding to D68, W73, and G109 of human $VPAC_1$ receptor) and all N-terminal cysteine residues are conserved. The amino acid

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

sequence differs from that of the cloned guinea pig gastric receptor by only two amino acid residues (Phe^{40}/Phe^{41} in lieu of Leu^{40}/Leu^{41}) in the ligand-binding N-terminal, and showed 87% homology to the sequence of rat and mouse $VPAC_2$ receptors. Mutation of these two residues to Leu^{40}/Leu^{41} so as to mimic gastric VIP receptor results in an equal high affinity for VIP and PACAP suggesting that the ligand specificity in this species is determined by a pair of adjacent phenylalanine residues in the NH_2-terminal ligand-binding domain.[35]

BIOLOGICAL ACTION WITHIN THE GASTROINTESTINAL TRACT

The main function of gastrointestinal motility is to propel ingested food and to mix the food with digestive enzymes for optimal digestion and absorption and excretion of undigested waste. The process of propulsion is initiated by luminal signals generated by components released from chyme, by mechanical stimulation of mucosa, or by distention of the gut wall.[3,6,7] These stimuli trigger a propagated peristaltic reflex consisting of two components: a contraction orad (ascending contraction) and a relaxation caudad (descending relaxation) to the site of stimulation. The reflex is mediated wholly by neurons of the enteric nervous system that are contained within the wall of the gut. The reflex is initiated on activation of intrinsic sensory neurons and is relayed by interneurons to motor neurons, which mediate the final contraction of circular muscle orad and relaxation of circular muscle caudad (Fig. 1). The excitatory motor neurons release acetylcholine and tachykinins, and the relaxant or inhibitory motor neurons release VIP, PACAP, and NO. This role as main relaxant transmitter of inhibitory motor neurons represents the major physiological action of VIP with regard to gut smooth muscle function.

VIP as Mediator of Descending Relaxation of Smooth Muscle

Gastrointestinal motility is mediated by the contractile activity of the smooth muscle cells that line the gastrointestinal wall. This contractile activity is regulated by enteric neurons. Increased contractility is meditated by acetylcholine and tachykinins, and decreased contractility is mediated by VIP/PACAP/NO. Decreased contractility can be reflected in a variety of ways: relaxation of tone or inhibition of ongoing rhythmic activity depending on the distinct regional and functional properties of gut smooth muscle.[19] Smooth muscle of the proximal stomach and gall bladder exhibits sustained tone with some rhythmic contractions, whereas smooth muscle of the distal stomach, small intestine, and colon exhibits variable tone on which are superimposed rhythmic contractions. The smooth muscle of the sphincters, however, is purely tonic in nature.[27] For peristalsis to propel luminal content in an anal direction, not only must there be an increase in contraction orad to a luminal stimulus but there must also be a concomitant relaxation or inhibition of contractility caudad to the stimulus. This same mechanism comes into play as a peristaltic reflex reaches a tonically contracted sphincter where release of VIP in conjunction with NO acts to allow propulsion of luminal material from one section of the gut to another or during the expulsions of material from the gut.[27]

VIP, its homologous peptide transmitters, and NO fulfill the criteria for inhibitory transmitters: they are present in the neurons innervating the muscle of stomach, intestine, and various sphincters and are released by pharmacological and electrical field stimulation of myenteric neurons.[1,2,8,9,11] Additionally, their release is activated by physiological stimuli and is coupled to the peristaltic reflex and muscle relaxation in a variety of species including human.[11,12] Also, in support of a role as relaxant transmitter, exogenous addition of VIP, PACAP, or NO induces muscle relaxation mimicking the response induced by nerve stimulation.

VIP-containing neurons also innervate epithelial cells, exocrine glands, and other neurons of the gastrointestinal tract.[6] In addition to smooth muscle relaxation, the biological effects of VIP on gastrointestinal system include stimulation of water and electrolyte secretion, enzyme secretion, and mucus secretion, as well as inhibition of absorption and of acid secretion. Although not the focus of this chapter, the stimulation of these secretions facilitates the digestion and propulsion of chyme through the gut and results in a coordinated response of the gut to a meal.

Interplay of Inhibitory Neurotransmitters

The neuropeptides VIP and PACAP, and nNOS, the enzyme responsible for formation of NO by enteric nerves, are colocalized in a subset of myenteric neurons that innervate the muscle and their release is functionally linked.[3,6,7,27,30] VIP and PACAP are stored in vesicles in the nerve endings, whereas NO is synthesized on demand by the nNOS. NO formed in the nerve terminals by nNOS regulates VIP and PACAP release, and in turn, VIP and PACAP stimulate smooth muscle eNOS to generate NO within the smooth muscle.[12,13,24]

In isolated myenteric ganglia devoid of smooth muscle, the release of VIP and PACAP, and NO production are inhibited by the blockade of nNOS activity implying NO-dependent VIP and PACAP release.[12] Consistent with this notion, exogenous NO increases VIP and PACAP release, whereas exogenous VIP or PACAP had no effect on NO production. In contrast, in isolated smooth muscle cells devoid of neural elements, VIP and PACAP induce NO production.[13,23,31] The ability of NO to stimulate VIP and

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

PACAP from nerve terminals, and the ability of VIP and PACAP to stimulate NO production in smooth muscle was evident in studies with innervated muscle preparations. In these preparations, nerve stimulation elicited stimulation of VIP (and PACAP) release, NO formation, and relaxation.[9] NOS inhibitors abolished NO formation and partly inhibited VIP release and relaxation, whereas VIP antagonist partly inhibited NO formation and relaxation. The ability of NOS inhibitors to block relaxation reflect inhibition of NOS in both myenteric neurons and smooth muscle cells, and inhibition of NO-dependent VIP and PACAP release from the myenteric neurons. The residual relaxation in the absence of NO production reflects the direct effect of VIP and PACAP that is independent of NOS activity in the smooth muscle. The ability of a VIP antagonist to block relaxation reflects suppression of VIP-induced stimulation of NOS and adenylyl cyclase activities in smooth muscle. The residual relaxation, in the absence of NO production and cAMP generation in smooth muscle, reflects the direct effect of NO derived from myenteric neurons on smooth muscle cells. The interplay between VIP and NO during relaxation can be summarized by the following results: (i) NO stimulates VIP from nerve terminals and VIP, in turn, stimulates NO formation in muscle, (ii) relaxation is mediated by NO and VIP release from nerve terminals and by NO formation in smooth muscle cells, and (iii) the effect of NOS inhibitors and VIP antagonists reflect their effects on both VIP release and NO formation.

Rattan et al.[4,5] have demonstrated that in the internal anal sphincter of the opossum VIP acts on both myenteric neurons and smooth muscle cells to generate NO. The major source of NO in response to VIP during relaxation, however, is from myenteric neurons with some contribution from the smooth muscle cells. Studies by Goyal et al.[20] using knockout animals have shown that VIP-induced hyperpolarization in the lower esophageal sphincter is abolished in nNOS deficient mice but is not affected in endothelial NOS deficient mice suggesting that nNOS is the major source of NO in the hyperpolarizing actions of VIP.

Mechanism of Smooth Muscle Relaxation Induced by VIP

VIP- and PACAP-induced activation of adenylyl cyclase by G_s-coupled $VPAC_2$ receptors and soluble guanylyl cyclase by $Gi_{1/2}$-coupled to NPR-C via NO generation leads to concurrent formation of cAMP and cGMP and activation of PKA and cGMP-dependent protein kinase (PKG). The intracellular levels of cAMP and cGMP, and the strength and duration of their physiologic effects depend on the rates of their synthesis by cyclases and degradation of phosphodiesterases (PDEs). The activity of these enzymes, in turn, is regulated by PKA and PKG, the downstream kinase of cAMP and cGMP. Cyclic AMP levels are regulated by feedback activation of cAMP-specific PDE3A and PDE4 and inhibition of adenylyl cyclase V/VI via PKA.[22] Cyclic GMP levels are regulated by feedback activation cGMP-specific PDE5 and inhibition of soluble guanylyl cyclase via PKG.[22] When there is concurrent generation of cAMP and cGMP, cGMP increases cAMP levels by inhibiting its degradation via PDE3A, whereas cAMP decreases cGMP levels by augmenting its degradation via PKA-mediated phosphorylation of PDE5.[21,22] Thus cAMP and cGMP levels are regulated by coordinated interplay between cyclases, phosphodiesterases, and protein kinases.

cGMP selectively activates PKG, whereas cAMP at lower concentrations activates PKA and at higher concentrations crossactivates PKG.[22] Autophosphorylation of PKG in the presence of cGMP greatly augments the affinity of cAMP for PKG. The ability of cAMP to crossactivate PKG is potentiated by concurrent generation of cGMP. Thus, concurrent generation of cAMP and cGMP and activation of PKA and PKG are the physiological norm in smooth muscle.

PKA and PKG act on several downstream targets in the cascades that mediate initial and sustained contraction, resulting in MLC_{20} (20-kDa regulatory light chain of myosin) dephosphorylation and muscle relaxation[22] (Fig. 3).

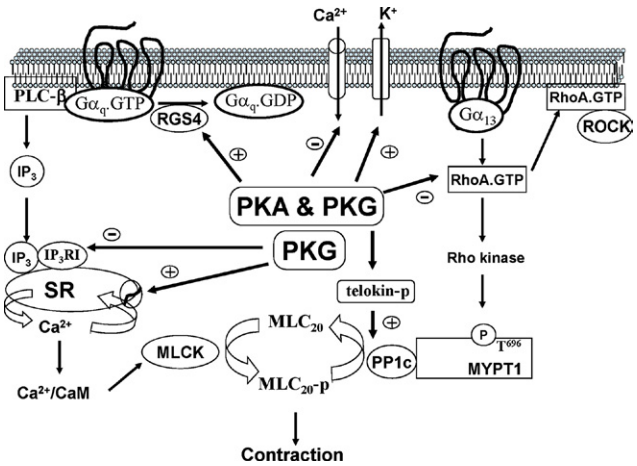

FIGURE 3 Downstream targets of PKA and PKG during VIP-induced relaxation of smooth muscle. PKG and PKA induce relaxation by targeting various components of the contractile signaling pathways. Both PKA and PKG phosphorylate RGS4 and stimulate inactivation of $G\alpha_q$, leading to inhibition of PLC-β1 activity and IP_3 formation. In addition, only PKG can phosphorylate IP_3R-I and the sarcoplasmic Ca^{2+}/ATPase pump, leading to inhibition of Ca^{2+} release and stimulation Ca^{2+} re-uptake. These mechanisms act to reduce intracellular Ca^{2+} and thus inhibit MLCK activity, MLC_{20} phosphorylation and initial contraction. Both PKA and PKG inactivate RhoA by phosphorylating RhoA at Ser^{188} leading to blockade of inhibition of MLC phosphatase via PKC/CPI-17 and Rho kinase/MYPT1. A distinct mechanism involves phosphorylation of telokin, an endogenous activator of MLC phosphatase, by both PKA and PKG leading to dephosphorylation of MLC_{20}.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Relaxation of initial Ca^{2+}-dependent phase by PKA and PKG correlates with the decrease in $[Ca^{2+}]_i$, which is achieved by decreasing inositol 1,4,5-trisphosphate (IP_3) generation and/or decreasing IP_3-dependent Ca^{2+} release. Both PKA and PKG inhibit $G\alpha_q$-dependent phospholipase C (PLC)-β1 activity. However, neither $G\alpha_q$ nor PLC-β1 is directly phosphorylated by PKA or PKG. The mechanism of inhibition involves acceleration of $G\alpha_q$ inactivation by phosphorylation of two regulatory proteins, RGS4 (regulator of G-protein signaling 4) and GRK2 (G-protein-coupled receptor kinase 2). Phosphorylation of RGS4 and GRK2 increases their binding to $G\alpha_q$ and enhances the inactivation of $G\alpha_q$ leading to inhibition of PLC-β1 activity and IP_3 generation.[25] PKG, but not PKA, in addition, induces phosphorylation of type IP_3 receptors expressed in smooth muscle resulting in inhibition of Ca^{2+} release and relaxation of initial Ca^{2+}-dependent contraction[22] (Fig. 3).

Relaxation of sustained Ca^{2+}-independent phase of muscle contraction is mediated by disinhibition of myosin light chain (MLC) phosphatase via PKA- and PKG-mediated phosphorylation of membrane-bound RhoA at Ser^{188} [22] (Fig. 3). Phosphorylation of RhoA stimulates its translocation back to the cytosol and inhibits the activity of downstream membrane-bound targets, Rho kinase, and phospholipase D (PLD). Inhibition of Rho kinase blocks phosphorylation of the regulatory subunit of MLC phosphatase (MYPT1) at Thr^{696}, whereas inhibition of PLD results in the decrease in diacylglycerol formation, protein kinase C (PKC) activity and PKC-mediated CPI-17 (17-kDa endogenous inhibitor of MLC phosphatase) phosphorylation at Thr^{38}. Thus, the blockade of two pathways, Rho kinase/MYPT1 and PLD/PKC/CPI-17 that converge to inhibit MLC phosphatase leads to the activation of MLC phosphatase and dephosphorylation of MLC_{20} leading to relaxation of sustained Ca^{2+}-independent, RhoA-dependent contraction. Recent studies have shown that PKA and PKG can directly phosphorylate telokin, an endogenous 17-kDa activator of MLC phosphatase, which results in dephosphorylation of MLC_{20} and muscle relaxation[22] (Fig. 3).

PATHOPHYSIOLOGICAL IMPLICATIONS

The significance of the physiological actions of VIP was initially revealed with classical physiological and pharmacological approaches.[29] The importance of VIP as a mediator of gut relaxation is also confirmed by pathological studies and more recent transgenic studies. Thus, in a recent study of Lelievre et al.,[18] $VIP^{-/-}$ mice were shown to have a distinctive gut phenotype that included reduced goblet cell mucus secretion, increased thickness of the circular muscle layer, reduced intestinal length, and a significant 36% reduction in the ability of the intestine to propel luminal contents. The authors conclude that the decreased length is the result of a state of enhanced tonic contraction resulting from the loss of relaxant VIP-ergic tone and that the failure to propel intestinal contents is the result of the loss of the relaxation component of peristalsis. Consistent with this notion, 10–15% of the mice die within the first year and have "an abrupt blockade in movement of intestinal contents" and a site of gut stenosis. Similarly, a role for VIP as a major relaxant in normal physiology is suggested from finding in pathologies such as intestinal ileus, Hirschsprung's disease, Chagas' disease, and achalasia. These diseases have in common loss of inhibitory relaxant neurons, which contain VIP and NO leading to impaired motility and propulsion.[28,34] Similarly, in studies of small bowel transplants in Lewis rats,[32–34] there is a significant impairment of the intestinal motility, which is the result of two compounding effects: an enhancement of the excitatory component of the peristaltic reflex mediated by tachykinin and a decrease in the relaxation component mediated by VIP. Thus alterations in neuropeptide content in general and VIP in particular may play a role in the changes in gut function after small bowel transplant. Based on the primary role of VIP as a key relaxant transmitter and stimulant of intestinal secretion, a role of VIP in the etiology constipation and diarrhea in several conditions has been postulated. These include inflammatory bowel disease, irritable bowel syndrome, diabetes, and aging-related changes in gut motility. The results have been widely variable depending on species and region of study. For example, VIP levels have been reported to be increased in patients with IBS and decreased in pediatric patients with slow transit constipation. These changes are consistent with the established physiology of VIP as outlined in this chapter and likely point to a key role of VIP in the genesis of motility changes which are symptomatic of many gut pathologies.

Chapter 185

Adrenomedullin Peptides

Johji Kato and Kazuo Kitamura

ABSTRACT

Isolated first from human pheochromocytoma, adrenomedullin (AM) is a 52 amino acid peptide with pleiotropic cardiovascular actions. Sequence analysis of the AM precursor preproAM revealed that proadrenomedullin N-terminal 20 peptide (PAMP) is processed from the N-terminal of proAM. AM belongs to the calcitonin-gene-related peptide (CGRP) superfamily, and the discovery of AM led to the identification of another member of this peptide family, AM2/intermedin. Numerous basic and clinical studies have been carried out to explore the actions or roles of AM and AM-related peptides in the heart and vasculature. As a result, AM has been shown to play an important role in cardiac or vascular tissues as a local modulator through pleiotropic actions mostly protective of the cardiovascular system. Based also on clinical studies, AM is assumed to be beneficial as a diagnostic or prognostic marker or as a therapeutic tool for cardiovascular diseases.

DISCOVERY AND THE PEPTIDE SEQUENCE OF AM AND RELATED PEPTIDES

In 1993, a biologically active peptide was isolated from the acid extract of human pheochromocytoma tissue by monitoring of the elevation of cAMP levels in rat platelets.[13] This bioactive peptide was named "adrenomedullin" because it was found to be abundantly present in the human adrenal medulla and in pheochromocytoma.[13] Human adrenomedullin (AM) consists of 52 amino acids with a ring structure formed by a disulfide bond and an amidated tyrosine at the C-terminal. The amino acid sequence of AM resembles those of calcitonin-gene-related peptide (CGRP) and amylin, belonging to the CGRP superfamily (Fig. 1). Sequence homology among these bioactive peptides is relatively low, but they share two molecular structures: a disulfide bond and an amidated C-terminal, both of which are essential for exerting biological actions.[3,10,12] In 2004, two independent research groups discovered another member peptide of the CGRP superfamily by searching the genomes of humans and other vertebrates.[31,34] The two groups named this 47-amino-acid peptide adrenomedullin-2 (AM2) and intermedin, respectively. As shown in Table 1, AM has a wide range of actions on the cardiovascular system, as described later in this chapter. The biological property of AM2/intermedin has also been examined since this discovery. According to the findings so far reported, the biological effects of this family peptide are mostly similar to those of AM, while some differences in potency or receptor selectivity have been detected, raising the possibility for a receptor or intracellular signaling system differing from those of AM.[5] AM2/intermedin is further discussed in the Renal Peptides section of this book.

STRUCTURE OF THE mRNA/GENE AND PROCESSING OF THE PRECURSOR

Cloning of the cDNA encoding AM reveals that the AM precursor peptide preproAM consists of 185 amino acids, with the C-terminal followed by a pair of basic amino acids, Arg–Arg, a typical processing signal (Fig. 2).[12] In addition to AM, preproAM contains another bioactive peptide, proadrenomedullin N-terminal 20 peptide (PAMP), in the N-terminal portion.[12] PAMP lowers blood pressure when injected intravenously, probably by the inhibition of catecholamine release from the sympathetic nerve endings, but its hypotensive action is weaker than that of AM, and there is little information available as to the role of PAMP in cardiovascular diseases.[12] In sequence analysis of genomic DNA for human preproAM, AM is encoded in the fourth exon and PAMP in the second and third exons (Fig. 2).[12] When processed from preproAM, AM-Gly, an intermediate form (iAM), is produced, and then iAM is converted by the amidation enzyme into the mature form of AM (mAM) having an amide structure at the C-terminal.[14] The mature form of PAMP is believed to be produced by a similar process (Fig. 2).

Various humoral or mechanical factors are involved in regulating the expression of the AM gene. In the 5′-flanking region of the genomic AM gene of humans, there are many consensus sequences of binding sites for transcription factors including NF-κB, ADRE-AR, AP-1, AP-2, C/EBP, Sp1, HIF-1, and NF-IL6.[17] Both the NF-IL6 and AP-2 sites are

TABLE 1 Biological Actions of AM-related to Cardiovascular Functions

Systemic actions	Reduction of blood pressure
	Suppression of oxidative stress
	Anti-inflammation
Blood vessels	Vasodilatation
	Stimulation of nitric oxide (NO) production
	Inhibition of apoptosis of vascular endothelial cells
	Inhibition of proliferation and migration of smooth muscle cells
	Inhibition of adventitial fibrosis
	Angiogenesis and lymphoangiogenesis
Heart	Inhibition of myocardial hypertrophy and fibrosis
	Positive or negative inotropic action
Kidney	Diuresis and natriuresis
	Inhibition of proliferation of mesangial cells
Lung	Pulmonary vasodilatation
	Bronchodilation
Endocrine system	Inhibition of aldosterone production
	Inhibition of ACTH and vasopressin secretion
Brain	Reduction of water and salt intake

essential for promoter activity in human vascular endothelial cells, which actively produce and secrete the AM peptide. The transcriptional factor NF-IL6 plays an important role in mediating inflammation by inducing acute phase proteins. Consistent with this, AM production is augmented by such inflammatory cytokines as interleukin-1 and tumor necrosis factor-α.[10] In cardiac myocytes, heterodimetric binding of α and β subunits of hypoxia-inducible factor-1 (HIF-1) protein to the HIF-1 site is assumed to be a mechanism for augmented AM production under hypoxic conditions.[11] Thus, various transcriptional mechanisms, which may differ depending on species, tissue, or type of cell, seem to be involved in controlling the expression of the AM gene.

DISTRIBUTION OF THE mRNA/PEPTIDE AND AM CIRCULATING IN THE BLOOD STREAM

Although isolated from pheochromocytoma tissue, substantial levels of preproAM gene expression are present in the cardiovascular organs or tissues, including cardiac atria and ventricles, blood vessels, kidneys, and lungs, where the AM peptide has been detected by radioimmunoassay and immunohistochemial methods.[3,10,12] In addition, various types of cultured cells isolated from these cardiovascular tissues express preproAM mRNA and secrete the AM peptide from the cells.[3,10–12] Despite the substantial expression of preproAM mRNA, the AM peptide concentrations in these tissues or cultured cells are relatively low, suggesting constitutive secretion of AM with little intracellular storage.[3,10–12]

Because AM circulates in human plasma at concentrations in the order of femtomoles per milliliter, efforts were made to identify the organ or tissue contributing to the AM peptide in human blood. We measured plasma AM concentrations in the adrenal vein as AM is abundantly detected in the adrenal medulla, but found no step-up compared with that of the inferior vena cava.[9] Moreover, no site in the blood vessels showing higher plasma AM concentrations than others could be detected in patients with ischemic heart disease.[9] Meanwhile, active production and secretion are observed in cultured cells derived from the cardiovascular tissues, such as cardiomyocytes and vascular endothelial cells.[10,11] According to our previous study of patients with ischemic heart disease, significant step-ups are observed in plasma mature AM (mAM) concentrations between the femoral artery and vein and between the aortic root and coronary sinus, suggesting AM secretion from the vasculature

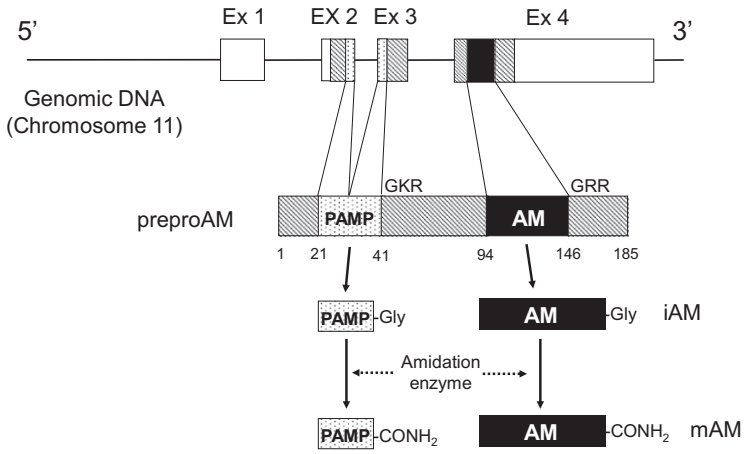

FIGURE 2 The AM gene and processing of AM and PAMP from preproAM. Ex, exon; PAMP, proadrenomedullin N-terminal 20 peptide; iAM and iPAMP, intermediate forms of AM and PAMP; mAM and mPAMP, mature forms of AM and PAMP.

and heart in humans.[10,11] In addition, either adipocytes or adipose tissue are recognized to be significant sources of circulating AM in humans.[9] Thus, various organs or tissues, including cardiovascular tissues, may contribute to plasma AM in humans.

We were able to measure mAM and total AM (mAM plus iAM) concentrations separately, showing the presence of both molecular forms in the plasma and tissues of humans and rats.[14] As mentioned earlier, the amidated C-terminal is essential for the biological action of AM; therefore, iAM itself is inactive. In human plasma, the concentration of mAM is lower than that of iAM; however, according to the *ex vivo* experiment, iAM exerts vasodilator action after conversion to mAM in blood vessels, raising the possibility of iAM serving as a reservoir hormone in plasma or tissues.[10,14] The ratios of mAM to iAM or to total AM concentrations have been examined in healthy volunteers and in patients with cardiovascular diseases, but there is no condition clearly showing a preferential increase of mAM concentrations as compared with that of iAM.

RECEPTOR AND SIGNALING CASCADES

AM was first isolated by the monitoring of an elevation of cAMP in rat platelets,[13] and indeed, an AM-induced increase in intracellular cAMP levels is widely seen in many tissues and cells derived from the cardiovascular system, while there had been controversy over the receptor subtypes of AM. In 1998, McLatchie et al. identified three subtypes of receptor-activity-modifying protein (RAMP1–3), an accessory protein required for the transport of calcitonin-receptor-like receptor (CLR) to the cell membrane.[22] This discovery reveals the receptor system for CGRP and AM: CLR can function as either an AM receptor or a CGRP receptor, depending on the subtype of RAMP expressed. CLR serves as a CGRP receptor when coexpressed with RAMP1, while it functions as an AM type 1 or 2 (AM1 or AM2) receptor when coexpressed with either RAMP2 or 3, respectively.[22] These receptor components are widely expressed in various tissues and organs, including those of the cardiovascular system.[15,22] The CGRP receptor of CLR/RAMP1 heterodimer has a high affinity for CGRP, whereas AM can interact with this receptor at a high concentration of peptide.[15] The AM1 receptor (CLR/RAMP2) is highly specific to AM in humans and rats, but in contrast, AM and AM2/intermedin show similar affinities to the AM2 receptor (CLR/RAMP3).[15]

Both the AM1 and AM2 receptors are linked to the intracellular system of cAMP generation and phosphatidylinositol (PI) hydrolysis, which may activate a PKA- or calcium-dependent pathway, respectively.[15,22] As shown in Table 1, AM has a wide range of cardiovascular effects, which seem to be mediated by different intracellular signaling systems depending on the type of cell or tissue. A study using RAMP2-transgenic mice revealed that the inhibitory effects of AM on vascular hypertrophy and inflammation are mediated by the AM1 receptor, CLR/RAMP2 heterodimer,[18] while there is little information on the role of the AM2 receptor in mediating the cardiovascular protective actions of AM. Interestingly, as discussed later, the generation of gene-manipulated animals reveals that RAMP2 is essential for the angiogenesis action of AM, and RAMP3 is unable to compensate for the role of RAMP2. Meanwhile, there is no report showing distinct intracellular signaling for RAMP2 and RAMP3,[15,22] suggesting an unknown intracellular mechanism mediated by the AM1 receptor.

There are many reports about the intracellular signaling systems for AM in the cardiovascular system, particularly those in the vascular endothelium and ventricular myocardium.[3,10–12,15] Acting on vascular endothelial cells, AM seems to activate phospholipase C, forming inositol

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

1,4,5-triphosphate, which stimulates nitric oxide (NO) production by endothelial NO synthase (eNOS). It is also probable that eNOS is activated by AM via the phosphatidylinositol 3′-kinase (PI3K)/Akt-dependent pathway. Then, generated NO activates soluble guanylate cyclase in vascular smooth muscle cells, leading to increased intracellular cGMP and vasodilatation.[10] In contrast, AM has been shown to induce endothelium-independent vasodilatation via the elevation of intracellular cAMP levels in vascular smooth muscle cells by directly acting on those cells.[10]

AM has direct actions on the heart myocardium.[11] *In vitro* experiments reveal that AM inhibits the hypertrophy of cardiomyocytes and the proliferation and collagen synthesis of cardiac fibroblasts, a finding supported by an *in vivo* study using heterozygotes of AM gene knockout mice.[29] The inhibitory action of AM on proliferation and collagen synthesis in cardiac fibroblasts is mediated by a cAMP-dependent pathway, while the mechanism of action in cardiomyocytes appears to be independent of cAMP and remains to be elucidated.[11] AM also affects contractility of the myocardium. AM induces reduction of the contractility and calcium concentration in rabbit cardiomyocytes, an effect mediated by the NO-cGMP pathway; AM also exerts a cAMP-independent positive inotropic action of AM in rat hearts.[11] Thus, it is probable that the intracellular mechanism by which AM exerts cardiovascular actions differs depending on the species, organ, tissue, and type of cell.

BIOLOGICAL ACTIONS WITHIN THE CARDIOVASCULAR SYSTEM

Cardiovascular Protective Effects

The biological actions of AM involved in cardiovascular functions are listed in Table 1. Not all the effects in this table have been proved to occur at a physiological concentration of AM, although AM exerts a wide range of actions in various organs and tissues, which are mostly protective of the cardiovascular system.[3,10,12] To investigate whether AM exerts cardiovascular actions *in vivo*, three experimental approaches have so far been adopted: long-term administration of AM, virally mediated overexpression of AM, and genetic manipulation of the AM gene.

Using the first method, Nishikimi and colleagues showed that in Dahl-salt-sensitive hypertensive rats fed a high-salt diet, AM has a minimal effect on blood pressure, but significantly inhibits left ventricular hypertrophy (LVH) and the transition from LVH to heart failure.[9,28] Long-term infusion of AM also lessens pulmonary congestion and the deterioration of left ventricular (LV) function, improving the survival of this animal model of hypertension and heart failure. The inhibitory effect of AM on LVH without a significant reduction of blood pressure suggests a possibly direct action on cardiac myocytes. Either preload or afterload on the heart results not only in LVH but also in cardiac fibrosis, where excessive fibroblast proliferation and collagen deposition occur, leading to impairment of diastolic dysfunction. To test the antifibrotic action of AM, we infused recombinant human AM into a rat model of acute myocardial infarction (MI), showing the reduction of myocardial collagen deposition after MI.[9] In addition, long-term administration of AM reduces perivascular fibrosis of the coronary arteries in rats with hypertension induced by chronic infusion of angiotensin II.[10] This effect is accompanied by the suppression of fibroblast activation and transforming growth factor-β1 expression, but not by a significant reduction of blood pressure, suggesting an AM action independent of hemodynamic factors. Renoprotective effects of AM have also been implied by *in vitro* experiments. Long-term infusion of AM reduces glomerular and arterio-arteriolar scleroses in Dahl-salt-sensitive rats given a high-salt diet and in spontaneously hypertensive rats (SHR) administered deoxycorticosterone acetate (DOCA) and salt.[9,27] As a result, urinary protein excretion is reduced and creatinine clearance preserved by AM infusion. These renoprotective effects occur without a significant reduction of blood pressure, suggesting direct actions of AM on the kidneys. Increased urinary excretion of cAMP and cGMP suggests roles for these cyclic nucleotides in mediating the actions of AM, but the detailed mechanisms involved remain to be specified. Regardless of the mechanisms, the plasma concentrations of exogenous AM lie within the physiological range in the above-mentioned long-term infusion studies, where 0.2–1.0 μg/h AM was used.[9] It is therefore possible that endogenous AM functions to inhibit cardiac and renal damage in rat models of cardiovascular and renal diseases.

Chao et al. showed that adenovirus-mediated systemic delivery of the human AM gene ameliorated cardiac and renal damage in rats with DOCA salt-induced and 2 kidney–1clip renovascular hypertension and in Dahl-salt-sensitive hypertensive rats fed a high-salt diet.[2] Similar to the results of long-term infusion experiments, the overexpression of AM lessened cardiac hypertrophy and fibrosis and glomerular sclerosis, improving urinary protein excretion and creatinine clearance. Urinary excretion of cAMP is increased by overexpression, whereas systolic blood pressure is reduced by about 20–30 mmHg; therefore, blood pressure-dependent mechanisms may have contributed to the beneficial effects of AM. In addition to systemic overexpression of the AM gene, the same group reported that the local delivery of AM to balloon-injured carotid artery inhibits neointimal formation in rats.[2] Leskinen et al.[16] showed that adenovirus-mediated AM gene delivery elevates AM

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

mRNA expression by 20.9-fold, attenuating angiotensin II-induced LVH. Meanwhile, they observed deteriorated LV function by the overexpression of AM, dilating the left ventricle and thinning the anterior wall in rats with myocardial infarction, raising the possibility that protective effects depend on the level of overexpressed AM or the time of delivering the gene in myocardial infarction.

Third, cardiovascular and renal protective effects have been suggested by genetic manipulation of the AM gene in mice. Shimosawa et al. showed that, when given angiotensin II and excessive salt, heterozygotes of AM knockout mice (AM+/−) show more severe perivascular fibrosis and intimal thickening of coronary arteries than do their wild-type littermates, despite a similar elevation of blood pressure between knockout and wild-type mice.[32] Based on increases in the production of reactive oxygen species (ROS) and in NAD(P)H oxidase expression in AM knockout mice, the possibility of augmented oxidative stress was raised as the mechanism responsible for the severe vascular lesions. Periarterial cuff-induced intimal thickening of the femoral artery is also more severe in knockout mice compared with that in control mice.[10,32] Enhanced neointimal formation is reversed by delivery of the AM gene and by an NAD(P)H oxidase inhibitor or tempol, a superoxide dismutase mimetic, further suggesting an inhibitory action of endogenous AM on oxidative stress. Niu et al. subjected heterozygotes of another strain of AM gene knockout mice to the cardiovascular stress of aortic constriction or angiotensin II infusion, resulting in LVH and perivascular fibrosis, changes that were more pronounced in knockout mice than in controls.[29] In addition, renal damage characterized by reduced creatinine clearance and glomerular sclerosis is worse in knockout mice than in controls. Caron et al. showed exacerbates LVH and renal damage in male mice with one copy of the AM gene, where AM mRNA is reduced by 50% in kidneys, but not in females with the same transgene, raising the possibility of a gender difference in AM effects.[1]

Effects on Pulmonary Vascular Bed

AM exerts a protective action on the pulmonary vascular bed.[24] In addition to the pulmonary vasodilator effect, prolonged subcutaneous infusion of AM inhibits medial thickening of the pulmonary artery of rats with pulmonary hypertension induced by monocrotaline; however, when infused intravenously, AM lowers not only pulmonary artery pressure but also systemic blood pressure. In an attempt to avoid an effect on the systemic circulation, Nagaya et al. administered AM as an aerosol with an ultrasonic nebulizer in rats with pulmonary hypertension.[24] Repeated inhalation effectively inhibits medial thickening of pulmonary arteries, reducing pulmonary artery pressure and total pulmonary resistance, without affecting systemic arterial pressure or the heart rate. Further, the same group reported that in patients with idiopathic pulmonary arterial hypertension, inhalation of AM lowers pulmonary artery pressure and resistance, improving exercise tolerance. Although the long-term outcomes of these beneficial actions need to be examined, this approach seems promising for the use of AM in the treatment of primary pulmonary hypertension, for which few effective medical treatments are currently available.

Angiogenesis Effects

A cardiovascular action recently described not only for AM but also PAMP is angiogenesis or lymphoangiogenesis.[21,25] In a mouse model of hind-limb ischemia, heterozygotes of AM knockout mice (AM+/−) showed impaired blood flow recovery with less collateral capillary development as compared with that of their wild-type littermates.[6] According to recent reports of gene manipulation, the AM-CRL/RAMP2 signaling system is essential for lymphatic vascular development: homozygotes of AM-, CRL-, or RAMP2-knockout mice (AM−/−, CRL−/−, RAMP2−/−) are all embryo lethal because of impaired lymphoangiogenesis.[4] Similar to AM, AM2/intermedin has angiogenesis action, an effect assumed to be mediated by the Akt- and NO-dependent pathway.[33] The next question is why the AM2/intermedin system is unable to compensate for deletion of the AM gene, and this important issue needs to be addressed in future research. In contrast to the loss of function experiments for angiogenesis, overexpression of the AM gene is beneficial in animal models of ischemic cardiovascular diseases, enhancing the angiogenesis action. For example, in a mouse model of chronic cerebral hypoperfusion, overexpression of AM results in faster cerebral perfusion recovery, lessening the decline of cognitive function.[20] These findings suggest that augmentation of the actions of AM is a therapeutic strategy for ischemic cardiovascular or cerebrovascular diseases.

Angiogenesis is also an important process for the growth of solid tumors. Several reports show the expression of AM receptor components of CLR and RAMPs and production of the AM peptide in various tissues and cells including vascular endothelium and tumor cells. Martinez et al. carried out a series of experiments in which PAMP promotes angiogenesis even more potently than AM, increasing migration and cord formation of human microvascular endothelial cells.[21] In addition, they showed that PAMP(12–20), a PAMP antagonist, inhibits tumor growth by a xenograft model. The intracellular signaling system for angiogenesis actions of PAMP remains to be clarified, although those of AM seem to be mediated by the PI3K/Akt cascade.[6] It is possible that, in contrast to ischemic cardiovascular diseases, blocking the actions of AM or PAMP

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

can be a therapeutic strategy to suppress the progression of malignant tumor.[6,21]

PATHOPHYSIOLOGICAL IMPLICATIONS

Tissue Expressions of AM and Receptors

The AM peptide is present at substantial levels in the cardiovascular or renal tissues, where the AM receptor components CLR and RAMPs are expressed.[3,10,12,15,22] Cultured cells isolated from those tissues actively secrete AM. Based on these findings, AM is assumed to function as a local regulator or modulator acting in an autocrine or paracrine manner in cardiovascular or renal tissues. To investigate the pathophysiological roles of AM, the tissue concentrations and gene expressions of AM have been examined in human patients or animal models of cardiovascular diseases.[9,28] In heart tissues, the results of these studies share a common finding of changes in the AM and its receptor system: the expression levels of mRNA for preproAM, CLR, RAMP2, or RAM3 are upregulated in the cardiac ventricles of a hypertrophied or failing heart of hypertension, heart failure, or myocardial infarction.[9,15,28] In addition to the heart, AM levels were shown to increase in atherosclerotic coronary plaques of unstable angina pectoris or renal medulla of rats with severe hypertension.[10,27] Taking the cardiovascular or renal protective effects of AM into consideration, these results suggest the roles of endogenous AM and its effecter system in acting against deterioration of the heart or renal diseases.

The mechanisms for augmented AM production in the cardiovascular tissues are not totally understood, but we can discuss this important issue based on the findings from cell culture studies.[10,11] According to our previous studies, AM production in cultured cardiomyocytes and cardiac fibroblasts is increased by the pressor peptides angiotensin II and endothelin-1 or simply by mechanical stretching of the cells.[11] The production of AM in cultured cardiomyocytes is also increased by hydrogen peroxide (H_2O_2), suggesting the involvement of oxidative stress. The production of AM by cultured mesangial cells and vascular smooth muscle cells is increased in response to such humoral factors or cytokines as angiotensin II, aldosterone, interleukin-1β, and tumor necrosis factor-α.[9,10] In vascular endothelial cells, AM production is modulated by glucocorticoid or the alteration of shear stress.[10] Thus, a number of factors seem to be involved in augmented AM production in cardiovascular and renal diseases.

Plasma AM Level as a Diagnostic Marker

To clarify the roles of AM in humans, plasma levels of the peptide have been measured in various cardiovascular diseases, such as hypertension, heart failure, acute MI, and peripheral vascular diseases.[3,9,10,12] There may be some differences in the mechanisms by which plasma AM levels were elevated, depending on the diseases, although a consistent finding is that the more severe the cardiovascular disease is, the higher the level of plasma AM.[3,9,10,12] For example, in patients with chronic heart failure, the plasma level of AM is elevated progressively in proportion to the severity of the New York Heart Association (NYHA) functional class.[3,9] In addition, plasma AM is closely correlated with other parameters indicative of disease severity, including LV ejection fraction and LV end-diastolic pressure. It is intriguing to see whether elevated AM is reduced by successful treatment for the above-mentioned cardiovascular diseases. Plasma AM levels in patients with essential hypertension remained unchanged after short- or long-term antihypertensive treatment, and instead, these levels are closely correlated with target organ damage.[9] Meanwhile, in patients with malignant hypertension or acute heart failure, the elevated concentrations of plasma AM are reduced after successful treatment. To see whether increased plasma AM precedes elevation of blood pressure, we conducted a prospective, cohort study with normotensive local residents.[8] As shown in Fig. 3, the rate of the future development of hypertension in normotensive residents with plasma AM concentrations above the median value is higher than in those with lower levels. Both atrial and brain natriuretic peptides (ANP and BNP) are endogenous, blood pressure-lowering hormones, but unlike AM, no such difference was noted between high and low ANP or BNP groups.

Many prospective studies have shown diagnostic or prognostic values of measuring plasma levels of AM or AM-related peptides in patients with cardiovascular diseases. According to the report by Richards and coworkers, the plasma AM level has a greater power in predicting the mortality and hospitalization of patients with chronic ischemic LV dysfunction than does LV ejection fraction.[30] In this study, carvedilol, a beta-adrenergic blocker, reduced mortality in patients with higher AM than the median value but not in those with lower AM. Plasma AM levels may predict LV reverse remodeling after cardiac resynchronization therapy (CRT): patients with higher plasma AM show an improvement of the NYHA functional class after CRT, but those with lower AM do not.[23] In a cohort of high-risk patients with multiple risk factors without heart failure, AM has superior power in predicting future cardiovascular events compared with C-reactive protein or adiponectin.[26] Midregional proAM (MR-proAM), a stable fragment peptide derived from the N-terminal portion of the proAM peptide, has been examined for diagnostic or predictive values in patients with heart failure or acute MI. Similar to AM, plasma MR-proAM levels are increased in relation to the severity of heart failure, providing prognostic information about the patients.[35] According to the Biomarkers in Acute Heart Failure (BACH) study, MR-proAM, like BNP, is useful in diagnosing acute

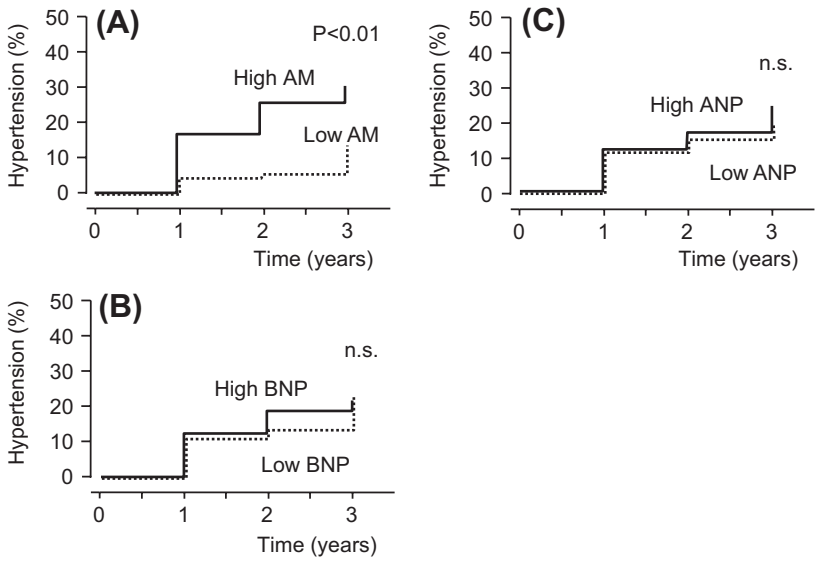

FIGURE 3 Development of hypertension in groups with high and low plasma levels of AM (A), ANP (B) and BNP (C) during a 3-year follow-up period. Data were analyzed by the Kaplan–Meier method and log-rank test. n.s., Not significant. Reprinted from Ref. 8.

heart failure in patients with acute dyspnea, providing a prognostic value to predict the 90-day survival of those patients.[19] Thus, MR-proAM, as well as AM itself, seems to be a useful biomarker of diagnostic or prognostic values for patients with cardiovascular diseases, particularly for those with heart failure.

AM as a Possible Therapeutic Tool

Lastly, we discuss the AM effects in healthy volunteers and patients with cardiovascular diseases based on the results of clinical studies performed to verify the cardiovascular protective effects of AM. Intravenous infusion of AM decreases blood pressure, total peripheral resistance, and pulmonary arterial and capillary wedge pressure, whereas it increases heart rate, cardiac index, urinary volume, and sodium excretion in patients with heart failure as well as in healthy volunteers.[3,10,12] Although plasma renin activity is elevated, possibly by sympathetic nerve activation resulting from the reduction of blood pressure, plasma aldosterone levels are reduced or remain unchanged. These hemodynamic or hormonal responses, which should be preferable for heart failure patients, are consistent with those observed in animal studies and cell culture experiments. Kataoka et al. performed a clinical study of patients with acute MI, in which reduction of infarct size and improvement of cardiac contractility occurred after intravenous infusion of AM after reperfusion therapy.[7] Additionally, as described earlier, in patients with idiopathic pulmonary hypertension, inhalation of aerosolized AM lowers pulmonary arterial pressure and pulmonary vascular resistance, improving exercise capacity.[24] Taken together, it is possible that AM can exert beneficial effects as a therapeutic agent for patients with cardiovascular diseases including heat failure, acute MI, and idiopathic pulmonary hypertension.

Chapter 186

Angiotensin II Peptides

Yasukatsu Izumi and Hiroshi Iwao

ABSTRACT

Much evidence supports the notion that angiotensin II (Ang II), the central product of the renin–angiotensin system (RAS), may play a central role not only in the etiology of hypertension but also in the pathophysiology of cardiovascular diseases in humans. Ang II, via the Ang II type 1 receptor, directly causes cellular phenotypic changes and cell growth, regulates the gene expression of various bioactive substances, and activates multiple intracellular signaling cascades in cardiac myocytes and fibroblasts, as well as vascular endothelial and smooth muscle cells. Recently, new factors have been discovered, such as angiotensin-converting enzyme 2, angiotensin-(1-7), and its receptor Mas. This section summarizes the current knowledge about the broad RAS in the pathophysiology of cardiac hypertrophy and remodeling, heart failure, vascular thickening, and atherosclerosis.

DISCOVERY

Research on the renin–angiotensin system (RAS) began with the discovery of renin from the kidney by Tiegerstedt and Bergman in 1898. In 1940, a peptide that had vasoconstrictive effects in the RAS was discovered, and it was named *hypertensin* by Braun-Menendez in Argentina, and *angionin* by Page and Helmer in the United States. These two terms persisted for about 20 years, until it was agreed to rename the pressor substance *angiotensin*. In the 1950s, two forms of angiotensin were recognized, the first a decapeptide (angiotensin I: Ang I) and the second an octapeptide (angiotensin II: Ang II). Skeggs et al. in the United States reported that Ang II was formed by the enzymatic cleavage of Ang I by another enzyme, termed *angiotensin-converting enzyme* (ACE). Schwyzer and Bumpus succeeded in the synthesis of Ang II in 1957. Gross suggested, in 1958, that the RAS was involved in the regulation of aldosterone secretion, and then Davis, Genet, Laragh et al. proved his hypothesis.

In the early 1970s, polypeptides either inhibiting the formation of Ang II or blocking Ang II receptors were discovered, but these were not orally active. Cushman and Ondetti succeeded in the development of captopril, the orally active ACE inhibitor in 1977. After that, many experimental and clinical studies with ACE inhibitors uncovered additional roles for the RAS in the pathophysiology of hypertension, heart failure, and vascular diseases. Furthermore, losartan (Dup 753), an orally active, highly selective and potent nonpeptide Ang II receptor blocker (ARB), was developed in 1988, and the cloning of Ang II receptors, type 1 (AT_1R) and type 2 (AT_2R) was accomplished in the early 1990s.

Angiotensin-(1-7) [Ang-(1-7)] was discovered in 1988 by Santos et al., and angiotensin-converting enzyme 2 (ACE2) was identified in 2000, which catalyzes the conversion of Ang I [Ang-(1-10)] to Ang-(1-9) by the removal of a single carboxy-terminal amino acid. ACE2 is an essential regulator of heart function and a functional receptor for the SARS coronavirus.

STRUCTURE OF THE PEPTIDES AND COMPONENT OF RAS

The RAS plays an important role in the regulation of arterial blood pressure. Renin is an enzyme that acts on angiotensinogen to catalyze the formation of Ang I. Ang I is then cleaved by ACE to yield Ang II. A representation of the biochemical pathways of RAS is shown in Fig. 1.

The major element of the rate of Ang II production is the amount of renin released by the kidney. Renin is synthesized, stored, and secreted into the renal arterial circulation by the granular juxtaglomerular cells. The secretion of renin is controlled predominantly by three pathways: The first mechanism controlling renin release is the intrarenal macula densa pathway and the second is the intrarenal baroreceptor pathway. The third mechanism is the β-adrenergic receptor pathway, which is mediated by the release of norepinephrine from postganglionic sympathetic nerve terminals. An increase in renin secretion enhances the formation of Ang II, and Ang II stimulates the AT_1R on juxtaglomerular cells to inhibit renin release.

The substrate for renin is angiotensinogen, an abundant α_2-globulin that circulates in the plasma. The primary

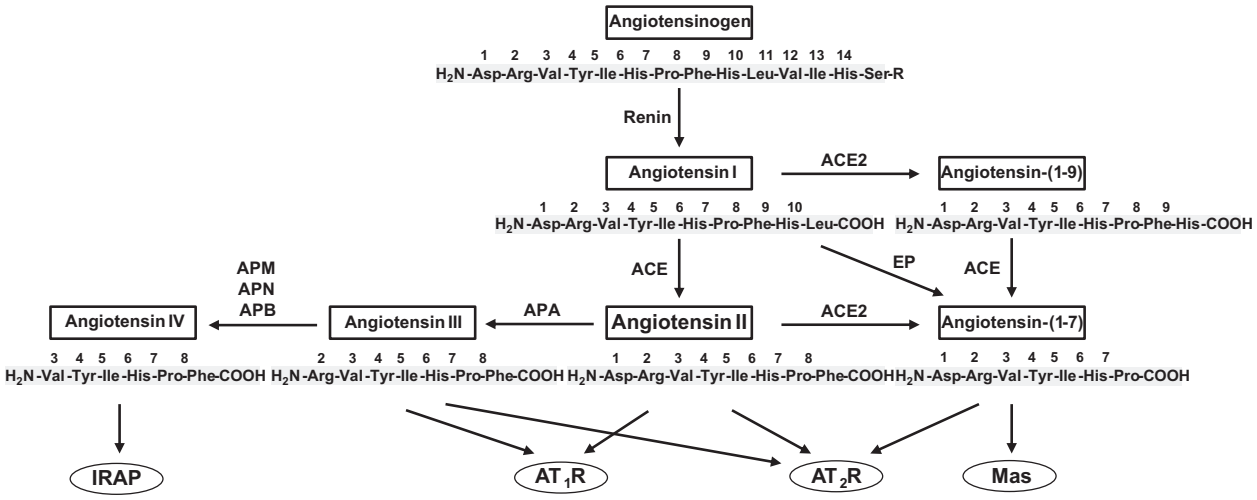

FIGURE 1 Formation of RAS peptides. ACE, angiotensin-converting enzyme; EP, endopeptidase; APA, B, M, N; aminopeptidase A, B, M, N; IRAP, insulin-regulated aminopeptidases.

structure of angiotensinogen has been deduced by molecular cloning. Angiotensinogen is synthesized primarily in the liver, although mRNA that encodes the protein is abundant in fat, certain regions of the central nervous system, and the kidney. The rate of Ang II synthesis can be influenced by changes in angiotensinogen levels.

ACE was discovered in plasma as the factor responsible for conversion of Ang I to Ang II. The ACE gene contains, in intron 16, an insertion/deletion polymorphism that explains 47% of the phenotypic variance in serum ACE levels. Individuals homozygous for the deletion allele have higher levels of serum ACE.

Ang I is rapidly converted to Ang II, when given intravenously. Ang III [Ang-(2-8)] can be formed by the action of aminopeptidase on Ang II. Ang III Ang II cause qualitatively similar effects. Ang III is approximately as potent as Ang II in stimulating the secretion of aldosterone. However, Ang III is only 25% as potent as Ang II in elevating blood pressure. Ang IV [Ang-(3-8)] is generated by the sequential cleavage of two amino acid residues from the amino terminus of Ang II by aminopeptidases localized to the endothelial surface.

There are bypass pathways in the RAS to produce Ang II besides the main enzymes such as renin and ACE. Arakawa et al. showed that trypsin and kallikrein can produce Ang II. One of the most famous enzymes in such bypass pathways is a heart chymase that is secreted by mast cells.

DISTRIBUTION OF RAS, PROCESSING, AND ENDOGENOUS FORM IN THE CARDIOVASCULAR SYSTEM

Circulating renin of renal origin acts on circulating angiotensinogen of hepatic origin to produce Ang I in the plasma, and circulating Ang I is converted by plasma ACE and pulmonary endothelial ACE to Ang II. Then, Ang II is delivered to its target organs via blood flow. This traditional pathway is called the circulating RAS. However, heart, blood vessels, and several other tissues contain and/or synthesize components of the RAS, called the tissue (local) RAS.

Many tissues, including heart, blood vessels, brain, kidney, and adrenal gland, express mRNAs for renin, angiotensinogen, and/or ACE. Furthermore, several other Ang I cleavage products have been found in the cultured cell types from these tissues, for example, Ang-(1-9), Ang-(1-7), Ang III, and Ang IV (Fig. 1). Ang I and Ang II have been localized in atria and ventricles. Therefore, it seems that the tissue RAS exists independently of the renal/hepatic-based system.

Several serine proteases, such as tonin and cathepsin G, have been shown to hydrolyze Ang II precursors. An aspartyl protease with cathepsin D-like properties was shown to convert angiotensinogen to Ang I. Conversion of Ang I to Ang II in human and dog cardiac ventricles may occur by heart chymase. Unlike ACE, human heart chymase shows high specificity for Ang I and does not degrade bradykinin or vasoactive intestinal peptide. It is likely that the relative contribution of ACE and chymase to cardiac Ang II formation varies with the cardiac chamber in the human heart, because ACE levels are the highest in the atria and chymase levels are the highest in ventricles. It is recently believed that chymase plays a crucial role in various tissues because chymase can not only produce Ang II but also convert precursors of transforming growth factor (TGF)-β and matrix metalloproteinase-9 to their active forms, whose increases damage various organs.[30]

RECEPTORS AND THEIR DISTRIBUTION IN THE CARDIOVASCULAR SYSTEM

The effects of angiotensins are exerted through specific cell surface receptors. There are two subtypes of Ang II receptors, types 1 and 2 (AT_1R and AT_2R). The successful

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

cloning of the AT_1R in 1991 and the AT_2R in 1993 allowed the development of further research on the structure and function of this receptor.

The AT_1R consists of two subtypes, $AT_{1a}R$ and $AT_{1b}R$, which have 94% homology with regard to amino acid sequence and have similar pharmacological properties and tissue distribution patterns. The AT_1R is a member of the seven-transmembrane-spanning, G protein-coupled receptor (GPCR) family; it binds to heterotrimeric G proteins and lacks intrinsic tyrosine kinase activity. The human AT_1R gene is mapped to chromosome 3, and the $AT_{1a}R$ and $AT_{1b}R$ genes in rats are mapped to chromosomes 17 and 2, respectively. The AT_1R is ubiquitously and abundantly distributed in adult tissues, including blood vessel, heart, kidney, adrenal gland, liver, brain, and the lung. The AT_1R mediates all the classic well-known effects of Ang II, such as elevation of blood pressure, vasoconstriction, increase in cardiac contractility, aldosterone release from the adrenal gland, facilitation of catecholamine release from nerve endings, and renal sodium and water absorption. Therefore, the AT_1R has a role in atherosclerosis, congestive cardiac failure, and several acute and chronic inflammatory diseases, conditions in which inflammation is known to play a significant role (Fig. 2). Numerous selective and potent nonpeptide AT_1R antagonists, such as losartan, candesartan, valsartan, irbesartan, eprosartan, telmisartan, tasosartan, have been developed.

In contrast, the AT_2R has high affinity for PD123177, PD123319, CGP42112, L-162,686, L-162,638, and CGP42112A. The cDNA and genomic DNAs of human, rat, and mouse AT_2Rs have been cloned. The AT_2R is mainly expressed in developing fetal tissues, and it is believed to have an essential role in physiological vascular development. The AT_2R expression rapidly decreases after birth,[19] and, in the adult, expression of this receptor is limited mainly to the uterus, ovary, certain brain nuclei, heart, and adrenal medulla. Unlike the AT_1R, which has been shown to have subtypes in rats and mice, there is no evidence for subtypes of the AT_2R. Although a comparison of amino acid sequences of $AT_{1a}R$ and AT_2R in rats, deduced from nucleotide sequences, shows a low homology between these receptors (32%), The AT_2R is also a seven-transmembrane domain receptor. In various cell lines, the AT_2R-activated protein tyrosine phosphatase was shown to inhibit cell growth or induce programmed cell death (apoptosis). The AT_2R inhibited AT_1R-mediated cell growth, demonstrating an antagonistic action. It is believed that the expression balance of AT_1 and the AT_2 is important for cardiovascular diseases.[8] There have also been conflicting findings regarding these receptors. For example, it is controversial whether cardiac hypertrophy is promoted by the AT_2R. However, the AT_2R plays a cardioprotective role on left ventricular function after myocardial infarction. In contrast to extensive data on the molecular and cellular functions and pathophysiological significance of the AT_1R, the role of the AT_2R in cardiovascular diseases remains to be defined. At present, the implications of overstimulation of AT_2R by long-term use of ARB are being investigated in clinical trials.[15]

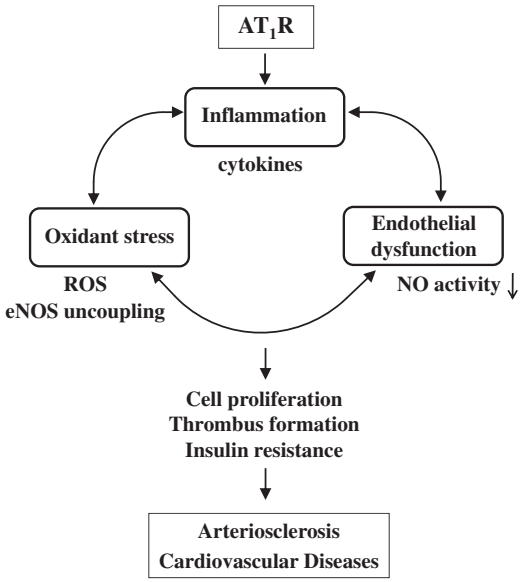

FIGURE 2 Proposed mechanism of the Ang II-mediated pathological cardiac hypertrophy. ROS, reactive oxygen species; eNOS, endothelial nitric oxide synthase.

It has been suggested that Ang-(1-7) mediates its effects by interacting with the GPCR Mas, a prototypic seven-transmembrane domain receptor, which is predominantly expressed not only in the brain and testis but is also found in the kidney, heart, and blood vessels.

The Ang AT_4 receptor was originally defined as the specific, high-affinity binding site for Ang IV. Therefore, it was suspected to be classically a GPCR. And then, Albiston et al. have identified it as the transmembrane enzyme, insulin-regulated aminopeptidase (IRAP),[3] an abundant protein that is found in specialized vesicles containing the insulin-sensitive glucose transporter GLUT4.

BIOLOGICAL ACTIONS AND PATHOPHYSIOLOGICAL IMPLICATION IN THE CARDIOVASCULAR SYSTEM

Molecular Characteristics of Pathological Cardiac Hypertrophy

Generally, pathological left ventricular hypertrophy is characterized not only by an increase in myocyte size (quantitative change) but also by myocyte gene reprogramming (qualitative change), as shown by enhanced expression of fetal phenotypes of genes such as β-myosin heavy chain (β-MHC), skeletal α-actin, and atrial natriuretic peptide (ANP). In the cardiac ventricle of most mammalian species, MHC consists of two isoforms, α- and β-MHCs.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

In the rat, α-MHC is the predominant isoform in adult hearts, whereas β-MHC is the predominant isoform in fetal hearts. Therefore, changes in the ratio of β-MHC to α-MHC in the cardiac ventricle significantly alter the contractile properties of the heart. Cardiac sarcomeric actin is also composed of two isoforms: cardiac α-actin and skeletal α-actin. Cardiac α-actin is predominantly expressed in adult rat hearts, whereas skeletal α-actin is normally expressed in fetal and neonatal rat hearts. The ratio of skeletal α-actin to cardiac α-actin in the ventricle plays a significant role in cardiac function, because skeletal α-actin has greater contractility than cardiac α-actin. Furthermore, in addition to showing enhanced expression of β-MHC and skeletal α-actin, hypertrophic ventricular myocytes are also characterized by significant upregulation of ANP, which is scarcely expressed in normal adult ventricular myocytes.

Another important property of pathological cardiac hypertrophy is increased accumulation of extracellular matrix (ECM) proteins such as collagen (particularly collagen types I and III) and fibronectin in the interstitium and around blood vessels within the heart. These changes play a central role in ventricular fibrosis or remodeling.[21,34] Increased interstitial collagen deposition in the heart enhances cardiac stiffness and results in diastolic dysfunction. Fibronectin is localized on the surface of cardiac myocytes, connects cardiac myocytes to perimyocytic collagen and is believed to affect cardiac systolic and diastolic functions. Thus, increased ECM accumulation, and the abovementioned ventricular myocyte gene reprogramming play critical roles in the impairment of cardiac performance and pathophysiology of cardiac failure. ECM proteins within the heart are predominantly produced by fibroblasts. Unlike cardiac myocytes, cardiac fibroblasts proliferate and increase the production of ECM proteins when the heart is exposed to hypertrophic stimuli such as hemodynamic overload. Thus, cardiac fibroblasts and cardiac myocytes play key roles in the development of pathological cardiac hypertrophy and dysfunction. Accumulating *in vitro* and *in vivo* evidence supports the concept that Ang II is involved in all these important processes of pathological cardiac hypertrophy, including myocyte hypertrophy, myocyte gene reprogramming, fibroblast proliferation, and ECM protein accumulation.

Effect of AT_1R on Cardiac Remodeling (Fig. 2)

Activated AT_1R can activate multiple signaling pathways. The acute vasoconstrictor function of Ang II is primarily mediated through AT_1R by classical G protein-dependent signaling mechanisms. Investigations of the effects of Ang II on cardiac intracellular signaling cascades are essential to elucidate the molecular mechanism underlying Ang II-induced pathological cardiac hypertrophy. Accumulating *in vitro* evidence on cultured cardiac myocytes or fibroblasts suggests that mitogen-activated protein (MAP) kinases, including extracellular signal-regulated kinase (ERK), c-jun amino terminal kinase (JNK) and p38MAP kinase (p38MAPK), may be responsible for myocyte hypertrophy and gene reprogramming or fibroblast proliferation. Ang II-induced cardiac activation of JNK occurs in a more sensitive manner than that of ERK.

The ERK cascade activates platelet-derived growth factor (PDGF), epidermal growth factor receptor (EGFR), insulin receptor pathways, and nonreceptor tyrosine kinases belonging to the c-Src family, prolinerich tyrosine kinase 2, focal adhesion kinase, and janus kinases (JAKs).[18] Besides the G protein-dependent effects of Ang II activated AT_1R, the activated AT_1R can also stimulate G protein-independent signal transduction mechanisms by directly associating with signaling molecules, such as β-arrestins, JAK, Cdc42, and Src.[10]

JNK activation by Ang II without ERK activation is followed by activation of activator protein-1 (AP-1). Importantly, AP-1 regulates the expression of various genes by binding the AP-1 consensus sequence present in their promoter regions. Interestingly, fetal phenotypes of cardiac genes such as skeletal α-actin and ANP, and cardiac fibrosis-associated genes such as TGF-β1 and collagen type I, have AP-1 responsive sequences in their promoter regions. Indeed, AP-1 activation has been demonstrated to lead to increased promoter activity of skeletal α-actin and TGF-β1. Therefore, it is intriguing to postulate that JNK activation, in part through the activation of AP-1, may be implicated in Ang II-induced cardiac hypertrophic response *in vivo*. An *in vivo* study showed that apoptosis signal-regulating kinase 1 (ASK1), one of the MAP kinase kinase kinases, plays an important role in Ang II-induced cardiac hypertrophy and remodeling, including cardiomyocyte hypertrophy, cardiac hypertrophy-related mRNA upregulation, cardiomyocyte apoptosis, interstitial fibrosis, coronary arterial remodeling, and collagen gene upregulation.[11]

The RAS, TGF-β, and β-adrenergic system network mediates this myocardial remodeling. TGF-β1 mRNA and protein expression is augmented in cardiomyocytes and cardiac fibroblasts, which in these situations transdifferentiate to myofibroblast phenotype, following progressive diastolic dysfunction. Ang II caused a significant increase in TGF-β1 mRNA. Chronic administration of Ang II-induced TGF-β1 protein expression in myocardium.[14] Ang II-induced hypertrophic growth of cardiomyocytes is mediated by TGF-β1, which is downstream to Ang II in network.[26] Mice expressing constitutively hyperactive TGF-β1 had a chronic hypertrophy, fibrosis, and cardiac dysfunction that was resistant to the ARB telmisartan but blocked by TGF-β antagonist.[24] The Ang II-mediated cardiac remodeling mechanism is thus dependent on TGF-β1. From all the studies performed so far, it is clear that Ang II/TGF-β1 induced autocrine–paracrine cellular responses in cardiac fibroblasts, in the myocardial

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

interstitium, and cardiomyocytes cause cardiac hypertrophy. Ang II-induced TGF-β1 signaling also induces translocation of Smad proteins into the nucleus to drive transcription of fibrotic marker proteins such as collagen, fibronectin, and connective tissue growth factor (CTGF).[17] CTGF is a profibrotic factor that stimulates TGF-β1 responses mediating fibrosis and apoptosis.[22] The inflammatory cytokines such as interleukin-8, interleukin-6, vascular cell adhesion molecule-1, and monocyte chemoattractant protein-1, are believed to have important roles in the coupling acute ischemic episodes and chronic myocardial remodeling with chronic angiotensin receptor stimulation.[9]

Ang II facilitates the release of norepinephrine from cardiac sympathetic nerve terminals. In Ang II-infused rats, surgical cardiac sympathectomy or treatment with β_1-adrenergic receptor blocker significantly prevented cardiac myocyte necrosis, showing that Ang II-induced cardiac damage is, at least in part, mediated by catecholamine release from cardiac sympathetic neurons. Thus, the activation of cardiac sympathetic neurons by Ang II also contributes to pathological cardiac hypertrophy.

Ang II, via the AT_1R, is also known to be a potent mediator of oxidative stress and reactive oxygen species (ROS)-mediated signaling. A large body of evidence indicates that ROS plays a major part in the initiation and progression of cardiovascular dysfunctions associated with diseases such as hyperlipidemia, diabetes mellitus, hypertension, ischemic heart disease, and chronic heart failure.[32] In addition, Ang II signaling activates membrane NAD(P)H oxidases in VSMCs to produce ROS, which mediate the pleiotrophic effects of Ang II.[28] Ang II signaling mediated activation of NAD(P)H oxidases involves the upstream mediators Src/EGFR/PI3K/Rac-1 and PLD/PKC/p47phox phosphorylation.[28,33] Transcription factors such as nuclear factor-κB, AP-1, and Nrf2 that are implicated in the pathogenesis of atherosclerosis are activated by ROS.[20] ROS may cause vessel inflammation by inducing the release of cytokines and causing an increase in the expression of the leukocyte adhesion molecules in the cell membranes. This may increase recruitment of monocytes to the area of endothelial damage. Thus, activated AT_1R-induced ROS production can lead to changes in structural and functional properties of the vasculature and is the central aspect of vascular pathobiology in hypertension, diabetes, and cardiovascular diseases.[7]

Effect of AT_1R on Vascular Remodeling

Numerous *in vivo* experiments have shown that Ang II can induce VSMC proliferation *in vivo*.[13] Ang II infusion increased mesenteric vascular media width, media cross-sectional area, and media/lumen ratio. Despite detailed investigations into the molecular mechanism of Ang II-mediated VSMC growth *in vitro*, this process is poorly understood. Ang II infusion, at least in part independent of its blood pressure-elevating effect, increased aortic mRNA and protein expression of fibronectin, which is an ECM protein that induces phenotypic change of VSMCs from a contractile to a synthetic phenotype. Basic fibroblast growth factor (bFGF) may play a key role in Ang II-mediated VSMC replication *in vivo*, as shown by the observation that the injection of anti-bFGF antibody significantly inhibited the mitogenic effect of Ang II infusion on rat carotid arteries. Ang II infusion in rats doubled superoxide production in rat aorta by activation of NAD(P)H oxidase. On the other hand, norepinephrine infusion did not increase vascular superoxide production, despite a hypertensive effect comparable to that of Ang II, suggesting that VSMC growth due to Ang II may be specifically mediated by increased superoxide generation. Ang II infusion in rats increased heme oxygenase-1 (HO-1) mRNA and protein in the endothelium.[16] Because HO-1 is an oxidant-sensitive gene, it is possible that increased oxidative stress is a trigger for HO-1 mRNA upregulation in the Ang II-infused rat aorta and that HO-1 may serve to abrogate this increased stress caused by Ang II. Ang II infusion stimulated aortic thrombin receptor mRNA expression in rats, which was blocked by either ARB or the heparin-binding chimera of human Cu/Zn superoxide dismutase but not by normalization of blood pressure with hydralazine treatment, suggesting that Ang II increases vascular thrombin receptor by AT_1R-mediated superoxide production and may be implicated in the pathophysiology of atherosclerosis by thrombin cascade activation. The injection of Ang II resulted in increased oxidized low-density lipoprotein uptake by peritoneal macrophages and increased macrophage proteoglycan content, suggesting that Ang II may accelerate atherosclerosis by promoting foam cell formation and cholesterol accumulation in the vascular wall.

Endothelial dysfunction in the context of hypertension and cardiovascular diseases is partly dependent on the production of ROS. AT_1R-induced ROS not only burns nitric oxide (NO) but also reduces NO formation in the endothelium by oxidizing tetrahydrobiopterin, a crucial cofactor for endothelial NO synthase (eNOS).[27] Superoxide anion, a highly reactive ROS, is known to cause breakdown of endothelial-derived relaxing factor and dysfunction of endothelium. Regenerated endothelium has an impaired ability to release endothelial-derived relaxing factors, in particular NO. Activation of angiotensin receptors triggers an efflux of cytosolic calcium in endothelial cells (ECs). Calcium efflux activates PLA-2 to release arachidonic acid, which is metabolized by cyclooxygenase (COX) to generate various eicosanoids including endoperoxides and various prostaglandins that activate thromboxane A2/prostanoid receptors located on the VSMCs causing contractions. Endothelial COX activity also produces ROS. In addition, uric acid, despite its known antioxidant effects, may cause

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

human vascular EC dysfunction by local activation of RAS, inducing oxidative stress. ROS may, in turn, activate local RAS of whole vasculature, including EC, smooth muscle cells, fibroblast-enhancing Ang II production and concomitant stimulation of AT_1R to create a positive feedback loop between local RAS and ROS. Thus, in hypertensive cardiovascular diseases, endothelial dysfunction is characterized by blunted endothelium-dependent vasodilations or enhanced endothelium-dependent contractions.[7,31]

Effects of in AT_2R on Cardiovascular System

Generally, AT_2R is believed to promote apoptosis and inhibit proliferation and hypertrophy. Unlike AT_1R, AT_2R contributes to maintenance of blood pressure by controlling the vascular tone through vasodilatation. Available evidence indicates links between AT_2R and bradykinin B_2 receptor (B_2R) in NO production in vasodilation.[5,12] AT_2R stimulation by Ang II leads to an increase in cGMP levels through a mechanism involving B_2R, causing NO release. AT_2R activation stimulates bradykinin formation by activating kininogenases. Chronic infusion of Ang II into AT_2R overexpressing mice completely abolished the AT_1R-mediated pressor effect, suggesting vasodilatation by AT_2R. This was blocked by one of the inhibitors of B_2R and NOS. In addition, aortic explants from these transgenic mice overexpressing AT_2R showed greatly increased cGMP/NO production and diminished AT_1R-induced vascular constriction. Removal of endothelium or treatment with the inhibitors of B_2R and NOS abolished these AT_2R-mediated effects, indicating that endothelium is the primary site of effect manifestation by AT_2R. The AT_2R in aortic SMCs also stimulates the production of bradykinin, which stimulates the NO/cGMP system to promote vasodilation. In the AT_2R-deficient mice, bradykinin-induced dilation is seriously impaired. Bradykinin-induced dilation is inhibited by AT_2R antagonist but not by Losartan, an ARB. Thus, AT_2R and B_2R may form functional heterodimers, as recently shown, and this might lead to increased NO and cGMP production.[1] The physical association between the dimerized AT_2R and B_2R initiates changes in intracellular phosphoprotein signaling activities and enhanced production of NO and cGMP.[7,15]

Growth and apoptosis are also two opposite components of tissue remodeling. Cardiac remodeling happens in certain physiological or pathological circumstances, such as exercise, aging, hypertension, and myocardial infarction. It is known that although AT_2R expression decreases sharply after birth, it can increase again in some pathophysiological conditions. Stimulation of AT_2R expression may inhibit neointima formation, cell proliferation, inflammation in vascular injury, myocardial infarction, and ischemic diseases, suggesting its protective role. Conversely, in AT_2R-deficient mice, recovery from acute myocardial infarction was reduced compared to the wild-type mice.[2] Although neointima formation and VSMC proliferation after vascular injury were exaggerated in AT_2R-deficient mice, they were suppressed in $AT_{1a}R$-deficient mice. AT_2R possibly exerts antiproliferative effects and proapoptotic effects in VSMCs by controlling $AT_{1a}R$.[29] The number of apoptotic cells in the injured artery was increased significantly in $AT_{1a}R$-deficient mice but decreased in AT_2R-deficient mice, indicating that AT_2R mediates apoptosis. Selective AT_2R stimulation also inhibited restenosis after balloon angioplasty. Thus, experimental studies have shown a beneficial role for the reexpression of the AT_2R after vascular injury leading to inhibition of cell growth and promotion of apoptosis. Gene transfer studies *in vivo* have also supported that AT_2R expression attenuated neointima accumulation in injured carotid arteries by antagonizing growth-promoting effects of AT_1R. Vascular injury studies using mice with disrupted AT_2R expression showed enhanced neointimal formation compared with wild-type mice, suggesting a protective role for AT_2R.

AT_2R expression is upregulated in several disease conditions. In the left ventricle-specific AT_2R overexpression mice, elevated left ventricular endodiastolic pressure, increased systolic and diastolic dimensions, severely depressed left ventricular fractional shortening, and wall thinning were observed, suggesting that ventricular myocyte-specific expression of AT_2R promotes the development of dilated cardiomyopathy and heart failure *in vivo*. *In vivo* ectopic AT_2R overexpression in postnatal left ventricular myocardium is thus detrimental, explaining the sharp decline of AT_2R after birth. If prolonged ARB treatment turns out to be completely beneficial through clinical trials, then it is either a dosage effect or it depends on the time and site of AT_2R expression. The implications of overstimulation of AT_2R by long-term use of ARB are being investigated in clinical trials.

Effects of in Mas on Cardiovascular System

Ang-(1-7) mediates its effects by interacting with the GRCR, Mas,[25] a prototypic seven-transmembrane domain receptor, which is not only predominantly expressed in the brain and testis but is also found in the kidney, heart, and blood vessels.[4] Moreover, several studies have shown that the interaction of Ang-(1-7) with Mas induces the protective cardiovascular actions such as NO release, Akt phosphorylation and vasodilation.

Ang-(1-7) also functions as an antithrombotic, antiproliferative, and antioxidative agent. Although the mechanisms of action in the vascular system has not yet been well established, several studies have focused on control of the NO and O_2^- balance, which regulates cardiovascular function. A reduction in superoxide dismutase and catalase activity in Mas-deficient mice demonstrates impaired antioxidant properties in these animals.[35] Moreover, ROS

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

levels are increased in Mas-deficient animals. The Mas-deficient mice exhibit impaired *in vivo* endothelial function and increased blood pressure. The transgenic rats overexpressing human ACE2 in VSMCs, showed improved endothelial function and decreased vasoconstriction response to Ang II. Furthermore, the infusion of AVE 0991, a Mas agonist, increases the hypotensive effect of bradykinin in rats; one plausible mechanism for this effect involves an increase in NO levels.[6]

ACE2 protects endothelial cells from Ang II-mediated macrophage infiltration and oxidative stress in an Ang-(1-7)-dependent manner in atherosclerosis. The long-term Ang-(1-7) treatment induces atheroprotective effects in ApoE-deficient mice, an animal model for atherosclerosis. The improvement in endothelial function resulted from an increase in NO bioavailability, as the heptapeptide increased NOS expression and decreased O_2^- production. The genetic deletion of ACE2 significantly increases plaque formation in ApoE-deficient mice, which is decreased by targeted vascular ACE2 overexpression. Consequently, these actions of the ACE2-Ang-(1-7)-Mas system may be exploited in the treatment of atherosclerosis and other vascular diseases.

Thus, the ACE2-Ang-(1-7)-Mas system has opposite functions of the classical RAS in tissues responsible for blood pressure regulation and cardiovascular homeostasis. It decreases the production of ROS and increases eNOS, improving the antioxidant capacity of cardiovascular tissues. The ACE2-Ang-(1-7)-Mas system may become an important therapeutic target for cardiovascular protection.[23]

Chapter 187

Apelin

Ábel Perjés, Klára Farkasfalvi, Heikki Ruskoaho and István Szokodi

ABSTRACT

Apelin and its cognate G protein-coupled APJ receptor are emerging as an important regulator of cardiovascular homoeostasis. The expression of apelin and APJ receptor is widely abundant throughout the cardiovascular system. Soon after its discovery, potent vasodilator and positive inotropic effects of the peptide were revealed, a unique combination among endogenous agents. Despite sequence homologies with angiotensin II and its receptor, the apelin–APJ system seemingly antagonizes many potentially deleterious effects of angiotensin II. Further investigations show that the peptide may play a role in the regulation of cardiovascular development and angiogenesis. Apelin signaling is supposed to involve G_i and G_q proteins, activating protein kinase C, mitogen-activated protein kinases, and the phosphoinositide 3-kinase-Akt-nitric oxide pathway. Preclinical and preliminary clinical studies show beneficial effects of apelin in various cardiovascular diseases, such as heart failure, ischemia–reperfusion injury, and atherosclerosis. This chapter summarizes the rapidly growing literature of the apelin–APJ system in the cardiovascular field.

THE APELIN–APJ SYSTEM

Apelin was discovered as the endogenous ligand of the previously orphan G protein-coupled receptor (GPCR) APJ.[31] The APJ receptor shares sequence identity (30% in total, 54% in the transmembrane regions) with the angiotensin II type-1 receptor (AT_1-R).[25] The human apelin gene, encoding the 77-amino acid preproapelin is located on chromosome Xq25–26.1. The gene shows great sequence homology across all species examined, with the last 23 residues of the C terminus being identical in mammals. Sequence analysis of the mature peptide reveals identity, albeit limited, to angiotensin II.[22] The 77-amino acid preproprotein is cleaved to shorter active peptides, such as apelin-36, apelin-17, apelin-13, apelin-12, and the post-translationally modified (Pyr1)apelin-13. All these are C-terminal remnants of the original preproapelin. They are all agonists of the APJ receptor, but binding affinity and biological efficacy differ from isoform to isoform, with the shorter fragments being more potent.[32] (Pyr1)apelin-13 is the most potent and abundant form in cardiac tissue.[23] Fragments shorter than 12 amino acids are biologically inert.[32] For a more detailed review of the discovery, structure, and metabolism of apelin and APJ receptor, please refer to the Apelin chapters in the Brain Peptides and Gastrointestinal Peptides sections of this book.

DISTRIBUTION WITHIN THE CARDIOVASCULAR SYSTEM

Apelin and APJ receptor are expressed widely through the organism. In humans, preproapelin and APJ mRNA are abundant in the central nervous system, heart, lung, kidney, pancreas, and placenta. In human vasculature, both apelin and its receptor, APJ, are detectable immunohistologically in endothelial cells and vascular smooth muscle cells of large conduit vessels, small arteries, and veins. In the heart, APJ-like immunoreactivity is present in the endocardial endothelium and, to a lesser extent, also in the myocardium (reviewed in Ref. [19]). The apelin peptide is present in normal human plasma with a brief half-life of <5 min.[17] The plasma concentration of immunoreactive apelin is approximately 10^{-10} g/ml. Apelin-like immunoreactivity is present in the heart, being >200-fold higher in the right atria than in the left ventricles.[12] This distribution pattern, low plasma concentration, and short lifespan of circulating peptide suggest an autocrine or paracrine way of action in the cardiovascular system.

SIGNALING CASCADES

Apelin inhibits forskolin-induced cAMP production in cells expressing APJ. This finding suggests that APJ couples to inhibitory G proteins (G_i). Apelin peptides activate p70S6 kinase, a regulator of cell cycle progression, in umbilical endothelial cells through two separate phosphorylation signals. One regulator is the phosphoinositide 3-kinase (PI3 K)-Akt cascade and the other pathway is mediated via extracellular signal-regulated kinases (ERKs). These apelin-induced signaling cascades are pertussis toxin sensitive, strengthening the hypothesis that the APJ receptor is linked to G_i proteins.[24] On the contrary, pertussis toxin can

Copyright Elsevier 2024

only partially inhibit the biological effect of apelin in rat hearts. The apelin signaling appears to involve activation of phospholipase C and protein kinase C, a pathway known to be mediated through G_q proteins. Therefore, APJ receptor may be linked to G_q proteins as well.[29]

BIOLOGICAL ACTIONS IN THE CARDIOVASCULAR SYSTEM

Effects on Vasculature

Vascular Tone

Given the peptide's and its receptor's similarity in sequence and in tissue distribution profile with the Ang II/AT_1-R system, it is not surprising that apelin is a potent regulator of the cardiovascular system. Despite the shared sequences, Ang II does not bind to APJ receptors,[25] and apelin modulates blood pressure oppositely to Ang II. When administered to rats *in vivo*, apelin reduces systolic and diastolic arterial blood pressure significantly, with a slight or no increase in heart rate. The drop is transient, lasting for 3–4 min.[22,32] Besides arterial vasodilatation, intravenous bolus apelin injection to rats causes a drop in the mean circulatory filling pressure, an indicator of systemic venous pressure, suggesting that apelin is a potent venodilator as well.[7] The arterial vasodilator effect of apelin exists also in humans both *in vivo*[17] and ex vivo.[23] Furthermore, direct vasodilatation of the coronary arteries is also detected. On the contrary, apelin does not seem to affect peripheral venous tone in humans.[17] Conversely, apelin exerts a biphasic hemodynamic response in sheep, characterized by an acute fall in arterial pressure and an increase in the heart rate, followed immediately by an increase in arterial pressure and a fall in heart rate. The secondary hypertensive phase is associated with a fall in cardiac output.[4]

The APJ is the single receptor involved in the depressor effect of apelin, because genetic knockout of APJ abolishes the blood pressure lowering effect of exogenous apelin administration in mice.[15] The apelin-induced reduction in blood pressure is most probably mediated by nitric oxide (NO), because it is almost completely abolished by pretreatment with the NO synthase (NOS) inhibitor L-NAME. Moreover, plasma nitrite and nitrate concentrations are significantly increased after apelin administration.[32] Endothelial NOS (eNOS) is supposed to be the main source of NO during the apelin-induced vascular response, as eNOS regulatory phosphorylation (on Ser^{1176}) is markedly increased after apelin treatment in wildtype mouse endothelial cells, an effect not seen in endothelial cells from APJ knockout mice.[15] Parallel to this, the net NO bioavailability significantly increases in apelin-treated mice compared with controls. L-NAME administration abolishes this effect, further strengthening the hypothesis that apelin stimulates NOS activity.[8] Therefore, the depressor effect of apelin seems to be mediated by the well-described Akt-eNOS pathway, leading to NO formation, which activates the soluble guanylate cyclase in vascular smooth muscle cells and consequently relaxes vessels (Fig. 1).

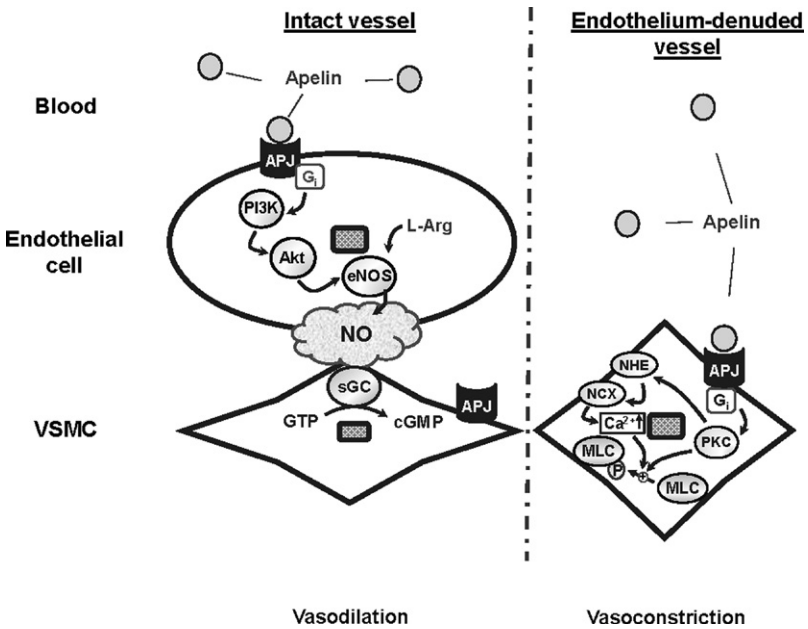

FIGURE 1 The effect of apelin on vascular tone. In intact vessels, apelin activates the PI3 K/Akt pathway in endothelial cells, leading to NO formation by eNOS. NO diffuses to VSMCs and activates soluble guanylate cyclase (sGC), inducing cGMP production, which results in vasodilatation. On the contrary, apelin generates vasoconstriction in the absence of endothelium. MLC is the key regulator of contraction in smooth muscles. Activated APJ on VSMC induces MLC phosphorylation via PKC, NHE, and NCX.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Interestingly, apelin acts as a potent vasoconstrictor on isolated, endothelium-denuded human saphenous veins, and mammary arteries.[23] These results suggest that the endothelium is essential for the vasodilator effect of apelin in the vasculature. The peptide supposedly triggers different signaling pathways when binding to receptors directly on vascular smooth muscle cells (VSMCs), resulting in vasoconstriction. The possible mechanisms involved in vascular contraction have been examined by Hashimoto et al.[14] They show that apelin stimulates myosin light chain (MLC) phosphorylation in VSMCs, an event responsible for smooth muscle contraction. Apelin-induced phosphorylation of MLC is accompanied by myosin phosphatase target subunit phosphorylation, which inhibits MLC phosphatase activity and induces phosphorylation of MLC. Their results suggest that apelin may cause vasoconstriction in VSMC by inducing MLC phosphorylation, a process that involves pertussis toxin-sensitive G proteins and activation of protein kinase C (PKC), sodium–proton exchanger (NHE), sodium–calcium exchanger (NCX), and myosin phosphatase target subunit but not phospholipase C (PLC)[14] (Fig. 1). Nevertheless, according to the *in vivo* results with the overall vasodilatation observed, vasoconstriction is overpowered by a more dominant NO-signaling, either because NO is more potent than apelin on the VSMCs or local tissue distribution of apelin favors the endothelium-derived vascular response.

Angiogenesis

Apelin signaling is necessary and sufficient to trigger embryonic angiogenesis in Xenopus,[21] and apelin-deficient mice have impaired retinal vascularization.[18] Apelin acts as a potent mitogenic[24] and chemotactic factor[21] *in vitro* for human primary endothelial cells. The mitogenic effect is associated with the activation of p70S6 K, suggesting the involvement of ERK and Akt-dependent cascades.[24] Apelin seemingly acts as a downstream mediator of vascular endothelial growth factor in Xenopus and mice as well, most probably in an autocrine or paracrine fashion.[21,18] These results implicate a possibly important role for the apelin–APJ system in embryonic and tumor angiogenesis.

Apelin and the Renin–Angiotensin System

The relationship between Ang II and apelin is not limited to structural similarity and shared localization within the organism, but the two-peptide systems interfere with each other on multiple sites of function. Ishida et al. provided evidence for this interaction: APJ knockout mice, in contrast to the wild-type animals, are highly sensitive to low dose Ang II treatment, suggesting a possible regulatory effect of the endogenous apelin system to counterbalance the pressor effects of Ang II. These findings are further supported by other experiments, in which the blood pressure values of APJ/AT_1-R double knockout mice show partial normalization compared with those of AT_1-R single knockout mice.[15] Moreover, studies on rat primary aortic smooth muscle cells show that apelin has direct inhibitory effects on Ang II-mediated increases in gene expression. Interestingly, APJ and AT_1-R are physically associated in HEK293 cells expressing both receptors, and this association of APJ seems to inhibit AT_1-R signaling in a stoichiometric fashion, independent of the presence of apelin, implicating a direct receptor–receptor crosstalk.[8]

Effects on Heart

Contractility

Apelin is a potent inotropic agent in isolated rat heart preparations in a dose-dependent manner.[29] Similar results are observed in isolated adult rat ventricular myocytes.[10] Although the ex vivo positive inotropic effect of apelin has been repeatedly shown, its effect *in vivo* is less clear. For instance, although *in vivo* acute administration of apelin increases certain load-dependent and load-independent (e.g. preload recruitable stroke work) parameters of cardiac contractility, the increase in cardiac output is not significant in rats.[2] Apelin treatment causes a reduction in left ventricular end-diastolic area and increased left ventricular elastance; however, it fails to increase cardiac output in mice. Therefore, the change in loading conditions after acute apelin administration, together with changes in the viscoelastic properties of the ventricle, may influence the net effect of apelin on cardiac output. Chronic administration of apelin (two-week continuous infusion) to mice results in significant increase in the velocity of circumferential shortening and cardiac output. Importantly, these hearts show no evidence of left ventricular hypertrophy, which is frequently seen after chronic administration of other positive inotropic substances.[1] Apelin and APJ knockout mice develop a modest impairment of baseline cardiac contractility *in vivo* in both load-dependent and load-independent measures. Moreover, in isolated left ventricular myocytes from apelin$^{-/-}$ and APJ$^{-/-}$ mice, impaired sarcomere function is observed with no change in baseline sarcomere length.[5] Finally, acute administration of apelin could increase cardiac output in healthy humans. Because apelin causes a simultaneous decrease in peripheral resistance, its effects on cardiac function may be partly attributable to a reduction in afterload. However, an additional direct inotropic effect is probable, as the increase in cardiac output occurs without significant changes in the heart rate or the blood pressure.[17]

Being active in the subnanomolar range (EC_{50} values: 33 pmol/L), apelin seems to be one of the most potent endogenous positive inotropic agent yet identified. The maximum increase in developed tension induced by apelin is approximately 70% of that of isoproterenol response, and it is comparable in magnitude to the results seen previously with

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

the inotropic peptides endothelin and adrenomedullin. The inotropic effect of apelin develops slower than that of the beta-adrenergic response, but lasts longer ex vivo, having its peak between 20 and 30 min after the initiation of treatment. The apelin-induced increase in cardiac contractility develops independently of the release of catecholamines, other vasoactive peptides (endothelin, Ang II) or NO.[29]

Szokodi et al. also investigated the intracellular mechanisms underlying the inotropic effect of apelin. Their results show that pertussis toxin treatment only partly reduces the apelin-induced positive inotropic response, suggesting that apelin may act via both pertussis toxin-insensitive G_q and —sensitive G_i proteins. Experiments with a variety of pharmacological inhibitors imply the involvement of PLC, PKC, NHE, and NCX in the positive inotropy-related signaling.[29] The role of NHE in this process is confirmed by the observation that apelin increases intracellular pH and NHE activity in adult cardiomyocytes.[10] Stimulation of the NHE can lead to intracellular alkalization and sensitization of cardiac myofilaments to intracellular Ca^{2+}. However, NHE-mediated accumulation of intracellular Na^+ can indirectly promote a rise in intracellular levels of Ca^{2+} via reverse mode NCX. Concomitant inhibition of NCX and NHE supports the hypothesis that NHE and NCX are proximal and distal components in this signaling pathway[29] (Fig. 2). However, the impact of apelin on intracellular Ca^{2+} homeostasis is still controversial. Wang et al. reported a double effect of apelin on intracellular Ca^{2+} concentrations in isolated rat cardiac myocytes, such as systolic increase and diastolic decrease via PKC-dependent mechanism. Additionally, they found that apelin enhances the activity of NCX and SERCA.[33] On the contrary, apelin stimulation in perforated patch-clamp experiments does not modulate Ca^{2+} flux through L-type Ca^{2+} channels,[29] moreover, no apelin-induced changes of Ca^{2+} transients could be detected with fluorescent indicators.[10] These results suggest that apelin may exert its positive inotropic effect by enhancing the sensitivity of myofilaments to Ca^{2+} rather than increasing intracellular Ca^{2+} concentrations. Overall, these results indicate that apelin may contribute to the regulation of physiological cardiac contractile function.

Electrophysiology

The localization of APJ receptor in the intercalated disc region, the cellular structure involved in the electric coupling between cardiomyocytes, makes apelin likely to influence electrophysiological properties of cardiac tissue. Farkasfalvi et al. could show in monolayers of cultured neonatal cardiomyocytes that apelin increases the frequency of spontaneous activation and conduction velocity, and

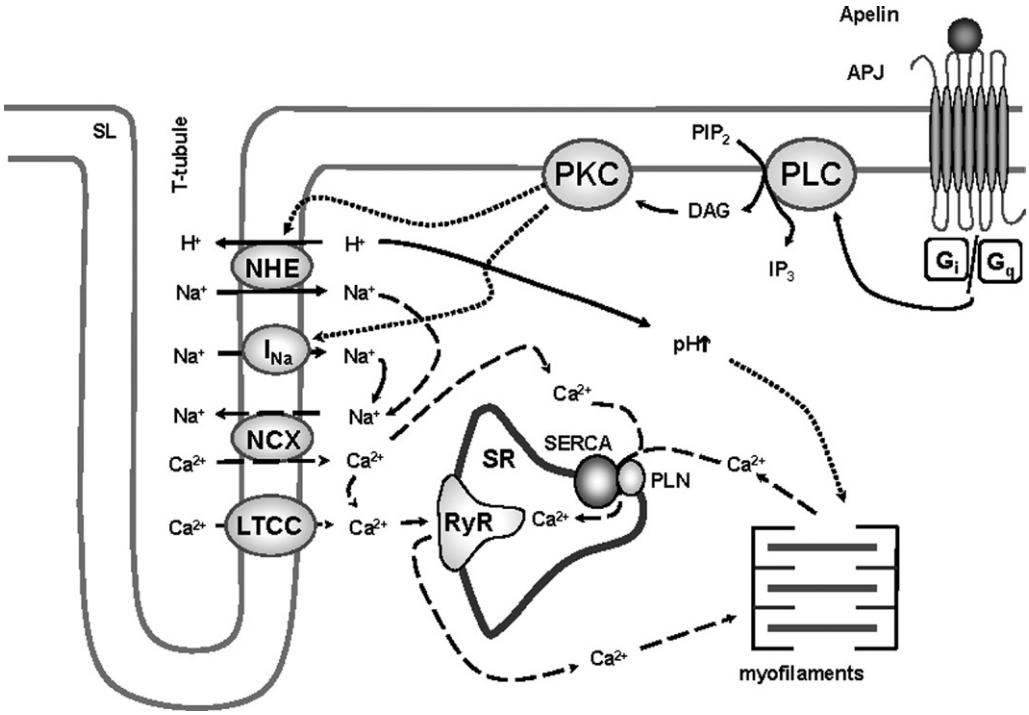

FIGURE 2 Apelin increases cardiac contractility. Apelin may exert positive inotropic effect via both Gq and Gi proteins. PKC can induce NHE activity. Stimulation of the NHE can lead to intracellular alkalization and consequent sensitization of cardiac myofilaments to intracellular Ca^{2+}. Furthermore, NHE-mediated accumulation of intracellular Na^+ can indirectly promote a rise in intracellular levels of Ca^{2+} via reverse mode NCX. Continuous and dotted arrows represent apelin-mediated changes. Dotted lines mark indirect evidences. Dashed arrows stand for mechanisms of regular excitation of cardiomyocytes.

decreases the duration of field potential.[10] In canine cardiomyocytes, apelin increased cardiac peak sodium current (I_{Na}) and shifted channel opening probability to more negative voltage. In line with these findings, apelin increases cardiac excitability. These results suggest that apelin-related changes in I_{Na} may contribute to the positive inotropic effect of the peptide. Moreover, apelin slows I_{Na} recovery from inactivation, thereby prolonging the refractory period. This latter effect may confer antiarrhythmic properties to apelin.[3]

There are controversial results about apelin's effect on the heart rate *in vivo*. Usually, no significant change in the heart rate can be detected in anesthetized animals,[22,32] while conscious animals or animals in superficial narcosis produce a slight increase in response to acute apelin administration.[1,7] However, apelin causes reductions in mean arterial pressure without changing heart rate in the sympathetic ganglionic-blocked rats, implying that the increase of the heart rate in intact animals probably results from a vegetative reflex to hypotension, and apelin has no significant independent chronotropic effect.[7] Suppression of the same reflex in deep anesthesia could also explain the different results obtained.

Cardiomyogenesis

Results in zebrafish provide evidence that the apelin–APJ pathway is required to mediate migration of myocardial progenitors to the correct position at the onset of gastrulation.[35] D'Aniello et al. identified APJ and apelin as effectors of the Cripto/Smad2 pathway, a mechanism necessary in the early phase of mammalian cardiac differentiation. Their results suggest that apelin activates ERK-, but not Akt-dependent p70S6 K cascade in cardiac development.[9] The importance of the apelin–APJ system in cardiomyogenesis is also shown by the deletion of APJ gene. Homozygous APJ null-mutant mice have significantly lower birth rates, whereas early stage embryos produce multiple cardiac developmental defects.[5]

PATHOPHYSIOLOGICAL IMPLICATIONS

Apelin and Atherosclerosis

Atherosclerosis is a major cause of morbidity and mortality in the western world. Evidence suggests an important regulatory role of the apelin–APJ system in the pathophysiology of atherosclerosis; however, the exact function of apelin is not entirely clear yet. Chun et al. reported that apelin–apolipoprotein E (ApoE) double knockouts develop significantly greater atherosclerotic lesion areas compared with that in ApoE-knockout mice, irrespective of the type of diet that was administered. It indicates that endogenous apelin has antiatherogenic properties. As seen above, apelin can antagonize some Ang II-induced cardiovascular effects. Consequently, concomitant apelin administration completely blocks exogenous Ang II-induced atherosclerosis and abdominal aortic aneurysm formation in ApoE-KO mice. This antiatherogenic feature of apelin is NO-dependent, and it cannot be explained solely by its blood pressure lowering effect, because another antihypertensive drug (hydralazine) does not reduce plaque size formation during Ang II treatment. Proatherogenic effect of Ang II is, at least partly, linked to excessive reactive oxygen species (ROS) production. It is, therefore, interesting, that apelin can also limit Ang II-induced elevation in vascular ROS production.[8]

On the contrary, another study by Hashimoto et al. shows that APJ and ApoE double knockout mice on high cholesterol diet have atherosclerotic lesion significantly smaller in size compared with that in the $APJ^{+/+}/ApoE^{-/-}$ animals. This strongly contrasts with the findings of Chun et al., because it proposes that the presence of apelin signaling is proatherogenic. Furthermore, Hashimoto et al. found that vascular production of superoxide radicals is decreased in $APJ^{-/-}/ApoE^{-/-}$ mice compared with that in $APJ^{+/+}/ApoE^{-/-}$ mice, suggesting that activation of APJ receptors by endogenous apelin potentially increases ROS generation.[13] Further investigations are needed to clarify these controversial findings.

Even though the net atherogenic effect of the endogenous apelin–APJ system remains to be determined, Peltonen et al. reported that aortic valve stenosis in humans is characterized by overexpression of both apelin and APJ in the sclerotic plaques of the valves. They suggest that the peptide and its receptor may play a role in neovessel formation, macrophage chemotaxis and activation, and fibroblast proliferation, all of which are well-documented phenomena in the atherosclerotic disease process.[26]

Apelin in Ischemia and Reperfusion

Simpkin et al. provided the first evidence for the direct cardioprotective effect of apelin against ischemia–reperfusion injury. The peptide, given in pharmacological doses during reperfusion, can reduce infarct size in ex vivo and *in vivo* murine ischemia–reperfusion models. In addition, in isolated cardiomyocytes apelin delays the opening of the mitochondrial permeability transition pore, the major determinant of cellular death or survival. These apelin-induced cardioprotective effects are all mediated via PI3 K- and ERK-dependent pathways,[28] the components of the reperfusion injury salvage kinase (RISK) cascade. Apelin-related reduction of infarct size was also seen in rats *in vivo* by Tao et al. They found that apelin blocks ischemia–reperfusion injury via modulating endoplasmic reticulum (ER) stress-dependent apoptosis with a strong correlation within activation of ER-stress induced apoptotic pathways, proportion of apoptotic cells, and cardiac infarct size. Intact PI3 K/Akt,

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

ERK, and AMP-activated kinase (AMPK) function was necessary for the apelin-derived inhibition of ER stress and in line with this, also for the reduction of infarct size. It is remarkable, that unlike numerous other apelin-induced cardiovascular effects, blockade of ER stress was independent from eNOS. However, suppression of eNOS activity abolishes the apelin-induced reduction of infarct size after 2 h of reperfusion, but in a later phase (between 2 and 24 h), apelin develops further cardioprotection without functional eNOS, indicating that NO contributes only to the early phase of the cardioprotective effect of apelin unrelated to ER stress. Further interesting findings of Tao et al. suggest interactions among the above-mentioned signaling cascades. PI3 K/Akt and AMPK phosphorylation levels are partially blocked by inhibition of the other. In addition, the inhibition of either PI3 K/Akt or AMPK also partially attenuates eNOS activation, indicating that both signaling pathways function upstream to eNOS. ERK activation seems to be independent of PI3 K/Akt, AMPK, or eNOS signaling.[30] Thus, apelin can be considered as a postconditioning agent in ischemia reperfusion. Of note, the effect of apelin on preconditioning is not known.

These experimental findings suggest that the apelin–APJ system could be a potential target in the treatment of acute coronary syndrome. Furthermore, Weir et al. report that plasma apelin is reduced in man after myocardial infarction,[34] indicating that apelin system may be involved in the pathophysiology of acute cardiac ischemia.

The Apelin–APJ System in Heart Failure

Cardiac Expression and Plasma Levels in Heart Failure

As described above, apelin is one of the most potent endogenous inotropic substances known so far. Moreover, it causes vasodilatation in both arterial and venous systems, thereby reducing cardiac afterload and preload, making apelin unique among inotropic agents. These characteristics brought the apelin–APJ system into the focus of heart failure research.

Chen et al. reported that apelin plasma concentrations are elevated significantly in humans in early stages of heart failure, but fall below baseline level in patients suffering from severe heart failure.[6] This is in line with the findings of Földes et al., who observed that plasma concentrations of apelin are significantly decreased in patients with advanced heart failure.[12]

Expression of apelin and APJ receptor changes also within the failing heart. Left ventricular apelin mRNA levels are significantly increased in humans with heart failure resulting from coronary heart disease or idiopathic dilated cardiomyopathy; however, atrial apelin mRNA levels are similar in failing and nonfailing hearts. Simultaneously, cardiac APJ mRNA expression is significantly decreased in heart failure. Thus, one could propose that induction of apelin gene expression in the failing ventricles constitutes an adaptive mechanism triggered by increased cardiac overload. Downregulation of the APJ receptor, however, could be maladaptive, because lower expression level could lead to lower receptor density and to consequent impaired apelin efficacy.[12] This hypothesis is supported by the findings of Chen et al. showing that the APJ receptor is one of the most upregulated genes in the myocardium after placement of left ventricular assist device. Moreover, mechanical offloading of the failing left ventricle also increases cardiac tissue apelin levels.[6] Thus, although the apelin–APJ signaling cascade is capable of increasing inotropy and reducing peripheral resistance, both beneficial in heart failure, this pathway is probably endogenously downregulated in severe heart disease.

Effect on Cardiac Function in the Failing Heart

Because the APJ receptor is downregulated in heart failure, one may speculate that apelin would not increase cardiac contractility in failing hearts as much as seen previously in normal, healthy myocardium. There are, however, several studies showing that the positive inotropic effect of apelin is conserved in heart failure. Acute apelin administration increases cardiac contractility *in vivo* in rats with myocardial infarction-related heart failure similar to that in control animals.[2] These results could be reproduced in adult ventricular myocytes, when the rate of increase in sarcomere shortening is the same in cells isolated either from normal or failing hearts.[10] Additionally, short-term apelin infusion increases cardiac output and reduces cardiac preload *in vivo* in humans, with the hemodynamic effects being preserved in patients with heart failure.[17]

Loss-of-function mutant animal models can also provide interesting features from the role of apelin–APJ system in preventing pathophysiological processes. For instance, mice lacking apelin gene, and, therefore, the functional peptide, develop impaired cardiac function with age. Older apelin$^{-/x}$ knockout animals have progressive systolic dysfunction in the absence of histological abnormalities, while systolic function is maintained in wildtype littermates. It is remarkable that two weeks of apelin infusion restores this loss of systolic function. Moreover, the same apelin$^{-/x}$ knockout mice develop more serious systolic and diastolic heart failures than the wildtype animals in the chronic pressure overload model of aortic constriction. The loss of apelin has no marked effect on pressure overload-induced adaptive cardiac hypertrophy, whereas it results in increased interstitial fibrosis.[20] Like the lack of apelin peptide, deletion of the APJ receptor does not cause marked changes of basal contractile function in adult mice. However, with exercise stress both mutant lines show consistent decreases in exercise capacity.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

In addition, isolated left ventricular cardiomyocytes lacking either apelin or APJ manifest less sarcomere shortening and impaired velocity of contraction and relaxation with no difference in calcium transient.[5] These results propose that endogenous apelin–APJ system has a modest role in maintaining basal cardiac contractility, but this cascade possesses more substantial role during stressed conditions.

Apelin Influences Fibrosis

Chronic heart failure is characterized by the progressive activation of the renin–angiotensin–aldosterone system. Ang II is responsible for many deleterious processes during the progression of the disease, including stimulation of growth in cardiomyocytes and proliferation in smooth muscle cells, and increase in extracellular matrix formation. The apelin–APJ cascade can affect Ang II signaling and vice versa[15,8] (see Section 4.2). Double transgenic rats harboring both the human angiotensinogen and human renin genes develop severe hypertension and cardiac hypertrophy. Apelin expression is significantly reduced in those animals.[29] Parallel with this, Iwanaga et al. report that apelin and APJ mRNA levels are markedly downregulated in Dahl salt-sensitive hypertensive rats with decompensated heart failure. This downregulation is restored after treatment with AT_1-R blocker (ARB).[16] According to Siddiquee et al., apelin attenuates, but does not entirely block Ang II-induced cardiac and perivascular fibrosis *in vivo* in wildtype mice.[27] This is in line with the observations of Kuba et al., who found excessive fibrosis in chronic pressure overloaded apelin$^{-/x}$ mice. The lack of apelin changes the gene expression profile of the heart during chronic pressure overload, upregulating sets of genes involved in extracellular matrix remodeling and fibrosis.[20] The antifibrotic effects of apelin are similar to those reported for ARBs. Activation of plasminogen activator inhibitor-1 (PAI-1) is a key step in promoting Ang II-induced fibrosis. Consequent with the observations of decreased fibrosis *in vivo*, apelin inhibits Ang II-linked upregulation of PAI-1, as well as several other Ang II-target genes that contribute to the development of fibrosis *in vivo*. Moreover apelin alone significantly decreases the cardiac expression of PAI-1. Of note, apelin alone increases the expression of the collagen-degrading enzyme matrix metalloproteinase-2, while simultaneously reducing the expression of collagen *in vitro*. Ang II stimulates PAI-1 through Rho kinase. Apelin decreases phosphorylation of MLC and myosin phosphatase subunit, two targets downstream of Rho kinase.[27] This, however, conflicts with another report showing that apelin administration could increase phosphorylation of MLC.[14] Siddique et al. have proposed that inhibition of PAI-1 expression by apelin results from the antagonism of Ang II-induced activation of Rho-kinase pathway. NO synthase-inhibitor L-NAME exerts effects similar to that of Ang II under the same conditions regarding fibrosis and PAI-1 upregulation; however, apelin could not reduce these changes at all. Moreover, administration of L-NAME abolishes the apelin-related inhibition of Ang II-induced upregulation of PAI-1 or fibrosis, suggesting that the beneficial effects of apelin are mediated through NOS. In addition, relative levels of NOS mRNA are significantly increased in the hearts of mice receiving apelin. Interestingly, addition of Ang II together with apelin further increase NOS mRNA levels. Conversely, NOS mRNA is significantly decreased in the hearts of mice receiving apelin plus L-NAME or apelin plus Ang II plus L-NAME. These findings propose a positive feedback loop, where apelin enhances NOS expression in a nitric oxide-dependent manner.[27]

Role in Cardiac Hypertrophy

Besides fibrosis, hypertrophy also occurs during cardiac remodeling. It is believed that ventricular hypertrophy represents a compensatory mechanism in response to an increased workload on cardiac muscle from different etiologies, such as exercise stress, myocardial infarction or pressure overload. However, the compensative mechanisms of remodeling could become unbalanced, leading to excessive hypertrophy or dilated cardiomyopathy, both deleterious for cardiac function and potentially resulting in heart failure. It is therefore very important to note that *in vivo* chronic apelin treatment can improve cardiac contractility in wildtype mice, without any signs of cardiac hypertrophy.[1] ROS have emerged as key mediators of hypertrophic remodeling. In cardiomyocytes, excessive ROS generation mediates the hypertrophic response to various forms of mechanical or neurohumoral stress. Apelin is able to abolish serotonin-induced hypertrophic response in isolated rat cardiomyocytes, in which the signaling pathway is known to involve monoamine oxidase-dependent hydrogen peroxide (H_2O_2) generation. Apelin completely blocks serotonin-related H_2O_2 formation as well. It was suggested that upregulation of H_2O_2-degrading enzymes are responsible for this effect, because apelin increases catalase mRNA expression and enzyme activity in rat cardiomyocytes. Parallel results are obtained in the murine model of pressure overload-induced cardiac hypertrophy, where apelin blunts cardiac hypertrophic growth significantly. Heart weight to body weight comparisons, histological analysis of cardiac tissues, and echocardiographic measurements all show reduced cardiac hypertrophy in apelin-treated animals. The antihypertrophic effect of apelin is associated with significant suppression of oxidative stress *in vivo*.[11]

PERSPECTIVE

Apelin and its cognate G protein-coupled APJ receptor are emerging as an important regulator of the cardiovascular homoeostasis. The expression of apelin and APJ receptor

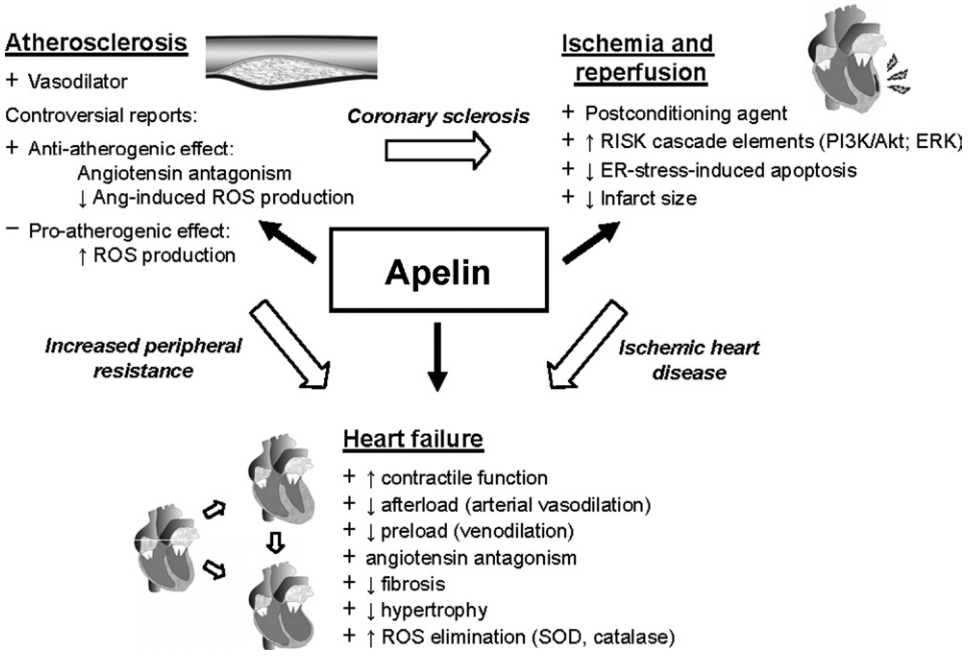

FIGURE 3 Potential role of apelin at pathological cardiovascular conditions. "+" and "−" mark beneficial and deleterious effects, respectively. Empty arrows represent connections between pathological entities.

is widely abundant throughout the cardiovascular system. In view of the putative antiatherogenic effect of apelin, the vasodilator effect on both arterial and venous side of the circulation, the involvement in regulation of cardiac contractile function, the antagonism of the renin–angiotensin system, the inhibition of cardiac hypertrophy and fibrosis, and the cardioprotective effect in ischemia and reperfusion (Fig. 3), the apelin–APJ system represents a promising therapeutic target in cardiovascular disease states, such as ischemic heart disease, myocardial infarction, and heart failure.

Chapter 188

Bradykinin Peptides

Duncan John Campbell

ABSTRACT

The kallikrein–kinin system (KKS) generates a family of bioactive peptides with varying biological activities. These include hydroxylated and nonhydroxylated bradykinin and kallidin (Lys^0-bradykinin) peptides and their respective carboxypeptidase metabolites, des-Arg^9-bradykinin and des-Arg^{10}-kallidin. Although bradykinin and kallidin act mainly via the bradykinin type 2 (B_2) receptor, des-Arg^9-bradykinin and des-Arg^{10}-kallidin act mainly via the bradykinin type 1 (B_1) receptor. Kinins are potent vasodilators, promote natriuresis and diuresis, and have beneficial cardiovascular effects; however, kinins may also promote inflammation. Peptidases are important determinants of kinin levels, and increased kinin levels may contribute to both the beneficial and adverse effects of peptidase inhibitor therapy.

DISCOVERY

Bradykinin and its related peptides are generated by the action of kallikrein enzymes on kininogen substrates. Initial discoveries of the kallikrein–kinin system (KKS) took place in the laboratories of Frey and Kraut in Germany (reviewed by Werle[35]) and Roche e Silva in Brazil.[30] In the laboratory of Frey and Kraut, kallikrein-like activity was initially revealed by the hypotensive effects of intravenous injection of urine.[35] It was also found that plasma and serum deactivate this activity. Subsequent isolation of this hypotensive material in large amounts from the pancreas led to it being named kallikrein, although it was evident that the pancreas was not the only source of kallikrein. Kallikrein could be extracted from the pancreas in both the active and inactive forms. A similar hypotensive material was also isolated from plasma in both the active and inactive forms and was named plasma kallikrein. Moreover, the inactive forms of kallikrein were activated by trypsin. The biological activity of kallikrein extracted from the submandibular salivary gland was found to be due to its enzymatic release of a low-molecular-weight, thermostable compound from a serum protein. This low-molecular-weight compound, believed to be a polypeptide, was initially called DK, and later called kallidin, and its inactive precursor was called kallidinogen.[35]

In the laboratory of Roche e Silva, bradykinin was initially identified as a hypotensive and smooth muscle-stimulating factor released from plasma globulin by snake venoms and by trypsin.[30] It was named bradykinin because it produced a slow contraction of the guinea pig ileum.[30] Trypsin digestion of an ammonium sulfate fraction from ox serum produced the nonapeptide bradykinin, the sequence of which was reported by Elliott et al. in 1960.[13] However, digestion of human plasma with human urinary kallikrein produced two peaks of bioactivity, one (named kallidin I) corresponding to bradykinin and a second (named kallidin II) that corresponded to lysine bradykinin.[27] Because human urinary kallikrein can hydrolyze synthetic arginine esters but not lysine esters, Pierce and Webster concluded that human urinary kallikrein produced lysine bradykinin (now known as kallidin).[27]

STRUCTURE OF KININOGEN mRNA AND GENE

Kininogens are glycoproteins that contain the bradykinin sequence in their midportion. There are two forms of kininogen that differ in structure, size, and susceptibility to cleavage by plasma and tissue kallikreins.[3] Human high-molecular-weight kininogen (HMWK) has 626 amino acids, with a mass of 88–120 kDa, whereas human low-molecular-weight kininogen (LMWK) has 409 amino acids, with a mass of 50–68 kDa.[32] The human kininogen gene encompasses 11 exons spanning approximately 27 kb and codes for both HMWK and LMWK by differential splicing of the initial messenger RNA (mRNA) transcript (Fig. 1).[18,32] In the rat, T-kininogen (major acute phase protein) is a potential precursor for Ile,Ser-bradykinin and Met,Ile,Ser-bradykinin.[14] However, there is no evidence that T-kininogen is a precursor of kinin peptides *in vivo*.[9]

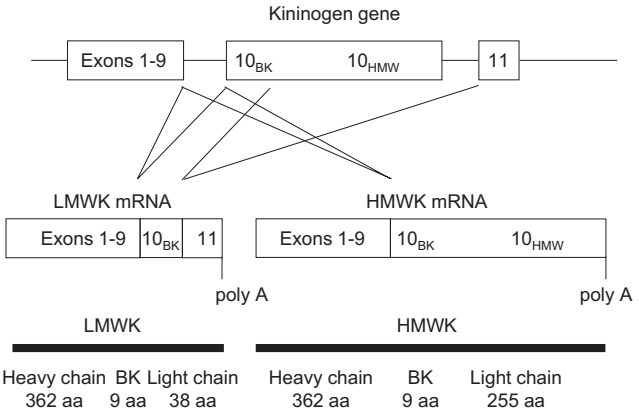

FIGURE 1 Diagrammatic representation of differential splicing of the kininogen gene transcript that produces high-molecular-weight kininogen (HMWK) and low-molecular-weight kininogen (LMWK) mRNA. HMWK represents exons 1–9 spliced to the whole of exon 10, whereas LMWK represents exons 1–9 and the first 78 base pairs of exon 10 spliced to exon 11.[18,32] Both HMWK and LMWK contain the bradykinin (BK) sequence in their midportion, between their respective heavy and light chains. aa, amino acid. Not drawn to scale.

PROCESSING OF THE PRECURSOR

Bradykinin and kallidin are released from kininogens predominantly by the action of the serine proteases plasma kallikrein and tissue kallikrein. Plasma kallikrein is initially secreted as the inactive prekallikrein, and tissue kallikrein is initially secreted as inactive prokallikrein. Both plasma prekallikrein and tissue prokallikrein are activated by serine protease activity. Although a single gene codes for plasma prekallikrein, there is a large family of tissue prokallikrein genes that code for tissue-kallikrein-like serine proteases. In humans, *Klk1* codes for true tissue kallikrein, the only member of the tissue-kallikrein-like family of serine proteases known to generate kinin peptides.[20] However, in rats, true tissue kallikrein is referred to as *Klk1b3*, although Lundwall et al. recommended that this sequence be given the gene symbol *Klk1*.[20]

In humans, plasma kallikrein forms bradykinin from HMWK, whereas tissue kallikrein forms kallidin from HMWK and LMWK (Figs 2 and 3). By contrast, both plasma and tissue kallikrein generate bradykinin in rodents.[3,5] In humans, a proportion of kininogens are hydroxylated on Pro^3 of the bradykinin sequence, leading to the formation of hydroxylated kinin peptides (Hyp^3-bradykinin and Hyp^4-kallidin). Hydroxylated kinins have biological activities that are similar to those of nonhydroxylated kinins.[29]

Alternative pathways of kinin formation involving enzymes other than kallikreins may operate in disease states.[5] Although LMWK is a poor substrate for plasma kallikrein, cleavage by neutrophil elastase renders it much more susceptible to cleavage by plasma kallikrein to release bradykinin. Moreover, the combination of mast cell tryptase and neutrophil elastase releases bradykinin from oxidized kininogens that are resistant to cleavage by kallikreins.

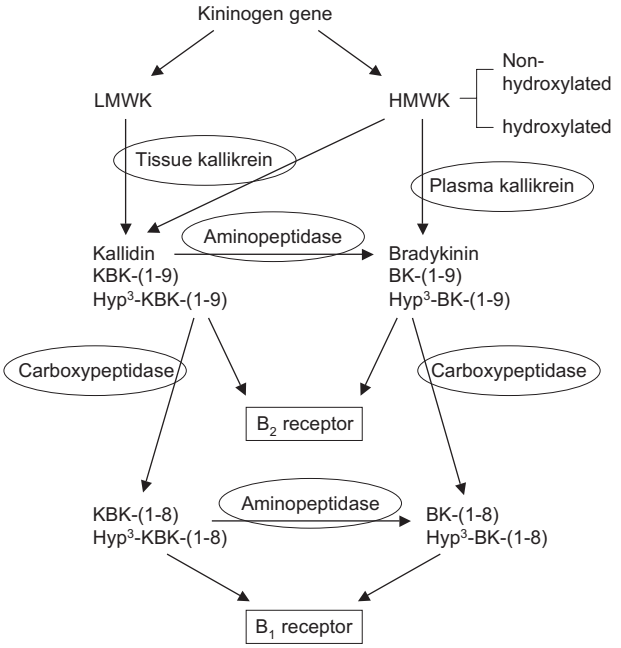

FIGURE 2 Overview of the kallikrein–kinin system in humans. LMWK, low-molecular-weight kininogen; HMWK, high-molecular-weight kininogen; Hyp, hydroxyproline. A proportion of kininogen is hydroxylated on the third amino acid (Hyp^3) of the bradykinin sequence of the precursor. Thus, bradykinin peptides may be nonhydroxylated [BK-(1-9)] or hydroxylated [Hyp^3-BK-(1-9)]. Kallidin is Lys^0-bradykinin and may also be either non-hydroxylated [KBK-(1-9)] or hydroxylated [Hyp^3-KBK-(1-9)]. Similarly, the carboxypeptidase metabolites des-Arg^9-BK-(1-9) and des-Arg^9-KBK-(1-9) may also be either non-hydroxylated [BK-(1-8), KBK-(1-8)] or hydroxylated [Hyp^3-BK-(1-8), Hyp^3-KBK-(1-8)].

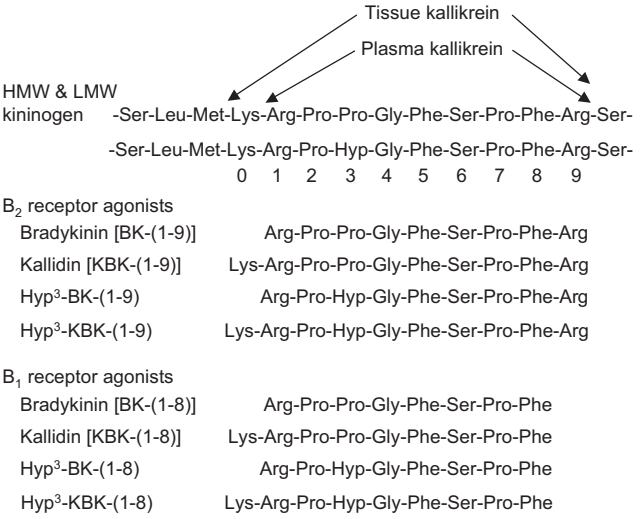

FIGURE 3 Amino acid sequences of the agonists of the type 1 (B_1) and type 2 (B_2) bradykinin receptors. Hyp, hydroxyproline. Bradykinin [BK-(1-9)] and kallidin [Lys^0-bradykinin, KBK-(1-9)] are excised from the interior of the kininogen molecules. Tissue kallikrein cleaves both HMWK and LMWK between Met^{379} and Lys^{380} (the same numbering for human HMWK and LMWK precursors) to produce the amino-terminus and between Arg^{389} and Ser^{390} to produce the carboxy-terminus of kallidin. Plasma kallikrein cleaves HMWK between Lys^{380} and Arg^{381} to produce the amino-terminus and between Arg^{389} and Ser^{390} to produce the carboxy-terminus of bradykinin.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

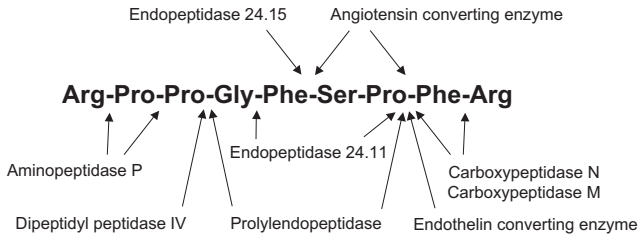

FIGURE 4 Metabolism of bradykinin. Carboxypeptidase N is known as kininase I and angiotensin-converting enzyme is also known as kininase II. Carboxypeptidases M and N produce sequential cleavage of amino acids from the carboxy-terminus of the peptide. Aminopeptidase P produces sequential cleavage of amino acids from the amino-terminus of the peptide. Angiotensin-converting enzyme is a carboxy dipeptidase that produces sequential cleavage of dipeptides from the carboxy-terminus of the peptide. Dipeptidyl peptidase IV cleaves des-Arg[1]-bradykinin.

Kinin production *in vivo* is controlled partly by endogenous inhibitors of the kallikrein enzymes. The main inhibitors of plasma kallikrein are C1 esterase inhibitor, α_2-macroglobulin, and antithrombin III.[3] An important inhibitor of tissue kallikrein is kallistatin, although there is continuing uncertainty about the function of kallistatin *in vivo*.[5]

Kinin peptide metabolism is an important determinant of kinin levels in blood and tissue. Many different peptidases participate in the conversion of bradykinin and kallidin to alternative bioactive peptides and their degradation (Fig. 4). Aminopeptidase-mediated cleavage of kallidin generates bradykinin. Carboxypeptidase (kininase I)-mediated cleavage converts bradykinin and kallidin, which are more potent on the type 2 (B_2) bradykinin receptor, to des-Arg[9]-bradykinin and des-Arg[10]-kallidin, respectively, which are also bioactive and more potent on the type 1 (B_1) receptor (Fig. 2).[29] Thus, there are 8 bioactive kinin peptides in humans, hydroxylated and nonhydroxylated bradykinin and kallidin peptides, and their carboxypeptidase metabolites (Fig. 3).

Angiotensin-converting enzyme (ACE) plays an important role in bradykinin metabolism, producing bradykinin-(1-5) [BK-(1-5)], the most abundant bradykinin metabolite,[23] by sequential cleavage of dipeptides from the carboxy-terminus of bradykinin. Other peptidases play a greater role in kinin peptide metabolism during ACE inhibition.

DISTRIBUTION OF KININOGEN AND KALLIKREIN mRNA, AND KININ PEPTIDES

The liver is the main site of kininogen production and, in humans, HMWK mRNA is also found in the kidney, pancreas, placenta, heart, and colon, whereas LMWK mRNA is found in the kidney, brain, placenta, testis, pancreas, thymus, heart, spleen, lung, colon, and small intestine.[24]

Plasma prekallikrein mRNA is present in all tissues examined and is most abundantly present in the liver and pancreas.[24] In humans, the *Klk1* gene is highly expressed in the kidney, pancreas, salivary gland, endometrium, ovary, skin, and pituitary.[12] Other sites of *Klk1* gene expression include the colon, heart, blood vessels, and adrenal.[25,26,28]

TABLE 1 Blood Kinin Peptide Levels in Humans

Peptide (fmol/mL)	Placebo
BK-(1-7)	1.4 (0.5–4.3)
BK-(1-8)	0.08 (0.02–0.41)
BK-(1-9)	0.18 (0.02–1.90)
Hyp[3]-BK-(1-7)	<0.14
Hyp[3]-BK-(1-8)	0.53 (0.12–2.37)
Hyp[3]-BK-(1-9)	0.18 (0.04–0.91)
KBK-(1-7)	0.46 (0.07–3.33)
KBK-(1-8)	0.10 (0.01–1.35)
KBK-(1-9)	0.22 (0.02–2.70)
Hyp[3]-KBK-(1-7)	0.04 (0.01–0.49)
Hyp[3]-KBK-(1-8)	<0.03
Hyp[3]-KBK-(1-9)	0.04 (0.01–0.26)

Data shown as geometric mean (95% confidence interval), n = 19 for bradykinin (BK) peptides; n = 18 for kallidin (KBK) peptides. Hyp, hydroxyproline.
Data from Campbell et al.[10]

Bradykinin peptides are present in all tissues studied (blood, heart, aorta, brown adipose tissue, adrenal, lung, and brain).[9] In humans, circulating levels of kinin peptides are low, usually <3 fmol/mL (Table 1). Studies in rats show that the levels of bradykinin in tissues are higher than in blood,[9] and in humans, bradykinin and kallidin peptide levels are higher in venous than in arterial blood,[5] consistent with the tissue being the main site of formation of these peptides. Bradykinin peptides are more abundant than kallidin peptides in the blood and atrial tissue of humans.[5,10] In human urine, kallidin peptides are more abundant than bradykinin peptides, and the levels are several orders of magnitude higher than that in blood.[5]

RECEPTORS AND SIGNALING CASCADES

In the basal state, the B_2 receptor is constitutively expressed throughout and mediates the majority of the vascular and metabolic actions of kinins, whereas the B_1 receptor is not detectable but is induced by a variety of pathological conditions, including inflammation, toxins, cytokines, and tissue trauma.[19,22] Both B_1 and B_2 receptors can be expressed by the same cell types: vascular endothelial and smooth muscle cells, nonvascular smooth muscle such as the uterus and

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

intestine, fibroblasts, epithelial cells, various tumor cells, and also on leukocytes and in the central nervous system.[19] Immunohistochemical studies show a different distribution of B_2 receptors in arteries and arterioles. B_2 receptors are predominant in the endothelium of arteries with minor immunohistochemical staining in smooth muscle cells, whereas there is intense staining of the tunic media and minor staining of the endothelium of arterioles.[5]

The pharmacology of kinin receptors has been reviewed by Leeb-Lundberg et al.[19] The B_1 and B_2 receptors are G protein-coupled, 7-transmembrane-spanning receptors. The B_2 receptor signals through $G\alpha_q$, and also interacts with $G\alpha_s$ and $G\alpha q_{12/13}$. Stimulation of the $G\alpha_q$-sensitive phospholipase Cß produces phosphoinositol hydrolysis and increased intracellular free Ca^{2+}. Moreover, translocation of protein kinase C isoenzymes α, ε, and ζ has been observed in fibroblasts and endothelial cells. B_2 receptor stimulation can also result in phospholipase A_2 and phospholipase D activation.[19] These second messenger systems result in stimulation of endothelial nitric oxide synthase and nitric oxide production through Ca^{2+}-mediated mechanisms in endothelial cells, in addition to cellular release of prostacyclin, reactive oxygen species, and tissue-type plasminogen activator.

The B_1 receptor interacts with $G\alpha_q$, and $G\alpha_i$, through which it stimulates many of the same signaling pathways as the B_2 receptor, including phosphoinositol hydrolysis, elevation of intracellular free Ca^{2+}, arachidonic acid release, eicosanoid production, endothelial nitric oxide synthase activation, and nitric oxide production. Although they seem to couple to similar cellular signaling pathways, the pattern of signaling of B_1 and B_2 receptors may differ. In vascular smooth muscle cells, B_2 receptor stimulation leads to transient phosphoinositol hydrolysis that exhibits little dependence on extracellular Ca^{2+}, whereas B_1 receptor stimulation is more sustained and significantly dependent on extracellular Ca^{2+}. Moreover, the B_2 receptor elicits a transient increase in intracellular Ca^{2+}, whereas the B_1 receptor elicits a sustained signal characterized by a plateau of elevated Ca^{2+}, or baseline oscillation that is dependent on extracellular Ca^{2+} influx.[19]

The interaction between angiotensin type 2 (AT_2) and B_2 receptors is discussed by Izumi and Iwao elsewhere in this volume. Several studies have also suggested interaction between the angiotensin type 1 (AT_1) and B_2 receptors, although others have found no evidence for this interaction.[15]

There is evidence that the B_2 receptor also interacts with ACE.[19] Initial evidence for this interaction came from studies showing that ACE inhibitors potentiate the effects of B_2 receptor agonists that are resistant to cleavage by ACE. Furthermore, ACE inhibitors reactivate the B_2 receptor after desensitization and prevent sequestration of the B_2 receptor to caveolae, and there is evidence for the direct association of the B_2 receptor and ACE in the cell membrane.[19]

In addition to activation by kinin peptides, the B_2 receptor may be directly activated by serine proteases such as kallikreins by a mechanism that involves receptor proteolysis.[6]

BIOLOGICAL ACTIONS WITHIN THE CARDIOVASCULAR SYSTEM

The role of kinins in amphibia is described by Conlon, and in the lung by Couture, in this volume. Kinins are potent vasodilators and also promote diuresis and natriuresis. Most of the circulatory effects of kinins are determined by the stimulation of endothelial cells with subsequent endothelial release of nitric oxide and prostacyclin, which diffuse to the vascular smooth muscle causing vasodilatation.[19]

Evidence for a role for kinins in the regulation of vascular tone and blood pressure in man has come from the studies of the effects of the B_2 receptor antagonist icatibant. Icatibant caused coronary artery vasoconstriction, suggesting a role for basal kinin levels in the control of coronary vascular tone.[5] Moreover, icatibant attenuated the hypotensive effects of ACE inhibition in normotensive and hypertensive patients.[5]

BK-(1-5) has antithrombin activity.[16] However, it is unlikely that endogenous BK-(1-5) levels inhibit thrombin *in vivo* because plasma BK-(1-5) levels (30–40 pmol/L) are at least 6 orders of magnitude below the micromolar concentrations required to inhibit thrombin.[16]

Contact System

The "contact system" comprises HMWK complexed with plasma prekallikrein, Hageman factor (XII, FXII), and FXI. It is so called because its components require contact with artificial, negatively charged surfaces for zymogen activation *in vitro* (Fig. 5).[17] *In vivo*, the contact system is assembled on endothelial and neutrophil cell membranes where it may participate in basal kinin peptide production. This complex associates with endothelial membranes through a binding site formed by the 33 kDa cell-surface receptor for the first component of complement (gC1qR/p33), urokinase plasminogen activator receptor, and cytokeratin.[4] Endothelial prolylcarboxypeptidase and/or heat-shock protein 90 initiates the reciprocal activation of plasma prekallikrein to kallikrein, FXII to FXIIa, and FXI to FXIa. Plasma kallikrein, FXIIa, and FXIa all cleave HMWK to release bradykinin. FXIIa also activates plasminogen to plasmin. Plasmin cleaves HMWK to release bradykinin that may contribute to the angioedema that occurs with administration of recombinant tissue plasminogen activator. In addition, plasma prekallikrein may cleave HMWK directly.[17] C1 esterase inhibitor plays a critical role in the control of bradykinin production by inhibiting plasma kallikrein, FXIIa, FXIa, and plasmin (Fig. 5). Thus, C1 esterase inhibitor deficiency leads

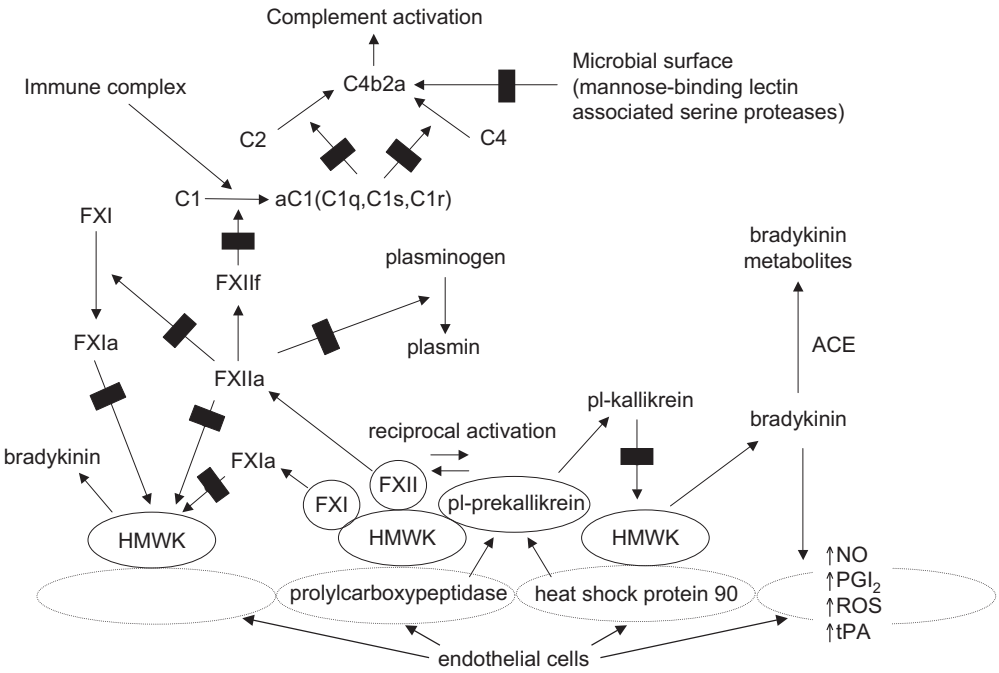

FIGURE 5 Outline of the contact system and its relationship to the complement pathway, which contributes to angioneurotic edema. The black rectangles indicate enzymes inhibited by C1 esterase inhibitor. The contact system comprises high-molecular-weight kininogen (HMWK) complexed with plasma prekallikrein (pl-prekallikrein), Hageman factor (factor XII, FXII), and FXI. This complex associates with endothelial membranes, where endothelial prolylcarboxypeptidase and/or heat-shock protein 90 initiates the reciprocal activation of prekallikrein to kallikrein, FXII to FXIIa, and FXI to FXIa. Kallikrein, FXIIa, and FXIa can all cleave HMWK to release bradykinin. FXIIa also activates plasminogen to plasmin and plasmin cleaves HMWK to release bradykinin. Not shown in this figure is the role of plasma kallikrein and plasmin in the conversion of FXIIa to FXII fragment (FXIIf). FXIIf activates the first component of the complement cascade (C1) that subsequently cleaves C2 and C4. Bradykinin stimulates endothelial cell B_2 receptors to cause the release of nitric oxide (NO), prostacyclin (PGI_2), reactive oxygen species (ROS), and tissue-type plasminogen activator (tPA), which together lead to increased vascular permeability and angioedema. The complement pathway is also activated by the classical pathway (immune complex), and the lectin pathway (microbial surface, mannose-binding lectin pathway). Activation of any of these pathways leads to the reduction in C2 and C4 levels. ACE, angiotensin-converting enzyme.

to increased bradykinin formation, particularly during conditions that increase the activity of the contact system, such as tissue trauma.

In addition to kinin peptide formation, the contact system activates the intrinsic coagulation, complement, and fibrinolytic systems. Moreover, kinin-mediated stimulation of endothelial release of tissue-type plasminogen activator further promotes fibrinolysis.

Tissue prokallikrein may also participate in the contact system by binding to HMWK.[6] Activation of the contact system and kinin peptide formation occurs in cardiopulmonary bypass, whereby both bradykinin and kallidin peptides are increased, indicating activation of both plasma prekallikrein and tissue prokallikrein.[8]

Genetic Models of Deficiency of Components of the Kallikrein–Kinin System

Detection of kininogen-deficient human subjects is based on their severe abnormality in surface-activated intrinsic coagulation, fibrinolytic and kinin-generating pathways, although they have little or no bleeding abnormality.[5] Kininogen deficiency in humans is reported to be relatively asymptomatic, suggesting that kinin peptides may have little role in normal physiology. However, studies in experimental animals provide evidence for an important role for kinin peptides in the regulation of blood pressure and sodium homeostasis, and in contributing to inflammatory processes.[5] The kininogen-deficient Brown–Norway Katholiek strain of rat shows increased sensitivity to the pressor effects of increased dietary salt, mineralocorticoid administration, and angiotensin II infusion, and an impairment of the cardioprotective effects of preconditioning.[5] In addition, the Brown–Norway Katholiek rat shows a reduced response to inflammatory stimuli.[5]

Gene knockout mouse models have also helped demonstrate the role of the KKS in normal physiology and in disease states. There is some controversy about the effects of B_2 receptor gene knockout on blood pressure and cardiac function.[22] However, the B_2 receptor gene knockout mouse has an exaggerated pressor response to angiotensin II infusion and chronic dietary salt loading, and a diminished cardioprotective

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

response to ACE inhibitor and AT_1 receptor blocker (ARB) therapies, indicating an important role for endogenous kinins in mediating the effects of these therapeutic agents. B_2 receptor gene knockout mice have reduced insulin sensitivity despite the increased B_1 receptor expression in this model.[19] B_2 receptor gene knockout mice also have less efficient myocardial metabolism with increased propensity to ischemic myocardial injury and increased cardiac oxygen consumption.[22] In addition, B_2 receptor gene knockout mice demonstrate increased urinary concentration in response to vasopressin, indicating that endogenous kinins acting through B_2 receptors oppose the antidiuretic effect of vasopressin.

Studies of the tissue kallikrein gene knockout mouse suggest that tissue kallikrein is the major kinin-forming enzyme in most organs, including the heart and blood vessels, and have identified a role for tissue kallikrein and kinins in protection from acute cardiac ischemia and post-ischemic cardiac failure, and a nephroprotective role for tissue kallikrein in diabetes.[28] However, in contrast to the nephroprotective role of tissue kallikrein, targeted deletion of the B_2 receptor protects against the development of diabetic nephropathy, thereby suggesting that the B_2 receptor contributes to the pathogenesis of diabetic nephropathy.[33]

In a direct comparison of B_2 receptor and tissue kallikrein gene knockout mice, both models had similar blood pressures to wild-type mice and displayed normal hemodynamic and echocardiographic parameters.[34] However, the heart rate was lower in B_2 receptor gene knockout mice than in tissue kallikrein gene knockout or wild-type mice. In addition, B_2 receptor gene knockout mice, but not tissue kallikrein gene knockout mice, exhibited lower coronary and renal blood flows and greater corresponding vascular resistances than did wild-type mice, indicating a tonic physiological vasodilating effect of bradykinin in these vascular beds. However, maximal coronary vasodilator capacity, estimated after dipyridamole infusion, was similar in the 3 groups of mice. B_2 receptor gene knockout mice were significantly more sensitive than were tissue kallikrein gene knockout mice to the vasoconstrictor effects of angiotensin II and norepinephrine. Moreover, renin mRNA levels were significantly higher in B_2 receptor gene knockout mice and lower in tissue kallikrein gene knockout mice, compared with that of wild-type mice. Taken together, these results indicate that under basal conditions, the B_2 receptor is not an important determinant of blood pressure in mice but is involved in the control of regional vascular tone in the heart and kidney.[34] The phenotypic differences observed between B_2 receptor and tissue kallikrein gene knockout mice may represent the contribution of plasma kallikrein to bradykinin production and/or B_1 receptor activation.

Given the vascular and renal actions of kinin peptides, reduced KKS activity has long been a candidate mechanism for essential hypertension.[21] However, heterozygous individuals with a loss of function polymorphism (R53H) of the *Klk1* gene have normal blood pressure, although they have an alteration of the geometry of the brachial artery. Moreover, although the R53H polymorphism was associated with reduced plasma and urinary levels of tissue kallikrein, it was not associated with alteration in urinary kallidin levels.[2]

Gene knockout models also indicate an important role for bradykinin in inflammation and nociception. The B_1 receptor gene knockout mouse has a reduced hypotensive response to bacterial lipopolysaccharide and reduced accumulation of polymorphonuclear leukocytes in carrageenan-induced inflammation, although accumulation of mononuclear cells and endothelial permeabilization are preserved.[5] By contrast, the B_2 receptor gene knockout mouse has reduced paw edema in response to intraplantar injection of carrageenan.[5] Moreover, both the B_1 and B_2 receptor gene knockout mice show evidence of reduced nociception, indicating an important role for endogenous kinins in perception of pain.[5]

PATHOPHYSIOLOGICAL IMPLICATIONS

As noted above, the B_2 receptor is constitutively expressed, whereas the B_1 receptor is not detectable but is induced by a variety of pathological conditions, including inflammation, toxins, cytokines, and tissue trauma.[19,22] Kinin peptides are well recognized for producing cardioprotection mediated by the B_2 receptor, as indicated by the prevention of cardioprotection by icatibant.[22] Cardioprotection mediated by the B_2 receptor includes ischemic preconditioning, the reduction in myocardial infarct size, and the reduction of cardiac hypertrophy and cardiac remodeling post myocardial infarction.[19] Kinins protect against ischemia–reperfusion injury by decreasing endothelial adherence of leukocytes, leading to attenuation of post-ischemic leukocyte adherence and disruption of the microvascular barrier, and reduced tissue injury.[3] Both the B_1 and B_2 receptors are implicated in ischemia-induced angiogenesis.[19,31]

In addition to their induction by inflammation, toxins, cytokines, and tissue trauma, B_1 receptors are induced and upregulated by disturbances in circulatory homeostasis, such as induction of experimental hypertension by salt loading, renal artery clipping, or exogenous angiotensin II infusion, as well as by the normal aging process. But the most important stimulus causing overexpression of the B_1 receptor was found to be the disruption of the B_2 receptor, whether it was due to functional inactivation via a selective B_2 receptor antagonist or to the deletion of the B_2 receptor gene. In such cases, the B_1 receptor can take over some of the vasodilatory functions of the B_2 receptor, but not its metabolic (insulin-sensitizing) function. Patients with end stage cardiac failure have increased cardiac B_1 receptor

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

mRNA and protein levels, in contrast to B_2 receptor mRNA and protein levels, which are significantly downregulated.[22] It is unclear whether the upregulation of the B_1 receptor in patients with heart failure contributes to tissue protection by enhancing regional blood flow, or has a detrimental effect by interacting with inflammatory mediators and further exacerbating the inflammatory process.[22]

Both ACE inhibitor and ARB therapies increase kinin peptide levels[5,10] that may contribute to the therapeutic effects of these agents. Recently, the renin inhibitor aliskiren was shown to increase bradykinin levels in the heart and lung of the rat, associated with increases in tissue kallikrein mRNA and protein levels.[11] Studies with tissue kallikrein gene knockout mice confirm the role of the KKS in mediating cardioprotection by ACE inhibitor and ARB therapies.[28] The importance of the B_2 receptor in mediating in part the benefits of ACE inhibitor and ARB therapies is illustrated by the effects of icatibant, which attenuates the hypotensive effects of ACE inhibition in humans,[5] and also attenuates angiogenesis and reduction of cardiac hypertrophy, infarct size, and fibrosis produced by these therapies in animal models. The B_2 receptor is also implicated in the improvement in ischemic preconditioning, and in insulin sensitivity, reported with ACE inhibition.[19,22] By contrast, treatment with a selective B_1 receptor antagonist in the setting of myocardial infarction did not modify myocardial infarct size, but reversed the cardioprotective effects of ARB therapy, an effect attributed to cross-talk between the AT_1 and B_1 receptors.[22] Both the B_1 and B_2 receptors are implicated in the promotion of angiogenesis by ACE inhibition.[19,31]

The potential for the KKS to contribute to inflammation is well illustrated by the clinical condition of angioneurotic edema, whereby C1 esterase inhibitor deficiency results in unpredictable activation of the contact system, leading to angioedema and increased circulating bradykinin levels (Fig. 5).[5] The role of kinins in angioneurotic edema is demonstrated by the therapeutic benefits of icatibant and plasma kallikrein inhibition.[17] Local tissue trauma and sepsis produce local kallikrein activation, possibly involving the contact system, and kinins contribute to the cardinal features of inflammation, producing vasodilatation, increased blood flow, vascular permeability, edema, neutrophil chemotaxis, and pain.[3]

Increased kinin peptide levels may contribute to the increased incidence of angioedema associated with ACE inhibitor and ARB therapies.[5,10] Kinin levels are increased further when neutral endopeptidase 24.11 (NEP) inhibition is combined with ACE inhibition. Consequently, the incidence of angioedema is higher with combined ACE and NEP inhibition than with ACE inhibition alone.[7] Moreover, reduced plasma levels of aminopeptidase P are associated with ACE inhibitor-induced angioedema.[1] Patients with heart failure have reduced circulating levels of bradykinin and kallidin peptides[5] that may account for the lower incidence of angioedema in subjects with heart failure treated with ACE inhibitors or vasopeptidase inhibitors.[7]

In summary, kinin peptides exert a broad range of cardioprotective and inflammatory actions. In general, low physiological levels of kinin peptides play an important role in cardiovascular homeostasis, particularly in relation to sodium homeostasis and in cardioprotection, whereas the high pathological levels of kinin peptides that occur when the contact system is activated and may also occur when key kininase enzymes such as ACE, NEP and aminopeptidase P are inhibited, contribute to inflammation.

Chapter 189

CGRP

Ross King and Susan D. Brain

ABSTRACT

Calcitonin gene-related peptide (CGRP) is a 37-amino acid neuropeptide that belongs to a family of structurally related peptides, including adrenomedullin (AM), adrenomedullin II (AM2, or intermedin), and amylin (AMY). CGRP expression is largely concentrated within small-diameter primary sensory afferents that innervate the vasculature. When released into and around the vasculature, CGRP acts as a potent vasodilator. To achieve its effect, CGRP binds to a Class B G protein-coupled receptor, known as the calcitonin receptor-like receptor (CLR), which in turn is coupled to a receptor activity modifying protein 1 (RAMP1) to confer specificity for the CGRP ligand. Abnormal CGRP activity has been identified as a potential causative factor within the pathophysiological setting of migraine and, as such, antagonists of the CGRP receptor are in development for the treatment of this disease. Given its potent activity and ability to be released throughout the body, CGRP has the potential to maintain cardiovascular homeostasis, warranting future work to fully characterize its effects.

DISCOVERY

Calcitonin gene-related peptide (CGRP) is a 37-amino acid neuropeptide that was first identified in 1982 by Amara et al. It was discovered in the thyroid tissue of aging rats, where alternative processing of RNA transcripts from the calcitonin gene was shown to result in the production of distinct mRNAs encoding CGRP. Calcitonin mRNA comprises exons 1, 2, 3, and 4 of the calcitonin gene, whereas CGRP mRNA comprises exons 1, 2, 3, 5, and 6, as shown in Fig. 1. Expression of calcitonin mRNA was shown to be largely confined to the thyroid tissue, while CGRP-specific mRNA is considered to predominate throughout the sensory nervous system.[2] After this discovery, a human form of CGRP was isolated from medullary thyroid carcinomas.[22] Two distinct isoforms of CGRP are now known to exist, termed αCGRP and βCGRP. αCGRP is formed from the alternative splicing of mRNA transcribed from the calcitonin gene located on chromosome 11, whereas the beta isoform is transcribed from its own gene located on the same chromosome.[1] Because of the similar organization of both genes, it is believed that the two separate genes arose by duplication. Both isoforms of the mature peptide are structurally similar, with the β isoform only differing by 3 amino acid residues in humans and 1 amino acid in rodents. Indeed, both isoforms display comparable biological activity and primarily differ in their tissue distribution. αCGRP is most commonly found within peripheral sensory neurons, whereas βCGRP seems to be more restricted to nerves of the enteric plexuses. Little is known about the specific function of the β isoform, and thus from this point, only αCGRP will be discussed.

DISTRIBUTION OF THE mRNA/PEPTIDE IN THE CARDIOVASCULAR SYSTEM

Neuronal Localization of CGRP

CGRP is widely distributed throughout the central and peripheral nervous systems. It is primarily located within unmyelinated, small-diameter sensory C, and thinly myelinated Aδ fibers that are commonly found in close contact with the vasculature, although with a greater degree of innervation on the arterial side of the circulation. Sensory nerve terminals have been shown to protrude as far into the vascular wall as the adventitial–medial border, enabling a direct influence over vascular function. A well-established mechanism by which CGRP and other neuropeptides are released from sensory nerves is after neuronal stimulation with the potent chilli-pepper extract, capsaicin. Capsaicin is a highly selective agonist for the vanilloid subtype of transient receptor potential class of ion channel (TRPV1), and its binding to TRPV1 induces the opening of a central pore that is permeable to the influx of extracellular cations, with a degree of selectivity for divalent ions, such as calcium. An increase in intracellular calcium leads to depolarization of the neuronal membrane and triggering of calcium-dependent exocytotic mechanisms and release of CGRP. Indeed, long-term treatment of rodent neonates with capsaicin leads to neuronal excitotoxicity and subsequent sensory nerve loss. Other activators of TRPV1 include noxious heat and the high concentrations of protons associated with lowered

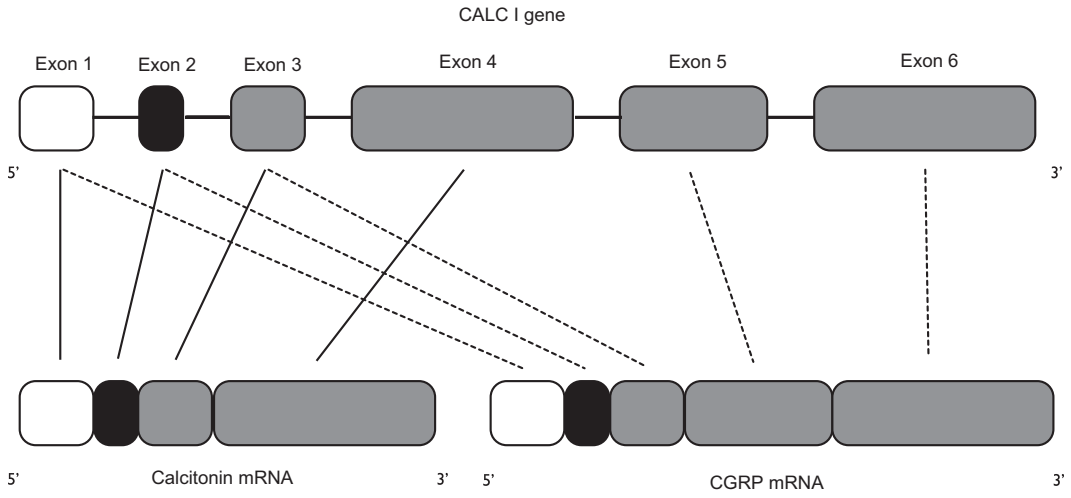

FIGURE 1 Arrangement of CALC I exons encoding either calcitonin or CGRP mRNA.

environmental pH.[28] There has been recent research involving other TRP receptors, one of which is the ankyrin receptor TRPA1. This is found on 50% of sensory nerves and when stimulated is capable of releasing vasodilator CGRP, depending on the circumstance.[24] Physiological plasma levels of CGRP in humans are usually within the low picomolar range, and this low level is generally attributed to overspill from the site of release, as opposed to having a systemic circulatory effect. Once released, it is unclear as to how CGRP may be metabolized to an inactive form, and several removal mechanisms are likely to take place.[4] Mast cell tryptase and other peptidases have been shown to be capable of breaking down CGRP at extravascular sites, and there also exists a role for a matrix metalloprotease II enzyme in CGRP metabolism. Furthermore, there is some evidence to suggest that CGRP is taken up by the nerve terminal following its repolarization, where it may be recycled for reuse or marked for degradation.

Novel, Nonneuronal Sites of CGRP Expression

Aside from the canonical synthesis and release of CGRP from perivascular sensory neurons, other nonneuronal sources of the peptide are slowly beginning to emerge. A range of studies have been performed to investigate endothelial progenitor cell (EPC) function, and this cell type has been shown to actively express and release CGRP.[11] Moreover, it has been suggested that mature endothelial cells (ECs) possess the ability to express both isoforms of CGRP and release CGRP in a TRPV1-dependent manner. This endothelial-derived CGRP has been suggested to play an important role in the protection of endothelial function induced by acute heat stress.[31] Furthermore, a study published by Wang et al. in 2002 suggests that human lymphocytes constitutively express both isoforms of CGRP, although this finding is yet to be confirmed in subsequent experiments.[30]

RECEPTORS AND SIGNALING CASCADES

Our knowledge of the CGRP receptor and its associated signaling cascades has increased in a short span of time. Historically, two distinct receptors for CGRP were initially believed to exist: the $CGRP_1$ and $CGRP_2$ receptors. The idea of heterogeneous CGRP receptor subpopulations was put forward when it was discovered that responses to CGRP in the guinea pig atria could be blocked by the peptide antagonist, $CGRP_{8–37}$, whereas in the rat vas deferens, this fragment was less capable of antagonizing CGRP-induced effects.[9] However, by using molecular and pharmacological techniques, we can now appreciate that apparent differences in CGRP activity may be ascribed to the activation of receptors for other members of the calcitonin family, such as adrenomedullin and amylin.[13] The identity of the CGRP receptor takes the form of a multiprotein oligomer comprising a secretin-like ("Class B") G protein-coupled receptor (GPCR), known as the calcitonin receptor-like receptor (CLR), bound to a receptor activity modifying protein (RAMP)1 molecule. Dimerization of the CLR to other RAMPs confers pharmacological activity on other members of the calcitonin family of peptides: RAMP2 and RAMP3 association leads to the formation of AM_1 and AM_2 receptors, respectively.[29] Fig. 2 illustrates how all CGRP receptor protein subunits combine to form a fully functional receptor.

Assembled CGRP receptors are known to be expressed in a variety of cell types throughout the cardiovascular system, including vascular smooth muscle cells (VSMCs), endothelial cells, cardiac myocytes, some populations of leukocytes, and on the cell bodies of perivascular sensory neurons.

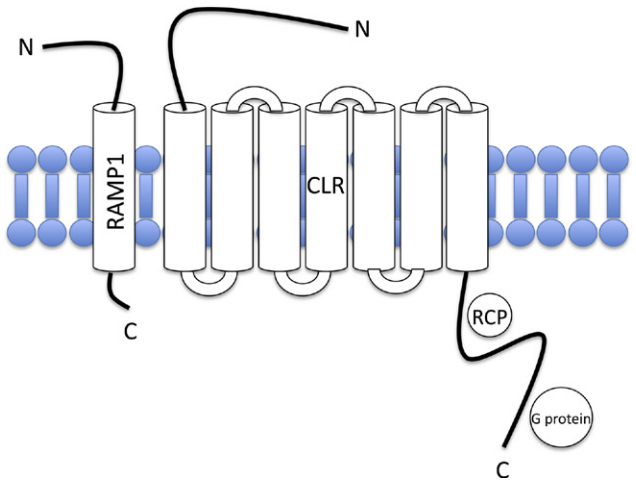

FIGURE 2 Schematic representation of the oligomerization of CGRP receptor components. The CLR binds to RAMP1 to confer ligand specificity to CGRP. CGRP receptor activation typically results in the activation of a G protein, usually Gαs. The RCP positively regulates Gαs-mediated signal transduction.

Critical to the advancing of our insight into receptor function and into the formation of novel therapeutic strategies is the development of a "pharmacological toolkit," including antagonists selective for distinct receptor subpopulations. The first antagonist for the CGRP receptor was developed with the finding that truncation of the first seven amino acid residues of the peptide (resulting in the $CGRP_{8–37}$ peptide fragment) binds to the receptor complex without activating signaling pathways, thereby competing with the full-length peptide for receptor occupancy.[6] However, in keeping with its peptide nature, $CGRP_{8–37}$ is not an ideal tool for interrogating specific signaling pathways. More recently, however, novel nonpeptide antagonists have been designed to selectively target the interface between CLR and RAMP1, binding to the CLR at methionine-42 and RAMP1 at tryptophan-74, and these have been shown to have considerable efficacy in the treatment of migraine-associated headache: olcegepant (BIBN4096; 1-[N2-[3,5-dibromo-*N*-[[4-(3,4-dihydro-2(1H)-oxoquinazolin-3-yl)-1-piperidinyl]carbonyl]-D-tyrosyl]-1-lysyl]-4-(4-pyridinyl)piperazine) and telcagepant (MK-0974; [N-[(3R,6S)-6-(2.3-difluorophenyl)-2-oxo-1-(2,2,2-trifluoroethyl)azepan-3-yl]-4-(2-oxo-2,3-dihydro-1H-imidazo[4,5-b]pyridin-1-yl)piperidine-1-carboxamide]).[21]

CGRP Receptor Components

The main functional component of the CGRP receptor critical for signal transduction following agonist binding is the CLR. Consistent with the highly conserved structure of GPCRs, the CLR contains regions that are critical for GPCR signaling. The CLR possesses a large N-terminal extracellular domain (ECD), three extracellular loops (ECLs), seven transmembrane (TM) domains, three intracellular loops (ICLs) and an intracellular C-terminus. The manner in which peptide ligands bind to Class B GPCRs, including the CLR/RAMP1 complex, is generally described as the "two-domain" model. In this model, the C-terminus of the peptide binds with high affinity to the N-terminal ECD and is subsequently delivered to the ECL and extracellular TM domains of the receptor while also binding to the RAMP molecule, resulting in the activation of the receptor by inducing a change in receptor conformation.[15]

The CLR alone is incapable of responding to CGRP stimulation and requires the heterodimerization of the single transmembrane-spanning RAMP1 to offer full functionality. Indeed, association of RAMP1 with the CLR is critical for the maturation of the CLR via N-terminal glycosylation and subsequent export of the receptor from the endoplasmic reticulum to the plasma membrane, where it is able to interact with its peptide agonist.[19] Coupling of the CLR to RAMP1 produces a receptor that is responsive to CGRP and is blocked by BIBN4096BS/$CGRP_{8–37}$. Association of the CLR with RAMP2 produces a receptor for AM that is blocked by its associated peptide fragment $AM_{22–52}$, and binding of RAMP3 produces a receptor responsive to both CGRP and AM, about which very less is known.

In addition to RAMP1, It is now known that a small intracellular peripheral membrane protein also associates with the CLR, as shown by coimmunoprecipitation studies. This receptor coupling protein (RCP) is important for the amplification of signal generated by CGRP receptor activation. Endogenously expressed by most cell types, molecular knockdown techniques have shown that ablation of RCP activity leads to a decreased production of cAMP secondary to CGRP receptor activation but not from other receptor systems that are coupled to Gαs. Therefore, it seems that the association of RCP with the CLR is important for the regulation of efficient intracellular signal transduction.[10]

CGRP Receptor Signaling

Activation of the CGRP receptor is typically associated with an increase in the formation of the intracellular second messenger molecule cyclic 3′-5′-adenosine monophosphate (cAMP), as a result of the small G protein Gαs associating with the CLR and promoting adenylyl cyclase activity. Accumulation of cAMP within subcellular signaling compartments results in the temporospatial activation of the cAMP-dependent protein kinase (PKA), which itself is capable of targeting multiple protein substrates for phosphorylation, thereby altering their functionality. PKA-dependent events occurring downstream from CGRP receptor stimulation have been shown to include alterations of the activity of critical signaling proteins pertaining to cell excitability, such as ATP-sensitive potassium channels and

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

L-type calcium channels, and DNA transcription as a result of the activation of the cAMP response element binding protein (CREB). Furthermore, consistent with other members of the GPCR superfamily, it is likely that the CGRP receptor may couple to multiple additional signaling networks, such as other G proteins including $G_{i/o}$ and $G_{q/11}$. In addition, there is a growing body of evidence to suggest that CGRP receptor stimulation may result in the activation of mitogen-activated protein kinases (MAPKs), which are essential to cell proliferation and survival. It is yet unclear how the receptor might signal to these kinases, though a possible mechanism may be through β-arrestin-mediated signaling; β-arrestin has been shown to associate with the CGRP receptor and facilitates receptor desensitization and internalization. Therefore, it is plausible that the CGRP receptor may transmit a signal in this manner, as it has been shown with other receptor systems.[29]

To be able to maintain efficient control of CGRP activity, the signal generated by the receptor must be terminated in a suitable manner. Although Class B GPCRs are less well characterized than Class A GPCRs, it is known that they both share the ability to undergo agonist-induced homologous desensitization, and this has indeed shown to be the case for the CGRP receptor. In cultured human neuroblastoma cells and VSMCs, pretreatment of cells with CGRP for 20min resulted in an attenuated elevation of cAMP on a secondary exposure. It has since been shown that after the binding of CGRP to its cognate receptor, the CLR undergoes rapid phosphorylation and binds β-arrestin where it is thereby internalized as part of a ternary complex comprising the CLR, RAMP1, and β-arrestin molecules. The association of β-arrestin with the receptor complex is stable and long lasting, showing an internalization profile similar to that of the V_2 vasopressin receptor.[12]

BIOLOGICAL ACTIONS WITHIN THE CARDIOVASCULAR SYSTEM

CGRP may have a variety of roles within the cardiovascular system, but the feature that is best characterized is its ability to act as a potent vasodilator. Often considered the most potent microvascular vasodilator to date, its property was first discovered by Brain et al. in 1985,[3] where intradermal injections of femtomolar concentrations of CGRP into the human forearm was sufficient to induce surface erythema of the skin, attributable to local vasodilatation and, as a result, increased blood flow. Higher doses of CGRP were found to produce a reddening of the skin that lasted for several hours.[3] Intravenous delivery of CGRP into rodents causes systemic hypotension coupled with a positive inotropic and chronotropic response from the heart, though these effects are considered to be secondary to stimulation of the sympathetic nervous system as part of the baroreceptor reflex, rather than a direct action of CGRP on the heart. The vasodilator activity of CGRP is predominantly mediated by the binding of CGRP to the CGRP receptor complex embedded within the plasma membrane of VSMCs and, to an extent, the ECs lining the blood vessels. Within the VSMC, stimulation of the CGRP receptor leads to an increase in the formation of cAMP and subsequent activation of PKA, which has been shown to target the ATP-sensitive potassium channel for phosphorylation, leading to cellular relaxation as a result of membrane hyperpolarization. Alternatively, CGRP may interact with receptors located on ECs, leading to the downstream phosphorylation and activation of endothelial nitric oxide synthase (eNOS) and liberation of nitric oxide (NO) from the EC, which is then capable of diffusing to the VSMC layer and causing relaxation via the stimulation of soluble guanylate cyclase and triggering an accumulation of intracellular cGMP as a result.[4]

CGRP and Control of Blood Pressure

Although it is evident that CGRP possesses clear vasomotor activity, it is less clear as to what sort of effect it has on hemodynamics under normal physiological conditions. A range of studies has been performed using murine knockout models to address this question, with some conflicting results. Some groups report no change in baseline blood pressure in mice with the removal of αCGRP, whereas others have witnessed a significant increase in blood pressure in its absence. Difficulty arises when interpreting these findings, however, as the generation of CGRP knockout mice can differ between groups, where some animals have the complete CALC I gene removed (thereby preventing both calcitonin and αCGRP synthesis) and others lack only αCGRP. It is worth noting, however, that mice holding the sole deletion of CGRP seem to be more likely to have normal resting blood pressures.[27] Adding further credence to the hypothesis that CGRP plays a minor role in baseline blood pressure regulation, studies performed in a variety of species have shown that injection of the CGRP receptor antagonist $CGRP_{8–37}$ or CGRP receptor-directed antibodies has no effect on systemic blood pressure. Furthermore, injection of the selective CGRP receptor antagonist BIBN4096BS has also been shown not to exert an effect on resting heart rate or blood pressure across a range of species, including humans.[23] Therefore, it may be the case that the functional consequences of CGRP are more pronounced within the microcirculation of specific tissues, as opposed to the entire circulation. This is supported by findings that indicate that administration of CGRP at doses below those required to produce systemic hypotension produces facial flushing, indicative of a specific sensitivity to CGRP within the cutaneous microcirculation. Indeed, capsaicin-induced denervation of peripheral sensory nerves in neonatal rats

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

typically results in the formation of skin lesions resulting from the removal of neuropeptidergic control of the dermal microcirculation. Furthermore, skin flap survival in sensory nerve-depleted rats is reduced when compared with those with sensory nerves intact and skin flap survival can be rescued with the administration of CGRP. In mice subjected to hind limb ischemia, neovascularization is significantly impaired after blockade of CGRP. These findings are in keeping with the principal role of CGRP as a regulatory microvascular neuropeptide, being released from perivascular sensory nerves at specific sites to produce local vascular control as opposed to behaving in an endocrine manner.[4]

Cardiac Effects of CGRP

The role of CGRP within cardiac physiology is less clear. CGRP-immunoreactive fibers have been shown to innervate regions of the myocardium and the coronary vessels that supply the heart with blood. A range of studies has been performed that propose a cardioprotective role for CGRP. Isolated heart preparations using mice with mixed CGRP/calcitonin gene deletion were found to have an increased susceptibility to ischemia/reperfusion injury, associated with a marked increase in markers of myocardial cell damage, coupled with an increase in reactive oxygen species generation. Recovery of coronary flow after acute myocardial ischemia was also significantly impaired in mice lacking CGRP. Similar results were obtained with pharmacological blockade of the CGRP receptor with $CGRP_{8–37}$.[17] More recently, it has been shown that mice subjected to streptozotocin-induced diabetes mellitus have an impaired ability to produce cardioprotection via ischemic preconditioning, and this is attributed to a loss of CGRP activity. This effect was rescued by CGRP adenoviral gene delivery and, interestingly, post-IR myocardial function was also improved in nondiabetic hearts receiving CGRP gene transfer.[34] Furthermore, in cultured rat cardiomyocytes, CGRP was shown to inhibit the accelerated apoptosis of myocardial cells induced by norepinephrine.[32] This finding may have particular relevance to research into heart failure, as patients often present with an increased activity of the sympathetic nervous system and increased catecholamine release. Although the cardiac effects of CGRP are not as well documented as those in the vasculature, it is conceivable that increasing cardiac CGRP activity by pharmacological or genetic means may represent a new way to prevent the deleterious effects of ischemia/reperfusion injury and associated cell death.

PATHOPHYSIOLOGICAL IMPLICATIONS

Migraine

Despite affording apparent protective effects within the cardiovascular system, CGRP has also been shown to play a key role in the pathophysiology of migraine. Migraine is a debilitating cerebrovascular condition affecting around 15% of people, characterized by a headache comprising a unilateral throbbing sensation with a range of associated symptoms. Migraine may manifest in an episodic or chronic manner, with both instances impacting in a detrimental manner on society and the patient. Current standard treatment for the symptoms of migraine is generally limited to the triptan family of drugs, which possess dual pharmacological activity at $5\text{-}HT_{1B/1D}$ receptors. However, because of their ability to constrict blood vessels, the use of triptans is contraindicated in patients with cardiovascular complications, such as hypertension and coronary artery disease.[14] Interestingly, pharmacological treatment of migraine now seems to be moving in the direction of CGRP receptor antagonism. Soon after the discovery of CGRP, early localization studies showed its presence in cranial blood vessels and in the trigeminal peripheral neurons that innervated this region of the vasculature, where it seemed to function as a protective neurotransmitter that exerted reflex control over hypercontractile vessels. Experiments were also performed in human patients suffering from migraine, in whom collection of blood from the external jugular vein draining the extracerebral tissues was analyzed and found to contain elevated concentrations of CGRP (92 pM versus 40 pM in healthy control subjects), but not of other neuropeptides. Moreover, intravenous delivery of CGRP was shown to dilate cerebral arteries and arterioles concomitant with an increased incidence of migraine-like headache. One theory suggests that the pain associated with migraine is a result of the extracerebral blood vessels (e.g., the middle meningeal artery and its dural arterioles) that supply the dura mater relaxing to an exaggerated extent and thereby stimulating the perivascular nociceptive neurons. These observations together led to the rational development of the nonpeptide CGRP receptor antagonists: olcegepant (BIBN4096BS, administered intravenously) and telcagepant (MK-0974, given orally). Owing to its oral availability, telcagepant has superseded olcegepant in the treatment of migraine.[14]

Raynaud's Phenomenon

Another clinical problem that may benefit from manipulation of the CGRP system is Raynaud's phenomenon. Characterized by inappropriate vasoconstriction and pain within the cutaneous microcirculation (commonly affecting the digits of the hand), the syndrome can restrict adequate tissue perfusion, leading to ischemia and potentially the development of gangrene. Patients suffering from Raynaud's have been shown to have increased levels of the potent pressor agent, endothelin, and decreased levels of CGRP within the digital circulation. Moreover, patients receiving CGRP infusion at room temperature were found to respond in a

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

manner similar to that of healthy control subjects. However, at cold temperatures (5 °C), patients were shown to exhibit a significantly attenuated response to CGRP infusion.[5] Therefore, the disease may present as a result of increased responsiveness to endothelin and a lack of responsiveness to CGRP, opening a potential avenue for CGRP receptor agonists in the treatment of the disease. Indeed, recent *in vivo* and ex vivo studies have shown that CGRP is capable of terminating long-lasting vasopressor responses to endothelin, further strengthening a potential therapeutic role for CGRP within this setting.[20]

Hypertension and Vascular Inflammation

Finally, there is developing evidence to show that CGRP activity seems to become more important in resisting the onset of hypertension and its associated vascular dysfunction within several experimental models. Indeed, it has recently been shown that global overexpression of RAMP1 in mice results in a significant attenuation of ATII-induced hypertension and improved baroreceptor reflex activity.[26] Similarly, studies performed with the peptide CGRP receptor antagonist $CGRP_{8–37}$ have shown that blockade of the CGRP receptor exaggerates cardiovascular pathologies induced by hypertensive stimuli, such as salt-induced hypertension and L-NAME–induced hypertension.[27] Moreover, although plasma CGRP concentrations in humans are generally considered to be low, there is evidence to suggest that circulating levels of CGRP can become reduced in patients with essential hypertension. These clinical findings are supported by rodent studies, which have shown that CGRP release and activity may be reduced when levels of angiotensin (AT) are raised. Furthermore, in spontaneously hypertensive rats (SHR—considered a relevant model of essential human hypertension), the level of CGRP mRNA expression by the dorsal root ganglion cells (the principal site of CGRP synthesis) has been shown to decline with age. Therefore, the development of hypertension and associated vasculopathy may be linked to a decrease in CGRP activity within the cardiovascular system. Indeed, there is some evidence to suggest that chronic supplementation of the traditional Chinese medicine and TRPV1 agonist rutaecarpine may have an antihypertensive effect that is attributable to increased CGRP release into the systemic circulation.[8] This protective effect has been documented in hypertension induced by renal phenol injury, two-kidney, one-clip surgery, and in spontaneously hypertensive rats. Additionally, CGRP released from TRPV1 after rutaecarpine stimulation was demonstrated to have a beneficial effect in reducing platelet aggregation by inhibiting the release of platelet-derived tissue factor.[18] Therefore, targeting of TRPV1 with agonists such as rutaecarpine may provide a valid strategy for the treatment of hypertension and its associated conditions.

Hypertension often copresents as an increase in systemic blood pressure and also extensive vascular remodeling and dysfunction. This commonly includes an accelerated rate of hypertrophy and hyperplasia of the VSMCs within the medial wall of the blood vessel. Furthermore, endothelial dysfunction is known to occur, typically characterized by an impaired capability of the endothelial cell to produce the vasoactive mediator, NO. Transgenic overexpression of the RAMP1 component of the CGRP receptor has been shown to protect against ATII-induced endothelial dysfunction, measured by the ability of isolated vessels to relax in response to acetylcholine stimulation of the endothelium to produce NO.[7] Critical to the repair of damaged regions of the endothelium are circulating EPCs: bone marrow-derived circulating cells that are now appreciated to play an important role in vascular repair after injury and also neovascularization. It is believed that a decline in blood EPC content and activity could predispose patients toward future cardiovascular events. CGRP is known to be synthesized and secreted by this cell type, and it has been shown that EPC-derived CGRP can protect against acceleration of EPC senescence induced by ATII and downstream production of oxygen radicals.[35] EPC-derived CGRP also seems to attenuate the degree of VSMC hypertrophy within an ATII model of hypertension.[11] This finding is strengthened by *in vitro* studies examining ATII-induced VSMC proliferation and how this activity can be inhibited by exogenous CGRP application.[25] Furthermore, CGRP-expressing EPCs have been shown to be of some therapeutic value in a model of pulmonary hypertension, where animals receiving CGRP-positive EPCs had a lowered vascular resistance within the pulmonary circulation and decreased smooth muscle thickening.[33] Another characteristic associated with hypertension is an exacerbated incidence of vascular inflammation. Huang et al. showed that exposure of activated microvascular ECs to CGRP significantly attenuated the ratio of inflammatory cells such as neutrophils and monocytes migrating through the endothelial monolayer. This was attributed to a decrease in chemokine expression by the endothelial cell following CGRP stimulation, as a result of a reduced activation of the proinflammatory transcription factor, NFκB.[16] Chronic activation of NFκB is known to predispose arteries to developing atherosclerotic lesions. As interactions between circulating leukocytes and the vasculature are important factors in the etiology of inflammatory diseases such as atherosclerosis, there may be some benefit in manipulating the CGRP signaling pathway to prevent atherogenesis and related inflammatory conditions within the vasculature.

In summary, it is now appreciated that CGRP has a wide range of effects in the cardiovascular system and may be involved in multiple pathophysiological circumstances. It is probable that we will witness the progression of CGRP

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

receptor antagonists for the treatment of migraine into the clinic within the coming years. With particular interest to more prevalent and serious cardiovascular diseases, however, it is possible that CGRP plays an important protective role in the pathophysiology of hypertension and its associated vascular disease component. Therefore, future basic and clinical research may lead us in the direction of developing ways by which CGRP activity may be selectively stimulated to develop novel treatments for cardiovascular conditions.

Chapter 190

Endothelins

Takashi Miyauchi and Katsutoshi Goto

ABSTRACT

A potent vasoconstrictor peptide, endothelin (endothelin-1), was discovered from culture supernatant of porcine endothelial cells in 1988. From human genomic DNA analysis, two other family peptides, endothelin-2 and endothelin-3, were found. They showed different effects and distribution, suggesting that each peptide may play separate roles in different organs. Endothelins act via the activation of two receptor subtypes, ET_A and ET_B receptors, both of which are coupled to various GTP-binding proteins depending on cell types. Endogenous ET-1 may be involved in the progression of various cardiovascular diseases, and ET antagonists are currently used clinically in the treatment of patients with pulmonary hypertension and are considered to have further target diseases such as systemic hypertension, heart failure, cardiac diseases, renal diseases.

DISCOVERY

Vasoconstriction dependent on or enhanced by intact endothelium has been observed in response to various chemical and physical stimuli such as norepinephrine, thrombin, hypoxia, increased transmural pressure, mechanical stretch. These observations lead to the speculation that endothelial cells may release certain vascular constricting substance(s), endothelium-derived contracting factors (EDCF). In 1985, Hickey et al. attempted to test the biological activity of the culture medium of bovine aortic endothelial cells on isolated porcine coronary arteries, and they found that the culture supernatant contained peptide-like factor(s), which triggered a slowly developing and long-lasting contraction of the coronary arteries. Based on gel chromatography analysis, they suggested that this particular EDCF is a peptide with a molecular mass of approximately 8500 Da.[8] At about the same time, Gillespie et al. also detected vascular constricting activity in the culture supernatant of porcine aortic endothelial cells. They subsequently reported that the activity was increased when the cultured endothelial cells were stimulated by thrombin, and they suggested that this EDCF is a peptide with a molecular mass of approximately 3000 Da.[19]

In 1987, we performed experiments similar to those of Hickey et al. and confirmed that the supernatant from confluent monolayer cultures of porcine aortic endothelial cells contained a slowly developing and long-lasting vascular constricting factor(s), peptidic in nature, because the vascular constricting activity was abolished by pretreatment of the conditioned medium with trypsin. The activity was also detected in serum-free conditioned medium, and no appreciable change in activity was observed even after long-term (2–3 weeks) maintenance of the endothelial cell culture in serum-free condition. The successful attempt at serum-free maintenance and detection of vascular constricting activity prompted us to isolate and purify the active peptide in the supernatant because of the absence of interference with proteins and/or peptides in the serum itself.

Cells isolated from porcine thoracic aortas and grown to a confluent monolayer were maintained in serum-free minimum essential medium. The medium was changed every 5 days, and the conditioned medium was pooled at −20 °C. The pooled conditioned medium was first centrifuged at 1000 g for 20 min, and subsequently, the supernatant was desalted and concentrated. The concentrated medium was loaded onto an anion-exchange column and eluted by applying a linear gradient of NaCl. The vascular constricting activity of the eluent was assayed by adding a small amount of each fraction directly into a muscle chamber where a helical strip of porcine coronary artery with the intima denuded was suspended, and the active fraction was collected. The active fraction was subjected to reversed-phase high-performance liquid chromatography (HPLC) and elution with a linear gradient of acetonitrile, and the vascular constricting activity of each fraction was similarly assayed. A second trial of reversed-phase HPLC enabled us to purify the active component. Approximately 3 nmol of the final product was obtained, which was just enough to perform subsequent amino acid analysis.

The purified peptide was subjected to amino acid sequence analysis by means of an automated gas-phase peptide sequencer and carboxy-terminal analysis by hydrazinolysis (Edman's reaction). As a result, the peptide was revealed to be composed of 21 amino acid residues with

free amino- and carboxy-termini. At first, the carboxy-terminal amino acid (tryptophan) was not detected, and a 20 amino acid peptide synthesized artificially did not exhibit any biological activity. It was soon recognized that the structure of tryptophan (indole ring) is easily degraded during Edman's reaction. The peptide comprising 21 amino acid residues subsequently synthesized did exhibit vascular constricting activity identical to that of natural peptide. The four cysteine residues at the amino-terminal portion were found to form two intramolecular disulfide bonds, the topological analysis of which revealed that the arrangement of disulfide bonds is a coaxial form (1–15 and 3–11). Because it was originally discovered from the culture supernatant of endothelial cells, the peptide was termed "endothelin."[27]

STRUCTURE OF THE mRNA/GENE

Based on the amino acid residues 7–20 of endothelin, several kinds of oligonucleotides were synthesized according to the mammalian codon usage statistics. Using one of the synthesized oligonucleotides as a single "optimal" DNA probe, approximately 2×10^6 clones were screened from aλgt10 cDNA library constructed for porcine endothelial cell mRNA, and 38 hybridization-positive clones were soon identified. Four of these clones were subjected to further characterization, and finally, a complete nucleotide sequence of porcine preproendothelin cDNA and the deduced amino acid sequence were determined.

PROCESSING OF THE PRECURSOR

The 203 residue porcine preproendothelin contains 19 residues of deduced N-terminal amino acid sequence, being characteristic of a secretory signal sequence, that is, a hydrophobic core followed by residues with small polar side chains. As anticipated, paired basic amino acid residues Lys^{51}-Arg^{52}, which are recognized by the usual processing endopeptidase, furin (see the furin chapter in Peptide Biosynthesis/Processing section of the book), directly precede the endothelin sequence, but no dibasic pair is found thereafter until Ara^{92}-Arg^{93}. This indicates that the intermediate peptide of 39 amino acids, called big endothelin (Cys^{53}-Arg^{92}), may be first generated, and subsequently, mature endothelin may be generated via the unusual proteolytic processing between Try^{73} and Val^{74} in big endothelin by an endopeptidase exhibiting chymotrypsin-like specificity, which was putatively termed "endothelin-converting enzyme (ECE)." This presumptive pathway of endothelin biosynthesis in endothelial cells was confirmed later. The human preproendothelin cDNA was soon cloned, and its sequence of 212 amino acid residues containing big endothelin of 38 amino acid sequences was determined (Fig. 1).

The cDNA of ECE was also cloned, and it was revealed that ECE is a 785 amino acid metalloprotease containing a single membrane-spanning sequence with only a 56-residue N-terminal cytoplasmic tail and an extracellular C-terminal of 681 amino acid residues that contains the catalytic domain.[26] Amino acid residues 593–601 match the highly conserved consensus sequence of a zinc-binding motif, HEXXH, which is shared by many known metalloproteases. The ECE protein has ten predicted sites for N-glycosylation in the extracellular domain, suggesting that ECE behaves as a highly glycosylated protein.

DISTRIBUTION OF THE mRNA/PEPTIDE IN THE CARDIOVASCULAR SYSTEM

Southern blot analysis of human genomic DNA under low hybridization stringency with a 42-mer synthetic oligonucleotide probe corresponding to amino acid residues 7–20 of endothelin, showed that three different restriction fragments were always detected regardless of the restriction endonucleases used. The nucleotide sequences encoding amino acid residues of the three endothelins are highly conserved among the three genes, with 77–82% of the nucleotide residues being identical. By contrast, the nucleotide sequences upstream from the mature peptides are very poorly conserved. These observations suggest that although the three genes are evolutionally relatively distant from each other, the genes evolved from a common ancestral gene under strong pressure to preserve mature endothelin sequences. The three peptides were designated endothelin-1, endothelin-2, and endothelin-3.[10] Endothelin-1 is the original peptide corresponding to that detected in the culture medium of porcine aortic endothelial cells. Although vascular endothelial cells are the major source of endothelin-1, Northern blot analysis revealed that the genes encoding the three endothelin isopeptides are expressed with different patterns in a wide variety of cell types including cardiac myocytes, vascular smooth muscle cells, pituitary cells, macrophages, and mast cells, suggesting that the peptides may participate independently in complex regulatory mechanisms in various organs.

The conservation of numerous endothelin-related genes was also observed in several mammalian species examined, including humans, pigs, and rats. Further, four cardiotoxic peptides highly homologous to endothelins, sarafotoxins (S6a–S6d), were isolated from the snake venom of *Atractaspis engaddensis*. Endothelin-like immunoreactivity was also found in several species of invertebrates and fishes, indicating that endothelins found in humans seem to have a long evolutionary history.

Since endothelin-1 was discovered first and showed a wide variety of actions not only on the cardiovascular system but also on various other tissues, much information has accumulated on endothelin-1 compared with the two other peptides. The method for measurement of endothelin-1 levels in plasma or various tissues by means of

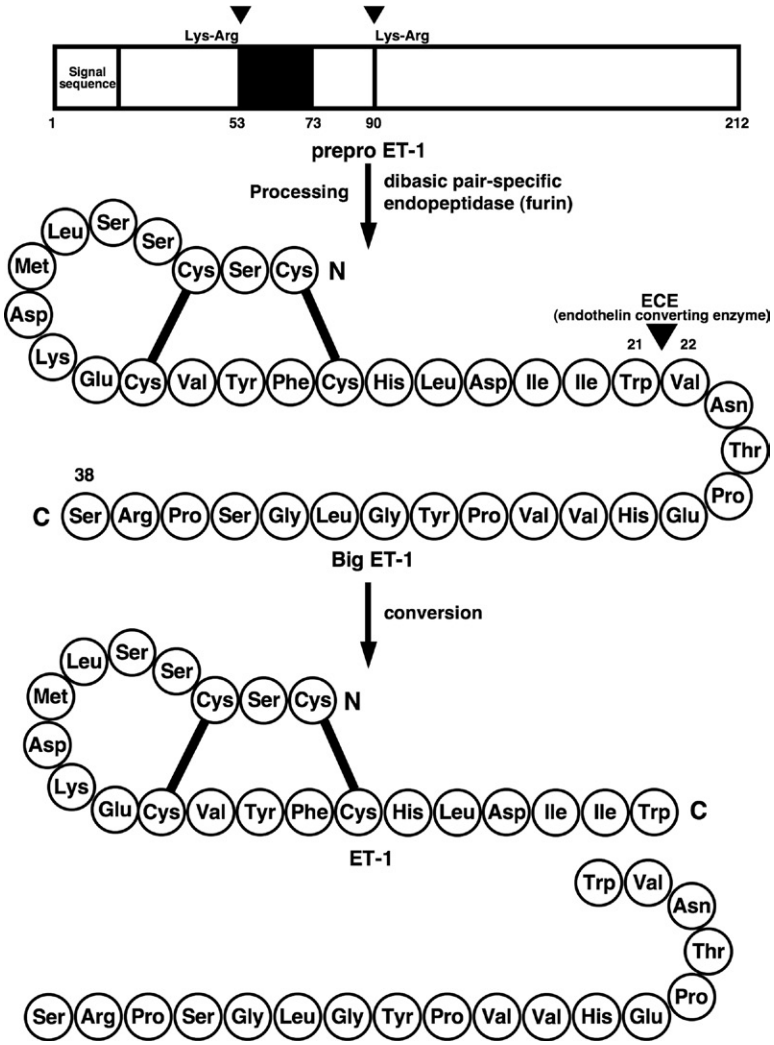

FIGURE 1 The biosynthesis, intracellular processing of endothelin-1 (ET-1) from preproET-1. Endothelin-converting enzyme (ECE) specifically catalyzes the conversion of big ET-1 to ET-1. Cys–Cys represents the intramolecular disulfide bond.

radioimmunoassay (RIA) or enzyme immunoassay (EIA)[25] was established soon after the discovery of endothelin-1. RIA uses only one kind of antibody against endothelin-1, whereas EIA uses two kinds of antibodies, each recognizing the N-terminal and C-terminal portions of endothelin-1, respectively. At an early stage, the reported plasma concentrations of endothelin-1 in humans were fairly divergent, ranging from 0.2 to 18.5pg/ml in healthy subjects. To avoid unnecessary confusion, the reason for the difference in the values of plasma endothelin-1 level was examined thoroughly and, as a result, it was generally agreed that the divergence originated mostly from differences in the specificity of the antibodies used and in the recovery rate during extraction of endothelin-1 from plasma or tissues. It is now accepted that the plasma concentration of endothelin-1 in healthy subjects is 1.0–2.0pg/ml,[13–16] which is at least one order of magnitude lower than that of circulating human natriuretic peptides and several times less than that of angiotensin II. Plasma concentrations of endothelin-1 increase drastically in the case of various cardiovascular diseases.[13–16]

Endothelin-1 may be released in both luminal and abluminal directions from endothelial cells *in vivo*. Luminal released endothelin-1 may be diluted by the blood stream, and its circulating concentration (1.0–2.0pg/ml) is below the threshold concentration producing vasoconstriction. Although the exact concentration in the abluminal space (vascular smooth muscle surface) is not known, endothelin-1 is more likely to be a locally acting rather than a circulating hormone. When endothelin-1 production and secretion are increased drastically in certain sites under pathophysiological conditions, severe local vasoconstriction might be anticipated.

When endothelin-1 is intravenously administered as a bolus, it disappears quite rapidly from the blood stream with a half-life of a few minutes. This rapid removal of endothelin-1 from the circulation results from uptake into

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

various tissues, including the lung, kidney, spleen, and liver. The lung seems to be one of the most important tissues for uptake, because approximately 60% of endothelin-1 is removed after a single passage through the pulmonary circulation. In lung tissues, the ET_B receptor is highly expressed and endothelin-1-ET_B receptor complex may be taken up into cells through an internalization process and degraded by lysozomal enzymes, for example, aspartic proteases. Neutral endopeptidase and lysozomal cathepsin G are also concerned with enzymatic degradation of endothelin-1. Despite such a rapid disappearance from the circulation, the blood pressure–elevating effect of endothelin-1 continues for an extremely long period; stabilization of the endothelin-1-ET_A receptor complex may contribute, but the exact reason for this phenomenon is unknown.

RECEPTORS AND THEIR DISTRIBUTION

Endothelin-induced responses can be divided into two major groups, according to the pharmacological potency order of the three isopeptides. In the first group of responses, including vascular constriction, broncho-constriction, uterine smooth muscle constriction, and stimulation of aldosterone secretion, endothelin-1 and endothelin-2 act as far more potent agonists than endothelin-3 do. In the second group, which includes endothelium-dependent vascular relaxation, astrocyte proliferation, and inhibition of ex vivo platelet aggregation, the three isopeptides possess almost equal potency. These findings suggest that there are at least two distinct endothelin receptors mediating these two distinct groups of pharmacological responses. The existence of multiple receptors was also supported by biochemical studies, for example, crosslinking experiments and radioligand-binding affinity study. Subsequently, two cDNAs encoding for endothelin receptors were cloned and their amino acid sequences were deduced.[1,21] The order of affinity of the three endothelin isopeptides for one receptor type, designated ET_A, is endothelin-1≧endothelin-2 ≥ endothelin-3. The other type of receptor, designated ET_B, shows equipotent affinity for all three endothelins. These results are consistent with the results of previous pharmacological and biochemical studies and, thus, definite molecular evidence for the existence of two distinct subtypes of endothelin receptors was provided.

The existence of more subtypes of endothelin receptor has been a matter of controversy. Much pharmacological evidence has accumulated to suggest that there may exist an ET_C receptor specific for endothelin-3, or further sub-subtypes of ET_A and ET_B receptors. However, there has been no report thus far on the isolation of the cDNA clone encoding for such a subtype or sub-subtype of endothelin receptors from mammalian tissues. One possible explanation is posttranslational modification of ET_A or ET_B receptor proteins, but to solve such discrepancies, further pharmacological, biochemical, or molecular biological analyses may be necessary.

In addition to causing constriction of vascular tissue, endothelin isopeptides exert pleiotropic effects on nonvascular tissues, for example, respiratory and gastrointestinal tissues, kidney, endocrine glands, and peripheral and central nervous system. Each endothelin isopeptide has been considered to play specific physiological and/or pathophysiological roles independently in various tissues. The pharmacological effects of endothelin-1 on various tissues and distribution of ET_A and ET_B receptors is collectively shown in Table 1.

TABLE 1 Distribution of ET_A and ET_B Receptors

Tissue (effect)	ET_A	ET_B
Vascular tissues		
Arterial smooth muscle (contraction)	+++	+
Venous smooth muscle (contraction)		++
Endothelial cell (release of EDRF)		+++
Cardiac muscle		
(Positive inotropism)	++	+
(Positive chronotropism)	++	+
Coronary vessel (contraction)	+++	+
Nonvascular smooth muscle (contraction)		
Airway, gastrointestinal tract, bladder, uterus, etc.	++	+
Lung (clearance receptor)		
Other than airways and vascular smooth muscle	+	+++
Endocrine glands		
Adrenal cortex (release of aldosterone)	+	+++
Anterior pituitary (release of ACTH and prolactin)	+	++
Ovary (stimulation of female hormone synthesis)	++	+
Kidney

BIOLOGICAL ACTIONS WITHIN THE CARDIOVASCULAR SYSTEM

Endothelin-1 causes extremely potent and long-lasting vasoconstriction in most mammalian species including humans, both *in vivo* and *in vitro*. The *in vivo* hemodynamic responses to intravenously injected endothelin-1 are complex, depending on the vascular bed, and include both direct vasoconstriction and indirect endothelium-mediated vasodilatation, and reflex-mediated responses. In most arterial and some venous smooth muscle cells, endothelin-1 causes constrictor responses via the stimulation of ET_A receptors on the cell membrane. By contrast, endothelin-1 stimulates ET_B receptors on endothelial cells and releases EDRF (endothelium-derived relaxing factor: nitric oxide), thereby producing vasodilatation. In cardiac muscle cells, endothelin-1 produces positive inotropic and chronotropic responses via stimulation of mostly ET_A receptors. Both ET_A and ET_B receptors are coupled to various GTP-binding proteins (Gq, Gs, Gi, Go, etc.), suggesting that the downstream signal transduction may differ in various cells depending on the type of GTP-binding proteins coupled.

In addition to vasoconstrictor actions (acute effects), endothelin-1 exerts potent mitogenic actions on vascular smooth muscle cells and cardiac myocytes (chronic effects), hence causing vascular and cardiac hypertrophy.[18,23,24] These effects are mediated via the stimulation of either ET_A or ET_B receptors and may be provoked through the sequential activation of intracellular kinase cascade, including raf-1, mitogen-activated protein kinase (MAPK) kinase, MAPK, and S6 kinase.[6,7,18]

PATHOPHYSIOLOGICAL IMPLICATIONS

The development of ET_A and/or ET_B receptor antagonists and gene-manipulated animals greatly accelerated elucidation of physiological and/or pathophysiological roles of endogenous endothelin-1. In normal states, the release of endothelin-1 seems to be sparse, and it plays no appreciable physiological role in the maintenance of blood pressure.

When the production and release of endothelin-1 are increased, endothelin-1 contributes to the pathogenesis of and stimulates the progression of various cardiovascular diseases.[11,17,18,20] Although the involvement of endothelin-1 in mild to moderate hypertension remains controversial, it is undoubtedly implicated in certain types of hypertension,[12] particularly in malignant stages of the disease. Pulmonary hypertension (PH) is a progressively deteriorating condition characterized by an increase in pulmonary vascular tone and enhanced proliferation of pulmonary vascular smooth muscle cells. There has been no effective therapeutic method for the treatment of this disease. PH is associated with the increase in plasma endothelin-1 levels, which is strongly correlated with the severity of the disease.[16–18] These aspects are discussed in more detail in the Respiratory Peptides section of this book. The endothelin receptor antagonists are remarkably efficacious in all animal models thus far investigated.[17,18] Bosentan (ET_A and ET_B receptor antagonist) is now available for the clinical treatment of PH (Fig. 2).[2,11] In atherosclerosis and in various kinds of vascular remodeling, endothelin-1 plays causing or progressing roles in the diseases. Currently, orally active endothelin receptor antagonists, such as bosentan, ambrisentan, macitentan, are applied to cardiovascular patients.[2,9,12,22] The concept of the cardiovascular continuum and angiotensin II was put forward by Dzau et al.[3–5] As for endothelin, we illustrate the concept of the cardiovascular disease continuum and the target diseases of the endothelin receptor antagonists as in Fig. 3. Endothelin antagonist will be extensively used for cardiac diseases, including cardiac hypertrophy, acute and chronic heart failure.[11,18]

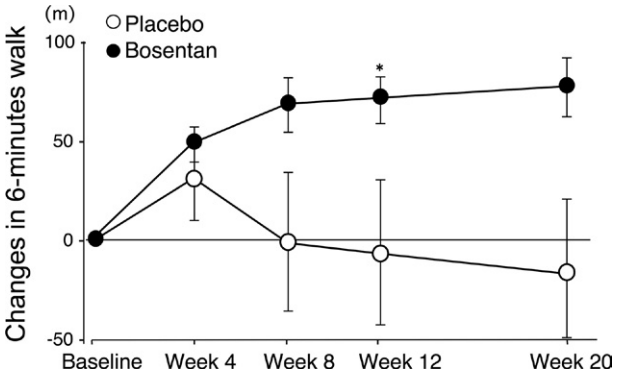

FIGURE 2 Effects of the $ET_{A/B}$ dual receptor antagonist bosentan treatment on 6-min walking distance. In double-blind, placebo-controlled study, 32 patients with pulmonary hypertension were randomly assigned to receiving bosentan (62.5 mg twice daily) for 4 weeks, then 125 mg twice daily or placebo. From baseline to week 20, bosentan increased the mean 6-min walking distance from 360 m to 437 m, whereas the distance was decreased in the placebo group from 355 m to 340 m. *: $P<0.05$ versus baseline, $P=0.021$ versus placebo. (From *The Lancet* 2001;**358**:1119–1123 (Ref. 2). With permission from Elsevier.)

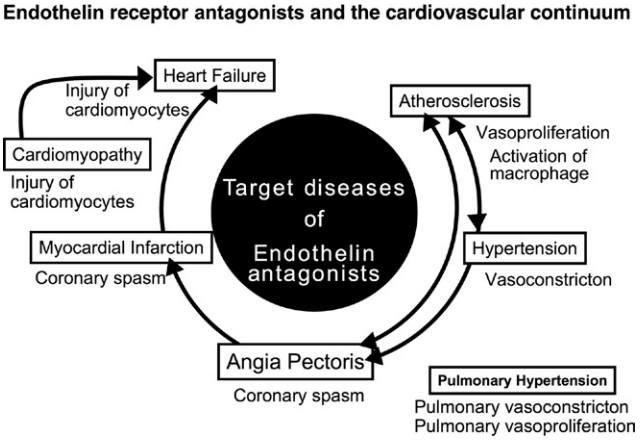

FIGURE 3 The cardiovascular disease continuum and the target diseases of the endothelin receptor antagonists.

Endogenous endothelin-1 is considered to be involved in the progression of atherosclerosis, hypertension, angina pectoris, myocardial infarction, heart failure, and pulmonary hypertension, and these diseases may become target diseases of the endothelin receptor antagonists (Fig. 3). Endothelin receptor antagonists have been shown to exhibit desirable preventive and/or curative effects in various animal models of these cardiovascular diseases,[11,18] suggesting that they are of potential therapeutic value, and some of them are already under clinical use.

Ghrelin

Ichiro Kishimoto, Takeshi Tokudome, Hiroshi Hosoda, Mikiya Miyazato and Kenji Kangawa

ABSTRACT

Ghrelin, a peptide isolated from the stomach, exerts potent growth hormone-releasing and orexigenic actions. Recently, several lines of evidence suggest the beneficial effects of ghrelin in cardiovascular diseases. Administration of ghrelin for heart failure improves cardiac dysfunction and remodeling in humans and in animals. In addition, ghrelin treatment early after myocardial infarction effectively reduces fatal arrhythmia and, consequently, mortality. Moreover, ghrelin effectively reduces pulmonary hypertension induced by chronic hypoxia. Ghrelin provides various beneficial effects such as an increase in plasma growth hormone level, an improvement of energy balance, direct actions on cardiovascular cells, and regulation of autonomic nervous activity. It is, therefore, suggested that ghrelin would be a novel promising therapeutic agent for cardiovascular diseases.

INTRODUCTION

Ghrelin was purified from rat stomach by a reverse pharmacology paradigm in a stable cell line overexpressing its receptor.[14] Purification of ghrelin from the stomach indicates that the release of growth hormone (GH) from the pituitary is regulated not only by hypothalamic GH-releasing hormone but also by a peripherally derived hormone. Given the hemodynamic and metabolic effects of GH and its mediator, insulin-like growth factor-1 (IGF-1), ghrelin may have beneficial effects on the cardiovascular system. In addition, ghrelin has several actions on the heart and the vessel independent of GH/IGF-1. This chapter mainly focuses on the biological actions and therapeutic potential of ghrelin in cardiovascular diseases.

DISCOVERY

It has been known that small synthetic compounds called growth hormone secretagogues (GHS) stimulate the release of GH from the pituitary.[31] They act through their receptor (GHS-R), a G protein-coupled receptor (GPCR) with seven-membrane spanning domains.[8] In 1999, by a screening technology that matches orphan GPCRs with unknown cognate ligands by detection of the agonist-induced increase in intracellular calcium levels, a 28-amino acid peptide was purified from the stomach as the endogenous ligand for GHS-R.[14] It was named "ghrelin," from the word root "ghre" in Proto-Indo-European languages meaning "grow." Ghrelin also represents an abbreviation for "GH-release," a characteristic feature of the peptide.[14]

In the brain, ghrelin acts on GHS-R in the pituitary with its potent GH-releasing activity. The discovery of ghrelin shows that the release of GH from the pituitary is regulated not only by hypothalamic GH-releasing hormone (GHRH) but also by a peripherally derived hormone. In addition to its GH-releasing activity, ghrelin stimulates appetite by acting directly or indirectly on the hypothalamic arcuate nucleus, the region known to control food intake in humans and in rodents.[7,26] Furthermore, peripheral roles of ghrelin in the cardiovascular, bone, gastrointestinal, and immune systems have been implicated.[15]

STRUCTURE OF THE mRNA/GENE

The human ghrelin gene consists of five exons, which span 5 kb of genomic DNA on chromosome 3p25-26. Although the first exon encodes the 5′-untranslated region, the second and third exons encode the 28 amino acids of ghrelin peptide.[11] As described previously, the stomach is the major tissue, which produces ghrelin, and in situ analysis revealed that ghrelin and its mRNA are mainly localized in the submucosal layer of the stomach. Among four types of endocrine cells, that is, ECL, D, enterochromaffin, and X/A-like cells in the oxyntic mucosa of the stomach, ghrelin is found in X/A-like cells,[5] which were named so because of its previously undefined function and of the morphological similarity to pancreatic alpha cells. Cells producing ghrelin mRNA are also found in the intestines[5] and in the brain,[26] but at a much lower level than in the stomach.

PROCESSING OF THE PRECURSOR

The 28 amino acids of ghrelin are cleaved from its precursor, preproghrelin, which consists of 117 amino acids in

Handbook of Biologically Active Peptides. http://dx.doi.org/10.1016/B978-0-12-385095-9.00191-3

Copyright Elsevier 2024

rats and in humans.[16] The amino acid sequences of ghrelin precursors are well conserved among mammalian species. The distinguishing structural feature of ghrelin is its fatty acid modification at the third residue (serine in most species including humans).[14,16,31] Interestingly, the acylation, particularly the *n*-octanoyl modification, is conserved among many species including mammals, fish, birds, and amphibians and is necessary for full binding of ghrelin to its receptor, GHS-R, and thus for expressing the biological function.[14] Although an enzyme that catalyzes the acyl modification of ghrelin had been proposed, the attachment of octanoate to the third serine residue of ghrelin is catalyzed by a membrane-bound enzyme, named ghrelin O-acyltransferase (GOAT)[35] (see the chapter on GOAT in the Peptide Biosynthesis/Processing section of this book for details).

REGULATION OF PLASMA GHRELIN CONCENTRATION

From the submucosal layer of the stomach, ghrelin is secreted not into the gastrointestinal tract but into the blood stream. Results from patients with gastrectomy or gastric bypass surgery suggest that a major portion of the circulating ghrelin in plasma is from the stomach.[4,16] The plasma level of ghrelin and mRNA level in the stomach are increased by fasting and decreased by feeding,[3] and it is low in obese people and high in lean people.[4,34] In addition, oral or intravenous administration of glucose or meals with high lipid content decreases plasma ghrelin level. Furthermore, fasting plasma ghrelin concentrations are high in patients with anorexia nervosa. Thus, the nutritional state seems to be a major determinant of release of ghrelin from the stomach. Together with the potent orexigenic action, it is speculated that ghrelin serves as a "hunger hormone."[3]

Although it does not correlate with left ventricular systolic function, plasma ghrelin concentrations are elevated in cachectic patients with congestive heart failure (CHF)[25] or with chronic obstructive pulmonary diseases (COPD).[10] Given the anabolic effects of ghrelin, the increased plasma concentration may represent a compensatory mechanism under conditions of metabolic imbalance in such patients.

DISTRIBUTION OF THE mRNA/PEPTIDE IN THE CARDIOVASCULAR SYSTEM

Studies using polymerase chain reaction reveal that ghrelin mRNA can be found in parts of the body other than the stomach or brain, including heart, lung, kidney, and pancreas, although the significance of the localization and the production of mature ghrelin are not fully known. In brain, GHS-R mRNA is predominantly expressed in the arcuate and ventromedial nuclei and in the hippocampus,[8] although it is also detected in other parts of the neuronal system such as the pituitary and dentate gyrus. In the periphery, GHS-R mRNA can be found in various organs including the heart, lung, liver, kidney, pancreas, and the gastrointestinal tract. In addition, there is expression of ghrelin peptide and mRNA in a cultured cardiomyocyte cell line and in human vascular endothelial cells. Furthermore, although to a much lower extent than in the pituitary, GHS-R is also expressed in human myocardium[9] and in the aorta. Interestingly, in some cultured cells such as H9C2 cardiomyocytes and endothelial cells, a subtype of ghrelin receptor, which is distinct from GHS-R, is speculated to occur, since the binding affinity of either acylated or nonacylated ghrelin to the receptor was similar.[1]

RECEPTORS AND SIGNALING CASCADES

As stated, GHS-R, which was identified by expression cloning in 1996, acts as a receptor for ghrelin and ghrelin-induced GH release and appetite promotion are mediated through it.[32] So far, two types of transcript variants have been identified in several tissues and in several species. One transcript, GHS-R1a, encodes the functionally active protein and defines the effect of ghrelin for GH release. The second transcript, GHS-R1b, is derived only from the first exon by alternative splicing, retains the intron and does not function as a receptor for ghrelin. It might, however, attenuate the activity of GHS-R1a by acting in a dominant negative fashion. The amino acid sequences of the ghrelin receptor are well conserved across all vertebrate species examined from mammals to fish, implicating the important role of ghrelin and its receptor system in basic physiological functions.

In the pituitary, although GHRH stimulates GH release through a cyclic AMP-dependent pathway, ghrelin stimulates GH release through an elevation of intracellular calcium concentration. In different cell types, it is reported that ghrelin activates mitogen-activated protein kinase, Akt, nitric oxide synthase, or AMPK cascades.

BIOLOGICAL ACTIONS WITHIN THE CARDIOVASCULAR SYSTEM

Since the administration of ghrelin decreases blood pressure, reduces cardiac afterload, and increases cardiac output without affecting the heart rate in humans and in animals, the significance of ghrelin in cardiac diseases deserves to be studied.[21] In addition, ghrelin potently stimulates GH release from the pituitary gland, improves energy balance, and modulates the autonomic nervous system, all of which could have potentially beneficial effects on the cardiovascular system. Moreover, the receptor for ghrelin, GHS-R, can be found in cardiac ventricles and in blood vessels, suggesting that ghrelin may have direct cardiovascular actions.

Growth Hormone Release

Ghrelin was originally discovered as an endogenous ligand for GHS-R and has potent GH-releasing activity (see the ghrelin chapter in the Brain Peptides section of this book). Ghrelin increases GH release from cultured pituitary cells. In addition, intravenous ghrelin administration markedly increases circulating GH in rats and in humans with a potency comparable to that of GHRH. After bolus ghrelin injection, the concentration of GH peaks between 15 and 20 min and the elevation lasts >60 min afterward.[22] Interestingly, ghrelin-induced GH release is abolished by resection of the gastric branch of the vagus nerve, suggesting that the effect of ghrelin is mediated via vagal afferent nerve activity.[6] In fact, the receptor for ghrelin is synthesized in vagal afferent neurons and transported to the afferent nerve terminals.[6]

GH and its mediator, IGF-1, are anabolic hormones that are essential for skeletal and myocardial growth and for metabolic homeostasis. Therefore, through the GH/IGF-1 pathway, ghrelin may have beneficial effects on cardiac function and on energy metabolism in diseases such as CHF. Because GH exerts both direct and indirect effects on cardiac structure and function, the cardiovascular effect of ghrelin might be mediated by the elevation of GH levels. Ghrelin when given in a physiological dose has no acute effects on cardiac function in patients with severe GH deficiency, suggesting that most of its acute actions in individuals with an intact GH system are mediated by GH. In addition, in hypophysectomized rats with GH deficiency, ghrelin plays a minor role in the control of cardiac function after ischemia/reperfusion injury.

However, the therapeutic effect of ghrelin is not accompanied by increases in GH-induced serum IGF-I levels or in heart weight, suggesting that ghrelin has actions independent of GH, especially in disease states. In addition, several lines of evidence showing the GH-independent mechanisms of ghrelin action are accumulating as described below.

Improved Energy Balance

The hypothalamic arcuate nucleus, the center of controlling the appetite, is one of the main sites of the ghrelin action (see the ghrelin chapters in the Brain, Ingestive, and Gastrointestinal Peptides sections of this book). Nakazato et al. first described that exogenously administered ghrelin has a potent appetite-stimulating effect.[26] Because the orexigenic effect of ghrelin can be observed in GH-deficient dwarf rats, the appetite-promoting effect is independent of GH release. In addition, ghrelin induces weight gain by reducing the use of fat.[33] In patients with end-stage CHF, both left ventricular dysfunction and cardiac cachexia are observed. Cardiac cachexia, which is a catabolic state characterized by weight loss and muscle wasting, is associated with hormonal changes and cytokine activation in patients with CHF. The presence of cardiac cachexia is a strong independent factor for mortality in patients with CHF. Therefore, cardiac cachexia and left ventricular dysfunction are therapeutic targets in the treatment of CHF. Because ghrelin causes a positive energy balance through GH-dependent and independent mechanisms, the administration of ghrelin may be of clinical value in cachectic patients with CHF. In fact, in ghrelin-treated patients with CHF, the improvement of cardiac function is associated with increases in body weight, in lean body mass, and in muscle strength.[23] Therefore, the orexigenic action of ghrelin might contribute to improving energy balance in patients with cachexia resulting from severe pathological conditions such as end-stage cardiovascular disease.

Direct Cardiovascular Actions

The presence of GHS-R mRNA in cardiovascular cells suggests direct actions of ghrelin in these cells. Because intra-arterial ghrelin effectively increases forearm blood flow measured by plethysmograph in humans, it is proposed that ghrelin acts directly on blood vessels.[27] Supporting this, in isolated human arteries, it is seen that ghrelin has an endothelium-independent vasodilating property.[13]

In addition, treatment with ghrelin is reported to inhibit apoptosis of cultured cardiomyocytes and endothelial cells possibly through the activation of extracellular signal–regulated kinase-1/2 and Akt serine kinases.[1] Interestingly, des-acyl ghrelin, which lacks the acylation at the third Ser residue, does not bind GHS-R, and is devoid of any endocrine activity, is also effective in inhibiting apoptosis.[1] The findings raise the possibility that ghrelin may act as a survival factor directly on the cardiovascular system possibly through binding to a yet to be identified receptor distinct from GHS-R.

Cardiac Sympathetic Efferent Pathway

Administration of ghrelin significantly suppresses the increased heart rate in cardiac diseases.[30] In addition, in both humans and animals, ghrelin significantly suppresses plasma norepinephrine concentrations. Furthermore, intracerebroventricular administration of ghrelin inhibits sympathetic nerve activity.[19] We investigated the subcutaneous administration of ghrelin in a rat model of myocardial infarction and, by the direct recoding of cardiac sympathetic nerve activity, showed that ghrelin prevents an increase in cardiac sympathetic nerve activity, which was accompanied by the reduction in mortality.[28] In acute myocardial infarction, because it is the initial increase in cardiac sympathetic nerve activity that considerably contributes to ventricular arrhythmia and, consequently, a high mortality, it is suggested that ghrelin injection after myocardial infarction

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

would attenuate the early increase in sympathetic nerve activity, which could potentially improve cardiac prognosis.

Cardiac Vagal Afferent Pathway

Peripherally administered ghrelin stimulates hypothalamic neurons, which results in the increase in the food intake. Date et al. showed that ligation of the gastric branch of the vagal nerve suppressed the orexigenic effect of peripherally administered ghrelin.[6] In addition, chemical denervation by capsaicin, a neurotoxin specific for sensory afferents, also blocked the orexigenic effect of ghrelin, indicating that the appetite-promoting effect of peripherally administered ghrelin was mediated via vagal sensory afferent nerves.[6] Furthermore, microinjection of ghrelin into the nucleus of the solitary tract (NTS), the brain region important for controlling the autonomic nervous system, decreases the heart rate and mean arterial pressure.[18] Because cardiac vagal afferent nerves send projections to the NTS, it is speculated that ghrelin might decrease cardiac sympathetic nerve activity through vagal afferent nerves and the NTS. In addition, immunostaining with a specific antibody against GHS-R clearly shows the presence of the ghrelin receptor on the nerve terminals of the infarcted heart.[12] Taken together, these results suggest that the administration of ghrelin might exert its potent sympathetic inhibitory action by acting on the peripheral nerve terminals within the heart, which, through vagal afferent nerves, sends signals to the vasomotor center of the medulla via the NTS, resulting in decreases in sympathetic activity and in the heart rate upregulated in myocardial infarction. The proposed neuronal pathway of peripherally administered ghrelin is summarized schematically in Fig. 1.

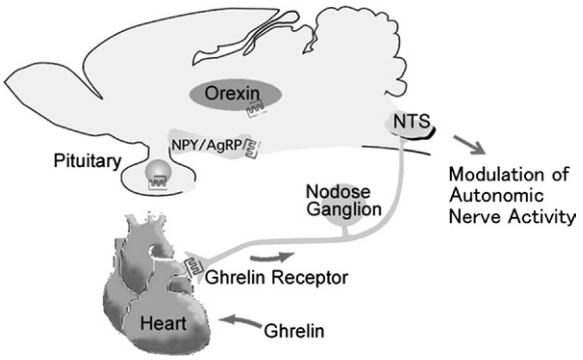

FIGURE 1 Schematic representation of the neuronal pathway in autonomic modulatory actions of ghrelin. Peripheral administration of ghrelin potently inhibits the cardiac sympathetic nerve activity in diseases such as myocardial infarction and heart failure. Ghrelin acts on cardiac vagal afferent nerve terminals, which send signals to the vasomotor center of the medulla through the nucleus of the solitary tract (NTS). The resultant inhibition of sympathetic nerve activity could protect the heart from excessive damage. *(Modified from Ref 12.)*

Anti-inflammatory Action

Ghrelin suppresses the production of proinflammatory cytokines, including interleukin-1β (IL-1β), interleukin-6 (IL-6), and tumor necrosis factor-α (TNF-α). In addition, ghrelin inhibits the activation of nuclear factor-κB (NF-κB), a transcriptional factor regulating the gene expression of proinflammatory cytokines.[17] In patients with pulmonary infections, chronic administration of ghrelin decreases inflammatory cytokine levels. Inhibition of the release of proinflammatory cytokines could be mediated at least partly by the ghrelin-induced activation of the vagus nerve. Because cardiovascular diseases are often accompanied by an augmented inflammatory response, ghrelin may exert its protective actions through these anti-inflammatory responses.

PATHOPHYSIOLOGICAL IMPLICATIONS

Plasma Concentrations of Ghrelin in Cardiopulmonary Diseases

Patients with CHF often exhibit some cachexia, which is an independent risk factor for mortality in such patients. Although plasma ghrelin concentrations do not differ significantly between patients with CHF and control subjects, they are significantly higher in CHF patients with cachexia than in those without cachexia. Similarly, plasma ghrelin is elevated in lean patients with COPD. Considering the known potent anabolic effect of ghrelin, the increase in plasma ghrelin in cachectic patients could be a compensatory mechanism.

Therapeutic Potential of Ghrelin in Heart Failure

A previous animal study revealed that chronic ghrelin treatment improved cardiac performance in rats with chronic heart failure, as shown by increases in cardiac output and left ventricular fractional shortening.[24] In addition, when intravenous bolus ghrelin (2 μg/kg, twice a day) was administered to the patients with CHF for three weeks, left ventricular ejection fraction was significantly improved ($27 \pm 2\%$ to $31 \pm 2\%$; $P < 0.05$), which was accompanied by an increase in peak workload and peak oxygen consumption during exercise.[23] Furthermore, three-week administration of ghrelin resulted in a dramatic decrease in plasma norepinephrine (1132 ± 188 to 655 ± 134 pg/mL; $P < 0.001$). These results, therefore, suggest the therapeutic potential of ghrelin in patients with CHF.

Therapeutic Potential of Ghrelin in Myocardial Infarction

Left ventricular remodeling after myocardial infarction is often associated with subsequent heart failure, which could

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

lead to a fatal outcome. In a rat model of experimental myocardial infarction, we examined whether peripheral ghrelin administration attenuates left ventricular dysfunction and remodeling.[30] A two-week subcutaneous administration of ghrelin (100 μg/kg, twice a day) significantly improved left ventricular enlargement induced by myocardial infarction. In addition, there was a substantial decrease in left ventricular end-diastolic pressure and increases in the peak rate of the rise and fall (d*P*/d*t* max and min) of left ventricular pressure in ghrelin-treated rats compared with saline-treated controls. Furthermore, ghrelin attenuated an increase in morphometrical collagen volume fraction of the noninfarct region. Interestingly, the beneficial effects of ghrelin were accompanied by the complete suppression of the infarction-induced increase of heart rate.[30] Because the effect of ghrelin on the heart rate is more marked than on other parameters examined, it is speculated that ghrelin might have an inhibitory action on the infarction-induced activation of the sympathetic nerve independent of the improvement of cardiac function.

We next examined whether a subcutaneous injection of ghrelin (150 μg/kg) 1 min after the infarction leads to a beneficial effect.[28] Surprisingly, the early one shot bolus injection of ghrelin significantly reduced the high mortality rate associated with myocardial infarction. Although the mortality rate after infarction was 61% in vehicle-treated rats, it was significantly reduced to 23% in ghrelin-treated rats.[28] In the ghrelin-treated group, there were significantly fewer arrhythmic insults by the second to third hour after myocardial infarction.[28] Because one of the key factors that contributes to a high mortality after acute myocardial infarction is malignant ventricular arrhythmia, these results indicate that ghrelin treatment early after myocardial infarction improves survival by preventing fatal ventricular arrhythmias.

Effects of Ghrelin on Myocardial Ischemia/Reperfusion Injury

Administration of ghrelin protects the heart against ischemia/reperfusion injury.[2] The cardioprotective effects of ghrelin are independent of GH release and probably involve binding of the peptide to receptors in the heart. The beneficial effect of ghrelin infusion on myocardial ischemia/reperfusion injury might be attributed to the antiapoptotic effect of ghrelin via the ERK 1/2 and PI3 K/Akt-dependent pathway.

Therapeutic Potential of Ghrelin in Pulmonary Hypertension

In COPD, a sustained alveolar hypoxia leads to irreversible remodeling of the pulmonary artery. The consequent elevation of arterial pressure increases the workload of the heart, which can lead to heart failure and to increased morbidity and mortality. We tested whether ghrelin would impede pulmonary arterial hypertension during chronic hypoxia.[29] Under a hypoxic condition (10% of oxygen), conscious male rats received a daily subcutaneous injection of ghrelin (150 μg/kg) and pulmonary arterial pressure was continuously measured by radiotelemetry. In control rats, chronic hypoxia significantly increased pulmonary arterial pressure (110% increase in mean pressure), wall thickness of peripheral pulmonary arteries, and, consequently, right ventricular hypertrophy. In ghrelin-treated animals, the hypoxia-induced development of pulmonary hypertension was significantly attenuated to 48% increase in mean pressure, which was accompanied by improvement of pulmonary vascular remodeling, and right ventricular hypertrophy.[29] In addition, hypoxia-induced overexpression of endothelial nitric oxide synthase and endothelin-1 mRNA were attenuated in ghrelin-treated group. In patients with COPD, it is, therefore, suggested that ghrelin prevents pulmonary hypertension and right ventricular hypertrophy. Furthermore, patients with COPD often show a certain degree of cachexia, which is an independent risk factor for mortality in COPD. The repeated administration of ghrelin improves body composition, muscle wasting, functional capacity, and sympathetic augmentation in cachectic patients with COPD.[20] Taken together, these results indicate that the administration of ghrelin could be an effective therapy to these patients.

Atherosclerosis

Plasma ghrelin level is negatively correlated with atherosclerosis in elderly patients with metabolic syndrome or with hypertension, and in patients with endothelial dysfunction. Administration of exogenous ghrelin can improve endothelial dysfunction, an early marker for atherosclerosis, in patients with metabolic syndrome. It is speculated that the antiatherosclerotic effect of ghrelin could be mediated by increasing the bioavailability of nitric oxide, by decreasing oxidative stress, or by inhibiting inflammatory process.

CONCLUSIONS

Ghrelin is a GH-releasing peptide, isolated from the stomach, which has been identified as an endogenous ligand for GHS-R. Administration of ghrelin improves body composition, muscle wasting, functional capacity, and sympathetic hyperactivation seen in cachectic patients. In addition, ghrelin exerts cardioprotective actions in diseases such as heart failure, myocardial infarction, pulmonary hypertension, and fatal arrhythmias through various mechanisms including GH release, direct actions on cardiovascular cells, and inhibition of the sympathetic nervous activity (Fig. 2).

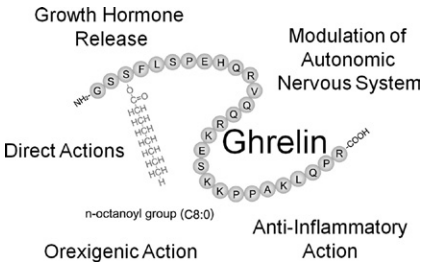

FIGURE 2 Structure of ghrelin and underlying mechanisms of its cardioprotective actions Ghrelin is a 28-amino acid peptide isolated from the stomach. A distinguishing structural feature of ghrelin is its *n*-octanoylation at the third serine residue, which is necessary for its receptor binding and function. Ghrelin potentially protects the diseased heart possibly through growth hormone (GH)-releasing activity, orexigenic action, direct effects on the cardiovascular cells, and inhibition of activated sympathetic nerves in cardiac diseases.

Treatment with ghrelin offers several advantages: ghrelin treatment for a short period of time in the acute setting is sufficient to exert protective actions, it can be administered by the convenient subcutaneous route, and it probably can be used more safely than chemically synthesized drugs because it is an endogenous hormone. Because of these advantages over other medications, ghrelin can be a promising new treatment for cardiac diseases.

Chapter 192

Natriuretic Peptides

Naoto Minamino and Toshio Nishikimi

ABSTRACT

The natriuretic peptide family in mammals consists of three homologous peptides: atrial (A-type) natriuretic peptide (ANP), brain (B-type) natriuretic peptide (BNP), and C-type natriuretic peptide (CNP). ANP and BNP bind to natriuretic receptor-A, whereas CNP acts on natriuretic receptor-B. Natriuretic receptor-A and B are receptor-guanylyl cylases, and these peptides dilate blood vessels and induce diuresis/natriuresis by increasing the intracellular cGMP concentration. ANP and BNP are most abundantly synthesized in cardiomyocytes, whereas CNP is expressed in neurons, endothelial cells, and cardiac fibroblasts. Natriuretic peptide receptors are widely expressed in the peripheral tissue, and these peptides not only regulate blood pressure and body fluid volume but also inhibit remodeling of heart and blood vessels. The plasma concentrations of ANP and BNP are increased in the cardiovascular disease. Thus, natriuretic peptides are crucial regulatory factors and biomarkers in the cardiovascular system.

DISCOVERY OF NATRIURETIC PEPTIDES (NPs)

Mammalian atrial cardiac myocytes exhibit the morphology of endocrine cells and contain "atrial specific granules." By the beginning of 1980s, atrial extracts were shown to induce potent diuresis/natriuresis and hypotension when injected into rats. Soon after confirmation of the correlation between diuretic/natriuretic activity and smooth muscle relaxant activity of the atrial extracts, the diuretic/natriuretic and hypotensive factor was isolated, and its structure was determined in 1983–1984. As many research groups competed for its identification, this peptide was first given a variety of names, such as atriopeptin, cardionatrin, and auriculin but is now generally called atrial natriuretic peptide (ANP).[19,21,23]

The second member of the NP family was isolated from pig brain extracts by monitoring of the relaxant activity of chick rectum in 1988 and named brain natriuretic peptide (BNP).[19,21,23] In a few years, this peptide was shown to be a cardiac peptide mainly expressed in the ventricle;[12] the concentration of BNP in brain was extremely low in rodents and human. BNP is now recognized as B-type NP of the NP family.

The third NP was also identified in 1990 in the pig brain extracts by the same procedures and named C-type natriuretic peptide (CNP).[19,21,23] CNP is present in human brain, not at a high concentration but at the highest concentration of the members of the NP family. CNP is considered to be a true brain NP, but this peptide is produced in the vasculature, heart, bone, macrophages, and elsewhere.[19,21,28] CNP is an original and ancestral peptide of the NP family, as described elsewhere in this book.

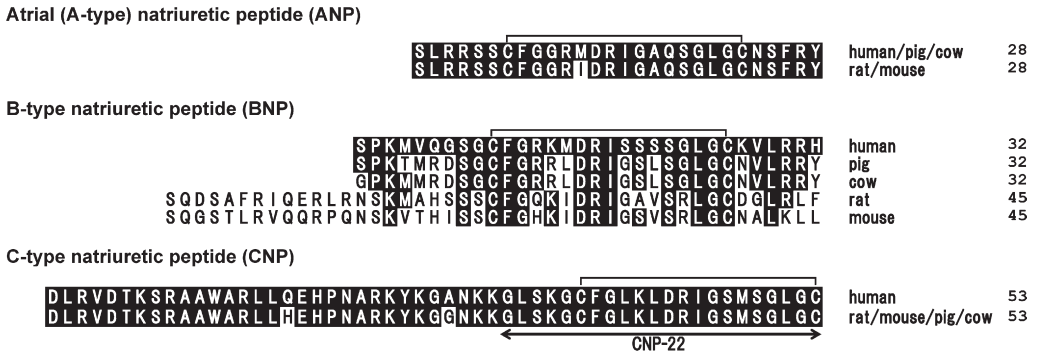

FIGURE 1 Amino acid sequences of major active forms mammalian ANP, BNP, and CNP. Highlighted letters (white in black) indicate amino acids common to human NP in each group, and bracket over top NP sequence of each group indicates a disulfide linkage that forms the ring structure. CNP-22 sequence is shown by arrowed line at the bottom. Number on the right edge is residue number of each peptide.

Figure 1 shows the amino acid sequences of major active molecular forms of human ANP, BNP, and CNP.[19,21,23,25] All NPs have two cysteine residues in the molecule, and a 17-residue ring structure formed by a disulfide linkage is essential for exerting biological activity. In this ring structure, the amino acid sequence is well conserved among the three NPs. In the case of ANP and BNP, the C-terminal extension from the ring structure is essential for their biological activity, while CNP does not have it. In all NPs, the N-terminal extension does not alter the primary potency of biological activity. In mammalian ANPs, α-ANP of 28-amino-acid residues is an endogenous and active form, and only one amino acid replacement (Met/Ile) is observed. There are many replacements in the case of BNPs, and the length of a major endogenous form is different between rodents (BNP-45) and other mammals (BNP-32). CNP is present as CNP-22 and CNP-53, both of which have a comparable activity. CNP-53 is generally a major endogenous form. The amino acid sequence of CNP-22 is identical in all mammals, and two replacements are observed in the CNP-53 sequence.

STRUCTURE OF THE NP mRNAs/GENES

The exon–intron organization, structure of mRNA, precursor protein, active form, and other endogenous forms of three mammalian NPs are schematically represented in Figure 2. Three mammalian NP genes are each coded in three exons. Human ANP and BNP genes are neighboring genes located at 11,905,766–11,907,840 (reverse strand) and 11,917,521–11,918,988 (reverse strand) in chromosome 1, and no transcript from the 9.7 kb intervening sequence has been recorded. Human CNP gene is located at 232,786,530–232,791,113 (reverse strand) in chromosome 2.

In the 5′-flanking region (FR) of rat ANP gene, GATA, NKE, TBE, AT-rich, and phenylephrine-responsive elements, and CArG boxes/SRE are present as *cis*-acting elements, and the binding of transcriptional factors, GATA4/6, Nkx2.5/Csx, Tbx5, MEF2C, Zfp260, and SRF, to these elements are reported to be important for ANP gene transcription. Neuron-restrictive silencer factor (NRSF), which binds to the 3′-untranslated region (UTR) of the ANP gene, also regulates the ANP gene transcription.[3,10] In the 5′-FR of the BNP gene, GATA, M-CAT, SRE, shear stress- and thyroid hormone-responsive element, and NFAT, NRSF and AP-1/CRE-like binding sites are observed, and binding of transcriptional factors to these elements and sites increases BNP gene transcription. Most of these transcriptional factors in the ANP and BNP gene expression are essential for embryogenesis and morphogenesis of heart tissue.[3,10] Regulation of CNP gene expression has been less well studied. Human CNP gene has an inverted CCAAT box, 2 GC boxes, and a CRE-like sequence in the 5′-FR. Although the GC box is crucial for TGF-β- and shear stress-induced gene expression, the number of GC box is different between human and rodents. The rodent CNP gene in the kidney is positively regulated by the Wnt

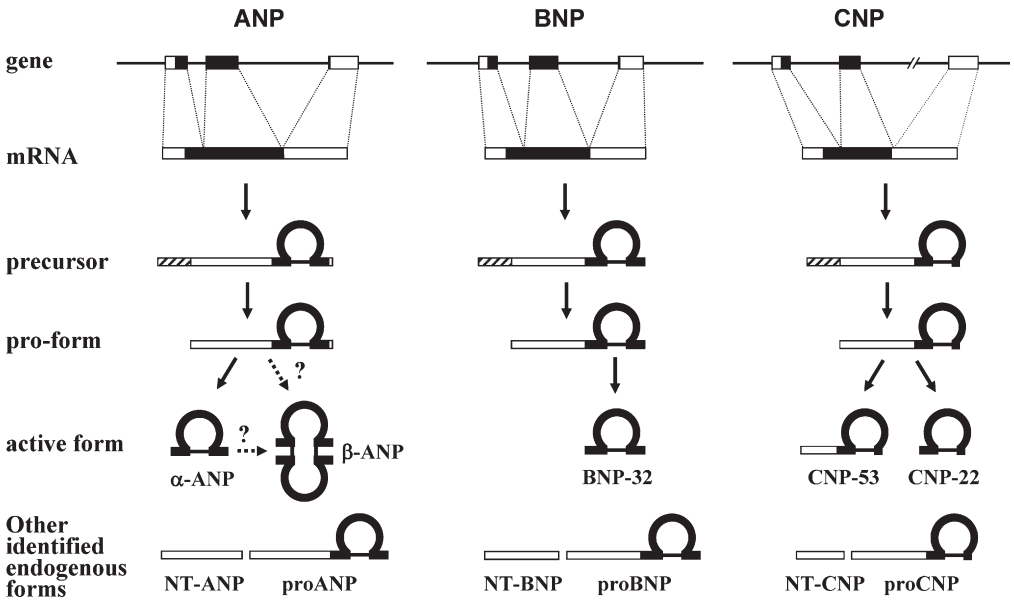

FIGURE 2 Schematic representation of genes, mRNAs, precursors, and active forms of human ANP, BNP and CNP. Boxes in the gene row indicate exons, and black and white regions represent coding and noncoding regions, respectively. In the precursor, proform and active form rows, hatched bar, white bar and ring structure indicate signal peptide, N-terminal intervening peptide and active unit of each NP, respectively. In ANP, 2 arginines are usually inserted after α-ANP as shown by a white bar. In addition to major active forms, identified endogenous forms of NPs are shown at the bottom. The proform of each NP has weak but significant biological activity.

signaling pathway, operating through β-catenin and T-cell factor/lymphoid enhancer binding factor, of which the binding site is shared with human CNP gene.[3,28]

The apparent length of human NP mRNAs is about 850–900 bp for ANP and BNP, and 1300 bp for CNP, and the difference in the mRNA length mainly results from that in the 3′-UTR. In the 3′-UTR of BNP gene, AUUUA repeats are present, which accelerates mRNA degradation. The BNP gene expression is considered to be posttranscriptionally controlled for adapting to dynamic physiological alterations.[19,21,25]

The precursor proteins of human ANP, BNP, and CNP are 153, 134, and 126 amino acids in length, and the active structure is located at the C-terminus in each precursor. In the cases of the ANP precursor, two arginines are inserted after α-ANP, except for pig and dog.[19,21,23,25] There are two human ANP genes; one has this insertion, whereas another not.

PROCESSING OF THE NP PRECURSORS

ANP is stored in the cardiac myocytes as a 126-residue polypeptide called γ-ANP, which lacks the C-terminal 2 arginines from proANP. In the normal heart tissue, ANP is almost exclusively present as γ-ANP. When secreted, it is cleaved after a Pro-Arg sequence mainly by corin, a specific converting enzyme for ANP, to generate α-ANP and an N-terminal intervening peptide (NT-ANP).[35] In the atrium of patients with heart failure, α-ANP is present in the myocytes along with a unique antiparallel dimer of β-ANP. In the plasma, α-ANP is a major circulating and active form, along with inactive NT-ANP (Fig. 2). In mammals other than humans, γ-ANP and α-ANP are major forms in the heart and plasma, respectively.[21,23]

In the case of human BNP, proBNP is processed probably by furin to BNP-32 and an N-terminal 76-residue peptide (NT-BNP). In heart tissue, BNP is present as both proBNP and BNP-32. BNP-32 is a major molecular form in the atrium, whereas proBNP is a major form in the ventricle.[17] Both proBNP and BNP-32 circulate in the plasma, and proBNP is a major form in severe heart failure. In the pig, BNP is present as proBNP in the heart and as BNP-32 and BNP-26 in the plasma. As expected from its sequence heterogeneity (Fig. 1), an endogenous form of mammalian BNP is different in each animal. In the rat, BNP-45 and proBNP are major forms in the atrium and ventricle, respectively, whereas BNP-45 is a major form in the plasma. NT-BNP is present in the plasma at a much higher concentration than BNP-32.[19,21,25] A high percentage of human plasma proBNP and NT-BNP are *O*-glycosylated, which increases their molecular masses >10 KDa. There are 7 *O*-glycosylated Ser/Thr residues, T36, S37, S44, T48, S53, T58, and T71,[26] and glycosylation of T71 inhibits the conversion by furin from proBNP to BNP-32.[29] (see the Furin chapter in the Peptides Biosynthesis/Processing section of this book).

CNP is present in all mammals in the uniform molecular forms as deduced from its high sequence identity.[19,23] In the cardiovascular system, vascular endothelial cells (ECs), cardiac fibroblasts, and monocyte–macrophage system are known to produce CNP.[19,21,28] For ECs, CNP is mainly present as CNP-53 along with CNP-22 in a manner similar to that in the brain. Furin is also considered to process proCNP to CNP-53, but not convert CNP-53 to CNP-22.

DISTRIBUTION OF THE NP mRNA/PEPTIDE IN THE CARDIOVASCULAR SYSTEM

ANP mRNA is detected in a variety of tissues, including brain, pituitary, and kidney, but it is most abundant in the heart.[19,21,23] Within the heart, the atrium is a major site of ANP production. The primary stimulus for ANP secretion is an increase in atrial-wall tension, which is attributable to elevation of venous blood pressure. Tachycardia also promotes atrial ANP secretion. Several hormones and neurotransmitters, such as endothelin (ET), vasopressin, and catecholamines (especially α-adrenergic agonists), directly stimulate ANP secretion from atrial and ventricular myocytes.[32]

Peptide concentrations of ANP in human, rat, and pig cardiac ventricles are 250- to 1000-fold lower than those in atria. ANP mRNA levels are also much lower in the ventricles than in the atria. Although little ANP is produced by ventricular tissue in normal adults, a high level of ANP is present in the fetus ventricle. Gene expression and synthesis of ANP are enhanced in both atrium and ventricle during early embryogenesis, but its expression in the ventricle is decreased after the prenatal period. ANP expression in the ventricle is reinducible postnatally in hypertrophied and failing hearts.[19,21,23,25]

Although BNP was first identified in pig brain extracts, this peptide is found in the circulation, and its highest concentration in the tissue is observed in heart in all mammals. Tissue concentrations of BNP other than the heart are low, and its distribution is limited to brain, amniotic membrane, and uterine. In human and rat hearts, both atrium and ventricle express the BNP gene at a high level. The total BNP mRNA content is about 3-fold higher in the ventricle than in the atrium, whereas ANP mRNA content in the ventricle is ~10% than that in the atrium. The peptide concentration of BNP in the ventricle is <1% of that in the atrium. In an experiment with isolated perfused rat hearts, however, the majority of BNP secretion (~60%) was maintained even after atrial removal, in contrast to the observation that ANP secretion was reduced to <5% by atrial removal. In the human heart, predominant BNP secretion from the ventricle has been confirmed by a step-up of plasma BNP level in the anterior interventricular vein compared with that in the aorta. Thus, BNP is a cardiac hormone that is predominantly synthesized in and secreted from the ventricle.[12,19,21,25]

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

CNP was initially believed to act solely as a neuropeptide, as CNP and its CNP mRNA are found predominantly in the brain and pituitary. However, subsequent studies have shown that CNP is synthesized in peripheral tissues including vasculature, bone, blood cells, heart, kidney, and reproductive system. Significant CNP production is observed in vascular ECs. The expression and secretion of CNP from the ECs is markedly stimulated by transforming growth factor β (TGF-β) and tumor necrosis factor α, and moderately by interleukin-1, basic fibroblast growth factor (bFGF), lipopolysaccharide, ANP and BNP, and shear stress.[28,31] Vascular smooth muscle cells (VSMC) also produce CNP, which is stimulated by TGF-β. Platelet-derived growth factor-BB has a strong effect on the CNP expression, but elicits reverse effects on human and rat VSMCs. CNP is now recognized as an important regulator within the vascular wall under various pathological states.[27,28]

Although much lower than ANP and BNP, CNP is expressed and present in both cardiac atrium and ventricle. Failing heart locally produces CNP at a level higher than in normal heart.[7] An *in vitro* study verified significant gene expression and secretion of CNP from cultured rat cardiac fibroblasts but not from myocytes, indicating a distinct profile of cardiac CNP. The secretion of CNP from cardiac fibroblasts is augmented by TGF-β, bFGF, and ET-1, and the secreted CNP inhibits hypertrophy and remodeling of heart tissue.[6,33]

NP RECEPTORS AND SIGNALING CASCADES

Natriuretic receptor-A (NPR-A) and natriuretic receptor-B (NPR-B) are guanylyl cyclase (GC)-linked receptors, and they use cGMP as the intracellular messenger (Fig. 3). Both ANP and BNP bind preferentially to NPR-A, whereas CNP specifically binds to NPR-B. NPR-B has an extremely low affinity for ANP and BNP, while CNP does not bind to NPR-A even at a high concentration. NPs stimulated cGMP accumulation via NPR-A with a rank order potency of ANP≥BNP>>CNP, whereas that via NPR-B was CNP>ANP≥BNP. All three NPs bind to a third receptor NPR-C, known as a clearance receptor. NPR-C is not linked to guanylyl cyclase, and mainly acts to clear the NPs and control their concentrations.[19,21]

NPR-A and NPR-B transcripts were widely detected in all peripheral tissues. NPR-A is highly expressed in kidney, adrenal gland, terminal ileum, adipose, vasculature, and lung, whereas NPR-B is expressed in vasculature, heart, adrenal gland, kidney, lung, uterus, ovary, and bone, in addition to pituitary and brain including cerebellum. In the vasculature, VSMCs express NPR-B at a high level. NPR-B is desensitized more easily than NPR-A, and sphingosine 1-phosphate is one of desensitizing factors in the serum.[2,19,21]

In the heart, both cardiac myocytes and fibroblasts express NPRs. Myocytes predominantly express NPR-A, whereas fibroblasts express NPR-A and NPR-B. Indeed, ANP and BNP increase an intracellular cGMP level in myocytes, whereas ANP, BNP, and CNP increase it in fibroblasts. These results indicate that the NPs also act as autocrine and/or paracrine factors in the heart tissue.[2,19,21]

All three NPs bind to NPR-C with high affinity. The order of affinity to NPR-C is ANP>CNP>BNP, but their differences in the affinity are much smaller than those to NPR-A and NPR-B. Although NPR-C primarily functions as a clearance receptor, this receptor suppresses adenylyl cyclase and activates phospholipase C through the Gαi-mediated pathway.[22] Osteocrin with limited similarity to the NPs is reported to induce some natriuretic peptide-like effects by blocking the NP binding to NPR-C.[21]

Crystallographic studies reveal that the extracellular domains of NPR-A and NPR-C form 2:1 complexes with ANP, and that the structure of ANP in the complex of NPR-A is similar to that of NPR-C (Fig. 3). As the dimers of the extracellular domains of NPR-A and NPR-C have a 2-fold rotational symmetry and ANP is located along the center of the receptor dimer axis, the interaction between ANP and one of the two NPRs is not symmetrical. It is postulated that ANP binding to the dimers of NPR-A extracellular domains induces rotation of the juxtamembrane domains, which intracellularly induces a similar rotation in each of the catalytic domains to form an active structure of GC domains. ATP is a requisite or at least stabilizing factor for GC activation, and chloride ion binding may modulate an allosteric effect of the NPR-A.[11]

BIOLOGICAL ACTIONS OF NPS IN THE CARDIOVASCULAR SYSTEM

Because NPR-A is widely distributed, ANP and BNP have a wide range of physiological actions. In the kidney, ANP inhibits tubular reabsorption at a low dose, and induces renal vasodilation at a higher dose. Renal functions of the NPs are discussed in detail in that section of this book.

ANP acts on multiple sites to reduce blood pressure. ANP at first dilates the vasculature and shifts fluid to the extravascular compartment. The reduction of blood volume and an increase in venous capacitance are considered to be responsible for the reduced cardiac output. Thus, ANP seems to have a 'depressor' effect rather than a direct vasodilator effect. A lowering of peripheral resistance in response to ANP is not observed in normotensives but is seen in hypertensives associated with an increased vascular tone. This most probably explains the discrepancy in the hemodynamic responses to ANP in normotensives and hypertensives.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

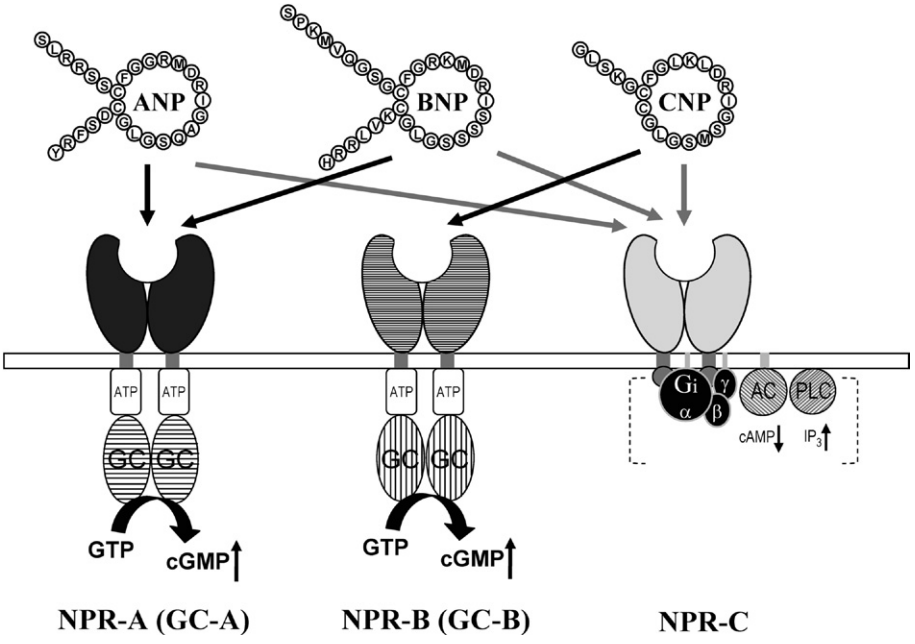

FIGURE 3 Schematic representation of NPRs and ligand–receptor relationship of the NP family. Black arrows indicate interaction with active receptors, NPR-A and NPR-B, and gray arrows interaction with clearance receptor, NPR-C. NPR-A and NPR-B are also called GC-A and GC-B, respectively, because they are membrane-bound guanylyl cyclases (GCs). NPR-C is in some cases coupled with Gi protein, suppresses adenylyl cyclase (AC), or stimulates phospholipase C. One NP molecule binds to each dimer-formed NPR.

In the endocrine/neuroendocrine system, ANP diminishes secretion of renin, aldosterone, adrenocorticotropic hormone, and vasopressin along with reduction of sympathetic tone. All these actions lead to lowering of the blood pressure. Intracerebroventricular administration of ANP attenuates angiotensin II-induced water intake and pressor response. Centrally injected ANP produced a greater reduction of water intake, and 1-week intracerebroventricular infusion of ANP also reduced salt appetite in spontaneously hypertensive rats. Thus, the ANP/NPR-A system antagonizes the renin–angiotensin system in both central and peripheral systems.[21] Effects of the NPs in the endocrine and central nervous systems are discussed in detail elsewhere in this book.

NPs are also potent growth regulators of multiple cell types. ANP inhibits proliferation of mesangial cells induced by angiotensin II or ET-1. The ANP/NPR-A system negatively regulates MAPK/ERK2 activity and proliferation of mesangial cells through a cGMP-dependent-protein kinase pathway. In studies with cultured neonatal myocytes and fibroblasts, NPs elicited marked antihypertrophic and antifibrotic actions. Later endogenous NPs were verified to have antihypertrophic and antifibrotic effects.[5] Mice lacking NPR-A develop ventricular hypertrophy and fibrosis independent of their blood pressure.[8] These results suggest that ANP and BNP are autocrine and/or paracrine antiremodeling factors. In cultured VSMCs, NPs inhibit proliferation and migration induced by growth factors or angiotensin II, suggesting that NPs act as antiatherosclerotic factors. Doubly deficient NPR-A(−/−) and ApoE(−/−) mice showed greater atherosclerotic lesion size and more advanced plaque morphology compared with NPR-A(+/+) and ApoE(−/−) mice. Aortic medial thickness was also increased in NPR-A(−/−) and ApoE(−/−) mice.[1]

Adipose tissues express NPR-A and NPR-C. ANP activates hormone-sensitive lipase in human fat cells *in vitro* via its phosphorylation through a cGMP-mediated mechanism.[30] Hormone-sensitive lipase then breaks down triglycerides into free fatty acids and glycerol. Systemic ANP infusion that increases its plasma concentration to the pathophysiological level is reported to stimulate lipid mobilization and oxidation. These results suggest that NP-induced lipid mobilization might contribute to cardiac cachexia in heart failure.

CNP is a vasorelaxant with particularly venodilator effects, contrasting with the arterial bias of ANP and BNP. CNP causes relaxation of canine saphenous, femoral, and renal venous tissue but does not cause arterial relaxation. Systemic administration of low-dose CNP in man induces no hemodynamic response, but higher-dose CNP lowers blood pressure. CNP does not seem to have any marked influence on renal sodium handling, either. Thus, systemic hemodynamic effects of CNP are much less than those of ANP and BNP.[21,28]

As CNP is produced in ECs, endothelium-derived CNP can elicit direct vasodilation through NPR-B abundantly expressed in VSMCs. CNP suppresses various growth factor-stimulated VSMC migration and proliferation more potently than ANP and BNP. CNP might also inhibit

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

ET-1-mediated VSMC proliferation, as CNP directly inhibits secretion of ET-1 from ECs. These findings suggest that CNP regulates vascular tone and growth as an autocrine/paracrine factor in the vascular wall.[27,28]

In vitro studies have shown the direct effects of CNP on cardiac myocytes and fibroblasts.[33] CNP inhibits fibroblast proliferation and extracellular matrix production more potently than ANP and BNP. ET-1 secretion from cardiac fibroblasts and ET-1-induced hypertrophy of cardiac myocytes are also inhibited by CNP. Taken together with the CNP production in the fibroblasts, CNP may also act as a local autocrine/paracrine regulator in the heart. These results indicate that the NP/cGMP system plays a key role in the growth regulation of various cells.[19,21,28]

PATHOPHYSIOLOGICAL IMPLICATIONS OF NPs

It is well known that plasma concentrations of ANP and BNP are increased in various pathological conditions such as heart failure, acute myocardial infarction (AMI), hypertension, left ventricular hypertrophy, coronary artery disease, pulmonary hypertension, and renal failure.

In heart failure, plasma ANP and NT-ANP concentrations are elevated in patients with symptomatic congestive heart failure in proportion to the severity of the disease and also in asymptomatic patients with left ventricular dysfunction. As plasma BNP and NT-BNP concentrations in patients with heart failure change more dynamically and correlate well with the New York Heart Association functional class and hemodynamics, these plasma concentrations are used to evaluate heart failure severity and to identify patients with asymptomatic left ventricular dysfunction.[12,16] Several studies have examined the diagnostic value of ANP, BNP, NT-ANP, and NT-BNP for the detection of left ventricular systolic dysfunction and showed that the levels of these peptides are useful biomarkers for both in the general population and in patients with cardiovascular disease. Further, the measurement of BNP can rule out congestive heart failure in newly symptomatic subjects with a high negative predictive value for heart failure. In the urgent-care setting, BNP is useful to discriminate acute dyspnea resulting from congestive heart failure from other causes. Thus, the measurement of plasma NP concentrations is useful not only for evaluating the severity of heart failure but also to rule out the screening test for left ventricular dysfunction and heart failure. Increased expression and secretion of NPs in heart failure are considered to be a compensatory action of the NPs, which is mediated by their natriuretic actions and not by altering hemodynamics.[14] Further, induction of heart failure in NPR-A(−/−) mice resulted in a more severe outcome than that in NPR-A(+/+) mice, indicating a protecting role of the NPs/NPR-A system against heart failure.[16]

In AMI, plasma ANP concentrations are already increased at the time of admission and decrease thereafter. By contrast, plasma BNP concentrations are increased on admission and reach a peak at 12–24 h after admission. Then, the BNP concentration decreases and has a second peak on day 5–7, after which BNP concentrations gradually decrease.[16] In a rat AMI model, BNP levels are increased in and around the necrotic tissues of the infarcted region, indicating the augmented production of BNP in the remaining myocytes.[16] Thus, the height of the second peak of BNP may be a good index for evaluating left ventricular remodeling in patients with AMI. Because ANP and BNP have potent antihypertrophic and antifibrotic effects, augmented production of NPs in the ventricle may also be aimed to inhibit the remodeling.

Several studies show that plasma ANP and BNP concentrations are increased in patients with hypertension compared with that of normotensive subjects. In hypertension, plasma ANP and BNP concentrations are higher in patients with left ventricular concentric hypertrophy than in those without it or with other types of hypertrophy or remodeling.[15] ANP(−/−) mice exhibit salt-dependent hypertension, suggesting that ANP regulates blood pressure via its natriuretic actions, whereas BNP(−/−) mice show normal blood pressure with slight focal fibrosis in the ventricle.[8] Interestingly, NPR-A(−/−) mice show salt-independent hypertension as well as cardiac hypertrophy and fibrosis.[8] The differences in phenotype between ANP(−/−) mice and BNP(−/−) mice may result from different sites of action and/or different gene expression regulatory systems of ANP and BNP. The increased production of NPs in the hypertrophied ventricle is thought to inhibit cardiac hypertrophy and fibrosis via their direct effects on the myocytes and fibroblasts.[8] Thus, ANP and BNP play pivotal roles in the pathogenesis of hypertension and subsequently occurring left ventricular hypertrophy.

In patients with right ventricular pressure overload resulting from pulmonary hypertension, plasma ANP and BNP concentrations are higher than those in patients with right ventricular volume overload resulting from atrial septal defect. The plasma ANP and BNP concentrations correlate with mean pulmonary artery pressure, right atrial pressure, right ventricular end-diastolic pressure, and total pulmonary resistance in these patients. After long-term vasodilator treatment, their plasma concentrations decrease according to a reduction of total pulmonary resistance.[13] Plasma BNP concentrations are also high in patients with acute pulmonary embolism, in whom BNP levels are associated with right ventricular overload. Thus, both right atrial and ventricular pressure overloads stimulate ANP and BNP secretion independent of etiology, and plasma ANP and BNP concentrations are good indices especially for the evaluation of the severity and treatment efficacy in patients

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

with right ventricular overload. Chronic hypoxia produces a greater increase in right ventricular systolic pressure and more muscularization of pulmonary arterioles in NPR-A(−/−) mice compared with NPR-A(+/+) mice.[8] Thus, NPs/NPR-A system regulates tone and remodeling of pulmonary vasculature, and right ventricular hypertrophy in pulmonary hypertension.

Elevated plasma ANP and BNP concentrations are prognostic indicators of heart failure, AMI and pulmonary hypertension. Medical therapy can reduce the ANP and BNP concentrations in parallel with hemodynamic and clinical improvement in these patients. These findings strongly indicate that the measurement of NPs can be used to optimize therapy. After NT-BNP-guided therapy was firstly reported,[34] BNP- or NT-BNP-guided treatment of patients with chronic heart failure has been investigated in a number of randomized controlled trials and showed that this approach leads to fewer hospital readmissions and a lower mortality due to heart failure. However, a meta-analysis shows that the risk of all-cause hospitalization and survival free of any hospitalization is not significantly different between groups.[20] At present, there seems to be a limitation in the usefulness of BNP-guided therapy in chronic heart failure patients.

Infusion of ANP significantly decreases pulmonary capillary wedge pressure and aldosterone concentrations, and increases stroke volume index, urine volume, excretion of sodium, and endogenous creatinine clearance in patients with heart failure.[16] The similar effects of BNP are observed in patients with heart failure.[16] These results indicate the possibility that BNP and ANP could be used as a drug in patients with heart failure. Indeed, ANP and BNP are widely used in clinical setting in many countries. Although Sackner-Bernstein et al. pointed out that BNP may worsen renal function in patients with acutely decompensated heart failure,[24] succeeding studies negated such a harmful effect of BNP.[18]

NPs may also be applicable to AMI. An earlier study showed that ANP infusion group had greater improvement of left ventricular ejection fraction than the nitroglycerin group.[4] A recent prospective, randomized, and multicenter study shows that ANP reduces an infarct size and reperfusion injury compared with controls.[9] As ANP/BNP/NPR-A signaling is deeply involved in the pathophysiology of cardiovascular disease, ANP and BNP can be applied to a series of heart diseases, in addition to their usefulness in the clinical test for the cardiovascular diseases.

CNP potently inhibits VSMC proliferation and migration, suggesting that this peptide may play a protective role against abnormal growth of VSMCs in the disorders such as atherosclerosis and postangioplasty restenosis. CNP can limit neointimal formation of arteries subjected to balloon injury by inhibiting VSMC proliferation and migration as well as rapid reendothelialization of the injured vessel. Elevated circulating concentrations of CNP are found in hypoxemia, sepsis, and chronic renal failure, but not in essential hypertension.[19,21,28] Endothelial damage caused by hypoxia and endotoxin may provoke CNP secretion from ECs. Marked elevation in plasma CNP observed in renal failure is probably attributable to impaired clearance.

No significant increase in the plasma CNP level was reported in patients with chronic heart failure, in contrast to that of ANP and BNP. However, tissue levels of CNP are increased along with ANP and BNP in the ventricular myocardium of patients with heart failure. A significant cardiac production of CNP is observed in chronic heart failure, along with the correlation of coronary sinus CNP concentrations with mean pulmonary capillary wedge pressure.[7] Both cardiac myocytes and fibroblasts express NPR-B, and the NPR-B mRNA level is markedly increased in the hypertrophied left ventricle. Collectively, cardiac CNP may act as a key local regulator in some pathological states of the heart, though further investigations are required.

Chapter 193

Salusins

Masayoshi Shichiri, Hajime Izumiyama and Takuya Watanabe

ABSTRACT

Salusin-α and salusin-β, endogenous peptides biosynthesized from the same precursor – prosalusin – exert a variety of cardiovascular activities. Initially, the presence of salusins was predicted from a full-length-enriched cDNA library. Later salusins were discovered in human biological fluids. Thus, they were the first peptides to be successfully discovered using an "in silico" approach. Salusins exhibit similar mitogenic and antiapoptotic properties but exert contrasting activities on atherosclerosis. The salusin-β peptide causes potent hemodynamic effects by parasympathomimetic actions. Attempts to elucidate the bioactivity of salusin-β were enormously difficult because of its physicochemical property of adhering firmly to the experimental apparatus material, such as polypropylene, polystyrene, and glass. Despite its potent bioactivity, because of this adherent feature, salusin-β was not discovered by conventional methods, including reverse pharmacology. We speculate that other unidentified ligands possessing similar or other characteristics preventing their isolation/discovery may be discovered by in silico analyses.

DISCOVERY

Discovery of a novel endogenous bioactive peptide in humans has been a frustrating and lengthy process. Because circulating bioactive peptides in mammals usually exist at very low concentrations, purification and identification of such peptides buried by vast amounts of more abundant proteins still remain an extremely difficult task. In the history of bioactive peptide research, the reverse pharmacology approach has come to the fore relatively recently and has successfully unraveled many important endogenous peptides. However, this method requires sequence information on ligand candidates to test their responsiveness in each orphan G protein–coupled receptor, and the number of bioactive peptides with unidentified receptors is limited. We initiated bioinformatics analyses using full-length cDNA and genomic DNA information anticipating that this novel approach could markedly shorten the lengthy identification process for novel endogenous bioactive peptides, and this resulted in successful identification of salusin peptides with cardiovascular activities.

Our prediction of salusin-α and salusin-β derived from a search of a large collection of full-length, enriched cDNA libraries owned by the Helix Research Institute, a joint research project principally funded by the Japanese Ministry of International Trade and by the major pharmaceutical industries in Japan.[33] The library included human clones that had been constructed with a mammalian expression vector driven by the SRα promoter, pME18S-FL3, by the oligo-capping method[24] and sequenced in the governmental New Energy and Industrial Technology Development Organization Human cDNA Sequencing Project.[33] We first chose putative secretory polypeptides from the human cDNA library using the SignalP server (http://www.cbs.dtu.dk/services/SignalP/), which predicts the presence and location of signal peptide cleavage sites in amino acid sequences.[8] Selected cDNAs that encode preproproteins having cleavable signal peptide sequences were further assessed with ATGpr[13] and PSORT algorithms,[6] which provide information as to whether translated proteins could be released extracellularly. Promising candidates were subjected to further scrutiny on the basis of common structural features characteristic of endogenous bioactive peptides.

Major bioactive peptides are biosynthesized from their precursor preproproteins with amino acid lengths ranging from 90 to 250. After cleavage of their signal sequence, the proproteins can be further digested at the C-terminal site of dibasic amino acid residues by several types of prohormone convertases.[21] The resultant C-terminal dibasic amino acid residues are usually removed by carboxypeptidase E, and the C-terminal glycine residue is converted to NH_2 by peptidylglycine α-amidating monooxygenase to produce an amidated peptide[1] (see the chapters on all these enzymes in the Peptide Biosynthesis/Processing section of this book). Our initial selection of bioactive peptide candidates from the cDNA library information used the above features, which are characteristic of human bioactive peptides and predicted processed peptide sequences of <30 amino acid residues. We did not restrict endogenous peptide candidates to those containing disulfide bonds or to those containing a C-terminal NH_2. Predicted candidate sequences were synthesized and

tested for the ability to increase intracellular free Ca^{2+} ($[Ca^{2+}]_i$) in cultured mammalian cells derived from the vasculature. Because synthetic salusin-α and salusin-β induced potent and sustained increases in $[Ca^{2+}]_i$ in human and rat vascular smooth muscle cells and rat fibroblasts, they were subjected to subsequent studies to further clarify their bioactivities. The cleavage prediction approaches we used in discovering salusin peptides have recently been shown to predict prohormone cleavage sites with high accuracy even in genome libraries.[20]

The discovery process of novel bioactive peptides using in silico selection of cDNAs and cleavage prediction strategies are not complete until the predicted peptide sequences are proven to exist in the circulation or in other biological fluids. The specific radioimmunoassay for salusin-α was relatively easily established, which allowed confirmation of the existing molecular forms in humans. Immunoreactive salusin-α in serum and urine was analyzed by high-performance liquid chromatography and gel permeation chromatography, and the findings coincided with the predicted authentic salusin-α sequence.[15] However, confirmation of salusin-β in human plasma required several years because of its peculiar physicochemical characteristics.

We originally described that salusin-β exerts very potent and unique hemodynamic activities,[19] which aroused wide interest. We soon received a number of personal communications that noted varying degrees of biological activities of salusin-β. Some scientists could not reproduce our results at all,[2] others found less potent effects,[12] and several other investigators successfully unraveled novel actions and/or mechanisms.[28,31,32] Especially puzzling were the findings that many investigators shared in common: The effects of salusin-β sometimes varied from experiment to experiment, making it difficult to finish a series of planned procedures. Major commercial testing laboratories in Japan failed to establish an assay because of extraordinarily unstable results when determining plasma and urine salusin-β concentrations. This mystery was soon resolved after we found that the salusin-β peptide sticks to commonly used laboratory tubes, tips, plates and pipettes, whether they are made of polypropylene, polystyrene, or glass.[18] Addition of a very low amount of NP-40 or Tween 20 when reconstituting purified salusin-β avoids this property and allowed us to successfully establish an assay system and stably reproduce experiments.[16] These procedures confirm that salusin-β is also present in human serum and urine as was originally predicted. It is probable that published results performed without this knowledge had either required a far larger dose than it should have[12] or failed to achieve positive results.[2,32]

STRUCTURE OF THE mRNA/GENE

Salusins derive from an alternatively spliced product of TOR2a, a torsin dystonia-family gene. TOR2a has 5 exons, is located at 9q34.11, and encodes a protein of 321 amino acids[9,10] Its splice variant, preprosalusin (PSEC0218, HEMBA 1005096, AK075520), contains a frameshift resulting from the deletion of exon 4 that results in a deduced 242-amino acid protein with an alternate C terminus (Fig. 1).

PROCESSING OF THE PRECURSOR

Preprosalusin, the precursor of salusins, has a 26-amino acid signal peptide at the N terminus, and the resultant proprotein of 216 amino acids is termed prosalusin. The C-terminal end of prosalusin tandemly contains salusin-β and salusin-α, which should be cleaved by prohormone convertases. Carboxypeptidase E probably removes the resultant C-terminal dibasic amino acids between salusin-β and salusin-α to create the 20-amino acid salusin-β. Peptidylglycine α-amidating monooxygenase converts the glycine residue at the C-terminal end to NH_2 to yield the 28-amino acid salusin-α with C-terminal amidation. The processing

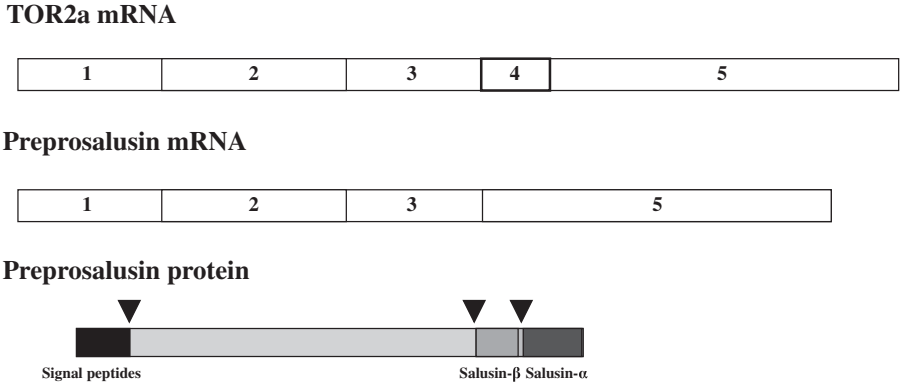

FIGURE 1 Schema showing transcripts of TOR2a and preprosalusin and biosynthesis of the salusin peptides from their precursor, preprosalusin. Open boxes represent mRNAs, and numbers indicate exons. Salusin-α and salusin-β in the C-terminal ends of preprosalusin are cleaved out. Arrowheads show signal peptide cleavage sites and two dibasic amino acid sites.

of preprosalusin into salusin-α and salusin-β may differ in various cell types.[7,14]

DISTRIBUTION OF THE mRNA/PEPTIDE IN THE CARDIOVASCULAR SYSTEM

TOR2a and preprosalusin are coexpressed almost ubiquitously throughout tissues, with preprosalusin transcripts expressed at quantitatively lower levels than TOR2A in most human and rat tissues.[19,22] Because semiquantification of the alternatively spliced product by RT-PCR is often misleading because of the low amplification efficiency of spliced transcripts, we quantified preprosalusin transcripts using the TaqMan hybridization probe format. In humans, preprosalusin mRNA is abundant in spleen, peripheral leucocytes, lung, kidney, and brain. Additionally, preprosalusin mRNA is abundant in the endocrine glands, including the pancreas, testis, ovary, and thymus, while the expression level is low in cardiac and skeletal muscle.[19] The low mRNA expression level of preprosalusin in the cardiovascular system, however, does not lessen the significance of salusins as cardiovascular peptides.

Similar to the ubiquitous distribution of preprosalusin mRNA, immunoreactive salusin-α and salusin-β are also widely expressed, but show distinct systemic distributions, which give an insight into their potential biological activities.[22,23] Salusin-α is conserved in mice and rats with a shorter amino acid length. In rats, it is detected abundantly in the epithelial tissues throughout the organs, in the gastrointestinal and immune systems, and in submucosal and myenteric plexuses in the stomach.[23] Salusin-β is undetectable in any of these tissues. By contrast, salusin-α and salusin-β are concomitantly present in macrophages in the spleen and lymph nodes, immature myeloid cells and megakaryocytes of the bone marrow, and proximal tubules of the kidney. Salusins are barely detected in the heart, and only a small amount of the immunoreactivity is present in the intact vasculature. Salusin-β-like immunoreactivity is most prominently present in the hypothalamus and posterior pituitary and coexists in vasopressin-expressing neurons,[22,25] suggesting its possible neural secretion into the systemic circulation via axon terminals. Salusin-β positive neurons and fibers in the supraoptic nucleus and the paraventricular nucleus are markedly increased after chronic salt loading and dehydration.[12] Thus, despite the limited expression levels of preprosalusin mRNA and salusin peptides in the heart, salusin peptides released into circulation from the hypothalamo-neurohypophyseal system and/or other systemic organs could contribute to the pathophysiologic condition of the cardiovascular system.

Further, the expression of salusin-α and salusin-β in the vasculature may be markedly modified in a variety of cardiovascular diseases associated with atherosclerosis. The exaggerated expression of salusin-β in atherosclerotic lesions in the vasculature and amelioration of vascular changes by antisalusin-β antibody suggests a mediatory role for endogenous salusin-β in the development and/or maintenance of atherosclerosis.[28] Especially remarkable is the marked immunoreactivity of salusin-β in contrast to trace amounts of salusin-α in human coronary atherosclerotic plaques. This study showed an especially predominant expression of salusin-β in macrophages, vascular smooth muscle, and fibroblasts.[28]

RECEPTORS AND SIGNALING CASCADES

Selective receptors for salusins still remain unidentified, although salusin-β is a surrogate ligand of the mas-like G protein–coupled receptor MrgA1.[27] Salusins can induce intracellular signaling and subsequent cellular responses, which are downstream to many G protein–coupled receptors. Thus, it is possible that a yet-unidentified G protein–coupled receptor directly or indirectly mediates the signaling cascades elicited by salusins. For example, salusin-β, released from a nerve ending in the neurohypophysis, increases intracellular free Ca^{2+} via influx through voltage-dependent Ca^{2+} channels, and stimulates the release of vasopressin and oxytocin from the posterior pituitary in an autocrine/paracrine fashion.[12] In neonatal rat cardiomyocytes, both salusin-α and salusin-β stimulate protein synthesis through the calcium, calcineurin, mitogen-activated protein kinase, and protein kinase C signal pathways.[32] They also protect cardiomyocytes against serum deprivation-induced apoptosis by the upregulation of GRP78.[31] Opposing effects of salusin-α and salusin-β in regulating human macrophage foam cell formation are mediated via G-protein, c-Src tyrosine kinase, protein kinase C, and mitogen-activated protein kinases.[28] Salusins are initially identified by their ability to induce increases in $[Ca^{2+}]_i$ and the expression of the immediate early oncogene, c-myc, and subsequent proliferation of vascular smooth muscle cells and fibroblasts.[19] The above signaling elicited by salusins implies direct and/or indirect mediation by their unidentified receptors.

BIOLOGICAL ACTIONS WITHIN THE CARDIOVASCULAR SYSTEM

The cardiovascular activities of the two salusin peptides can roughly be categorized into systemic and local actions. Remarkable systemic bioactivities of salusin-β include its potent hemodynamic effects. Intravenous salusin-β causes rapid, temporary, and profound decreases in the blood pressure and heart rate in rats.[19] These effects are mainly mediated by parasympathetic stimulation rather than direct suppression of cardiac contractility, because the effects are almost completely abrogated by pretreatment with atropine

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

sulfate.[3] In addition to its potent effects to facilitate vagal outflows to the heart, however, salusin-β induces negative inotropism via a direct myotropic effect as well.[3] Because salusin-β is found in human circulation in its authentic form,[16] it probably contributes to the maintenance and/or regulation of cardiovascular homeostasis. Salusin-α, on the other hand, may also reduce blood pressure, but the magnitude is far less: the salusin-β-like systemic hemodynamic effects are not evident.[19]

In contrast to the systemic actions, the two salusins exert a variety of local activities in the cardiovascular systems. In isolated rat cardiomyocytes, salusins promote hypertrophy,[32] whereas salusin-β inhibits L-type calcium currents in accordance with its negative inotropic effect.[17] Salusins also stimulate the proliferation of vascular smooth muscle cells and fibroblasts,[19] and protect against apoptotic death of cardiomyocytes.[31] Despite the similar *in vitro* effects of salusin-α and salusin-β on mitogenesis and antiapoptosis, they exert contrasting effects on atherosclerotic lesion development in apolipoprotein E-knockout mice.[5] These remarkable effects are probably mediated by the modulation of acyl-coenzyme A: cholesterol acyltransferase-1 (ACAT-1) expression and subsequent macrophage foam cell formation, which are also induced by salusins in an opposing manner.[28] Salusin-α not only inhibits ACAT1 expression and macrophage foam cell formation but it also reduces serum total cholesterol levels, thereby exerting antiatherosclerotic activities.[5] These results, together with the clinical observation that decreased serum salusin-α levels are associated with atherosclerosis in humans, leads to the hypothesis that salusin-α protects against the development of atherosclerosis.[30]

PATHOPHYSIOLOGICAL IMPLICATIONS

As delineated above, recent studies have exploited the evidence that salusin-α participates in the pathophysiology of cardiovascular diseases, presumably as a result of its potent antiatherosclerotic effects. Decreases in serum salusin-α levels occur in human cardiovascular diseases, such as hypertension[30] and chronic renal failure.[4] The decrease in essential hypertension is associated with the development of carotid atherosclerosis[30] and left ventricular diastolic dysfunction,[26] whereas in patients with coronary arteriography-proven acute coronary syndrome, the magnitude of serum salusin-α decrease is markedly exaggerated in accordance with the severity of coronary artery lesions.[28] Together with the potent antiatherosclerotic activities of salusin-α,[5] a predictive value of low serum salusin-α for hidden coronary artery diseases has been proposed.[29] However, a recent report shows that the negative correlation between serum salusin-α and common carotid intima-media thickness is lost in the presence of inflammatory diseases, such as rheumatoid arthritis.[11] Chronic renal insufficiency decreases serum salusin-α, but other conditions affecting serum salusin-α remain largely uninvestigated.[4]

Salusin-β, however, is implicated in the regulation of hemodynamics and atherosclerosis in the pathophysiology of cardiovascular diseases. Salusin-β exerts its hypotensive and bradycardic actions by parasympathetic stimulation.[3] Salusin-β that is biosynthesized in the neuroendocrine system may be released into the systemic circulation from the posterior pituitary, but the exact contribution of pituitary-derived salusin-β to circulating salusin-β levels remains unknown. Pituitary-derived salusin-β also acts on adjacent neurohypophyseal cells to stimulate the release of vasopressin and oxytocin. Thus, salusin-β is involved in the hemodynamic regulation not only by acting as an endogenous humoral factor to directly modulate the parasympathetic nervous system but also as an autocrine/paracrine factor involved in the regulation of water diuresis by regulating the secretion of vasopressin. However, a recently established radioimmunoassay to detect human salusin-β was not sensitive enough to directly determine its circulating levels. Because salusin-β in the blood could bind to common circulating proteins, exact roles for free and bound salusin-β need to be determined to elucidate its pathophysiological roles in human cardiovascular diseases.

Finally, human urine contains salusin-α- and salusin-β–like immunoreactivity that are immunologically indistinguishable from their authentic sequences.[15,16] Excreted salusins seem to derive from renal tissues, because renal epithelial cells abundantly express salusin-α- and salusin-β-like immunoreactivity.[19,22] Further, end-stage renal failure patients not on hemodialysis exhibit higher renal salusin-α clearance values exceeding their creatinine clearance.[4,16] These findings show that urinary salusin-α is, at least in part, of renal origin.

Chapter 194

Urocortins

Mark Richards and Miriam Rademaker

ABSTRACT

Since the discovery of Urocortin 1 (Ucn 1) in 1995 and identification of Ucns 2 and 3 in 2001, evidence of a cardiovascular role for these paralogs of corticotropin-releasing hormone (CRH) has grown rapidly. Ucns act through CRH-R2 G-protein-coupled receptors distributed widely in organs relevant to pressure and volume homeostasis including the heart, kidneys, adrenals, and vasculature. Effects occur via multiple signaling cascades including adenylyl cyclase/cAMP and MAP kinase pathways. Ucns lower blood pressure in animal models of hypertension and are cardioprotective in experimental ischemia reperfusion. Plasma concentrations of Ucn 1 are elevated in heart failure. Ucns 1, 2, and 3 exert beneficial hemodynamic, neurohormonal, and renal effects in experimental heart failure, and Ucn 2 has hemodynamic efficacy in human heart failure. Further research on the Ucns promises improved understanding of the pathophysiology of ischemia-reperfusion injury, hypertension, and heart failure with the attendant potential for novel therapeutic applications.

DISCOVERY

The Ucns are members of the corticotropin-releasing hormone (CRH) family of peptides, which includes CRH, fish urotensin 1, frog sauvagine, and urocortins 1, 2, and 3. In 1995, Vaughan et al.[32] discovered urotensin 1-like immunoreactivity in rat brain (Edinger–Westphal nucleus and lateral superior olive region). On analysis, the novel peptide concerned was named urocortin (now urocortin 1) in view of its structural and biological similarities to urotensin and CRH. Two further urocortins have been subsequently discovered in 2001 and named urocortin 2 (also known as stresscopin-related peptide) and urocortin 3 (also known as stresscopin). Murine and human cDNAs for Ucns 2 and 3 were identified from sequence homology searches of the respective genomes.[19,29]

STRUCTURE OF UROCORTINS mRNA/GENE

Human CRH and Ucn 1 genes are located on chromosomes 8(8q13) and 2 (2p23–p21) respectively.[13,16] The Ucn 1 gene has two exons with the coding region confined to the second exon. It codes for a 122 residue preprotein with the mature Ucn 1 within the carboxyl terminus. Several possible transcription-factor-binding sites have been identified in the Ucn 1 promoter but not tested for actual promoter function. Regulatory elements include a TATA box, a CCAAT enhancer-binding protein (C/EBP) binding site, GATA binding sites, a POU domain transcription factor Brn-2 and a cyclic adenosine monophosphate (cAMP) responsive element (CRE). Upstream of the CRE, the Ucn 1 promoter contains a glucocorticoid response element (GRE) consistent with the ability of glucocorticoids to upregulate Ucn 1 expression. Genes for Ucn 2 and Ucn 3 reside on chromosomes 3 (3p21.3–4) and 10 (10p15.1) respectively.

PROCESSING OF PRECURSOR PEPTIDES

Mature Ucns are about 40 amino acids in length. The Ucn 1 precursor is a122-amino-acid protein with an N terminal methionine and an amidated carboxy terminal. The amidation is necessary for bioactivity of the mature peptide.

Ucns 2 and 3 are derived from precursor proteins of 112 and 161 residues, respectively. There is some uncertainty about the mature forms of Ucns 2 and 3, and some investigators suggest amino-terminally extended versions of the putative 38 and 40 amino acid candidate forms. In the case of Ucn 2, this reflects possible cleavage at either serine–arginine or threonine–arginine sites with resultant 38- and 45-amino-acid mature forms respectively. For Ucn 3, a dibasic (arginine–arginine) cleavage site present in several species suggests a 40-amino-acid peptide (as initially predicted for Ucn 3 or Stresscopin), but this site is missing in humans, leading to the prediction of cleavage at a threonine–lysine site with production of a 38-amino-acid peptide. As mature Ucn 2 and 3 peptides are yet to be isolated and sequenced, this uncertainty remains for the time being.[13]

The amino acid sequence (primary structure) of Ucn 1 resembles that of CRH as much as it does that of Ucns 2 and 3. It has 63% homology to urotensin 1 and 45% homology to CRH (Table 1). CRH analog peptides have an alpha

helical conformation with varying amphipathicity, which may be relevant to their selectivity for CRH-R1 but not relevant to CRH-R2 binding. Ucn 2 (34 and 43 and 37–40% homology with CRH, Ucn 1 and Ucn 3, respectively) and Ucn 3 resemble each other more than CRH. It is hypothesized an ancient gene duplication event, predating evolutionary divergence of teleost fish from tetrapods, resulted in separate type 1 (CRH/Ucn 1) and type 2 (Ucn 2/Ucn 3) lineages.[13]

DISTRIBUTION OF UROCORTINS mRNA AND PEPTIDE IN THE CARDIOVASCULAR SYSTEM

The Ucns are widely expressed in the central nervous system, gastrointestinal tract, skeletal muscle, skin, immune system, and the heart.[18,21] Ucn 1 is expressed in vascular smooth muscle cells and cardiomyocytes. Ucn 1 is produced in the heart and stored there in larger molecular weight forms. Ucns 2 and 3 are expressed in the heart. Unlike Ucn 1, Ucns 2 and 3 do not seem to have any role in the regulation of the hypothalamic–pituitary–adrenal axis. Ucn 1 mRNA or immunoreactivity (i.e., peptide) has been found in the central nervous system (CNS) including the cerebellum, hypothalamus, and colocalizing with dopamine in the basal ganglia and hypothalamus. Ucn 2 is present in the tissues of the cardiovascular system (including the heart, peripheral blood vessels, and adrenals) and the central nervous system, stomach, skin, ovary, uterine smooth muscle, and skeletal muscle. Ucn 3 is distributed where CRH-R2 expression is high including the heart, adrenals, and kidneys (distal tubules).

RECEPTORS AND SIGNALING CASCADES

The actions of the Ucns are mediated via the 7 transmembrane, G-protein-coupled CRH receptors, CRH-R1 and CRH-R2 both of which have multiple splice variants.[13,16] Ucn 1 is a ligand for both receptors, but it has higher affinity for CRH-R2. In contrast, Ucns 2 and 3 bind exclusively to CRH-R2. CRH-R1 is found predominantly in the CNS, whereas CRH-R2 receptors appear in the CNS and in peripheral tissues including the heart, adrenals, gut, and lymphocytes. In humans, Ucn 1 and CRH-R2 alpha are present in the aorta and the myocardium and arterioles of all four chambers of the heart. Within the cardiovascular system, CRH-R2 alpha is the relevant receptor mediating Ucn bioactivity.

CRH-Binding Protein

CRH-binding protein (CRH-BP) was isolated from human blood in 1989.[3] This 37-kDa protein binds both CRH and Ucn 1 in humans. Its function seems to be restriction of access of these ligands to the CRH receptors. The half-life of Ucn 1 in sheep is markedly prolonged, and in humans, it exceeds that of Ucns 2 and 3 (~50 min compared with 10 minutes for Ucn 2; the half-life of Ucn 3 remains uncertain) and the binding protein which is selective for Ucn 1 may contribute to this difference in kinetics. In sheep, unpublished data (from Patel et al.) comparing Ucn pharmacokinetics indicate clearances of 0.486, 21.7, and 220 L/h for Ucns 1, 2, and 3 respectively. Steady-state volumes of distribution were similar for Ucn 1 and Ucn 2 (~8 L) but substantially larger for Ucn 3 (23.5 L). Disposition was adequately described by a two-compartment model for Ucn 1 and one-compartment models for Ucn 2 and Ucn 3. Elimination half-life for Ucn 1 was 8.3 h (α phase) and 2.9 h (β phase), and 15.7 and 4.4 min for Ucn 2 and Ucn 3, respectively.

Signaling Cascades

The cardioprotective effects of Ucns are CRH-R2-dependent and seem to involve multiple signal transduction pathways.[13] Generally, in most *in vitro* settings, this involves adenylyl cyclase and the second messenger cyclic AMP. Relaxation of VSMC via CRH-R2 is associated with adenyl cyclase activation and accumulation of cyclic AMP.[17] Ucn 1 may modulate cardiac hypertrophy at least in part through cyclic AMP.

Ucn 1-, 2-, and 3- induced cardioprotection involves MAP kinase signaling, as each peptide induces phosphorylation of Erk1/2-p42, 44 in neonatal cardiomyocytes and reduces postreperfusion infarct size in rodents via CRH-R2-dependent mechanisms.[31] These effects are abolished by inhibitors of MEK1, Ras, or Raf-1. Ucn 1 increases expression and activation of protein kinase C epsilon in primary cultures of rat cardiomyocytes and in the isolated perfused heart. The antiapoptotic effects of Ucn 1 on isolated cardiomyocytes subjected to ischemia reperfusion seems to be dependent on the presence of this PKC isozyme, and Ucn-1-induced protection of isolated whole hearts was absent in PKC-epsilon-deficient mice. Further, chelerythrine, a PKC inhibitor, prevented Ucn-1-related cardioprotection of the isolated rat heart after ischemia reperfusion.

In vitro (isolated cardiomyocytes) Ucn 1 inhibits ischemia-induced increases in the calcium-insensitive phospholipase A2 enzyme (iPLA2) and its toxic metabolite lysophosphatidylcholine.

Ucn 1 increases synthesis of the mitochondrial KATP potassium channel subunit Kir 6.1 in cardiomyocytes. General and mitochondrial-specific KATP channel blockers abolish the cardioprotective effects of Ucn 1 in isolated cardiac cells and in the intact heart. Finally, cardioprotection from Ucns also involves activation of the phosphatidylinositol-3 (PI-3) kinase/Akt-dependent pathway.[13]

Barry et al.[2] performed microarray experiments to provide an expanded view of molecular mechanisms potentially underlying the protection offered by Ucns in myocardial

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

ischemia reperfusion. In a rat coronary occlusion model of cardiac ischemia-reperfusion injury, Ucn 1 and Ucn 2 administered before reperfusion, differentially regulated 66 and 141 genes, respectively. Most of these effects on gene expression had not been previously described. Functional analysis demonstrated that Ucn-regulated genes are involved in many biological responses, including cell death, oxidative stress (e.g., nuclear factor erythroid derived 2-related factor 1/nuclear factor erythroid derived 2-like 1) and metabolism (e.g., Prkaa2/AMPK). Both Ucn 1 and Ucn 2 modulate expression of many genes involved in G-protein-coupled receptor (GPCR) signaling including Rac2, Gnb1, Dab2ip (AIP1), Ralgds, Rnd3, Rap1a, and PKA, indicating involvement of many previously unrecognized signaling intermediates downstream of CRH receptors. Moreover, several of these GPCR-related genes are involved in MAP kinase activation, further confirming links between CRH receptors and induction of MAPKs.

BIOLOGICAL ACTIONS WITHIN THE CARDIOVASCULAR SYSTEM

Ucns 1, 2, and 3 cause vasodilation and have positive chronotropic, inotropic, and lusitropic effects on the heart. Ucns lower blood pressure in hypertensive animal models. Ucns have protective effects in cardiac ischemia reperfusion and are anti-inflammatory. Finally, Ucns have powerful multifaceted beneficial effects in heart failure.

Blood Pressure Regulation

Although central administration of CRH in rats induces a pressor effect mediated through CRH-R1 receptors, peripheral CRH lowers blood pressure, an effect blocked by a nonspecific CRH antagonist but not by a selective CRH-R1 receptor antagonist indicating probable mediation of the peripheral depressor effect via CRH-R2 receptors. In genetically modified mice lacking CRH-R2 receptors, the marked hemodynamic effects of infused Ucns are lost indicating dependence on this receptor.[8] In this knockout model, the mice are hypertensive implying a role for the Ucns in regulation of basal vascular tone and arterial pressure; raising the possibility that the same is true in humans. A similar vasodilation and decrease in blood pressure is observed on intravenous administration of CRH to rats. Both Ucn 1 and 2 cause sustained lowering of blood pressure in rats when given intravenously. Ucn 2 produces substantial and sustained falls in blood pressure in hypertensive rat models.[11,15,20] Ucn 2 given twice daily to Dahl-salt-sensitive rats reduces blood pressure and diminishes left ventricular hypertrophy over five weeks of treatment.[11] Isolated perfused hearts from Dahl rats respond to perfusion with Ucn 2 with changes in intracellular calcium cycling, improved left ventricular systolic and diastolic function, and a raised ventricular fibrillation threshold.[15] In the chromogranin A-null mouse, characterized by raised catecholamine production and hyperadrenergic hypertension, Ucn 2 reduced blood pressure in association with reduced catecholamine synthesis and secretion.[20]

Ucn-induced decreases in blood pressure may involve both direct effects on VSMC tone and secondary effects via reduction in vasoconstrictor systems including endothelin 1 (ET-1), arginine vasopressin, and angiotensin II (AngII). Direct vascular actions seem to depend on both endothelium-dependent and independent mechanisms. Studies in isolated human internal mammary arteries and rat coronary arteries indicate endothelium-dependent Ucn 1-induced dilation involves both nitric oxide (via second messenger cGMP) and barium sensitive potassium channels. Vasodilation is blunted but not abolished in endothelium-denuded vessel preparations and both calcium independent phospholipase A1 and store-operated calcium flux have been invoked in this setting.[33]

Urocortins and Endothelial Function

Results on the effect of Ucn on the endothelium generally favor a protective role for this peptide family with respect to this crucial vasoregulatory organ.[14] The endothelium has important roles in regulation of vessel tone, blood pressure, and vascular remodeling. Endothelial dysfunction (ED) seems to be a universal precursor and accompaniment to atherosclerosis being associated with common vasculopathic factors such as hypertension, dyslipidemia, and smoking. Endothelial cells (EC) generate numerous autacoids, including NO, prostacyclin (PGI2), endothelium-derived hyperpolarizing factor (EDHF), bradykinin (BK), adrenomedullin, C-type natriuretic peptide, ET-1, AngII, thromboxane A2 (TXA2), hydrogen peroxide (H2O2), and free radicals. Hence, endothelium hosts both vasoconstrictor and vasodilator substances, which encompass trophic and antiproliferative, prothrombotic and thrombolytic, oxidative, and antioxidant effects. NO synthesized and released from EC is a fundamental vasodilator determinant of vascular tone. It also inhibits proinflammatory cytokines and chemokines, leukocyte adhesion molecules, proliferation of vascular smooth muscle cells (VSMCs), activation and aggregation of platelets, and the production of tissue factor. In addition to NO, ECs also releases the vasodilator prostaglandin, PGI2 in response to shear stress and hypoxia. Endothelium-derived vasoconstrictors include ET-1, the vasoconstrictor prostanoids TXA2 and PGH2, and AngII. AngII facilitates superoxide anion production by activation of vascular NADH/NADPH oxidase. Where do the Ucns fit in this delicate and complex meshwork of factors that

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

modulate endothelial function? It has been reported that the rat aortic ECs predominantly express CRH-R2b. The partially endothelium-dependent effects of Ucns on blood pressure and vascular tone have been mentioned already. Hence, Ucns exert part of their vascular effect via endothelial mediators. Ucn seems to enhance endothelial responses in several experimental settings. Ucn increases the coronary vasodilator response to acetylcholine when given either before ischemia or during reperfusion. Ucn 2 induces nitric oxide production via cAMP and calcium-related pathways in endothelial cells.[14] In studies of ischemia-reperfusion injury in isolated rat hearts, Ucn enhances synthesis of NO and decreases the serum superoxide dismutase (SOD) activity. Rademaker et al.[22–24] reported endogenous and exogenous Ucn reduce plasma AngII and ET-1 concentrations in ovine experimental heart failure. Ucns may also have antitrophic effects with an antiproliferative effect on cultured ECs. Concordant with this, mice deficient for CRH-R2 become hypervascularized.[1] Ucn treatment inhibits the formation of capillary-like tubes in three-dimensional collagen gels containing rat aortic ECs. Together, these findings support a protective role for Ucns with respect to endothelium-mediated vasodilator function and suggest Ucns inhibit vascular hypertrophy.

However, CRH and Ucn have exhibited proinflammatory effects in some settings. Ucn induces CRH-R2-dependent mast cell degranulation with abnormal increases in vascular permeability.[30] *In vitro* Ucns may also stimulate interleukin-1β (IL-1β) and interleukin-6 (IL-6) secretion. It can be speculated that such effects may trigger ECs to switch phenotype from their normal net antithrombotic character to a procoagulant state. Further, CRH-related peptides can abolish IL-1α-induced synthesis of PGI2 in bovine aortic ECs.

The endothelium seems to be an important target tissue for Ucns. Although in specific pathological settings Ucn actions may be deleterious, the weight of evidence favors an endothelial-protective role for Ucns in health and in most cardiovascular pathologies.

Urocortins and Cardiac Sympathetic Traffic

Intravenous administration of Ucns 1, 2, and 3 in conscious, intact sheep reduces cardiac sympathetic efferent traffic[6,7] as shown by direct recordings of sympathetic burst activity via electrodes implanted in the cardiac sympathetic efferent nerves in sheep. This unique biological action of the Ucns is apparent at doses of Ucn below the threshold inducing readily recorded changes in blood pressure. The effect remains evident at doses sufficient to lower arterial pressure and increase heart rate. This implies that the effects on heart rate do not reflect baroceptor responses mediated by the sympathetic afferent-efferent loop but are due to direct effects of Ucn on heart rate. This sympatholytic mechanism may be a further contributor to the blood pressure lowering effect of Ucns. Although not yet tested, if suppression of sympathetic traffic extends to renal sympathetic drive this may also contribute to reductions in renal vascular resistance, enhanced renal filtration, and Ucn-associated suppression of renin production, as observed in ovine experimental heart failure. It also raises the possibility of specific therapeutic benefit from Ucns in cardiac injury and/or heart failure, conditions in which sympathetic overdrive is both proarrhythmic and contributes to progressive cardiac dysfunction. The intracellular signaling pathways mediating the antisympathetic effect of the Ucns are as yet unknown.

Cardiac Actions of the Urocortins

The Ucns have direct CRH-R2-mediated positive effects on cardiomyocyte contractility as observed on application of Ucn 2 to isolated rabbit ventricular cardiomyocytes. Intracellular pathways induced by Ucn in this setting include increased PKA activity and subsequent L-type calcium channel and sarcoplasmic and endoplasmic reticulum calcium ATPase (SERCA)-mediated calcium uptake into the sarcoplasmic reticulum.[34] Ucn 2 injected into intact rats induced immediate onset of subsequently long-sustained enhancement of left ventricular shortening. Ucn 1 injection in sheep caused dose-dependent increases in cardiac output and dp/dt (index of contractility) lasting to 24 h after a single bolus intravenous dose.[22]

Urocortin Effects in Models of Ischemia-reperfusion Injury

Ucn 1 precursor is found in rat neonatal cardiomyocytes and is released from cells exposed to hypoxia. *In vitro* secretion is also triggered by inflammatory cytokines including interleukins 1 and 6 and tumor necrosis factor, local and circulating factors increased in cardiac ischemia and in heart failure. These findings raise the possibility of local, direct cardiac actions of Ucns mediated by cardiac CRH-R2 receptors. Ucn 1 reduces cardiomyocyte death in ischemia-reperfusion injury.[5] Ucns are protective both *in vitro* when added to postischemic/hypoxic cardiomyocytes and to isolated intact hearts during postischemic reperfusion. Ucn 1 enhances hemodynamic and bioenergetic recovery of isolated, paced rat hearts with improved ventricular performance postischemia reperfusion. Ucn 2 and Ucn 3 reduce infarct size in isolated rat hearts postischemia reperfusion.[4] Furthermore, sustained treatment with Ucn 2 in a mouse coronary ligation model of myocardial infarction protects against adverse postinfarction left ventricular remodeling and sustains cardiac function in the intact mouse.[12]

Urocortins in Experimental Heart Failure

Since 2002 the Christchurch Cardioendocrine research group has provided a series of pivotal studies documenting

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

the effects of Ucns 1, 2, and 3 in experimental ovine heart failure.[22–28] This group has also provided the only results available to date on the bioactivity of exogenous Ucns administered to both normal volunteers and to patients with stable heart failure.[9,10] All 3 Ucns produce a salutary array of powerful hemodynamic, neurohormonal, and renal effects in an ovine model of severe heart failure induced by chronic overpacing (Figure 1). This model in an intact, conscious large animal is one of the few which provides a faithful analog of many aspects of severe human heart failure and permits the observation of developing and resolving heart failure over periods of weeks with serial measurement of key hemodynamic, hormonal, and renal variables. In this model bolus intravenous doses of 25–100 μg of Ucns 1, 2, and 3 all markedly augment cardiac output, lower cardiac filling pressures to near normal levels and reduce systemic vascular resistance with relatively modest falls in arterial pressure.[22,23,25] These salutary hemodynamic effects are accompanied by significant falls in abnormally high levels of neurohormones including suppression of renin, AngII, aldosterone, ET-1, and AVP. The hemodynamic relief provided from Ucns leads to reduced plasma ANP and BNP plasma concentrations in spite of the known direct actions of Ucns stimulating release of natriuretic peptides *in vitro*. Markedly reduced renal filtration and avid antinatriuresis, both consistent features of this model are essentially returned to normal by administration of Ucns. This beneficial profile of effects is sustained over 4 days of dosing with Ucn 1 or Ucn 2.[24] Administration of Ucn from the outset of pacing stress markedly delays onset of heart failure in this model and a role for endogenous Ucns as a powerful beneficial compensatory response in heart failure is further supported by the exacerbation of hemodynamic, neurohormonal, and renal abnormalities in this model on administration of the Ucn blocker CRH[9–41].[26] As any new potential therapy in heart failure will probably function in addition to existing proven treatments, the combination of Ucn with diuretics, angiotensin-converting enzyme inhibitors, and beta adrenoceptor blockers (all mainstay therapy in clinical management of human heart failure) have all been studied in the ovine model.[27,28] Without exception the combinations have resulted in enhancement of beneficial hemodynamic effects compared with either agent alone together with blunting of undesirable effects of current therapies. The combination of Ucn 2 with the loop diuretic frusemide enhanced renal responses with less renin activation and no exacerbation of potassium loss or additional fall in arterial blood pressure.[27] Ucn 2 together with angiotensin-converting enzyme inhibitors, enhanced reductions in aldosterone, reduced increases in renin, enhanced increases in cardiac output, and further lowered systemic resistance without further fall in blood pressure.[28] Ucn 2 combined with beta blockade prevented the initial falls in cardiac output and renal function attendant upon introducing beta blockade in severe heart failure, in association with significantly enhanced suppression of plasma aldosterone.

Concordant with the extensive findings in the ovine model of heart failure, Ucn 2 infusion in a mouse model of dilated cardiomyopathy, because of deficiency of muscle specific LIM protein, markedly improves cardiac output and left ventricular function.[33]

Urocortins in Human Heart Failure

Plasma concentrations of Ucn 1 in human heart failure have been studied and reported by two groups with somewhat discrepant findings.[33] Ng et al developed an immunoassay for Ucn 1 and reported that levels are increased overall in human heart failure but puzzlingly exhibit a direct rather than inverse relationship with left ventricular ejection fraction and that although levels are elevated in milder heart failure (NYHA functional classes I and II) they tend to fall in more severely symptomatic heart failure. By contrast, Wright et al. using a separate locally developed radioimmunoassay reported elevated concentrations in heart failure with continuing increments in plasma concentrations with worsening functional class, an inverse rather than direct relationship with LVEF and significant direct correlations with other circulating markers of severity in heart failure including plasma BNP.[33] Plasma Ucn 1 concentrations are an independent predictor of a final diagnosis of heart failure in patients presenting to their family doctors with new onset of peripheral edema and/or breathlessness on exertion. Plasma Ucn 1 underperformed NTproBNP as a potential individual diagnostic marker for heart failure but, in combination with NTproBNP levels, it enhanced risk stratification for this diagnosis. Using the assay from Wright et al., regional blood sampling was undertaken in the course of cardiac catheterization procedures, in patients without acute disease and normal cardiac function, undergoing clinically indicated coronary angiography. These studies in 25 patients indicate net production of Ucn 1 from heart, kidney, liver, head, and neck, and musculoskeletal tissue (leg) but not from the pulmonary circulation. This suggests widespread synthesis and release of Ucn 1 concordant with the wide distribution of tissue immunoreactivity in preclinical *ex vivo* studies.

Biological Actions of Urocortins in Humans

Controlled short-term studies of the hemodynamic, hormonal, and renal effects of Ucns 1 and 2, administered at total doses between 25 and 100 μg, have been undertaken in both normal volunteers and patients with stable heart failure.[9,10]

Ucn 1 studies reveal little major effect at these doses. Modest increments in ACTH and cortisol are observed in normal but not in heart failure subjects with no significant hemodynamic or renal effects.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

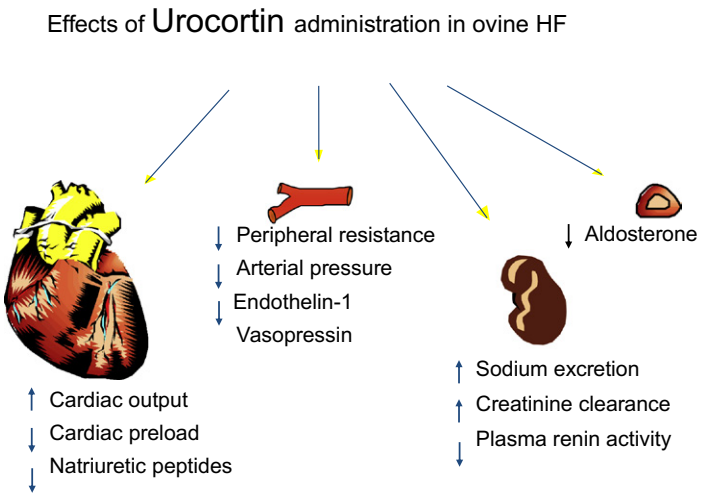

FIGURE 1 Biological actions of urocortins in experimental heart failure.

Both doses of Ucn 2 induce clear increases in cardiac output in both normal and heart failure groups.[9,10] This effect is associated with decreases in systemic vascular resistance that are sustained out to 3 and 6 h postdose for 25 and 100 μg doses, respectively, in heart failure. At the conclusion of the 1 h Ucn 2 infusions, cardiac ultrasound indicates decreases in left ventricular dimensions and a dose-related increase in LVEF in the heart failure group.[10] Calculated cardiac work is reduced by Ucn 2. Renal and neurohormonal effects are only minor, which is notable in that there is no renin or catecholamine rise despite significant falls in blood pressure. However, this latter finding contrasts with the accumulated results from the ovine model of severe untreated heart failure in which the neurohormonal and renal effects of administered Ucns are profound. Such effects in normal sheep are markedly blunted compared with sheep in heart failure, suggesting the full expression of Ucn-induced renal and neurohormone effects requires the markedly activated and abnormal milieu present in severe decompensated heart failure. Heart failure patients recruited to the Ucn studies to date have been stable on long-term therapy and only mildly symptomatic (despite a clear history of previous frank cardiac decompensation and clearly abnormal cardiac function). In this treated stable state, Ucns may not elicit substantial effects on kidney function or hormone levels acutely. However, the lack of neurohormonal response to the hypotensive effects of Ucn 2 is notable. At present, a clinical trial of 4-h infusions of Ucn 2 in recently decompensated heart failure is in progress and may answer some of these questions.

PATHOPHYSIOLOGICAL AND THERAPEUTIC IMPLICATIONS

Ucns have a significant role in the regulation of the heart and circulation in disease states. Their roles in normal health are more subtle although CRH-R2 knockout mice are hypertensive. Ucns are produced in a wide array of tissues and act via receptors that are widely distributed in the cardiovascular system and other organs with key functions in circulatory regulation including the kidneys and adrenal glands. The signaling pathways mediating Ucn's actions are multiple and complex suggesting the potential for tissue- and disease-specific derangements of local and systemic Ucn function with attendant potential multiple points at which Ucn signaling and bioactivity might be manipulated for therapeutic purposes.

Notable cardiovascular effects include vasodilation with lowering of blood pressure. In hypertensive animal models, Ucn 2 is a powerful blood pressure lowering agent. Ucns exert positive inotropic, chronotropic, and lusitropic effects on cardiac ventricular function. The most compelling results on the endogenous compensatory role of Ucns are found in the setting of heart failure. In both experimental and mild human heart failure, Ucns display powerful beneficial effects on the hemodynamic status. Despite the implicit therapeutic potential of the salutary beneficial effects of Ucns 1, 2, and 3 on neurohormones and renal function observed in an ovine model of severe heart failure, these are yet to be reproduced in the clinical setting. Further conclusions and developments await outcomes of exploratory trials in patients with recently decompensated heart failure.

Chapter 195

Urotensin Peptides

Kazuhiro Takahashi and Kazuhito Totsune

ABSTRACT

Urotensins, peptide hormones originally discovered in the fish neuroendocrine organ urophysis, consist of urotensin I (UI), a corticotropin-releasing hormone-like fish peptide, and urotensin II (UII), a somatostatin-like fish peptide. Human UII, a cyclic peptide consisting of 11 amino acids, is widely distributed in various organs including the cardiovascular system, together with its UT receptor. Urotensin-II-related peptide (URP) is an 8-amino acid peptide that has a common ring structure with that of UII. UII and URP bind to the UT receptor with a similar affinity. UII is a potent vasoconstrictor peptide, whereas UII causes endothelium-dependent relaxation that is mediated through NO production. Furthermore, UII has various actions, such as stimulation of cell proliferation and hypertrophy, a positive inotropic action and CNS actions on cardiovascular control. Plasma concentrations of UII are elevated in patients with congestive heart failure, hypertension, end-stage renal disease, and diabetes mellitus. UII and the UT receptor may therefore play important pathophysiological roles and provide novel targets for the treatment of these diseases.

DISCOVERY

Urotensins were originally discovered from urophysis, a fish neuroendocrine organ located in the caudal spinal cord.[26,30] There are at least two types of urotensins: urotensin I (UI), a corticotropin-releasing hormone (CRH)-like fish peptide and urotensin II, a somatostatin-like fish peptide. Urocortins (urocortins 1, 2, and 3) are human homologs of UI and belong to the CRH family of peptides. Urocortins are described in the previous chapter.

Human UII is a cyclic peptide consisting of 11 amino acids (Fig. 1)[1,7] Molecular cloning of human UII and frog UII cDNAs showed that human UII consists of only 11 amino acid residues, whereas fish and frog UII possess 12 and 13 amino acid residues, respectively.[1,7,30] The cyclic region of UII, which is responsible for the biological activity of the peptide, has been fully conserved from fish to human. Reverse pharmacology has revealed that human UII is an agonist for the orphan receptor GPR14 (now called urotensin II receptor or UT receptor).[1] Furthermore, human UII is a potent vasoconstrictor peptide and its vasoconstrictive potency is one order of magnitude greater than that of endothelin-1.[1]

Urotensin-II-related peptide (URP) is an 8-amino acid peptide identified as the UII-immunoreactive molecule in the rat brain [25](Fig. 1). In contrast to human and porcine UII, the amino acid sequences of the tentative rat or mouse precursor proteins for UII, which show high homology to human or porcine ortholog proteins, lack typical cleavage sites to generate mature UII peptides. Therefore, it has not been clarified whether mouse or rat UII peptide is present as an endogenous ligand for UT receptor in mouse and rat. URP was identified as an endogenous ligand for UT receptor in rats. The amino acid sequence of human and mouse URP is the same as that of rat URP. UII and URP genes originate from the same ancestral gene as the somatostatin and cortistatin genes.[28]

DISTRIBUTION OF THE mRNA/PEPTIDE IN THE CARDIOVASCULAR SYSTEM

UII mRNA and peptide are distributed widely in the cardiovascular system, including the heart and vascular vessels.[1,7,26,30] UII is expressed in the myocardium, and vascular endothelial and smooth muscle cells in various organs. In the kidney, UII is expressed in the epithelial cells of tubules and ducts, with greater intensity in the distal convoluted tubules, in addition to vascular vessels.[27] UII is also expressed in the endocrine organs, such as adrenal cortex and medulla, which have important physiological roles in the cardiovascular control.[12,19]

The expression of UII is enhanced in the cardiac tissue obtained from patients with heart failure.[10] Furthermore, strong UII immunostaining is observed in the blood vessels with atherosclerotic lesions, including endothelial, smooth muscle, and inflammatory cells and the atherosclerotic plaques.[4]

Real-time RT-PCR showed that URP mRNA is expressed in peripheral and central tissues of humans and rats, with higher expression found in the ovary, testis, and placenta in humans, and the thymus, spleen, testis, and spinal cord in

Copyright 2009 Elsevier Inc.)*

rats.[25] Expression levels of UII mRNA are particularly high in the spinal cord of human and rat, whereas the expression of URP mRNA in the spinal cord is not significant. URP mRNA is also expressed in cardiovascular tissues, such as the heart, aorta, and kidney.[14,18,20,25] URP mRNA levels are increased in the heart tissue obtained from rats with congestive heart failure resulting from coronary ligation,[20] and in the kidney and aorta from spontaneously hypertensive rats (SHR).[14]

RECEPTORS AND SIGNALING CASCADES

Both UII and URP bind to UT receptor with a similar affinity.[25] The UT receptor has 7 transmembrane domains, belongs to the class A family of G protein-coupled receptor, and is widely expressed in various organs including the heart and vascular vessels.[1,30] UT is expressed in various human tissues, including heart (atria and ventricles), coronary artery, aorta, kidney, adrenal, brain, and pituitary.[29] Immunocytochemical studies showed that UT receptor is expressed in the myocardium, and smooth muscle cells and endothelial cells of arteries and veins.[20] Expression levels of UT receptor mRNA are elevated in the atrium of rats with congestive heart failure resulting from coronary artery ligation,[20] and the atrium, ventricle, and aorta of SHR. In the kidney, UT receptor is expressed in the renal tubular cells and vascular endothelial cells.[18] Expression levels of UT receptor mRNA are elevated in the kidney of rats with hypertension or chronic renal failure due to 5/6 nephrectomy.

The dissociation of UII from the UT receptor is essentially irreversible.[9] Only about 15% of [^{125}I]UII is dissociated after 90 min by the addition of an excess of unlabeled UII in human SJRH30 rhabdomyosarcoma cells. Moreover, the UII/UT complex is internalized in a dynamin-dependent but arrestin-independent manner.[11] After dissociation from UII, the UT receptor recycles back to the plasma membrane. The low dissociation and the continuous externalization of the UT receptor may explain the repetitive and lasting UII-mediated vasoconstriction.

The main transduction mechanism associated with UT receptor is the coupling and activation of the $G_{\alpha q/11}$ subtype of heterotrimeric G proteins.[13,30] UT receptor is coupled to the phospholipase C/protein kinase C pathway. UII stimulates polyphosphoinositide turnover and provokes mobilization of Ca^{2+} from intracellular stores. UT may also couple to $G_{\alpha i/0}$ proteins. Furthermore, the UT receptor can activate several other signaling pathways, including the phospholipase A2, the MAP kinases ERK1/2, the NO synthase, and the Rho A/Rho kinase pathways.

BIOLOGICAL ACTIONS WITHIN THE CARDIOVASCULAR SYSTEM

Table 1 shows the biological actions of UII in the cardiovascular, endocrine, and renal systems. It was initially reported that human UII is a potent vasoconstrictor peptide, and its vasoconstrictive potency is one order of magnitude greater than that of endothelin-1.[1] UII and URP exert a potent contractile effect on endothelium-denuded rat thoracic aorta, monkey coronary artery, and human pulmonary artery.[1,6,17,30] By contrast, in intact rat small mesenteric arteries, UII causes endothelium-dependent relaxation that is mediated through NO production.[3] The vasoactive profile of UII is species dependent and varies substantially according to the type of blood vessel even within each single species.[8]

Infusion of UII into healthy human volunteers had no effect on forearm blood flow in one study,[34] whereas dose-dependent reductions in forearm blood flow were reported by another group.[2] Measurements of skin microvascular tone showed that UII produced a dose-dependent vasodilator response in normal subjects, whereas vasoconstriction was noted in patients with chronic heart failure, essential hypertension, and diabetes mellitus.[16,27]

UII has a strong inotropic action on the myocardium,[21] whereas bolus injection of UII in the cynomolgus monkey reduces myocardial contractility and provokes circulatory collapse and death.[1] UII stimulates the proliferation of vascular smooth muscle cells, fibroblasts, and some cancer cells.[27,30] It also stimulates the hypertrophy of cardiomyocytes and induces angiogenesis.[13,30]

UII and the UT receptor are expressed in the brain,[15,29,30] as described in the Brain Peptides section of this book. UII may also regulate the cardiovascular system via the brain. Injection of UII into the brain causes significant hemodynamic changes and plasma levels of hormones in rats, depending on the sites of injection,[15,30,33] as shown in Table 1. Intracerebroventricular injection of UII increases the heart rate and arterial blood pressure in rats. These

8.	Regulation of glomerular filtration rate and renal sodium and water handling in the kidney

responses are significantly attenuated by pretreatment with intravenous pentolinium (ganglion blocker), suggesting that UII-mediated responses partly result from increases in sympathetic activity. Intracerebroventricular injection of UII elevates plasma ACTH, epinephrine, and glucose levels. By contrast, microinjection of UII into the A1 area of the medulla produces dose-dependent depressor and bradycardiac responses. However, there is no effect of UII microinjection into the A2 area on mean arterial blood pressure or heart rate. Moreover, significant pressor and tachycardiac responses are observed on microinjection of UII into either the arcuate or paraventricular nuclei.

UII modulates the production and secretion of certain hormones.[27,30] UII may therefore affect the cardiovascular control and the pathophysiology of cardiovascular diseases via the effects on hormone secretion. UII inhibits insulin release from the perfused rat pancreas. UII suppresses basal secretion of corticosterone from *in vitro* cultured adrenocortical cells of Sprague–Dawley rats. By contrast, UT receptor activation *in vivo* in rats enhances the adrenocortical expression of immunoreactive aldosterone synthase.[12]

In the kidney, UII regulates glomerular filtration rate (GFR) and renal sodium and water handling. Injection of rat UII induces reductions in GFR, urine flow, and sodium excretion.[24] Infusion of a UT receptor antagonist, urantide, results in increases in these variables. Endogenous UII therefore seems to contribute to the regulation of GFR and renal sodium and water handling in the rat. UII infusion in anesthetized SHR and control Wistar Kyoto (WKY) rats produces marked reductions in GFR, urine flow, and sodium excretion rates, which are greater in SHR by comparison with WKY rats.[27] WKY rats also show an increase in fractional excretion of sodium in contrast to SHR in which no such change is observed. Blockade of the UII receptor with urantide evokes an increase in GFR, which is greater in SHR compared with that in WKY rats and is accompanied by a diuresis and natriuresis. By contrast, Zhang et al. reported that UII produces vasodilator and natriuretic effects in the kidney and that UII-induced vasodilation is associated with increased endothelial NO in the renal artery.[27]

There are a limited number of reports on the biological actions of URP. URP and UII share the same receptor, UT.[25] The biological actions of URP may therefore be similar to those of UII. URP has about the same binding affinity, but less potency, than UII in contracting rat aortic strips *in vitro*.[6] *In vivo*, intravenous injection of URP produces a long-lasting reduction of blood pressure.[13,27,30] URP dilates rat coronary arteries with 10-fold less potency compared with rat UII.[13,27,30]

PATHOPHYSIOLOGICAL IMPLICATIONS

Plasma concentrations of UII are elevated in patients with heart failure, hypertension, end-stage renal disease, diabetes mellitus, and portal hypertension[13,27,29,30] (Table 2). UII and UT receptor may therefore play important roles of the pathophysiology of these diseases.

Elevated concentrations of plasma UII were first observed in patients with chronic renal failure (Fig. 2). The mean concentration of urotensin II-like immunoreactivity in plasma is 4.4 ± 1.0 fmol/mL in healthy individuals ($n = 24$, mean ± S.D.). The very low concentration of UII in plasma suggests that the main (patho)physiological roles of UII are mediated in an autocrine or paracrine fashion, rather than in an endocrine fashion. Plasma concentrations of UII are 2-fold higher in patients not on dialysis and 3-fold higher in patients on hemodialysis by comparison with controls. These observations suggested that UII might act as an important regulator in the cardiovascular and renal systems. Urotensin II antagonists could, therefore, be useful in the treatment of diseases affecting these organs.

Plasma UII concentrations are elevated in patients with congestive hear failure, and the expression levels of UII and binding sites of UII are increased in the myocardium obtained from patients with end-stage heart failure.[10] UII may contribute to cardiac remodeling after myocardial infarction.[5] A selective antagonist of UT, SB-611812 significantly attenuates both myocardial and endocardial interstitial fibrosis, and reduces collagen type I:III ratio

in rats with coronary ligation. UII induces proliferation of cardiac fibroblasts and this mitogenic effect is significantly inhibited with 1 μM of SB-611218. Thus, the blockade of UII action attenuates remodeling in experimental ischemic heart disease.

There are several reports that suggest that UII promotes progression of atherosclerosis.[4,13,27,32] UII is abundantly expressed in endothelial cells, and myointimal and medial smooth muscle cells of atherosclerotic human coronary arteries in comparison with healthy arteries.[4] UII stimulates the proliferation of vascular smooth muscle cells and fibroblasts. Particularly, UII acts synergistically with mildly oxidized low-density lipoprotein to induce vascular smooth muscle cell proliferation.[32] UII activates migration and differentiation of adventitial fibroblasts from rat aorta. Targeted overexpression of the human UT transgene in smooth muscle cells shows a significant increase in atherosclerotic lesion in aorta, suggesting an important role for UT in the pathogenesis of atherosclerosis.[27]

Plasma concentrations of UII are elevated in patients with diabetes mellitus without apparent renal dysfunction.[27] Diabetic mice exhibit higher concentrations of UII and UT mRNAs in skeletal muscle compared with control.[30] Expression levels of UII and UT are enhanced in diabetic kidneys of rats and human compared with nondiabetic control.[27] Furthermore, single nucleotide polymorphism in the UII gene is associated with a higher risk of developing type 2 diabetes mellitus.[27,30] These reports suggest that UII plays roles in carbohydrate metabolism and the pathophysiology of diabetes mellitus and its complications, such as diabetic nephropathy.

In an accelerated rat model of diabetes mellitus prepared by injection of streptozotocin and unilateral nephrectomy, effects of palosuran (a UT receptor antagonist) have been studied.[27] Long-term treatment of these diabetic rats with palosuran improves survival, increases insulin, and slows down the increase in glycemia, glycosylated hemoglobin, and serum lipids. Furthermore, palosuran increases renal blood flow and delays the development of proteinuria and renal damage. These findings suggest that the blockade of UII has protective roles against the progression of diabetic nephropathy. Pharmacodynamics and pharmacokinetics of palosuran were studied in 19 macroalbuminuric, diabetic patients.[22] These 19 patients were treated with oral doses of 125 mg palosuran twice daily for 13.5 days in addition to treatment with either an ACE inhibitor or an angiotensin receptor blocker. An overall clinically significant reduction of 24.3% in the 24-h urinary albumin excretion rate was observed after 13.5 days of treatment. No effect was observed on renal hemodynamic parameters. In contrast to these two reports, palosuran did not affect albuminuria, blood pressure, GFR, or renal plasma flow significantly in 54 hypertensive patients with type 2 diabetic nephropathy treated with a single blocker of the renin–angiotensin–aldosterone system.[31] The antagonism of the UII system by palosuran did not influence insulin secretion or sensitivity or daily blood glucose levels in diet-treated patients with type 2 diabetes mellitus.[23]

Some studies suggest a protective role of UII by showing that plasma UII levels are lower in patients with acute cardiac ischemia, and that plasma UII levels predict better cardiovascular outcomes in patients with end-stage renal disease.[35] It is noteworthy, however, that there are very large variations in plasma UII levels of three orders of magnitude among the reports because of differences in the analytical methods.[27]

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Some assay methods of UII may detect not only UII but also the UII precursor, its fragment peptides, or nonspecific materials in plasma. Thus, difficulty remains in interpreting results of plasma UII levels reported by various research laboratories.

Chapter 196

VIP

Robert J. Henning

ABSTRACT

Exogenous vasoactive intestinal peptide (VIP) causes coronary dilation with an EC_{50} of 4×10^{-11} M, mediated by VPAC1 and VPAC2 receptors, adenylyl cyclase, and potassium channels. At greater concentrations, VIP can increase atrial and ventricular contractility and heart rate and decrease atrial ventricular refractory periods and conduction time. Endogenous VIP, released from vagal nerves, increases left coronary artery blood flow, right atrial and right ventricular contractility, and heart rate. Cardiac VIP concentration reflects a balance between local neurogenic synthesis and removal by veins and lymphatics. Circulating VIP is metabolized in the lung and liver by neutral endopeptidase and by mast cell chymase and tryptase. With coronary occlusion, VIP is released from coronary and myocardial neurons and acts as a vasodilator and free-radical scavenger that limits injury. With cardiomyopathies, hypertension, obesity, diabetes, and hypothyroidism the cardiac concentration of VIP, VIP receptor density, and coupling to adenylyl cyclase decreases with resultant increases in coronary vascular resistance and myocardial fibrosis and reductions in myocardial contractility and heart rate.

INTRODUCTION

Vasoactive intestinal peptide (VIP) is a 28-amino-acid neuropeptide discovered by Said and Mutt in 1970 with diverse cardiovascular effects that include vasodilation of the cerebral and coronary artery circulations and an increase in myocardial contractile performance [see the Chapter by S.I. Said in the Respiratory Peptides section of the book and Refs. 14–16, 28, 29]. VIP exerts its effects by activating signaling processes involving VPAC1 and VPAC2 receptors, adenylyl cyclase, guanylyl cyclase, and potassium channels.[16,28,29] VIP immunoreactive nerve fibers originate from the central, peripheral, and intrinsic nervous systems and innervate blood vessels in the myocardium and throughout the body.[11,28] VIP is metabolized in the circulation by neutral endopeptidase and by mast cell chymase and tryptase.[8] The VIP gene has been cloned, sequenced, and localized to chromosome 6q24. VPAC1 and VPAC2 genes are located on chromosomes 3p22 and 7q36.3, respectively.

DISCOVERY

After the seminal discovery in 1902 by Bayliss and Starling of an intestinal extract that had vasodepressor properties, Said and Mutt isolated and sequenced an acid-extractable peptide from the duodenum that produced in anesthetized dogs a decrease in the systemic arterial pressure and an increase in the stroke volume, heart rate, mesenteric, and femoral arterial blood flow. Because the action of the endogenous peptide was initially believed not to extend beyond the intestine because of metabolism by the liver, the peptide was named "Vasoactive Intestinal Peptide." Subsequent studies found this peptide in high concentrations in the plasma and tumor tissues of patients with pheochromocytoma and ganglioneuroblastoma, in neuroblastoma and astrocytoma cell lines, and also widely distributed in the central and peripheral nervous systems. In addition, numerous VIP immunoreactive cell bodies have been discovered in the heart, tracheobronchial tree, gastrointestinal and genitourinary tracts, and pancreas, which indicate that there is also a peripheral intrinsic VIP-ergic system.[28] The observation that VIP immunoreactive fibers innervate blood vessels in the atrial and ventricular myocardium, the conduction system of the heart and small intestine and brain led to additional studies to determine the role of VIP in the regulation of blood flow and cardiac performance.

DISTRIBUTION

VIP immunoreactive nerve fibers innervate blood vessels throughout the central and peripheral nervous systems, as well as the heart. In the heart of guinea pigs, rats, and dogs, VIP-ergic fibers primarily innervate the sinoatrial node, cardiac glomeruli of the proximal coronary arteries, intramural and terminal arteries of the atria, ascending aorta and pulmonary trunk.[28] A moderate number of VIP-ergic fibers innervate the atrioventricular node, perivascular nerve plexuses of the major coronary arteries, and atrial myocytes. VIP-ergic fibers also innervate the intracardiac ganglia and intramural and terminal vasculature

of the ventricles. In addition, intracardiac ganglia contain VIP immunoreactive cell bodies.[28] Although these fibers may be primarily of intrinsic origin, some extrinsic parasympathetic preganglionic efferent, parasympathetic and sympathetic postganglionic efferent, and parasympathetic and sympathetic afferent VIP-ergic fibers also exist.[11] An extrinsic VIP-ergic innervation exists, particularly in the canine right ventricle.[1,14,28] The concentration of VIP in the left ventricular epicardial coronary arteries varies between 0.7 and 2.2 pmol g^{-1} tissue, with the highest concentrations in the proximal coronary regions.[4] A VIP-ergic innervation of the epicardial coronary arteries may play a role in maintaining coronary vasorelaxation. In the cerebral circulation, interneurons containing VIP innervate arterioles and receive input from acetylcholine and serotonin containing neural projections that contact cell soma and proximal dendrites.[28] Electrical stimulation of these interneurons produces vasodilation of adjacent arterioles, supporting a role for VIP-ergic neurons in the control of cerebral blood flow. VIP, on a molar basis, is 50–100 times more potent than acetylcholine as a vasodilator.[16]

PROCESSING

The VIP peptide is derived from preproVIP, which consists of 170-amino-acid residues. Proteolytic cleavage of preproVIP yields preproVIP (22–79), peptide histidine isoleucine/methionine (PHI/PHM 81–107), preproVIP (111–122), VIP (125–152), and preproVIP (156–170). Peptide histidine isoleucine/methionine is structurally related to VIP and shares many of VIP's biological actions but is generally less potent than VIP. Other peptide sequences have been identified during the proteolytic cleavage of the VIP precursor but have limited biological effects. Nevertheless, the bioactivity of the partial sequences of VIP increases with increasing amino acid chain length.

VIP is metabolized by neutral endopeptidase (NEP), a transmembrane metallopeptidase that is abundant in the central nervous system, kidneys, liver, lung, and intestinal epithelium.[27] This enzyme cleaves a variety of peptides in addition to VIP, including enkephalins, angiotensin I, angiotensin II, substance P, neurotensin, and atrial natriuretic peptides. Topical application of two NEP inhibitors, phosphoramidon and thiorphan, enhances the vasodilatory effect of VIP in resistance vessels, showing a role for vascular NEP in limiting the vasoreactivity of VIP.[8,16,28] The plasma concentration of VIP increases 3.6-fold, from 30 to 108 fmol ml^{-1}, after a single dose of the NEP blocker UK77-568, but then returns to baseline after four consecutive daily doses of the NEP blocker, because of feedback inhibition of VIP release.[8] The major sites of VIP metabolism in circulation are the lungs, liver, and probably kidneys, which contribute to a VIP half-life of 2–5 min.[18] Other tissues, such as the intestine, brain, and heart, play little role in VIP metabolism. In the heart, the concentration of VIP reflects a balance between local neurogenic synthesis and release in the myocardium and removal by the circulatory and lymphatic systems. During chronic NEP inhibition, the myocardial VIP concentration can increase 2-fold.[8] Angiotensin converting enzyme (ACE) inhibition can increase myocardial VIP concentration by as much as 4.5-fold because of local VIP synthesis and release in the myocardium.[28] This increased concentration of VIP in myocardium can contribute to improvement of cardiac function in patients with cardiomyopathy who are treated with ACE inhibitors. However, chronic ACE inhibition does not change the concentration of VIP in the plasma, kidneys, and lungs because it increases the metabolism of VIP.[28]

RECEPTORS

Two subtypes of VIP receptor, VPAC1 and VPAC2, have been identified in the cardiovascular system.[13,16,28,29] These G-protein-coupled receptors are members of the secretin receptor family and bind VIP and pituitary adenylate cyclase activating peptide (PACAP) with equal affinity.[16] VIP receptors are present in heart and blood vessels and have a molecular weight of 43,000–80,000 Da.[16] In general, the density of VIP receptors in arteries is greater than that in veins. This accounts for VIP's greater vasodilatory effect on arteries than veins.[16] The N-terminal region of VIP plays an important role in selective recognition of VPAC or PAC1 receptors, while the formation of the α-helical structure in the C terminus of VIP seems to be important in VIP binding to VPAC receptors. VPAC1 and VPAC2 receptors have been identified in endothelium and smooth muscle of major arteries and arterioles of the right and left ventricle[29] (see Figure 1). VPAC1 and VPAC2 receptors are also present in endothelium and smooth muscle of cerebral arteries and arterioles.[28] Consequently, both receptors seem to be involved in the control of coronary and cerebral arterial blood flow. Involvement of VPAC1 and VPAC2 receptors in vascular regulation has been recently shown by blockade of pressure-induced cutaneous vasodilation with the VPAC1 or VPAC2 receptor antagonists PG97-269 or PACAP6-38, respectively.[28,29] This implies a series relationship in which both receptors are necessary for the full expression of this neurally mediated cutaneous vasodilatory reflex. VPAC2 and to a lesser extent VPAC1 receptors are also present in atrial myocardium.[34] The expression of both VPAC2 and VPAC1 receptors in coronary arteries, arterioles and myocardium contrasts with

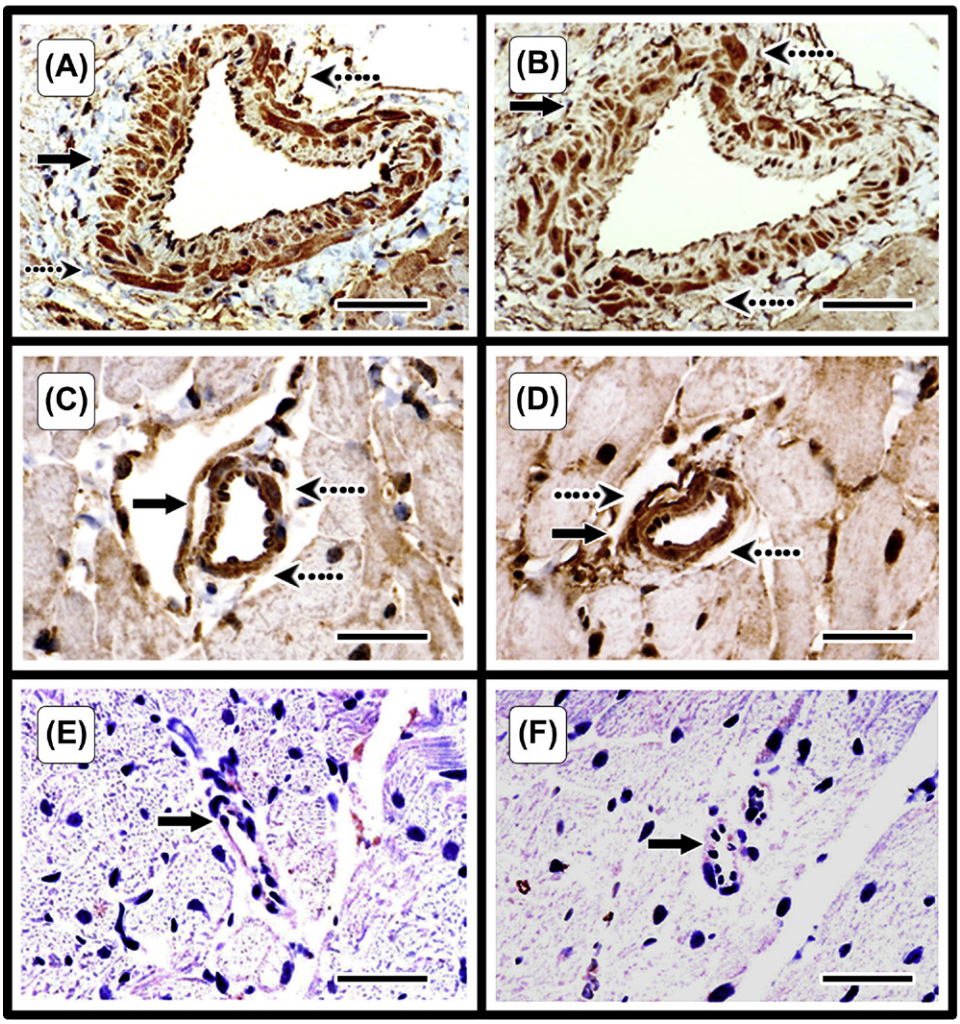

FIGURE 1 Presence of VPAC1 (A, C) and VPAC2 receptors (B, D) in the left ventricular coronary artery (A, B) and coronary arterioles of the left ventricle (C, D) of the rat as determined by immunohistochemistry. Negative controls are also shown (E, F). The primary stain is Dako DAB (*brown*) and the counterstain is hematoxylin (*blue*). Scale bar represents 50 μm for panels A and B and 25 μm for panels C, D, E, and F. Large arrow denotes location of artery or arteriole. Dashed arrow denotes regions expressing high levels of VPAC1 or VPAC2. See color plate 52.

that in intrinsic cardiac neurons, where primarily VPAC2 receptors are expressed.[16]

BIOLOGICAL ACTIONS

VIP produces vasodilation in the coronary, cerebral, mesenteric, pulmonary, and cutaneous circulations. In isolated coronary arterial strips and whole arteries, VIP produces vasorelaxation independent of endothelium.[3,11] VIP also produces coronary vasodilation and increases coronary blood flow in intact animals and in isolated heart preparations, which is mediated by a direct action on coronary vasculature. In isolated perfused rat hearts, for example, VIP produces coronary vasodilation with an EC_{50} of $4–5 \times 10^{-11}$ M without increasing heart rate, myocardial contractility, or myocardial oxygen consumption.[28,29] VIP is present in the proximal coronary arterial walls in concentrations of 1.2–2.2×10^{-12} mol/g tissue ($1.2–2.1 \times 10^{-9}$ M).[4,16] As a coronary vasodilator, VIP is 200-fold more potent than adenosine and 8000-fold more potent than sodium nitroprusside.[29] However, decreases in VIP concentrations in the coronary arteries may contribute to coronary spasm. In anesthetized dogs maintained with a fixed cardiac output, systemic arterial pressure, and heart rate, injection of VIP into the left main coronary artery increases coronary blood flow by as much as 84%, while increasing myocardial oxygen consumption by only 32%.[1,16] In patients, infusion of VIP at rates of 9 to 30 pmole min^{-1} into the left coronary artery decreases arterial-coronary sinus O_2 content difference and myocardial O_2 extraction by as much as 41% without changing left

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

ventricular preload, afterload, contractility, or heart rate.[24] In addition to a direct coronary arterial vasodilatory effect, intravenous VIP may also increase coronary blood flow in patients due to increases in heart rate and stroke volume, probably resulting from reduction in afterload.[31] Additional studies indicate that endogenous VIP is released in the coronary vasculature after parasympathetic nerve stimulation and produces significant coronary artery vasodilation. The magnitude of the coronary dilation is directly dependent on the frequency of vagal nerve stimulation. In this regard, VIP is most readily released during high frequency vagal stimulation in contrast to the classical neurotransmitter acetylcholine, which is released during low frequency nerve stimulation.[10,15,16] Vagal nerve stimulation in anesthetized dogs, after blockade of muscarinic and β-adrenergic receptors, can increase left coronary artery blood flow by as much as 62% without changing left ventricular contractility.[9,10] The increase in coronary artery blood flow is equivalent to the increase in blood flow that occurs during intracoronary administration of 9.0×10^{-11} mol of VIP or 1.0×10^{-8} mol of nitroglycerin.[16] This increase in blood flow is blocked by [4Cl-D-Phe6,Leu17]VIP, a sensitive and selective antagonist of VIP receptors.

The coronary vasodilatory response to VIP involves activation of calcium activated potassium channels and voltage sensitive potassium channels, sequestration of calcium in thapsigargin-sensitive stores and a decrease in the calcium sensitivity of the contractile apparatus.[20,28] Cyclic AMP is involved during maximal VIP-elicited coronary vasodilation however the vasodilatory response to VIP does not seem to involve cyclic GMP[28,29] (see Figure 2). VIP-elicited vasodilation in the cerebral, pulmonary, mesenteric, ovarian circulations may also involve activation of adenylyl cyclase.[16] However, the degree of VIP-elicited activation of adenylyl cyclase varies with the type of vessel studied, as well as species (rat, guinea pig, rabbit, cat, cow, or pig). Moreover, the vasodilatory effect of VIP may not be precisely correlated with an increase in cyclic AMP. VIP-elicited vasodilation in the cerebral circulation also involves nitric oxide and cyclic GMP through a direct action on vascular smooth muscle and in the mesenteric circulation involves inhibition of intracellular calcium mobilization independent of cyclic AMP.[16] In the pulmonary circulation, VIP-elicited vasodilation is dependent on endothelium and involves both cyclic AMP and cyclic GMP, and is probably increased by prostacyclin and nitric oxide, respectively.[19] VIP is currently being investigated for treatment of pulmonary hypertension in patients because of its vasodilator properties and the ability of VIP to inhibit pulmonary vascular endothelial cell proliferation.

At concentrations greater than that required for coronary vasodilation, VIP can increase myocardial contractility

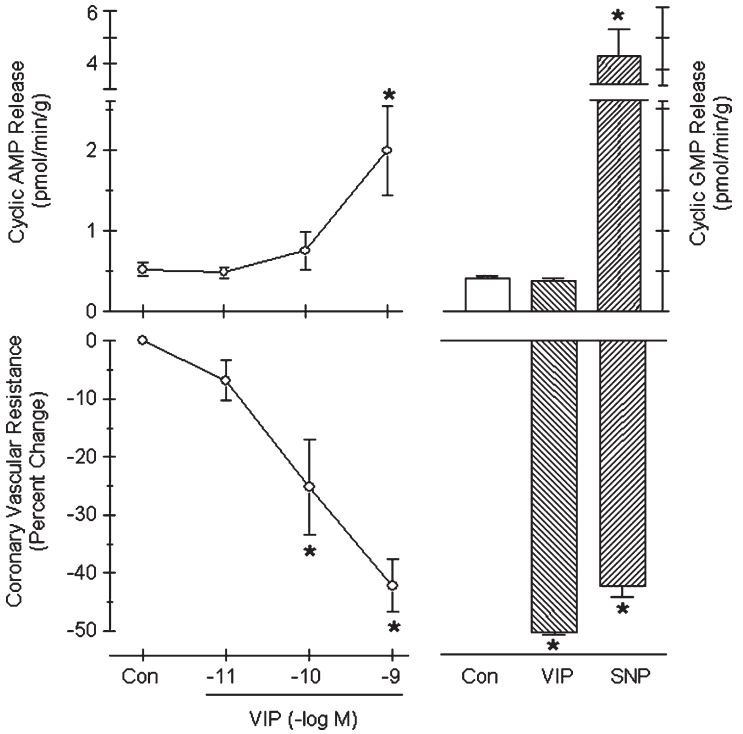

FIGURE 2 Effect of VIP at 1×10^{-11}, 1×10^{-10}, and 1×10^{-9} M on cyclic AMP release and the effect of VIP at 1×10^{-8} M and sodium nitroprusside (SNP) at 1×10^{-5} M on cyclic GMP release from the heart. Also shown are the effects of these agents on coronary vascular resistance. Values are mean ± SE of three hearts for cyclic AMP and three hearts for cyclic GMP. Asterisk indicates $P<0.05$.

and heart rate. In canine trabeculae, isolated from the right and left atria and ventricles, VIP at concentrations greater than 1×10^{-9} M can increase contractile force by as much as 100%.[16,25,28] Similar concentrations of VIP increase contractility of human atrial and ventricular trabeculae by 15–25%.[14–16] This increase in contractility appears to be mediated by the activation of adenylyl cyclase.[5,16] In anesthetized dogs, VIP release elicited by vagal nerve stimulation, after blockade of muscarinic and β-adrenergic receptors, increases right atrial and right ventricular contractility by as much as 28%, but does not significantly increase left ventricular contractility.[14,15] The significant increase in right ventricular inotropic responses to VIP is best explained by the fact that abundant VIP immunoreactive fibers innervate the right but not the left ventricle in the dog.[1,14,15,28] The increase in myocardial contractility elicited by exogenous VIP, but not the increase in coronary blood flow, can decrease after repetitive intracoronary infusions of VIP due to VIP receptor desensitization.[1,28] This observation suggests that the myocardial and coronary vascular effects of VIP may be mediated by different receptors and/or signaling mechanisms. Additional studies indicate that VIP increases adenylyl cyclase activity, L-type calcium channel current, and contractility in rat ventricular myocytes.[2,32] However, the increase in cyclic AMP is small compared with that elicited by isoproterenol and not all cells respond to VIP. These effects of VIP on adenylyl cyclase activity and contractility in rat ventricular myocytes appear to be mediated by activation of receptors that recognize both VIP and secretin.[2,5]

The discovery that VIP immunoreactive nerve fibers occur in high density in and around the sinus node and atrioventricular node of the heart strongly suggests that VIP affects heart rate. In the anesthetized dog, injection of VIP into the sinoatrial artery, after bilateral vagotomy, stellectomy, and blockade of muscarinic receptors, increases heart rate in a dose dependent manner by as much as 96%.[16,25,28] This increase in the heart rate is similar to that produced by norepinephrine; however, VIP is longer acting and twice as potent as norepinephrine. VIP also decreases the atrioventricular conduction time by as much as 30% and decreases atrial and ventricular refractory periods by 4–15%.[25,28] In addition, VIP can induce a shift of the pacemaker site to Bachman's bundle and can potentiate sinus arrhythmia.[22,23] After blockade of muscarinic and β-adrenergic receptors, vagal nerve stimulation increases the heart rate in a frequency dependent manner by as much as 50%.[14,15] This increase in heart rate is accompanied by an increase in VIP release from the right atrium and is attenuated or blocked by several VIP antagonists, including [4Cl-D-Phe6,Leu17] VIP. This heart rate response to VIP plays a role in "excess tachycardia," which is the increase in heart rate observed after muscarinic receptor blockade minus that observed after vagotomy. VIP also plays a role in "postvagal tachycardia," which is characterized by an increase in the heart rate after the initial bradycardia due to intense vagal stimulation has subsided.[14]

PATHOPHYSIOLOGY

Early investigations showed that hypertension, obesity, diabetes, and hypothyroidism reduce the ability of VIP to increase myocardial adenylyl cyclase activity.[5,26,28] This attenuation seems to result from a specific decrease in density of VIP receptors or uncoupling of receptors from adenylyl cyclase. In hearts isolated from 10-week-old spontaneously hypertensive rats, VIP-elicited adenylyl cyclase activity is reduced by as much as 69% compared with that of normotensive controls.[28] By contrast, adenylyl cyclase activity elicited by the β-adrenergic agonist, isoproterenol, is reduced by only 17%. These reductions are somewhat more pronounced in 14- and 30-week-old spontaneously hypertensive rats. Further, the reduction of VIP-elicited adenylyl cyclase activity precedes the reduction of Isoproterenol-elicited adenylyl cyclase activity. This selective impairment of VIP-elicited adenylyl cyclase activity is specific for the heart and occurs concomitantly with the development of hypertension and myocardial hypertrophy.[26,28] An impairment of VIP-elicited adenylyl cyclase activity can reduce VIP-elicited vasodilation and VIP affects on myocardial contractility and heart rate and can contribute to the development of heart failure.

During coronary artery occlusion and subsequent reperfusion, the release of VIP from the heart and the VIP concentration in the coronary sinus blood is increased. In the isolated perfused hearts of rats, interruption of coronary perfusion for 30 min increases the VIP concentration in the coronary effluent by as much as 250% during the ensuing 60-min reperfusion period.[16] Moreover, coronary perfusion with VIP immediately before the induction of ischemia significantly limits the effects of ischemia on myocardium as evidenced by a decrease in the release of creatine kinase, reduced formation of hydroxyl radicals, limitation of calcium overload in ventricular myocytes and an enhancement of myocardial contractile performance. These results indicate that VIP is released from neurons in the coronary vasculature and myocardium after acute coronary occlusion and acts as a vasodilator and free-radical scavenger to reduce myocardial ischemia and reperfusion injury. In patients with acute myocardial infarction, VIP plasma concentration in serum increases by 33% within 6 h after the onset of symptoms, from normal values of 12.2–16.2 fmol ml^{-1}, but then abruptly decreases below normal values to 8.9 fmol ml^{-1} after 24 h.[21] This abrupt decrease may be due to depletion of VIP from nerve endings and impairment of neurogenic synthesis of VIP in the heart. In patients

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

who die from acute myocardial infarction, the VIP plasma concentration is significantly lower than in those who survive after myocardial infarction. The normal plasma concentrations of VIP vary with a circadian rhythm which peaks at 2000 h in adults aged 25–50 years and at 1800 h in older adults aged 65–75 years.[28] Moreover, the VIP plasma concentration in older adults of 3.3–4.4 fmol ml^{-1} is significantly less than plasma concentration in younger adults of 12.7–17.0 fmol ml^{-1}. Recently VIP has been postulated to have an important role in the circadian regulation of heart rate. In this regard, VPAC2 or VIP deficient mice lose the circadian pattern in heart rate during constant darkness or constant light.[12,13,30] These studies suggest that VIP/VPAC2 signaling is necessary for circadian and light regulated heart rate control. Patients with heart transplants for treatment of primary dilated cardiomyopathy also lack a circadian pattern in heart rate.[28]

In animal models of heart failure and in patients with cardiomyopathy secondary to coronary artery disease, the left ventricular concentration of VIP can decrease as much as 85%.[33] Further, in patients with severe heart failure, the VIP receptor density in the left ventricle and the contractile response to VIP in right ventricle can decrease by as much as 62%.[17] These decreases in myocardial VIP concentration, receptor density and function may impair myocardial contractility and enhance coronary vascular resistance, thereby perpetuating heart failure. In addition, a decrease in myocardial VIP concentration can lead to myocardial fibrosis. In animal models of myocardial fibrosis, the myocardial concentration of VIP is inversely correlated with the degree of fibrosis present in the heart.[35] Normotensive Wistar Kyoto and spontaneously hypertensive rats fed a high salt diet have lower myocardial VIP concentrations and greater myocardial interstitial and perivascular fibrosis than rats fed a normal or low salt diet. In normotensive Wistar Kyoto rats fed a high salt diet and treated with the nitric oxide synthase inhibitor L-nitro-ω-methylarginine (L-NAME) to induce hypertension, the vasopeptidase inhibitor omapatrilat increases the myocardial VIP concentration and reduces the degree of interstitial and perivascular fibrosis.[35] These findings suggest that enhancing the myocardial VIP concentration may reduce myocardial fibrosis possibly by reducing the synthesis of one or more profibrotic mediators, such as angiotensin II, TNF-α and TGF-β.[7,35] Consequently, myocardial dysfunction and heart failure may result, at least in part, from myocardial VIP depletion.

Our understanding of the cardiovascular effects of exogenously administered and endogenously released VIP has evolved since the initial discovery of VIP in 1970 and suggests a role for VIP in the regulation of blood flow and cardiac performance. In addition, myocardial VIP depletion seems to be important in the development of cardiomyopathy and myocardial fibrosis. Additional studies are needed to determine the importance of endogenous VIP in the physiological regulation of blood flow, heart rate, and myocardial contractility. Studies are also needed to determine the roles of VPAC1, VPAC2, cyclic AMP, and other receptors and signaling mechanisms in the cardiovascular effects of VIP. These studies will be instrumental in the further development of VIP analogs, endopeptidase inhibitors and other novel VIP-related therapies for the treatment of patients with coronary artery disease and cardiomyopathy.

ACKNOWLEDGMENTS

This work was supported, in part, by grants from the Bugher Foundation, the Muscular Dystrophy Association, and by facilities of the Department of Veterans' Affairs. The author thanks Darrell Sawmiller, PhD, and Lillybeth Feliciano, PhD, who have made significant contributions to the investigations of VIP at our Center for Cardiovascular Research.

Chapter 197

VP/OT

Jolanta Gutkowska and Marek Jankowski

ABSTRACT

Two structurally similar neurohypophysial hormones, arginine vasopressin (AVP) and oxytocin (OT) have different actions in the cardiovascular system. The major cardiovascular function of AVP is to protect the blood volume and osmolality through influences on renal handling of free water and vasoconstriction. AVP acts as an important neurohormonal mediator of heart failure syndrome, septic shock, and hyponatremic states in humans. AVP agonists and antagonists are emerging as therapeutic agents for these disorders. OT stimulation of atrial natriuretic peptide release from the heart is associated with cardioprotection. Other OT cardiovascular effects include natriuresis and lowering of blood pressure; negative cardiac inotropy, and chronotropy; the NO pathway stimulation involved in vasodilatation and endothelial cell growth; anti-inflammatory activity and wound healing; antioxidant activity; and metabolic effects, including stimulation of glucose uptake in the cardiac muscle. In addition, both OT and AVP have the capacity to generate cardiomyocytes from stem cells.

DISCOVERY

Interest in the cardiovascular action of pituitary extracts dates back more than a hundred years. In 1895, the vasoconstrictive and hypertensive effects of pituitary extracts were demonstrated by Oliver and Schafer. Two years later, Howell concluded that glycerine and saline extracts of the pituitary anterior lobe produced little or no change in blood pressure and heart rate, and that Oliver and Schafer's results were explained by substance(s) residing in the gland's posterior lobe.

In 1928, Kamm et al. and Gaddum observed a wide diversity of physiological effects by extracts of the neurohypophysis and provided conclusive evidence using factional precipitation for the presence of the two active "principle," one, which produces an increase in blood pressure in dogs, another that stimulates the contraction of uterine muscles in guinea pigs; the two hormones were later recognized as arginine–vasopressin (AVP) and oxytocin (OT). In the 1940s, Woodbury et al. reported that uterine-active fractions of pituitary extracts are associated with the cardiovascular system and its depressor activity in various species, including humans. The results of Verney's pioneering studies in dogs, published in 1947, led to the concept of "osmoreceptors" and the hypothesis of antidiuretic hormone (ADH) present in the neurohypophyseal extract. The structures of OT and AVP were elucidated by Du Vigneaud et al. in the 1950s. Since these early studies, it has become widely accepted that AVP and OT, known as neurohypophysial hormones, are not only important to the central nervous system (CNS) but they also have physiological actions in the peripheral organs, including the kidneys, heart, and vascular beds.

PEPTIDE STRUCTURE

Both AVP and OT have a simple structure, being nonapeptides and consisting of a six-amino acid ring closed by a disulfide bridge with three amino acids in a side chain. The two hormones differ only by two amino acids (Fig. 1) and are encoded by distinct genes, but they lie on the same chromosome at 20 p, separated by a segment of DNA only 12 kb long. The similarities in structure, and the close localization, are suggestive of recent gene duplication. The peptides are synthesized in the distinct populations of magnocellular and parvocellular neurons of the hypothalamic paraventricular and supraoptic nuclei. They are transcribed as larger prohormones with the carrier protein neurophysin and are cleaved into their final forms while in transit by the supraoptic-hypophyseal tract to the secretory granules in the posterior pituitary gland. On appropriate stimulation, AVP and OT are released from the storage granules and rapidly enter

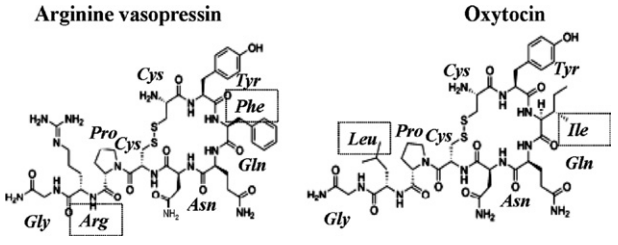

FIGURE 1 Structures of the oxytocin and arginine–vasopressin. The different amino acids are marked in boxes.

the bloodstream by the well-vascularized posterior pituitary capillary bed, which is devoid of a blood–brain barrier.

BIOLOGICAL ACTIVITY

The primary function of AVP in the body is to regulate the extracellular fluid volume by affecting renal handling of water, although it is also a vasoconstrictor and pressor agent (hence, the name "vasopressin"). The major stimuli to produce AVP in the supraoptic nuclei and paraventricular nuclei of the hypothalamus are low blood volume and hypernatremia (low blood sodium levels). Angiotensin II enhances and atrial natriuretic peptide (ANP) inhibits osmotically stimulated AVP release. AVP has long been suspected of playing a role in blood pressure control resulting from its vasoconstrictive effects, which have been well demonstrated *in vitro*. However, AVP elevation above normal concentrations in patients with the syndrome of inappropriate antidiuretic hormone secretion (SIADH) does not result in hypertension, but it renders patients hypervolemic and hyponatremic. Disorders of the AVP system also include neurogenic and nephrogenic diabetes insipidus (DI); when the hormone is absent or unable to activate its antidiuretic receptors, diuresis and consequently water needs are enhanced about tenfold.

OT represents the endocrine component of a neuroendocrine reflex that mediates suckling-induced lactation (the milk "let-down" reflex). It is also a potent stimulant of uterine contractions, especially in an estrogen-primed uterus. This latter effect is exploited in its major pharmacological application—induction or augmentation of labor—the the precise contribution of endogenous OT to normal labor is still controversial (i.e. parturition can occur in its absence). However, recent studies have shown that OT is a ubiquitous hormone, synthesized at many loci, and a wide array of physiological activities has been attributed to this peptide. Similar numbers of oxytocinergic neurons have been found in the male and female hypothalamus, and the same stimuli induce OT release in both genders, suggesting other physiological functions than its role in female reproduction. Recent evidence indicates that there are some unknown effects of OT. It has been shown that this peptide is involved in the regulation of memory, trust, food and water consumption, respiratory function, metabolic processes (regulation of carbohydrate and fat metabolism), and immune homeostasis. OT regulates the functions of the cardiovascular system. Systemic administration of OT has significant effects on blood pressure, vascular tone, and heart contractility.

RECEPTORS

The cellular effects of AVP and OT are mediated by the stimulation of tissue-specific G protein-coupled receptors with different kinases through specific motifs that are present in the carboxyl termini of the receptor. The signals are mediated through Gs and Gq protein subtypes. A single receptor can activate multiple second-messenger pathways by interacting with different G-proteins. OTs act on only one type of OT receptor (OTR), an integral membrane protein that is a member of the rhodopsin-type (class I) G protein-coupled receptor family, which includes AVP receptor subtypes (V1aR, V1bR or V3R and V2R). OTR can be considered a "nonselective" AVP receptor. OTR has equal affinity for AVP and OT, whereas V1aR has a 30-fold higher affinity for vasopressin than for OT.[29]

V1aR-stimulated Gq leads to the mobilization of endoplasmic reticulum calcium stores and generation of inositol 3 phosphate (IP3). The biological effects mediated through V1aR include vasoconstriction, myocardial hypertrophy, platelet aggregation, and growth of vascular smooth muscle cells. V1aR, which is abundant in vascular smooth muscles, causes vasoconstriction and a positive inotropic effect in cardiac muscle. Prolonged V1aR stimulation leads to the synthesis of proteins involved in cellular hypertrophy in vascular and myocardial tissues. V3R, predominantly found in the anterior pituitary gland, is linked to IP3 with intracellular calcium as a second messenger. The physiologic role of the V3R is not completely understood, and it is presumed to be involved in corticotropin and glucagon release, in addition to cellular proliferation and differentiation effects. V2R, however, couples to a Gs protein, which, by a cAMP (cyclic adenosine 3′,5′-monophosphate) dependent mechanism, allows for the active transport of water and sodium regulation and is found primarily in the principal cells of the renal-collecting duct. Consequently, the activation of cyclic AMP-dependent protein kinase (PKA) mediates the hydroosmotic effects of AVP. Through protein phosphorylation, AVP promotes trafficking of aquaporin 2 (AQP2) water channels, allowing free-water reabsorption back into the circulation. V2R has long been thought to be exclusively expressed in renal tubules, but there is increasing evidence of extrarenal V2R expression.[11]

OT has peripheral actions and actions in the brain. In addition to the mammary glands, OTR may be also found in the heart, vascular endothelium, kidney epithelium of mammals, hypothalamus, anterior pituitary, some areas of the cortex, and in the regions of the CNS that are not innervated by oxytocinergic fibers.[8] The activation of this receptor stimulates Gq and increases phospholipase-C with an increase in IP3 and diacylglycerol (DAG). IP3 triggers calcium release from intracellular stores, whereas DAG stimulates protein kinase C, which phosphorylates unidentified target proteins. A variety of cellular events are initiated in response to an increase in intracellular calcium. For example, forming calcium–calmodulin complexes trigger the activation of neuronal and endothelial isoforms of nitric oxide synthase (NOS). NO in turn stimulates the soluble

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

guanylate cyclase to produce cGMP, leading to vasodilation. Activation of cardiac OTR stimulates the release of atrial naturetic peptide (ANP), which also regulates diuresis and blood pressure using cGMP as a second messenger.[9] In smooth muscle cells, the calcium–calmodulin system triggers the activation of myosin light chain kinase activity, which initiates smooth muscle contractions (e.g. in myometrial or mammary myoepithelial cells)[8]

PATHOPHYSIOLOGICAL IMPLICATIONS IN THE CARDIOVASCULAR SYSTEM

Stimulation of AVP Release

A change in osmolality of 1–2% of the extracellular fluid compartment stimulates the release of AVP. An increase in plasma osmolality above approximately 280 mOsm/kg is the main stimulus for AVP release.[31] Hypothalamic osmoreceptors sense extracellular osmolarity and stimulate AVP release when osmolarity rises, as occurs with dehydration. Peripheral osmoreceptors are found in the portal veins. Baroreceptors located in the left atrium, carotid sinus, and aortic arch detect arterial underfilling, which stimulates the neurons in the supraoptic nucleus and paraventricular nucleus to produce AVP. Unlike osmoreceptors, baroreceptors must be suppressed in order to stimulate the release of AVP; this suppression in turn comes after a fall in blood pressure. In severe hypovolemic shock, when AVP release is very high, AVP contributes to the compensatory increase in systemic vascular resistance. Skin, muscle, and splanchnic arterial beds are highly sensitive to the vasoconstrictor actions of AVP, an effect that may be important for shunting blood to more vital organs. Exceptionally, rat mesenteric arteries were found to be particularly sensitive to AVP and constrict in response to concentrations of AVP as low as 1 pM.[13] The measurement of endogenous AVP in plasma is a useful tool for guiding therapy in heart failure and in different states of shock; however, serious concerns exist about the methodologic reliability of plasma AVP measurements because AVP is known to be unstable, largely attached to platelets, and rapidly cleared (half-life: 5–15 min). By contrast, the C-terminal portion of provasopressin (copeptin) is stable for several days after blood withdrawal and can be quickly measured, being secreted in equimolar amounts to AVP.[23] Recent studies have shown that copeptin is a strong prognostic marker in patients after an acute myocardial infarction and in patients with chronic heart failure.[34]

AVP in Septic Shock

AVP concentrations are inappropriately low in septic shock, although the reason for this is not clear. Loss of sensitivity to or downregulation of the AVP receptors may also be an important factor in the loss of pressor effects in some shock situations. However, in these conditions, which are caused by a bacterial infection in the blood, the infusion of AVP increases systemic vascular resistance and thereby elevates arterial pressure. Besides deficiency of AVP, there are two fundamental physiologic upsets: increased synthesis of NO and activation of ATP-sensitive potassium channels in vascular smooth muscle. The plasma concentration of NO is markedly increased in septic shock. The production of this endogenous vasodilator seems to occur because of the expression of inducible NOS by cytokines. Tissue hypoxemia, acidosis, and NO cause the activation of ATP-sensitive potassium channels, which facilitates the entry of potassium into smooth muscle cells and causes hyperpolarization of the membrane: the cells become resistant to depolarization and contraction. AVP agonists could provide an additive pressor to maintain cardiovascular dynamics in shock states. They reverse hypotension and restore vascular tone by activation of V1aR, modulation of ATP-sensitive potassium channels, interference with NO action, and potentiating of norepinephrine and other vasoconstrictor agents.[20]

AVP in Heart Failure

Heart failure commonly manifests as a syndrome of salt and water retention. The decrease in left ventricular (LV) systolic and diastolic function results in reduced cardiac output, stroke volume, and intraarterial blood volume. Arterial underfilling, sensed by arterial baroreceptors in the aortic arch and intrarenal sensors, leads to the subsequent activation of the sympatho-adrenal system and release of a cascade of neurohormones. Serum AVP concentrations are chronically elevated in several animal models of cardiac failure, and patients with heart failure consistently show elevated circulating levels of AVP in proportion to disease severity.[32] The increase in AVP observed in heart failure appears to be independent of osmotic stimuli. AVP worsens heart failure by causing vasoconstriction of arteries and veins, potentially contributing to remodeling of the LV and causing fluid retention and worsening of hyponatremia (Fig. 2). V2R receptor stimulation by AVP may contribute to volume expansion and therefore to increased cardiac preload. Increased preload exacerbates diastolic wall stress, in turn aggravating eccentric remodellng. This increase in AVP potentiates other pathways, including the renin–angiotensin–aldosterone system (RAAS), to promote retention of sodium and water and also the release of norepinephrine from the adrenal gland to increase inotropy. Moreover, AVP production and secretion by the heart has been suggested, especially in buffer perfused rat hearts.[14] The chronic elevation of AVP levels seen in patients with heart failure may ultimately have detrimental myocardial

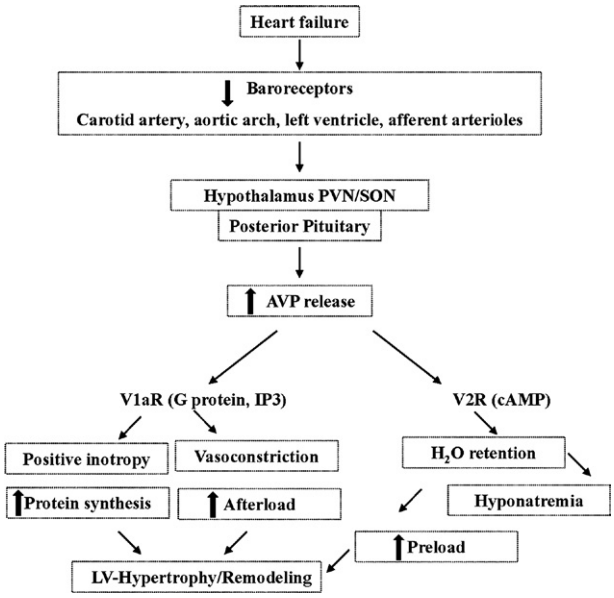

FIGURE 2 Mechanisms illustrating how the increased levels of circulating AVP worsen heart failure symptoms and function of left ventricle via activation cardiac V1AR linked to inositol 3 phosphate (IP3) and V2R in the kidney signaling cyclic adenosine 3′,5′-monophosphate (cAMP).

effects. The study of ratcardiomyocytes cultured in the presence of AVP has shown protein synthesis stimulation with concomitant increases in calcium concentration and activation of mitogen-activated protein kinase. Although it is not known whether AVP contributes to cardiomyocyte hypertrophy in humans, these mechanisms of cellular hypertrophy share many of the features seen in the typical hypertrophic response of the adult heart that is associated with other agonists, such as angiotensin II and endothelin-1.

AVP Antagonists

Because AVP regulates vascular tone and free-water reabsorption via V1aR and V2R, respectively, these receptors have become pharmacological targets for the treatment of congestive heart failure, and receptor antagonists are currently being tested in clinical trials.[21,27]. The problem with the treatment of congestive heart failure is to find drugs affecting both cardiac dysfunction and renal water balance function. Despite the recognized antagonistic effects of these molecules in animals, their use in the therapy of edematous disease has been hampered by marked species differences, partial agonist actions, poor bioavailability, and short half-life. As a result of subsequent developmental research, several studies have shown that AVP receptor antagonism increases urine volume, reduces body weight in patients with moderate to severe heart failure, and increases serum sodium concentrations, over hours to days, in the subset of patients with baseline hyponatremia. Tolvaptan (OPC-41061) is a selective competitive V2R antagonist approved by the Federal Drug Administration (FDA) for the treatment of hyponatremia associated with congestive heart failure, cirrhosis, and the syndrome of inappropriate antidiuretic hormone. Tolvaptan, when administered with traditional diuretics, increases excretion of excess fluids and improves blood sodium levels in patients with heart failure without producing side effects such as hypotension or hypokalemia (decreased blood levels of potassium) or having an adverse effect on kidney function. Lixivaptan and satavaptan are other highly specific antagonists of V2R, successfully investigated in clinical trials. Conivaptan is currently the only available dual V1aR/V2R nonpeptide antagonist approved for hypervolemic hyponatremia. Because AVP acts on both the receptors to cause water retention and vasoconstriction in heart failure, respectively, conivaptan represents an excellent treatment option. Decreased intracellular free calcium and mitogen-activated protein kinase activity have been observed to occur in a dose-dependent manner, suggesting a reduction in the intracellular protein synthesis and possibly cardiomyocyte hypertrophy.[4] However, conivaptan is yet to be approved for the treatment of heart failure in humans.

In summary, AVP antagonists are effective in treating volume overload by increasing diuresis in patients with heart failure, but there has been little evidence of associated symptomatic improvement. AVP antagonists have a favorable renal profile. Unlike other neurohormonal antagonists (β-blockers and RAAS blockers), inhibition of AVP receptors has no documented beneficial effects on ventricular remodeling .

OT in the Heart

The discovery of the cardiac OT system emerged from long-time investigations into the role of the brain in the control of cardiorenal homeostasis. These experiments led to the observations that OT and its OTR are synthesized in human and rat hearts and that OT exerts cardioprotection either directly or via stimulation of mediators, such as ANP and NO. OTR in the rat heart seems to be identical to those in the uterus and other organs. The presence of OTR in rat and human hearts was detected by RT-PCR and by in situ hybridization, autoradiography of atrial and ventricular sections, and confirmed by competitive binding assay with iodinated OT antagonist.[9,10] The functionality of heart OTR was shown by the ability of OT to release ANP from the isolated perfused rat heart.[9] OT injected intraperitoneally or intravenously induces dose-related increases in plasma ANP that correlate with increases in sodium and potassium excretion.[10] Blood volume expansion with isotonic and hypertonic saline stimulates ANP and OT release. Suckling, a physiological stimulus for OT release, is also associated

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

with significant increases in plasma ANP. OT antagonist inhibits the stimulated and also basal ANP release from perfused rat hearts, suggesting the presence of cardiac OT.[17] Indeed, the presence of OT in the heart has been detected in rodent and human hearts.

OT in the Vasculature

Because we discovered that OT is produced and released by the heart and acts on its cardiac receptors to decrease the cardiac rate and force of contraction, it was expected that OT might be generated in the vasculature and dilate vessels. Indeed, studies showed that an intrinsic OT system, sensitive to estrogenic regulation, exists in the vasculature.[18,35] Immunoreactive OT has been found in rat, sheep, and dog vessels by specific radioimmunoassay, and characterized by high-performance liquid chromatography. RT-PCR analysis has identified transcripts containing the coding sequence of OT and OTR genes in the aorta and vena cava.[18] Further studies have confirmed that OTR is present in several major cell types that are important in the progression of vascular pathologies, including vascular smooth muscle cells, endothelial cells, macrophages, and adipocytes.

Cardiovascular Effects of OT

Systemic administration of OT has significant effects on blood pressure, vascular tone, and cardiovascular regulation. Conversely, the absence of either OT or its receptors in knockout mice has not been reported to produce cardiac insufficiencies. Although OT knockout mice have a normal heart structure, experiments have shown increased intrinsic heart rates in these animals, indicating that an intracardiac OT system controls cardiac electrical activity.[2]

Accumulating evidence indicates multiple beneficial effects in the heart and vasculature (Fig. 3). To date, the cardiovascular properties of OTs include i. natriuresis and decreased blood pressure, possibly secondary to ANP release;[9,10] ii. negative inotropic and chronotropic effects[9] and parasympathetic neuromodulation;[24] iii. vasodilatation via the OTR-induced NO pathway and endothelial cell growth;[35] iv. wound healing and anti-inflammatory action.[15]

Both increases and decreases in blood pressure in response to OT have been reported, depending on the species, route of administration, dose, etc. Experiments with central administration of OT or OT antagonists have not provided unequivocal results. In some studies, OT has elicited a significant increase of blood pressure or cardioacceleration, whereas other investigations have provided evidence that OT enhances baroreflex bradycardia and reduces resting arterial blood pressure and exercise-induced tachycardia.[33] Peripheral administration of OT, on the contrary, lowers the average arterial pressure in rats and does not affect the heart rate.[30] So far, OT is the only known factor that protects the cardiovascular system from the excessive increases in blood pressure and heart rate during stress. However, in the absence of a central regulatory influence, OT can bring down the heart rate and reduce the strength of contractions of isolated atria during perfusion of rat hearts.[24] The negative chronotropic action of OTs has recently been associated with attenuation of cardiac damage evidenced by ischemia reperfusion.[25]

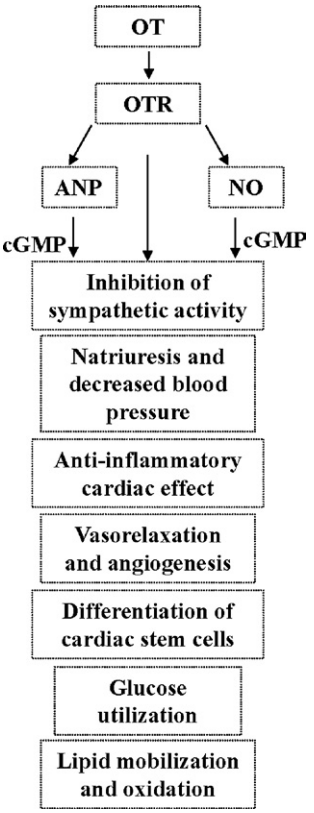

FIGURE 3 Cardiac OTR activation can induce several effects in the heart, including inhibition of sympathetic activity, stem cell differentiation, vasorelaxation, and angiogenesis, improved glucose utilization, lipid oxidation as well as anti-inflammatory outcomes. These actions of OT are mediated by atrial natriuretic peptide (ANP) or nitric oxide (NO), known to reduce oxidative stress and fibrosis, and result in improved intracellular Ca^{++} handling in pathological conditions.

Positive cardiac effects can be attributed to the fact that OT stimulates ANP release by improving hydromineral homeostasis, and cardiac hypertrophy and regulating and maintaining a balance of anti-inflammatory and proinflammatory cytokines within the injured heart in rats. The different cardioprotective mechanisms of OT have recently been demonstrated in animal models of myocardial infarction. In rat and rabbit models of ischemic heart disease, OT treatment significantly reduced infarct size and improved parameters of heart function.[15,19]

OT has an impact on metabolism.[8] OTR knockout in mice results in obesity. In fact, OT has insulin-like effects

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

and properties, that is, it stimulates glucose oxidation and lipogenesis in adipocytes, inhibits lipolysis, decreases the blood level of free fatty acids, and increases pyruvate dehydrogenase activity. Cardiovascular abnormalities in OTR-deficient mice are yet to be found. However, in the db/db mouse model of obesity and diabetes, a deficiency in the leptin receptor leads to increased cardiac apoptosis and fibrosis, as well as downregulation of OTR and natriuretic peptides expression in the heart.

OT signaling in Cardiac Cells

OT increases glucose uptake in cardiomyocytes via phosphoinositide-3-kinase (PI3 K) and potentiates the glucose uptake effect of 2,4-dinitrophenol, an uncoupler of oxidative phosphorylation targetting the mitochondria.[5] PI3 K pathways are considered beneficial during myocardial injuries. The calcium–calmodulin kinase kinase (Ca-CAMKK) and AMP-activated protein kinase (AMPK) pathways are also involved in OT-mediated glucose uptake in cardiomyocytes.[5] AMPK activation in the heart after ischemia and reperfusion is recognized as cardioprotective because it limits both apoptosis and cell damage.

Studies conducted *in vitro* have revealed that OT modulates processes that are critical to early lesion formation within vascular and immune tissues.[35] Specifically, OT has antioxidant effects on vascular smooth muscle cells, aortic endothelial cells, and macrophages through attenuation of NADPH-oxidase-dependent superoxide production.[10,15,19] *In vivo*, peripheral OT administration inhibits atherosclerotic lesions in the thoracic aorta. In addition, OT promotes the migration of human dermal endothelial cells (EC), breast-derived EC and human umbilical vein EC (HUVEC). The promigratory effect of OT requires OTR activation of the PI3 K/AKT/eNOS pathway. Moreover, OT increases the proliferation of EC and alters gene expression for adhesion molecules and matrix metalloproteinases, contributing to improved cell motility and growth. An angiogenic and antiapoptotic OT effect is indicated by increased cardiac $CD31^+$ microvessels. In this way, OT can control the flow of blood to the heart.

OT AND AVP IN CARDIOMYOGENESIS

Effect of OT in Embryonic stem (ES) Cells

OT possesses proliferative properties depending on the cell type and the subcellular localization of OTR. Furthermore, OT can induce mammalian stem cells into a special cell type that retains the ability to self-renew (i.e. undergo cell division in an undifferentiated state) indefinitely and to differentiate into specialized cells. The OT system activation in fetal and newborn hearts at a stage of intense cardiac hyperplasia[16] suggests a role for OT in cardiomyocyte differentiation. Initial experiments have shown that OT induces beating cell colonies in the murine embryonal carcinoma P19 cell line, an established cell model for studying early heart differentiation.[28] Since that study, several other reports have confirmed OT-stimulated cardiomyogenesis in different lines of embryonic stem cells. In embryonic D3 stem cells, spontaneously producing beating cell colonies on aggregation, the mesodermal derivatives formed in embryoid bodies include subtypes of cardiac cells (atrial cardiomyocytes, ventricular cardiomyocytes, and pacemaker cells) that are potently enhanced by treatment with OT as identified by histological, molecular, and electrophysiological criteria.[6] The OTR-NO-cGMP pathway that is essential for OT-elicited differentiation of P19 stem cells into cardiomyocytess (Fig. 4) is associated with elevation of GATA-4 and myocyte enhancer factor 2c (MEF2c).[3] GATA-4 regulates the expression of genes that are critical for cardiomyocyte differentiation. MEF2c is a member of the MEF2 family, which is involved in cardiac, skeletal and smooth muscle development. GATA-4 has also been implicated in intercellular crosstalk by inducing hypertrophy-associated angiogenesis via vascular endothelial growth factor (VEGF) release and targeting the endothelium.[12] Stimulation of cardiomyocyte differentiation can be concomitant with neovascularization because OT stimulates endothelial cell growth and angiogenesis.[35] The upstream sequence of OTR contains putative binding sites for GATA-4 and Nkx2.5 and GATA-4 also serves as a key transcriptional regulator of numerous cardiac peptides, including ANP, brain natriuretic peptide (BNP), and OTR. GATA-4 has also been identified in stem and progenitor cells of the heart in combination with OT-mediated cardiomyocyte differentiation.[3,22,26] Undifferentiated murine ES cells express BNP and its receptors, with its signaling being essential for cell survival and clonal growth.[1] This observation suggests possible interaction of the OT and natriuretic peptide systems in ES cells during cardiomyogenesis.

Effect of AVP in Cardiomyogenesis

Similarly to OT, AVP also induces the expression of early and late myogenic differentiation markers in cultured myogenic cell lines. As reported recently, AVP modulates spontaneous cardiomyogenesis in embryonic D3 cells by augmenting cardiomyocyte yield and promoting the selection of the ventricular electrophenotype.7 The AVP-mediated increase in endothelial NO synthase expression also seems to be partly regulated by OTR, inasmuch as lower endothelial NO synthase mRNA and protein levels have been observed in D3 cells treated with OTR antagonist.[7] There is considerable diversity of OT-mediated signaling pathways, including cAMP activation and cGMP-mediated growth stimulation with calcium increases, which corroborates AVP signaling mediated by V1aR and V2R. The specific pathway that activates cardiomyogenesis in response to OT and AVP is unknown. However, enhanced GATA-4 expression, consistently observed throughout cardiac differentiation upon AVP stimulation[7] and after OT exposure of stem cells,[3,11] may contribute significantly to the cardiomyogenic actions of both peptides.

OT and Cell Therapy of Cardiac Injuries

OT can be considered an established myogenic morphogen. The idea that OT has cardioregenerative capacities derives from the observation that this hormone induces the differentiation of cultured mice[22] and rats[26] resident cardiac stem cells (CSCs). In the adult heart, CSCs maintain a balance of survival, proliferation and self-renewal to replace mature cells that are lost during injury or turnover. Matsuura et al.[22] revealed the presence of a Sca-1$^+$ stem cell population in adult mouse hearts expressing telomerase reverse transcriptase, which has been associated with self-renewal potential. These cells, lacking hematopoietic markers, are easily distinguished from hematopoietic stem cells of bone marrow origin, and when treated with OT, differentiate into functional cardiomyocytes. Although the cells present the early cardiac markers GATA-4 and MEF2, they do not express Nkx-2 or genes encoding cardiac sarcomeric proteins. When exposed to OT, a small population of Sca-1$^+$ cells manifests sarcomeric structures and forms spontaneously-beating cardiomyocytes. In addition, after intravenous delivery, Sca-1+ cardiac stem cells can be recruited to the myocardium injured by ischemia/reperfusion and can functionally differentiate in situ.[22]

In pathological conditions such as cardiac ischemia and diabetes, OT can be used to stimulate the production of lost cardiac cells. The advantage of this therapy is supported by the fact that OT is endogenously produced in the organism, and does not have significant side effects when used in clinics. Moreover, it is now possible to transplant one's own stem cells after previous stimulation with OT inducers, as in the case of a myocardial infarct. Alternatively, direct treatment with OT molecules could promote cardiomyogenesis in situ and regeneration of a damaged heart.

Chapter 198

Adrenomedullin 2/ Intermedin

Yoshio Takei

ABSTRACT

Adrenomedullin 2 (AM2), or intermedin (IMD), is a new member of the calcitonin-gene-related peptide (CGRP) family that was formerly believed to consist of CGRP, AM, and amylin in mammals. Five AM peptides (AM1–5) form an independent subfamily in teleost fish, of which AM1 is an ortholog of mammalian AM. Comparative genomic analyses reveal that that AM2 and AM5 are also present in mammals. The AM2/IMD gene is expressed in various tissues, including the kidney, digestive tract, heart, brain, and pituitary, and the peptide exerts spectra of actions in these tissues such as diuresis/natriuresis, hypotension, and regulations of appetite and other hormone secretion. AM2/IMD also has cytoprotective functions against oxidative stress. Unlike other members of the CGRP family that have specific receptors, AM2/IMD binds almost all types of CGRP family receptors with lower affinity. The physiological and pharmacological results indicate that unknown AM2-specific receptor(s) may exist.

DISCOVERY

Because of the difference in the habitat, aquatic fishes and terrestrial tetrapods have developed distinct mechanisms for cardiovascular and body fluid regulation, which leads to the difference in major regulatory hormones, vasopressor and antidiuretic hormones in tetrapods and vasodepressor and natriuretic hormones in fishes. The CGRP family is one of the vasodepressor/natriuretic hormone groups, of which AM is most potent for these actions.[15] We expected that AM is an important cardiovascular and osmoregulatory hormone in fishes and searched for the AM ortholog in the genome database of tiger pufferfish, *Takifugu rubripes*, using the human AM sequence as query, which resulted in the identification of five AM-like peptides.[21] Molecular phylogenetic analyses reveal that five AM-like peptides form an independent subfamily in the CGRP family. Thus, we named them AM1–5 (Fig. 1). Fish AM1 is an ortholog of mammalian AM as determined by the synteny analysis and the presence of proadrenomedullin N-terminal 20 peptide (PAMP)-like sequence in the N-terminal region of the prohormone. Chromosomal localization of the five teleost AMs shows that duplication of AM1/AM4 and AM2/AM3 occurs at the third-round whole-genome duplication (3R) early in the teleost lineage, whereas the counterpart of the duplicated AM5 gene has disappeared[22] (Fig. 2). This shows that AM1/4, AM2/3, and AM5 already existed at the divergence of ray-finned fishes and lobe-finned fishes (tetrapods). Thus, we hypothesized that the AM2 and AM5 genes are still retained in mammalian genomes. The extensive search for AM2 and AM5 in the genome and EST databases of mammals, birds, and amphibians could identify probable candidates in most species.

Based on the molecular phylogenetic analysis and synteny analysis, we determined that the novel peptides are mammalian orthologs of teleost AM2 and AM5[22,30] (Fig. 3). Teddy Hsu's group[24] also found AM2 by comparative genomic analysis in fishes and mammals and named it intermedin (IMD) because of its dense localization in the intermediate lobe of the pituitary. The name "intermedin" has also been used for α-melanocyte stimulating hormone that is processed from the proopiomelanocortin in the intermediate lobe.[28] As many published articles have already used both names, the name AM2/IMD is used in this chapter to avoid confusion.

AM-like peptides were also identified in cartilaginous fish (sharks and rays) and cyclostomes (lampreys and hagfishes) that are most primitive extant vertebrates without jaw.[15] The cyclostome AM-like peptides seem to be hybrids of AM1 and AM2 because the mature sequence in the C-terminus is highly similar to AM2 but the PAMP-like sequence exists in the N-terminal region of the lamprey AM-like prohormone. The CGRP and amylin genes are not identifiable in the genome database of sea lamprey, *Petromyzon marinus*. CGRP/AM(1) and AM2/amylin exist on the same chromosome of teleost fish (Fig. 2). As CGRP/amylin and AM(1)/AM2 seem to be duplicated counterparts, CGRP or AM is an ancestral molecule of the CGRP family, and after

FIGURE 1 Amino acid sequences of the adrenomedullin family in fishes. Sequences conserved in more than half of the species are shaded. AM2 and AM3 duplicated at the third-round whole-genome duplication are more conserved and more potent than AM1 and AM4 (Fig. 2). Brackets show disulfide bridges.

tandem duplication of amylin or another AM, the two tandem genes are duplicated together probably at the 2R whole-genome duplication that seems to have occurred during the transition from agnathans (jawless fishes) to gnathostomes (jawed fishes). It should be determined whether an AM type or a CGRP type is an ancestral molecule of the family (Fig. 2). Other fish-derived hormones including AM2/IMD are also described in Chapter 211 of this volume.

STRUCTURE OF THE PRECURSOR mRNA AND GENE

The AM2/IMD gene consists of three exons and is located on chromosome 22 in the human, chromosome 15 in the mouse and chromosome 7 in the rat, chromosome 6 in medaka and chromosome 4 in zebrafish.[22] The AM2/IMD precursors deduced from the mRNA sequences have 147–151 amino acid residues including the signal sequence of 24–25 amino acids in mammals and 169 amino acids with 20-amino-acid signal peptide in the pufferfish (Fig. 3). Mature AM2/IMD is at the C-terminus of the prohormone and the C-terminal glycine residue is followed by a stop codon. This precursor sequence is characteristic only for AM2 and AM3 of fish and for AM2/IMD of mammals, as AM1 and AM4 precursors are followed by a C-terminal peptide connected by 4–5 consecutive arginine residues as observed by mammalian AM.[21] Molecular phylogenetic analysis using mammalian and fish AM peptides shows that AM2/IMD is in the same cluster within the AM subfamily and distinct from the clusters of CGRP and amylin[21,29] (Fig. 4).

DISTRIBUTION OF mRNA

The tissue distribution of mRNA shows that the pufferfish AM2 gene is expressed almost exclusively in the brain.[21] In mice, however, AM2/IMD transcripts are detected in various tissues; high expression is observed in the kidney, submaxillary gland, stomach, and mesentery, followed by the pituitary, lung, pancreas, intestines, spleen, and thymus.[29] High expression is also detected in the digestive tract, especially in the stomach and colon in humans.[24] Radioimmunoassay for AM2/IMD measures high concentrations in the kidney, stomach, and plasma of rats (39.3 ± 11.4 fmol/ml, $n = 5$).[31]

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

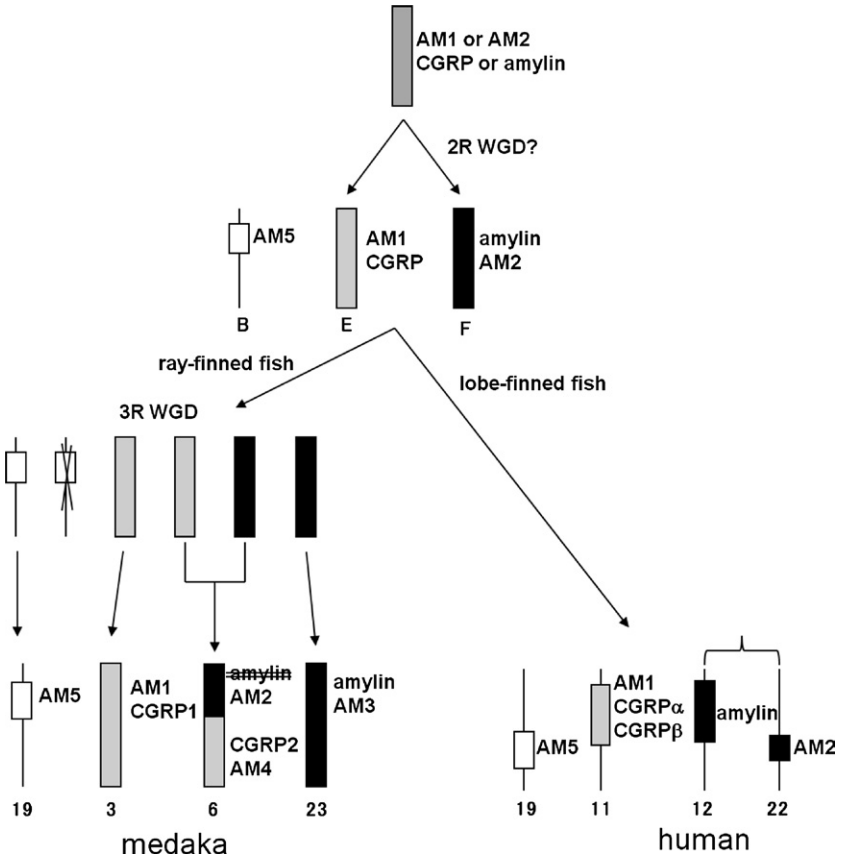

FIGURE 2 History of diversification of the calcitonin-gene-related peptide (CGRP) family. Adrenomedullin (AM) 1/AM2 and CGRP/amylin existed on the same chromosome before second-round whole-genome duplication (2R WGD) and AM5 may be generated from AM1 or AM2 by gene duplication after 2R WGD. AM1/CGRP, AM2/amylin, and AM5 existed before the divergence of ray-finned fish and lobe-finned fish, and all are retained in mammals, in which amylin and AM2 are separated after chromosomal reorganization and CGRPs are duplicated in tandem. In teleost fish, all genes are duplicated by third-round (3R) WGD but duplicated amylin and AM5 have disappeared. Duplicated AM2, AM4 (from AM1), and CGRP are on the same chromosome by chromosomal fusion. Chromosome name and number are shown below each chromosome.

AM2/IMD can be measured in human brain, pituitary, heart, and kidney, and its plasma concentration is 24.7 ± 1.8 fmol/ml ($n = 3$).[18] Immunoreactive AM2/IMD is localized in various brain areas including paraventricular and supraoptic nuclei in rats and humans.[27] AM2/IMD-positive cells increased profoundly after salt loading in rats. Immunoreactive AM2/IMD in the magnocellular neurons colocalizes with oxytocin in rats.[13] In the kidney, immunoreactive AM2/IMD is localized in glomerulus and vasa recta in mice[28] but only in the renal tubules in humans.[27] The heart also contains a moderate amount of AM2/IMD, where only endothelial cells of the coronary vessels exhibit positive staining in mice[28] but in the myocardial cells in humans.[27] Staining for immunoreactive AM2/IMD is localized in the intermediate lobe of pituitary in a few species,[24] though the pituitary concentration is lower than in the rat hypothalamus where the peptide is concentrated compared within other brain regions.[31] In addition, the AM2/IMD gene is expressed in the ovary but not in the testis, indicating some specific role for the female reproductive system.[29]

PROCESSING OF PRECURSOR

The inferred mature sequence of rat AM2/IMD consists of 47 amino acid residues (Fig. 3), assuming that proAM2/IMD is cleaved after two consecutive arginine residues by prohormone convertases, and that the C-terminal glycine residue is used for amidation. AM2/IMD-47 is more potent than N-terminally truncated AM2/IMD-42 for biological actions including vasodepressor and chronotropic effects as well as suppressive effects on food intake and gastric emptying.[24] However, the shorter AM2/IMD-42 is more potent for cAMP accumulation in cells expressing calcitonin-receptor-like receptor (CLR) and receptor-activity-modifying proteins (RAMPs), the combination of which produces AM receptors (see below). There are additional dibasic amino acids in the prosegment of rat and mouse AM2/IMD, and the cleavage at this site produces longer molecule consisting of 53 amino acid residues. This longer peptide seems to have a comparable cardioprotective activity.[33] Mature fish AM2 may be cleaved by a processing enzyme, furin,

FIGURE 3 Amino acid sequences of adrenomedullin (AM) 2/intermedin precursors from mammals and pufferfish, *Takifugu rubripes* (A) and mature amino acid sequences of AM2/IMD (B) and AM5 (C) in mammals. Amino acid sequences conserved in more than half species are shaded. Brackets show disulfide bridges. Lines and arrows in (A) are the signal sequence and processing site, respectively. Asterisks in (B) and (C) show the occurrence of nucleotide modification at the site, resulting in translation of different proteins.

because its processing signal (Arg–X–X–Arg) exists in the prosegment of all fish AMs. The truncation at this site produces mature AM2 of 55 amino acid residues in the tiger pufferfish.

The processed, mature AM2/IMD possesses an intramolecular ring structure of six amino acid residues flanked by a single disulfide bond in the N-terminal region and an amidated C-terminus (Figs. 1 and 3). The length of the N-terminal sequence extended from the intramolecular ring varies among species and has relatively minor effects on its biological activity. However, the amidated C-terminus may be essential for the activity as is the case for AM. With respect to AM, the C-terminally nonamidated (inactive) molecule circulates in the blood in amounts much larger than that of the amidated, mature AM. The AM2/IMD precursor terminates with a glycine residue, but the AM precursor is followed by 4 arginine residues and a C-terminal peptide. Thus, a complex processing is required before C-terminal amidation of AM with endopeptidase and carboxypeptidase. These differences may influence the efficiency of amidation.

RECEPTORS AND SIGNALING CASCADE

The CGRP family members bind the calcitonin receptor (CTR) or CLR associated with one of the three types of RAMPs and use the cAMP signaling cascade for biological action.[15] Cyclic AMP accumulation is increased by CGRP when given to cells coexpressing CLR and RAMP1, by AM in cells coexpressing CLR and RAMP2/3, and by amylin in cells coexpressing CTR and RAMP1/3. Although the potency of RAMP for cAMP accumulation is different among culture cell types used for the expression, AM2/IMD is ubiquitously effective in cells coexpressing CLR/CTR and various RAMPs, but in no case is it more potent than other CGRP family members.[15,24,28] Among

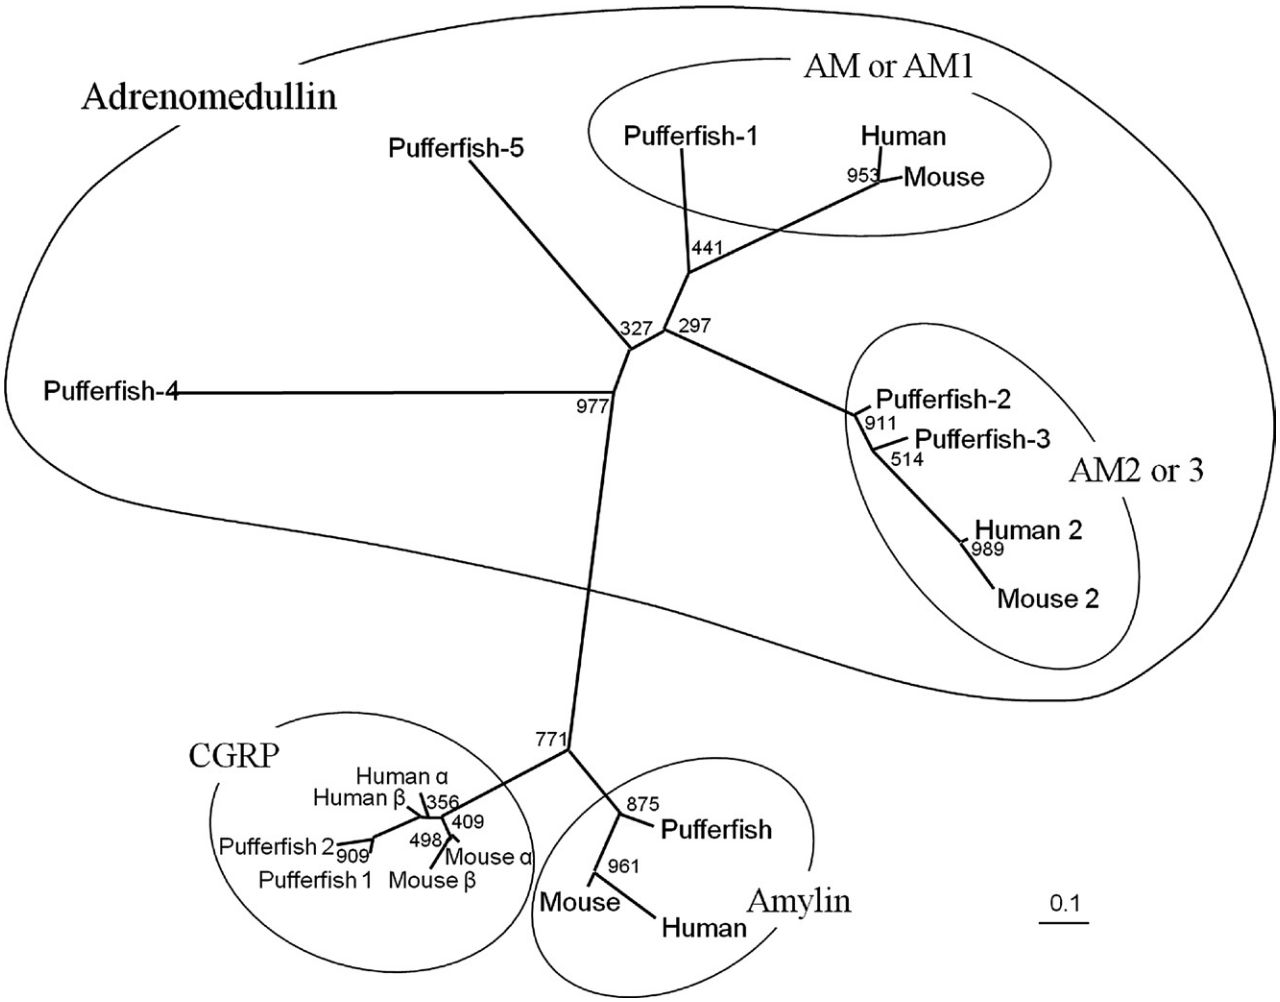

FIGURE 4 Molecular phylogenetic analyses of adrenomedullins (AMs), calcitonin-gene-related peptides (CGRPs), and amylin from mammals and pufferfish, *Takifugu rubripes*. Precursor sequences are analyzed by the Neighbor-Joining method. Numbers on the tree represent bootstrap values.

the combinations, CLR + RAMP3 and CTR + RAMP1 are most effective at10^{-9} M of AM2/IMD, but less effective than AM and amylin respectively for each receptor, suggesting the presence of AM2/IMD-specific receptors other than CTR/CLR associated with RAMP.

In fish, genes coding for two types of CLRs (CLR1 and CLR2), and five types of RAMPs (RAMP1–5) are identified in the pufferfish.[19] Molecular phylogenetic analyses and linkage analyses indicate that RAMP1/4, RAMP2/5, and RAMP3 are akin to RAMP1, RAMP2, and RAMP3 of mammals, respectively. Coexpression of CLR and RAMP shows that pufferfish AM2 increased cAMP production in cells expressing CLR1 and RAMP3, whereas pufferfish AM1, an ortholog of mammalian AM, is more widely effective in cells coexpressing CLR1 and RAMP2/3/5 and CLR2 and RAMP2.[19] Thus, the AM2-specific combination of CLR and RAMP is not found even in fishes having such diversified CLRs and RAMPs.

BIOLOGICAL ACTIONS

AM2/IMD exerts spectra of peripheral actions similar to AM in mammals. The cardiovascular and renal actions of AM2/IMD have been reviewed.[1] Intravenous (iv) infusion of AM2/IMD into the renal artery of rats at nondepressor doses is diuretic and natriuretic.[9] Because glomerular filtration rate does not change during diuretic/natriuretic dose of AM2/IMD infusion in rats, a direct tubular action is probable. Despite a high expression in the kidney of rodents and humans, the renal effects of AM2/IMD are generally less efficacious than those of AM in rats[9] and sheep.[3] Intravascular administration of AM2/IMD decreased arterial pressure and increased heart rate in rats,[10,24] mice,[29] and sheep.[3] The hypotension results from the dilatation of resistance vessels mediated by a local production of nitric oxide.[17] The cardiovascular effects of AM2/IMD are comparable with or somewhat more potent and shorter-lasting than

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

AM.[9] When administered into the cerebral ventricle (icv injection), AM2/IMD causes immediate hypertension and delayed tachycardia in rats through activation of the sympathetic nervous system.[14,31] The site of the cardiovascular action appears to be the nucleus tractus solitarius as icv injection of AM2/IMD increases *c-fos* gene expression in the nucleus.[13] The central effect of AM2/IMD is usually more potent than that of AM.

The icv injection of AM2/IMD stimulates prolactin and ACTH secretion and inhibits growth hormone secretion from the anterior pituitary of rats *in vivo* or *in vitro*.[2,27,32] The AM2/IMD gene expresses abundantly in the intermediate lobe and ACTH cells of rat anterior lobe of pituitary, and AM2/IMD administered to the cultured rat anterior pituitary cells stimulates prolactin secretion but not ACTH, GH, and FSH secretion.[2] These results are consistent with the brisk expression of CLR and RAMPs in the pituitary. The effect on ACTH secretion seems to be mediated by CRH secreted from the hypothalamus as evidenced by the use of CRH antagonist. AM2/IMD is synthesized in the adrenal medulla and its candidate receptors (CLR+RAMP1–3) are localized in the human adrenal tissue,[18] but there is no evidence for the direct action of AM2/IMD on glucocorticoid secretion. In the sheep, AM2/IMD infusion activates the renin–angiotensin system, and plasma angiotensin II stimulates aldosterone secretion (but not cortisol). The direct action of AM2/IMD on the adrenal glomerulosa cells for aldosterone secretion is unlikely in sheep.[4] The iv AM2/IMD infusion increases plasma ANP and BNP concentrations in sheep.[3]

The icv injection of AM2/IMD augments *c-fos* gene expression of the neurons in the supraoptic nucleus, paraventricular nucleus, and arcuate nucleus of rats as shown by *in situ* hybridization.[13] Immunohistochemical staining of the same section with antiserum specific to vasopressin or oxytocin revealed that most *c-fos*-positive cells are oxytocin-producing cells, and only few are vasopressin-producing cells. Consistent with this observation, plasma oxytocin concentrations are profoundly increased after icv administration of AM2/IMD but only slightly for vasopressin. In addition, the icv injection of AM2/IMD inhibits water and food intake in both satiated rats and those deprived of water and food overnight.[25,31] AM2/IMD also inhibits food intake and stomach motility in rats when given by intraperitoneal injection.[24] The effect on stomach may be mediated by locally produced AM2/IMD as the tissue abundantly synthesizes and stores this peptide.

AM2/IMD seems to have cytoprotective effects in various organs. AM2/IMD protects cardiac myocytes against ischemia/reperfusion injury.[33] In rats with chronic inhibition of nitric oxide, the expression of the AM2/IMD gene is induced solely by the oxidative stress, not by accompanying hypertension,[1] and AM2/IMD seems to protect the hypertrophied cardiomyocytes from oxidative stress in a paracrine/autocrine fashion. AM2/IMD protects endothelial cells in an autocrine manner from oxidative stress in the rat cerebral circulation.[7] Consistent with the high production in the kidney, AM2/IMD seems to function as a renoprotective peptide against oxidative stress,[12] but its expression was downregulated in the kidney of spontaneously hypertensive rats and with artificial injury.[16] AM2/IMD also has angiogenic effects in the ischemic rat hindlimb caused by femoral artery ligation as shown by the AM2/IMD gene delivery.[26]

The AM, CLR, and RAMP2 heterozygote females mated to wild-type males have reduced fertility, reduced litter size and fetal growth compared with that of wild-type females mated to the heterozygote males.[6] Although AM2/IMD gene knockout has not yet been successful, the AM2/IMD gene is expressed in the murine uterus and ovary and plasma immunoreactive AM2/IMD increases during pregnancy in rats. Thus, AM2/IMD may be involved in the female reproduction. Infusion of AM2 antagonist AM2/$IMD_{17–47}$ into the pregnant rat causes fetoplacental growth restriction through the activation of mitochondrial apoptotic pathways.[5] Apart from the direct effect, the maintenance of pregnancy by AM2/IMD results from the relaxant effect on mesenteric arteries to ensure sufficient blood supply to the fetoplacenta, as the vascular effect becomes more sensitive during pregnancy. The AM2/IMD gene is expressed in human placenta and seems to be involved in the regulation of trophoblast invasion and migration. In the rat uterus, the AM2/IMD gene is expressed in the implantation site and inhibition of AM2/IMD by its antagonist impairs the expression of factors responsible for implantation and growth of embryos such as MMP and VEGF.[6] The consensus sequence of estrogen response element exists in the AM2/IMD gene promoter, and injection of 17β-estradiol into the ovariectomized female rat restores AM2/IMD expression and prolactin secretion.[2]

The biological actions of AM2/IMD are basically similar to those of AM (see the Brain, Cancern, Endocrine, Gastrointestinal, Cardiovascular, and Respiratory Peptides sections of this volume), but some actions are apparently different from those of AM in mammals and fishes.[1,20] The difference in the response to receptor blockers suggests the presence of AM2/IMD-specific receptor that is different from CLR associated with RAMP. The AM2/IMD stimulates oxytocin secretion with higher potency than AM although affinity of AM2/IMD to CLR+RAMPs is lower than that of AM, and the AM2/IMD effect is blocked only slightly by pretreatment with $CGRP_{8–37}$ (CGRP/AM receptor antagonist) and $AM_{22–52}$ (AM receptor antagonist).[14] The inhibition of GHRH-induced GH release from the anterior pituitary cells occurs only by AM2/IMD and not by other CGRP peptides, and the effect is mediated at least in part via inhibition of intracellular cAMP production.[32] Further, AM2/IMD antagonist, AM2/$IMD_{17–47}$, inhibits peripheral cardiovascular actions, but it fails to inhibit orexigenic and dipsogenic effect of icv AM2/IMD *in vivo* and inhibitory effect on GHRH-induced GH

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

secretion from the dispersed anterior pituitary cells *in vitro*.[35] Likewise, the failure to displace ^{125}I-AM and ^{125}I-CGRP binding by AM2/IMD in dispersed rat spinal cord cells suggests the presence of distinct class of receptor for AM2/IMD.[23] In teleost fish, AM2 is >100-fold more potent than AM(1) in terms of cardiovascular and osmoregulatory actions in eels.[20] but AM2 exhibits less affinity to CLRs associated with various RAMPs in pufferfish.[19] Therefore, fish may be an ideal material to pursue novel non-CLR + RAMP receptor(s) specific for AM2/IMD in vertebrates.

PATHOPHYSIOLOGICAL IMPLICATIONS

AM2/IMD mRNA was initially registered in the EST database (accession number: AK024788) as a mRNA from the primary vascular smooth muscle cells of human coronary artery. In fact, immunoreactive AM2/IMD is detectable in the endothelial cells or smooth muscle cells of coronary vessels of mammals.[18,28] Consistently, AM2/IMD relaxes precontracted coronary of pigs more potently than AM.[11] Further, AM2/IMD protects the heart from ischemic injury.[33] These results suggest that AM2/IMD may be secreted from the coronary artery to protect the heart as a local paracrine system at the onset of ischemic heart failure as suggested by AM.[1] The expression of the AM2/IMD, CLR and RAMP genes increases in cardiomyocytes of rats with congestive heart failure and in spontaneously hypertensive rats. AM2/IMD and RAMP1 are also upregulated in the ventricular myocytes of hypertensive rats with inhibition of nitric oxide synthesis. In isolated, paced murine ventricular myocytes, AM2/IMD administration enhances contractility via protein kinase C and A activation.[8] Further, angiotensin II induces cardiac hypertrophy and increases AM2/IMD gene expression in the ventricular myocytes of rats, and the AM2/IMD treatment inhibited angiotensin II-induced hypertrophy.[34] AM2/IMD also inhibits fibroblast activation in angiotensin II-induced hypertrophic heart. Thus AM2/IMD may ameliorate the deterioration of dilated cardiomyopathy. The AM2/IMD knockout mice will delineate the cardioprotective action of this intriguing peptide more clearly.

Chapter 199

ANP

Jochen R. Hirsch and Wolf-Georg Forssmann

ABSTRACT

In the kidney, the main task of the atrial natriuretic peptide (ANP) is the induction of natriuresis and diuresis, but the mechanism behind these effects is far from being clarified. Although the involvement of ANP in the regulation of the cardiovascular system is well established, its regulatory role in transport processes in the nephron is still unresolved. Here, we take a closer look at the regulation of a variety of transport proteins in the renal nephron by ANP from the proximal tubule to the cortical and inner medullary collecting duct.

DISCOVERY OF ATRIAL NATRIURETIC PEPTIDE ACTIONS IN THE KIDNEY

For nearly half a century, an involvement of the heart in renal functions has been postulated. In 1969, a hormonal influence of the heart on the kidney was mentioned for the first time, whereas in 1974, it was observed that the granular index of myoendocrine cells is affected during experiments, altering the body fluid and electrolyte homeostasis. Application of atrial extracts led to a previously unknown strong natriuresis and diuresis. A further biological effect of atrial extracts, relaxation of vascular smooth muscle, was discovered by several research groups. The extract had a strong vasorelaxant effect on cortical arterial blood vessels. Based on these two main biological effects, the first isolation of atrial natriuretic peptides (ANPs) was performed. Depending on the bioassay used for isolation, the peptides were designated cardiodilatin (from the pig) or cardionatrin (from the rat). The first atrial natriuretic peptide isolated from the human heart was named a-human atrial natriuretic peptide (a-hANP). Since then, remarkable advances have been made regarding the characterization of its gene and protein nature, synthesis, intracellular processing, release, metabolism, second-messenger systems, and receptors. An explanation for ANP-induced natriuresis and diuresis has not yet been found, but most research groups favor a combination of hemodynamic and tubular effects.[9] Because the hemodynamic effects are well established, the following paragraphs focus on the tubular effects of ANP.

EFFECTS OF ANP ON TUBULAR TRANSPORT SYSTEMS

Effects of ANP on Proximal Tubules

Early investigations on proximal tubules regarding the possible actions and effects of ANP resulted in controversial results. Many *in vivo* and *in vitro* microperfusion studies of proximal convoluted, and straight tubules in the rat or rabbit have failed to find any effects of ANP on Na^+, bicarbonate, and Cl^- transport, and only a few managed to show ANP-induced transport changes. Solute delivery out of the proximal tubule increases by approximately 30–35%.[5] Furthermore, Harris et al.[10] reported that the stimulatory effect of angiotensin II on fluid reabsorption is inhibited by peritubular ANP at physiological concentrations and eliminated by higher concentrations of ANP. In contrast to the results of Cogan et al.,[5] the authors concluded that, at physiological concentrations, ANP acts within the kidney to decrease proximal reabsorption by the inhibition of angiotensin II-stimulated Na^+ and water transport.

With the introduction of modern techniques such as patch clamping, molecular biology, and protein chemistry, more reports showed direct effects of ANP and related natriuretic peptides (Fig. 1) such as urodilatin, B natriuretic peptide (BNP), and C natriuretic peptide (CNP) on various transport systems, ion channels, and pumps in the nephron and its various tubular structures.

ANP inhibits several Na^+-dependent transport systems. In proximal tubular brush border membrane vesicles, the Na^+/H^+-antiporter, which is responsible for approximately 50% of the Na^+ intake in this segment, is inhibited, as well as the Na^+-coupled PO_4^{3-} transport. Na^+-coupled PO_4^{3-}-transport has been extensively researched by Murer and his group, and in 2001, they reported that the inhibitory effect of ANP results from membrane retrieval containing the Na-Pi type IIa cotransporter.[2] Low-affinity high-capacity Na^+-glucose cotransporter (SGLT2) activity is drastically reduced when ANP is administered together with endothelin 3.[18] This transport system is the most important retrieval pathway for sugar in the kidney and accounts for 90% of the Na^+-coupled

sugar intake. Na^+/K^+-ATPase, essential for all secondary active transport processes, is deactivated in the proximal tubule by phosphorylation/dephosphorylation result from ANP-induced cGMP increase.[1] Deactivation of this enzyme's activity also occurs in isolated basolateral membranes and LLC-PK1 cells. Low concentrations of ANP and urodilatin (10 pM) are responsible for a 50% decrease in activity of the Na^+/K^+-ATPase through cGMP-dependent guanylate cyclase activation.[31] However, not just Na^+-dependent processes are involved in the regulatory pattern of ANP.

The organic cation transporter of the basolateral membrane of isolated human proximal tubules shows a 20–30% increase in transport after being stimulated by ANP or 8-Br-cGMP.[25] In the meantime, Cl^- as well as K^+ channels are also the target of regulation by natriuretic peptides. In cultured rat proximal convoluted tubule (PCT) cells, a DIDS-inhibitable Cl^- conductance is activated by ANP, urodilatin or their second-messenger cGMP,[7] and in the human proximal tubule cell line RPTEC, an inwardly rectifying K^+ channel is phosphorylated by a cGMP-dependent protein kinase (PKG) and stimulated by the application of ANP.[21]

Several inwardly rectifying K^+ channels have been identified in the proximal tubule.[11,19,21] Earlier, the authors described a K^+ conductance that is inhibited by various natriuretic peptides such as ANP, urodilatin, BNP, and CNP in a cGMP-dependent and -independent fashion in IHKE-1 cells, another human proximal tubule cell line. This K^+ conductance is the first directly cGMP-dependent K^+ channel described in humans. Interestingly, in IHKE-1 cells, this K^+ channel is regulated by cGMP, not only intracellular but also from the outside, showing that ANP and cGMP can also display regulatory effects from the luminal side of the tubule system.[11]

Therefore, ANP, urodilatin, and other cGMP-generating factors have three possible ways to regulate transport in the tubular system: (1) binding to glomerular cells and subsequently releasing cGMP into the proximal lumen, (2) binding to its specific receptor (NPR-A/GC-A) and increasing intracellular cGMP, and (3) binding to its specific receptor, increasing intracellular cGMP with the consecutive extrusion of cGMP via a specific transport system[30] into the lumen, and acting from the outside on the target transmembrane protein. An overview of transport proteins involved in the regulatory pathway of ANP in the proximal tubule cell is given in Fig. 2.

Effects of ANP on Henle's Loop

The functional responses of ANP in Henle's loop are unknown. It has been inferred that ANP may alter salt transport in this segment. However, most studies have shown little effect of ANP on the loop of Henle. Peterson et al.[24] investigated the effects of these hormones on thick ascending limb Na^+Cl^- reabsorption *in vivo*. With the microstop-flow conductivity technique, despite the presence of a dramatic natriuretic response, ANP does not significantly increase the minimum Na^+Cl^- concentration reached by the thick ascending limb. By contrast, vasopressin increased the rate at which luminal Na^+ concentration declined by 23%. Up to now, the only direct effects of ANP on Na^+Cl^- transport are a report on a decrease in Cl^- reabsorption[3] and an inhibitory effect of ANP on Na^+/K^+-ATPase.[29] An explanation might be the low response of the cells of Henle's loop in cGMP formation after incubation with ANP.[4]

Comparable to other segments of the nephron where ANP is able to modulate intracellular Ca^{2+} levels, a putative physiological importance of ANP could also be shown in

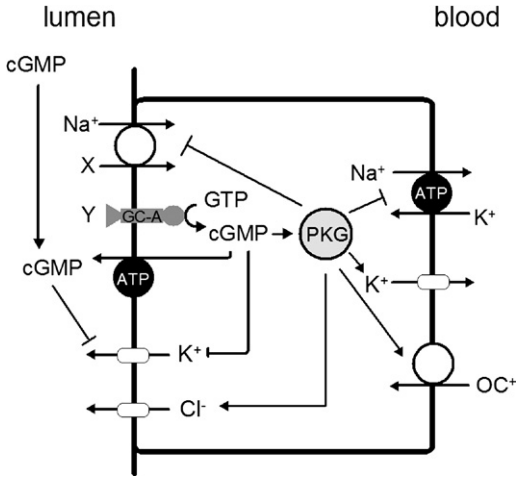

FIGURE 2 Cell model of the proximal tubule. Shown are the transport systems that are regulated via ANP and its second-messenger cGMP. In the luminal membrane, the guanylate cyclase receptor (GC-A) for ANP, urodilatin, and BNP (Y) is located and, after being activated, generates cGMP. This second-messenger can activate a cGMP-dependent kinase (PKG), which phosphorylates several Na^+ coupled transporters, such as the basolateral Na^+/K^+-ATPase and the Na^+/H^+ exchanger, Na^+-glucose and Na^+-PO_4^{3-} cotransporter (X) of the luminal membrane but also the Na^+ independent organic cation transporter (OC) of the basolateral membrane. Furthermore, PKG activates a Cl^--channel in the luminal membrane and an inwardly rectifying K^+ channel (location is not verified and the basolateral membrane was chosen accidentally). cGMP can also act as an inhibitor on a K^+ channel from the tubular lumen. When transported to the lumen by a specific pump, it can inhibit this channel from the outside. This mechanism also works when cGMP is released from glomerular cells because of stimulation by ANP or related natriuretic peptides.

this portion of the nephron.[6] In primary cell cultures, this group reported an ANP-induced receptor-mediated Ca^{2+} transient in cortical thick ascending limb cells resulting from internal release and influx across the plasma membrane. The authors discuss whether this receptor is most probably the clearance receptor that initiates Ca^{2+} signals. They conclude that these ANP-induced Ca^{2+} transients mediated by the putative clearance receptor may have significant physiological actions within Henle's loop.

The rather moderate effects of ANP, urodilatin, or cGMP on Henle's loop do not necessarily mean that natriuretic peptides are not involved in the regulatory processes of this tubular segment. A splice variant of the CNP-activated NPR-B/GC-B receptor, NPR-Bi, is highly expressed in human thick ascending limb and the cortical collecting duct. This receptor lacks guanylate cyclase activity and probably acts as a tyrosine kinase.[13]

Effects of ANP on the Collecting Duct System

There is evidence that ANP affects natriuresis and diuresis in part by inhibiting net Na^+ and water reabsorption in the collecting duct. The first review of the day-to-day regulation of fluid and electrolyte balance using the micro catheterization technique and the micropuncture method was in 1979, and the first ANP effects on the tubular system were reported in 1982. Experiments were performed in anesthetized rats to collect tubular fluid from the proximal and distal tubules and from the outer medullary collecting duct. Samples were taken from the same sites before and after intravenous (iv) administration of atrial tissue extract. Na^+ excretion increase 17-fold after injection of atrial extracts, whereas the clearances of insulin and single nephron filtration rates do not change significantly. The infusions of ANP do not alter the delivery of Na^+ and water to Henle's loop but lead to increases in Na^+ and water delivery out of the outer medullary duct. Because there is a large increment of fractional Na^+ excretion between the outer medullary collecting duct and the final urine, it is probable that the atrial extracts interfere with the capacity of solute load reabsorption in the inner medullary collecting duct (IMCD). Furthermore, the infusion of ANP is associated with increased Na^+ delivery and reduced fractional reabsorption in the duct, whereas K^+Cl^- infusion has no effect on fractional reabsorption, suggesting that ANP has a highly specific inhibitory effect on net Na^+ transport in this part of the nephron.[28] Even if the *in vivo* studies strongly indicate the actions of ANP by inhibition of net Na^+ and water reabsorption in the collecting duct, it cannot be excluded that these actions could also be caused by alterations of transepithelial driving forces. ANP can preferentially increase blood flow to juxtamedullary nephrons and augment *vasa recta* blood flow. ANP-induced alterations in transepithelial driving forces in the renal medulla cause unfavorable hydraulic gradients for net Na^+ reabsorption in the IMCDe.[20] These findings suggest that ANP can increase the hydraulic gradient from the *vasa recta* to papillary collecting duct, favoring reduced net volume and Na^+ reabsorption in the IMCD.

Effects of ANP on the Late Distal Tubule

HEK-293 cells display a variety of features of the late distal tubule. Furthermore, they have the ability to release urodilatin, the structural analog to ANP. These human distal tubule cells contain specific mRNA for the ANP/urodilatin receptor NPR-A/GC-A, whereas the receptors for other members of the natriuretic family, GC-B and GC-C, were not detectable. In these cells, ANP inhibits K^+ conductance via PKG that is rather inactive, but the effect becomes apparent when genistein activates a different K^+ conductance and thus, potentiates ANP-induced inhibition.[12] Novel observations show that ANP and urodilatin, besides activating and inhibiting K^+-channels, counterregulate the effects of bradykinin on Ca^{2+}-dependent Cl^- channels via PKG. However, natriuretic peptides do not interact directly with the target channels but with the bradykinin-activated Ca^{2+} pathway (unpublished results).

Effects of ANP on the Cortical Collecting Duct

Water reabsorption takes place in the cortical collecting duct (CCD) cells, induced by the peptide hormone vasopressin. An increase in 3'5'-cyclic adenosine monophosphate (cAMP) levels in these cells leads to an increasing permeability of the CCD apical membrane to water. The ANP-induced diuresis probably results from the direct inhibition of renal tubular epithelial water transport.[8] The results that ANP leads to an inhibition of the hydraulic conductivity response to the hormone vasopressin but not to either cAMP or forskolin suggests that ANP acts proximally to cAMP formation. A similar result was found for aquaporin (AQP-1),[23] which is also localized in the kidney but predominantly in the proximal tubule, descending limb of Henle's loop, and *vasa recta*. AQP-1 is upregulated when expressed in *Xenopus laevis* oocytes and treated with AVP. Water permeability increases and could be inhibited by ANP or incubation with 8-Br-cGMP.[23] A competing phosphorylation mechanism between protein kinase A (PKA) and PKG has been shown previously for dopamine and ANP in regulating the Na^+/K^+-ATPase of the proximal tubule[1] and might be a mechanism in the CCD as well. However, in several cell types, natriuretic peptides decrease cAMP concentration via the activation of the NPR-C receptor to which all natriuretic peptides can bind. This effect can either be mediated by the activation of the receptor's coupling to G-protein or by regular cGMP increase and subsequent stimulation of cAMP-sensitive phosphodiesterases. What is the effect of ANP on ion transport processes at this nephron site? A few groups were able to convincingly show that ANP neither has an effect on Na^+ transport in the CCD[26] nor does it regulate electrogenic electrolyte transport in principal cells of rat CCD.[27] With the localization of the NPR-A/GC-A receptor in the luminal membrane of intercalated cells, the authors show that ANP, urodilatin, and its membrane-permeable second-messenger 8-Br-cGMP inhibit Na^+/H^+ exchange activity,[11] thus regulating the acid-base equilibrium of these cells (Fig. 3).

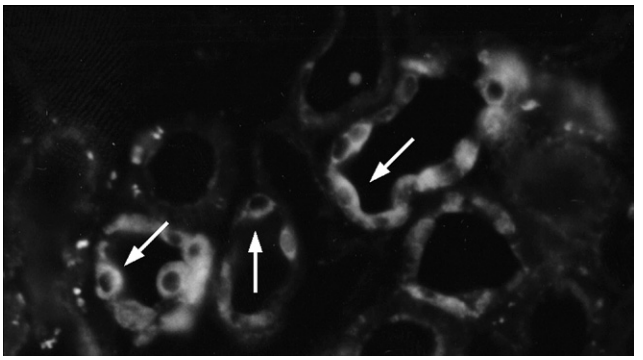

FIGURE 3 Immunohistochemistry of NPR-A/GC-A in the cortical collecting duct of rat. The white arrows show typical intercalated cells protruding into the lumen. Note that the staining is prominent in the luminal membrane.

Effects of ANP on the Inner Medullary Collecting Duct

There is strong evidence that most of the natriuretic effects of ANP contribute to the inhibition of Na^+ reabsorption in the IMCD. Great efforts have been made to clarify the mechanisms by which ANP acts and induces the natriuretic response in the IMCD. ANP inhibits transport-dependent oxygen consumption (QO_2) in the IMCD, yet has no effect on the outer medullary collecting duct. Furthermore, studies investigating the interaction of ANP with amiloride, ouabain, and amphotericin with QO_2 measurements suggest that ANP inhibits Na^+ entry into these cells.[34] ANP reduces isotopic Na^+ uptake in suspensions of IMCD cells by two-thirds at concentrations identical to those found effective in oxygen consumption studies.[33] To precisely characterize the ANP-induced effect on Na^+ reabsorption in IMCD, the patch-clamp technique shows that ANP and cGMP inhibit an apically located cation channel in cell-attached patches. Thus, it seems probable that the natriuretic action of ANP is related partly to the cGMP-mediated inhibition of electrogenic Na^+ absorption by the IMCD. This finding is also supported by Nonoguchi et al.[22] ANP and NO inhibit water transport in IMCD cells via activation of a guanylate cyclase when pretreated with vasopressin. Incubation of these cells with ANP leads to a retrieval of AQP-2 water channels from the plasma membrane into the cytosol.[17]

For some points, the contradictory results of several groups and some open questions may reflect the uncertainties and difficulties in precisely characterizing and defining the role of ANP in Na^+ and water homeostasis. Some authors even question the functional role of ANP in the kidney and favor a regulatory role primarily in the cardiovascular system. However, this view is highly unlikely, because the application of an NPR-A/GC-A antagonist counterregulates natriuresis induced by acute volume expansion.[32] Mice lacking the ANP gene show salt-sensitive arterial hypertension and elevated extracellular fluid volume.[15] Furthermore, ANP knockout mice are unable to inhibit Na^+ reabsorption in the collecting duct when kept on a high-salt diet and intravenous salt loading,[14] and the natriuretic effect is virtually absent in NPR-A knockout mice.[16]

In addition to the established hemodynamic effects of ANP, there are a growing number of reports showing direct inhibitory regulatory effects on transport proteins throughout the nephron. Among these are several Na^+-dependent transport systems such as the Na^+/H^+ exchanger, which accounts for 50% of the Na^+ intake in this segment; the Na^+-glucose and Na^+-phosphate transporters from the proximal

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

tubule; and the Na^+/K^+-ATPase from the proximal tubule and the thick ascending limb of Henle's loop. In the collecting duct system, ANP inhibits a nonselective cation channel and the Na^+/H^+-exchanger responsible for cellular pH regulation. Furthermore, ANP reduces the number of AQP-2 channels in the plasma membrane of IMCD cells, thus, leading to diuresis.

Taken together, these direct effects on tubular transport proteins add to the natriuretic and diuretic effect of ANP because all mentioned Na^+-coupled processes are inhibited by ANP and a diuretic effect is coupled with an increased Na^+ loss. Therefore, a combination of hemodynamic and direct tubular effects is the most probably the explanation for the natriuretic and diuretic effects of ANP. Whether ANP is solely responsible for these effects or the renal natriuretic peptide urodilatin with a higher stability is the key regulator in the kidney remains to be answered.

Chapter 200

Endothelin

David M. Pollock

ABSTRACT

Thanks to the development of highly specific receptor antagonists and cell-specific knockout mice over the past decade, we now know that endothelin-1 (ET-1) plays a critical role in the management of salt and water excretion, and, thus, in blood pressure regulation. In addition, an imbalance to the ET system, either through excessive ET-1 production with increased ET_A receptor activation or reduced ET_B receptor function, contributes to the development of hypertension, renal inflammation, and diabetic renal injury. The kidney is a major site of ET-1 synthesis, and ET is involved in the regulation of tubular transport and fluid–electrolyte balance. Progress in our understanding has been slowed down by the opposing functions of ET_A and ET_B receptors along with the autocrine and paracrine nature of ET-1. Nonetheless, recent studies have helped to clarify the physiological role of this peptide system, especially within the kidney.

BASIC COMPONENTS OF THE ENDOTHELIN SYSTEM

Other chapters in the Cardiovascular, Respiratory, and Cancer/Anticancer Peptides sections of this book provide more extensive overviews of the history of the endothelin system and so this will not be reviewed here in detail. The endothelin system consists of three distinct ET peptides, ET-1, ET-2, and ET-3 that are synthesized through a series of proteolytic cleavages of the original gene product to result in a 21-amino-acid biologically active peptide. ET-1 is the peptide primarily released from vascular endothelium along with its immediate precursor, big ET-1. Conversion of big ET-1 to ET-1 is primarily achieved by a unique serine protease referred to as the endothelin-converting enzyme (ECE) that has several intracellular and extracellular isoforms. A variety of different cell types in the kidney synthesize all three ET peptides, but little is known about specific ET-2 or ET-3 isopeptide function.

ET_A and ET_B receptors were originally classified by their binding affinity to the peptide isoforms. ET_A receptors bind ET-1 and ET-2 with high affinity, whereas the ET_B receptor binds all three ET isopeptides with equal affinity.[18] ET_A receptors located primarily on vascular smooth muscle cause constriction as well as promote cellular growth and proliferation. However, ET_B receptors are primarily located on endothelial cells to stimulate vasodilation through release of nitric oxide and other endothelial-derived vasodilators. However, there are some vascular beds, including the kidney, that also have ET_B receptors located on vascular smooth muscle to produce vasoconstriction. For reasons yet to be discerned, ET_B-dependent constriction appears only at pharmacological concentrations of ET-1. Endothelial and vascular ET_B receptors seem to be derived from the same gene, yet they can be distinguished pharmacologically. Some have referred to these as functional ET_B receptor subtypes and have been called ET_{B1} and ET_{B2} located on endothelium and vascular smooth muscle, respectively. The general function of the ET system in the vascular wall is depicted in Figure 1.

LOCALIZATION OF THE ET-1 SYSTEM IN THE KIDNEY

Physiological regulation of ET-1 synthesis within the kidney seems to occur primarily in response to dietary salt intake. Under healthy conditions, increases in dietary salt increase intrarenal expression of preproET-1 mRNA, ET-1 peptide content, and urinary ET-1 excretion.[18] There are many additional factors that have been shown to increase endothelial and epithelial cell ET-1 synthesis. These include hormonal factors, such as angiotensin II and aldosterone. Under pathophysiological conditions, factors such as hyperglycemia, inflammation, shear stress, oxidative stress, and hypoxia, are among the reported stimulators. Within the renal cortex, ET-1 can be synthesized not only by vascular endothelium but also by vascular smooth muscle, mesangial cells, podocytes, and tubular epithelial cells.[18] Within the renal medulla, ET-1 synthesis has been reported within vasa recta, thick ascending limb, and collecting duct cells.[18] Similar to the immunoreactivity studies, gene expression experiments confirmed the idea that sites of ET-1 mRNA expression include glomeruli, proximal tubules, thick ascending

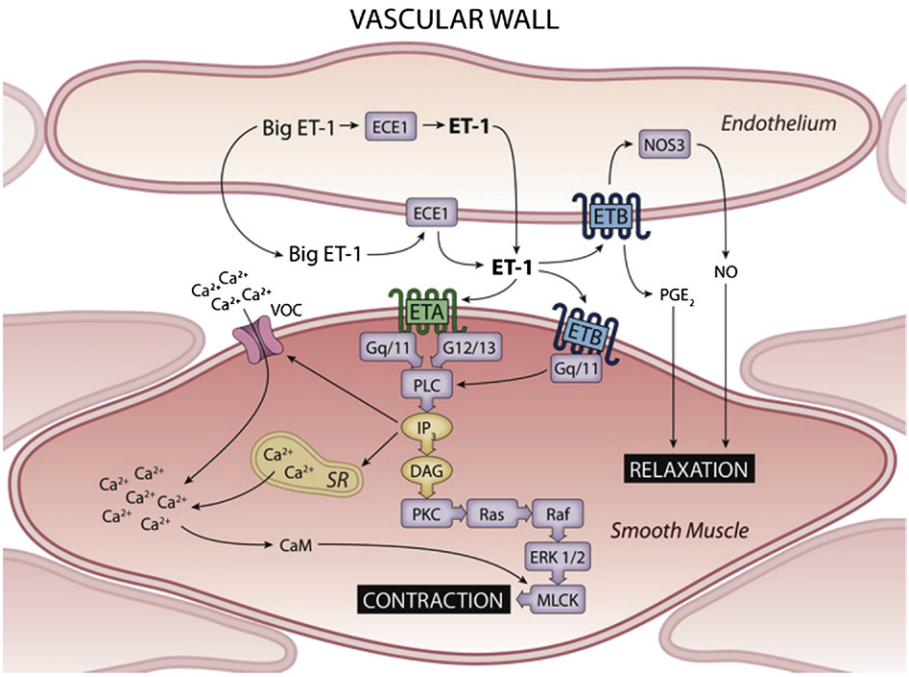

FIGURE 1 Basic function of the endothelin (ET-1) system in the vascular wall. (Used with permission from the American Physiological Society.[18])

limbs, vasa recta, and outer/inner medullary collecting ducts and that relatively higher amounts of ET-1 are synthesized within the renal medulla.[18]

Similar to ET-1 peptide, animal studies have reported that endothelin-converting enzyme mRNA and protein expression can be identified in glomeruli, proximal straight tubule, cortical/medullary thick ascending limb, and inner medullary collecting duct.[18] ECE-1 immunoreactivity in the human kidneys is observed in vascular and glomerular endothelial cells and vasa recta capillaries. The tubular epithelium of the outer/inner medullary collecting ducts also contains ECE-1.

Localization of ET receptors was first identified in autoradiography studies. Both ET_A and ET_B receptors are present in the kidney as described above for the ET-1 peptide. The common localization has confirmed the belief that the peptide serves as an autocrine and as a paracrine function rather than any sort of classic hormonal role. The net result of the binding studies has revealed the presence of ET_A receptors in the renal vascular smooth muscle, mesangial cells, and some tubular cells. The majority of specific binding sites in the renal cortex are localized in what appear to be endothelial cells of glomeruli and peritubular capillaries. However, the largest number of binding sites has been localized to the renal medulla, and in particular, to the inner medullary collecting duct.

RENAL HEMODYNAMIC EFFECTS OF ET-1

Intravenous infusion of exogenous ET-1 peptide in several species has resulted in a profound decreased renal blood flow and GFR.[18] However, direct infusion into the renal artery of dogs results in a short-lived vasodilation followed by a prolonged vasoconstriction. Vasodilatory actions of ET-1 have been difficult to discern in rodent species although blockade of ET_B receptors increases the vasoconstrictor response to ET-1. ET_B receptors in the kidney are also believed to be important in producing vasoconstrictor actions of ET-1, but when examining lower doses of ET-1, all of the vasoconstrictor actions can be blocked by an ET_A selective antagonist, thus suggesting that the ET_B constriction in the kidney is of only pharmacological significance.

When considering the renal hemodynamic effects of ET-1, there are significant differences within the renal cortex versus medulla. Gurbanov et al. were the first to show that an intravenous bolus of ET-1 actually increases medullary blood flow while at the same time decreasing cortical blood flow by using implanted single optical fibers for measuring blood flow velocity.[15] Subsequently, studies in our laboratory showed that a continuous intravenous infusion of the precursor, big ET-1, into the rat produces a decrease in renal cortical blood flow without a change in medullary blood flow.[31] However, when rats are maintained on a high salt diet, medullary blood flow actually increases, whereas the cortical blood flow decreases as before.

The difficulty with *in vivo* hemodynamic studies using exogenous peptide is that delivery of the peptide may not be the same as that seen with endogenous production. ET-1 is released preferentially to the basal side of the endothelial cell and binds irreversibly to its receptor.[18] Therefore, intravenous or intraarterial infusion may not always mimic endogenous activity.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Studies attempting to localize ET-1-receptor-dependent action in the preglomerular and postglomerular vessels have resulted in inconsistent results [18] In isolated rabbit renal arterioles, ET-1 has been shown to be equipotent at constricting afferent and efferent arterioles. By contrast, another study conducted in isolated rat vessels suggested that ET-1 is more potent in efferent arterioles compared with in afferent arterioles. ET-3 also constricts isolated renal arterioles, but at much lower concentrations, and so one would conclude that the primary function in the renal microcirculation is mediated by the ET_A receptor. In the hydronephrotic kidney, Endlich et al. reported that ET-1 induced preglomerular constriction largely results from ET_A receptor activation, whereas ET_B receptor dependent vasoconstriction is more evident in postglomerular vessels.

ET-1, and presumably ET_A receptor activation, increases cytosolic Ca^{2+} in vascular smooth muscle by activating T- and L-type channels.[18] However, there may be some Ca^{2+} independent effects of ET-1 to produce the renal vasoconstriction. Several studies have shown that ET-1 increases intracellular Ca^{2+} concentrations in isolated afferent arterioles or isolated preglomerular vascular smooth muscle cells.[29] In the hydronephrotic kidney, Ca^{2+} channel antagonism prevents ET-1 induced renal vasoconstriction. However, blockade of L-type Ca^{2+} channels *in vivo* has only minor effects, if any, on the renal blood flow response to ET-1 or sarafotoxin 6c, an ET_B receptor-selective agonist. Although it is apparent that ET-1 increases intracellular Ca^{2+} levels in vascular smooth muscle, it seems as though L-type Ca^{2+} channel activation does not play a major role in the renal vasoconstriction produced by ET-1 via either the ET_A or ET_B receptor.

Much of the known facts about the actions of endogenous ET-1 has been discerned from the use of receptor-selective antagonists. In a euvolemic rat, blockade of both receptors with a nonselective ET_A/ET_B receptor antagonist, has little effect on arterial pressure or renal blood flow, but produces a small decrease in GFR.[25] This is also associated with a decrease in glomerular blood flow caused by a significant increase in preglomerular arteriole resistance. However, selective blockade of the ET_A receptor produces the same effect on arterial pressure and renal blood flow as combined ET_A and ET_B blockade but does not change vascular resistance. These results support the idea that the physiological role of ET-1 in the renal vasculature is primarily vasodilation as a means of regulating GFR, presumably via the ET_B receptor. This effect is most probably a result of the release of vasodilator agents such as NO or prostacyclin, but little is specifically known about the endothelial-derived mediators that stimulate ET_B-dependent vasodilation in the kidney.

ET-1 CONTROL OF EXCRETORY FUNCTION

Historically, factors that increase blood pressure, such as angiotensin, norepinephrine and vasopressin, were all considered to also enhance retention of sodium and water in the kidney. Thus, it made sense when initial studies investigating the influence of ET-1 on renal excretion of salt and water suggested that ET-1 induced increases in renal perfusion pressure account for the natriuretic and diuretic effects of ET-1. However, systemic administration of ET-1 at relatively low doses that does not increase blood pressure or decrease the filtered load of salt and water were reported to have potent diuretic and natriuretic effects.[18] Consistent with this effect being via the ET_B receptor, the diuretic and natriuretic response to big ET-1 is not influenced by ET_A receptor blockade despite significant attenuation of the blood pressure response.[23] Increases in medullary blood flow have the potential for also facilitating natriuresis and diuresis. The medullary hemodynamic actions produced by ET-1 have also been shown to be mediated by ET_B receptors.[15,31] As discussed below, a series of elegant studies from the Kohan laboratory have established that direct renal tubular actions of ET-1 via the ET_B receptor on collecting duct cells account for the reduced reabsorption and increased renal excretion of sodium and water. Although the primary actions of ET-1 may be within the collecting duct, other tubular segments appear to have a functional ET-1/ ET_B receptor system.

Proximal Tubule

ET-1 seems to have a biphasic effect on ion transport in the proximal tubule by stimulating influx at low concentrations and inhibiting at high concentrations, yet both effects are protein-kinase-C-dependent (PKC).[18] There is additional evidence supporting both effects. The stimulatory effect of ET-1 on fluid transport at low concentration can be attributed to the stimulation of the Na^+/H^+ exchanger. This seems to result from the activation of ET_B receptors since Na^+/H^+ exchanger activity is increased in opossum kidney cells transfected with ET_B receptors but not ET_A receptors. In these same cells, ET-1 increases intracellular Ca^{2+} levels, decreases adenylyl cyclase activity, and increases tyrosine phosphorylation of several proteins, suggesting that the fluid transport effect is independent of these distinct pathways. Further, ET-1 has been reported to inhibit Na^+/K^+-ATPase activity along with increasing cGMP concentration in cultured proximal tubule cells. Consistent with most tubular actions of ET-1, inhibition of Na^+/K^+-ATPase activity probably results from ET_B receptor activation because ET-1 and ET-3 are equally potent. Other studies have shown that ET-1 inhibits proximal tubule fluid reabsorption by augmenting the production of arachidonic acid metabolites. At high concentrations, ET-1 not only stimulates PKC but also enhances phospholipase A_2 metabolite generation.

There is also evidence that 20-hydroxyeicosa-5,8,11, 14-tetraenoic acid (20-HETE), a cytochrome P450 metabolite, contributes to ET-1-mediated natriuretic responses. Inhibition of 20-HETE formation in isolated proximal tubules

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

prevented the blockade of ion transport produced by ET-1 providing fairly clear evidence that 20-HETE acts as a second messenger of ET-1 in this nephron segment.[20] In addition, blockade of the enzyme responsible for 20-HETE synthesis (CYP4A) prevents the increase in urinary sodium excretion produced by ET-1.[20] An additional link between the ET and cytochrome P450 systems comes from the observation that chronic ET_B receptor blockade reduces CYP4A expression in the kidney, although secondary actions of increased blood pressure and/or increased ET_A receptor activation could also play a role.

Thick Ascending Limb of Henle's Loop

Isolated segments of thick ascending limb express ET-1 mRNA and secrete ET-1.[18] ET_B receptor activation decreases chloride reabsorption in isolated mouse medullary and cortical thick ascending limbs via a cAMP-independent and Ca^{2+}-insensitive diacylglycerol-responsive PKC pathway. Plato et al. extended these observations to determine that activation of ET_B receptors in the medullary thick ascending limbs inhibits chloride influx via a NO-dependent mechanism.[21] The NO synthase inhibitor, L-NAME completely blocks the ET-1 induced decrease in chloride reabsorption. Blockade of ET_B receptors with BQ-788 also prevents the effects of exogenous ET-1 on chloride flux.

Collecting Duct

The renal collecting duct, more specifically, the principal cell, is a major site of ET-1 synthesis, receptor binding, and action.[18] ET-1 receptor expression and production increase along the length of the collecting duct from the cortex to the inner medulla. The inner medullary collecting duct produces up to ten times as much ET-1 than any other cell type in the nephron does, and most probably more than any cell type in the body.

Very little is known about factors that regulate ET-1 synthesis in the collecting duct. A fairly convincing case has been made that dietary salt intake has a major influence on ET-1 production within the kidney as reflected by increased urinary ET-1 excretion.[18] Work from Garvin's laboratory has provided evidence that a high salt diet produces a significant increase in renal medullary interstitial sodium concentration and that ET-1 production in the medullary thick ascending limb is directly correlated to extracellular sodium concentration. Further, there is evidence that increases in fluid shear rate within the renal tubular system, similar to that observed during increased salt and water intake, can stimulate ET-1 production. A wide range of other factors can influence ET-1 gene expression in the collecting duct including hypoxia. However, most other factors that work in this region of the kidney have relatively modest effects on ET-1 production, for example, atrial natriuretic peptide and nitric oxide. However, this is not to suggest that these other factors do not modulate ET-1 action, but there is relatively little known about mechanisms that control production.

Endothelin seems to be released from the basolateral side of the collecting duct similar to what has been reported for endothelial cell production and is consistent with an autocrine function given the preponderance of ET_B receptors on these same cells.[18] ET-1 effects on sodium versus water handling seem to be somewhat distinct, that is, the effects on water are not simply a response to changing sodium movement. ET-1 blocks water transport by inhibiting AVP-stimulated cAMP accumulation and osmotic water permeability in the inner medullary collecting duct. The ability of ET-1 to inhibit water reabsorption involves the inhibition adenylyl cyclase activity because administration of a cAMP mimetic to increase water reabsorption is unaffected by ET-1. Unfortunately, it has been very difficult to measure actual sodium transport in the inner medullary collecting duct where most of the ET-1 is produced because of technical limitations.

Soon after the discovery of ET-1, Zeidel et al. reported that ET-1 reduces sodium transport in freshly isolated inner medullary collecting duct cells by inhibiting the Na^+/K^+-ATPase on the basolateral side of the membrane, an effect dependent upon prostaglandin E_2 production stimulated by ET_B receptor activation.[35] ET-1 is also believed to decrease sodium transport by negatively regulating epithelial sodium channel (ENaC) activity. Several laboratories have reported that ET-1 decreases ENaC activity through activation of Src kinase and can be inhibited by a specific ET_B receptor antagonist, but not ET_A receptor blockade.[4] Stockand's laboratory has reported that ENaC activity measured by patch-clamping methods is absent in response to ET-1 in isolated, split open collecting ducts from collecting-duct-specific ET_B receptor knockout mice.[3]

Assessment of tissue homogenates from inner medullary tissue clearly show that the ET_B receptor is expressed at a much higher level compared with the ET_A receptor, although the precise ratio within the principal cell of the collecting duct itself is not clear because of the presence of receptors in other cell types including vascular tissue where the ET_A receptor is expressed at higher levels. Interestingly, the fact that infusion of ET-1 into the renal medulla can increase medullary blood flow indicates that many of the ET_B receptors could be on vascular elements.[15,31]

Activation of ET_B receptors inhibits vasopressin (AVP) stimulated water transport by decreasing cAMP levels through the activation of PKC.[30] Mineralocorticoid and AVP-stimulated sodium and chloride transport is diminished by ET-1 via inhibition of apical sodium and chloride entry.[9] *In vitro* studies have shown that ET-1 inhibits sodium transport by decreasing amiloride-sensitive sodium channel activity and increasing channel mean closed time.[9]

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Similar to the proximal tubule, ET-1 seems to have a biphasic response in the cortical collecting duct. A concentration of ET-1 in the picomolar range will decrease sodium channel activity through ET_B activation while a concentration in the nanomolar range can increase sodium channel activity through ET_A activation; however, this mechanism is not well understood.

Lessons from Genetically Modified Animals

A series of studies from the Kohan laboratory has provided more compelling evidence that ET-1 produced by the collecting duct plays a key role in fluid-volume balance and blood pressure regulation. Collecting-duct-specific ET-1 knockout (CD ET-1 KO) mice have altered renal sodium and water handling suggesting a physiological role of collecting-duct-derived ET-1 in regulating tubular fluid reabsorption.[1,14] Similar to CD ET-1 KO mice, the same laboratory generated collecting-duct-specific ET_B receptor knockouts that have a very similar phenotype although the increase in blood pressure at baseline and in response to a high salt diet are roughly half that observed in CD ET-1 KO mice.[12]

The low level of ET_A receptor expression in the collecting duct suggests a less important function compared with the ET_B receptor although there have been some reports that ET_A receptors regulate tubular transport by increasing endothelial nitric oxide synthase expression.[34] Ge et al. observed that collecting duct-specific ET_A receptor knockout (CD ET_A KO) mice have similar arterial pressure, sodium excretion, and water excretion as their control counterparts when challenged with normal and high salt diets.[14] However, CD ET_A KO mice are unable to excrete an acute water load appropriately and have an increased sensitivity to AVP-induced cAMP accumulation.[14] These results suggest that ET_A receptors in the collecting duct are not involved in the physiological regulation of arterial pressure or sodium excretion but more specifically help to regulate water reabsorption. Findings from the collecting duct knockout mice provide insight into the possibility that there may be an interaction between ET_A and ET_B receptors to function in a cooperative manner. As mentioned, CD ET-1 KO mice have a significant level of salt-sensitive changes in blood pressure that are roughly twice as much as CD ET_B KO mice while CD ET_A KO mice have similar blood pressures as control mice regardless of salt intake. When both ET_A and ET_B receptors are simultaneously knocked out of the collecting duct, the salt sensitivity is identical to CD ET-1 KO mice.[13] These findings suggest a cooperative, although not independent, role for the ET_A receptor in regulating blood pressure sensitivity to salt.

Additional evidence that ET-1 may contribute to fluid-electrolyte balance, and, thus, blood pressure regulation arises from increased renal ET-1 activity associated with increased dietary salt intake. Investigators generally agree that urinary ET-1 is exclusively derived from intrarenal sources. Because a high salt diet increases urinary ET-1 excretion and intrarenal mRNA expression, ET-1 production is clearly increased in the kidney in response to a high salt diet. It can be presumed that this increase in intrarenal ET-1 in response to high salt intake is a physiological mechanism designed to reduce sodium and water reabsorption and elimination of the increased salt ingested. There is little conclusive information on whether renal ET_A or ET_B receptor expression is changed in response to dietary salt intake. Increased ET_B receptor function in rats on a high salt diet is also evidenced by the observation that increases in medullary blood flow produced by big ET-1 are more pronounced in rats on a high salt diet.[31]

As discussed above, gene-targeting strategies have provided more specific evidence that ET-1 regulates salt and water excretion. The initial findings arise from the spotting lethal rat that carries a naturally occurring deletion of the ET_B receptor gene resulting in deadly megacolon.[11] Gariepy et al. rescued these rats with a dopamine-β-hydroxylase promoter that directed tissue-specific ET_B transgene expression to support normal enteric nervous system development yet remain without ET_B receptors on endothelial or renal tubular epithelial cells.[10] Rats homozygous for the ET_B receptor deletion have a higher basal arterial pressure compared to their control counterparts. Similar to pharmacological ET_B receptor blockade, ET_B deficient rats become hypertensive when challenged with a high salt diet.[10] Figure 2 summarizes the general mechanisms within the renal medulla whereby both vascular and tubular actions of both ET_A and ET_B receptors can influence sodium excretion.

RENAL ET-1 IN HYPERTENSION

The influence of ET-1 on sodium and water balance along with potent vascular actions suggests that the intrarenal ET system may contribute to the development of hypertension. This could occur by inappropriate or excessive ET_A receptor activation or a loss of ET_B function (Figure 3). Initial evidence that renal ET-1 may contribute to the development of hypertension came from a series of reports that administration of both ET_A selective and ET_A/ET_B antagonists reduce blood pressure in salt-dependent models' hypertension, but not in other models. These include DOCA-salt, chronic Ang II infusion, SHR-SP, and Dahl salt-sensitive rats. ET antagonists are not effective in all models such as the SHR and the 2-kidney, 1-clip Goldblatt hypertensive rat that have been reported to be unresponsive to ET receptor blockade. The blood-pressure-lowering effects appear to exclusively result from ET_A receptor blockade because selective inhibition of ET_B receptors exacerbates the elevated arterial pressure in models such as the DOCA-salt hypertensive rat. Further, in

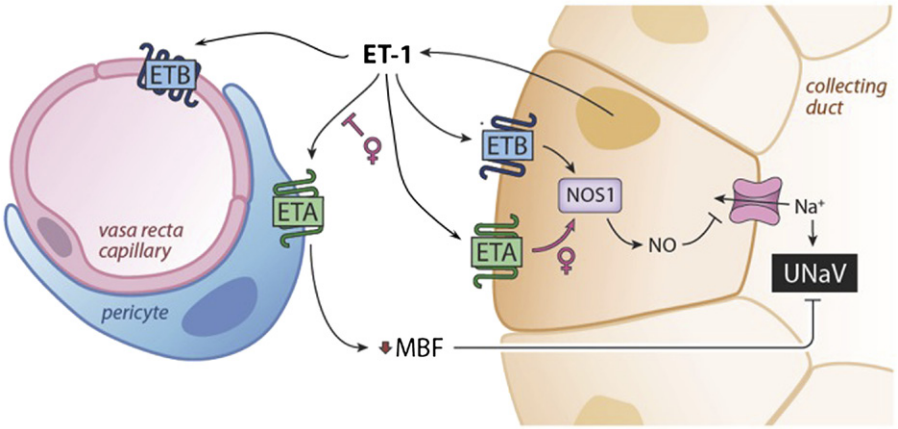

FIGURE 2 Basic function of the endothelin (ET-1) system in the renal medulla. (Used with permission from Morgan & Claypool Life Sciences.[22]) See color plate 53.

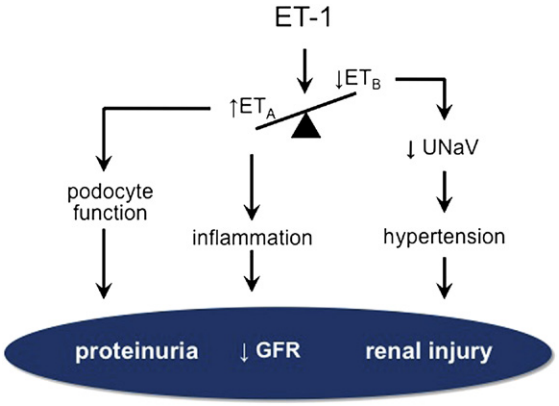

FIGURE 3 Hypothetical scheme for ET-1 contribution to renal injury associated with hypertension and diabetes.

normotensive rats, chronic ET_B receptor blockade elevates blood pressure in a salt-dependent manner.[24]

To date, there is no clear explanation for what triggers the imbalance of the ET system to contribute to hypertension. This could occur through inappropriately excessive ET-1 production that overwhelms the ability of ET_B receptors to protect against ET_A activation. However, inappropriate ET_A receptor activation could occur in response to a loss of ET_B receptor function without any change in ET-1 production.

A new hypothesis perhaps should be considered to explain why and/or how ET-1 causes hypertension, that is, the need to increase renal perfusion pressure and facilitate pressure natriuresis. Given the clear function of ET-1 to increase salt and water excretion, a concomitant elevation in systemic blood pressure in association with reduced renal tubular reabsorption can work synergistically to increase excretory function. This idea fits well with Guyton's view of renal control of blood pressure.

In human hypertension, early reports suggested that plasma concentrations of ET-1 are elevated.[28] However, this has not been a universal finding. There are many factors for this inconsistency including variety in specificity of many of the initial assays, the heterogeneity of patient populations, and the fact that plasma ET concentrations are more a factor of ET_B receptor function (clearance of circulating ET-1) as much as they are an indication of production. There has been one report also that the stress of venipuncture can increase plasma ET-1 acutely, and so the method of blood drawing could contribute to this variability as well (see Treiber et al., 2000, in *Hypertension*).

Some investigators have suggested that urinary ET-1 may be a marker for renal injury associated with chronic kidney disease.[6] Although ET-1 gene expression is elevated by many factors associated with CKD such as hypoxia and inflammation, ET-1 as a biomarker is questionable given the strong association between renal ET-1 production and dietary salt intake. In hypertension, there have been reports of elevated urinary ET excretion compared with subjects who are normotensive, but this has not always been observed. There have been no real attempts to use urinary ET-1 as a predictor of hypertension-dependent renal injury.

The use of ET receptor antagonists for the treatment of human hypertension and other cardiovascular diseases has received considerable attention.[5] Most results would suggest that ET antagonists are effective at reducing blood pressure in systemic human hypertension. A phase III trial for resistant hypertension provided evidence that darusentan, an ET antagonist with fairly high selectivity for the ET_A receptor, may be effective at producing significant reductions in blood pressure even in subjects already taking at least three different drugs for hypertension including angiotensin converting enzyme inhibitors and angiotensin receptor blockers.[32] In a follow-up to this promising study, a similar effective blood pressure reduction was observed when measured by ambulatory methods; however, acute blood pressure measurements did not reach the efficacy end point and so the company decided to discontinue

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

its efforts to develop this drug.[2] At present, there do not seem to be any major efforts to develop ET antagonists for hypertension despite the clear evidence for ET involvement.

ET AND KIDNEY DISEASE

A role for ET in the pathogenesis of a wide range of organ failure diseases has received considerable attention including acute and chronic renal disease. Animal model studies first suggested that ET-1 contributes to reduced renal function after ischemia/reperfusion or administration of nephrotoxic agents.[8] Hypoxia and a wide range of inflammatory agents can stimulate ET-1 production and so targeting the ET system became the focus of many drug discovery efforts. Treatment with ET antagonists can attenuate development of renal failure and end organ damage in many of these models although most studies have used preventative protocols. These observations also are valid for models of chronic kidney disease such as 5/6 nephrectomy.[19] However, clinical trials were disappointing for reasons that are not clear. It is possible that the mechanistic pathways whereby ET-1 is stimulated are well established and difficult to reverse by the time therapy is initiated.

In recent years, there has been a series of very promising developments for the use of endothelin-receptor blockade in the treatment of proteinuric renal disease including diabetic nephropathy (Figure 4). A large multicenter trial showed that avosentan, a modestly selective ET_A antagonist, produced an average of 50% reduction in proteinuria in patients with diabetic nephropathy, the vast majority of whom were already taking ACE and ARB therapy.[33] However, this trial had to be stopped because of widespread development of edema in roughly 40% of the subjects enrolled. Kohan et al. used a more selective ET_A antagonist, atrasentan, at very low doses and observed similar reductions in proteinuria without the high degree of edema.[17]

The rationale for targeting proteinuria with an endothelin antagonist has also been supported by mechanistic animal model studies. In glomeruli isolated from streptozotocin-induced diabetic rats, Saleh et al. showed that *in vitro* treatment with an ET_A antagonist acutely reduces glomerular permeability to albumin.[27] These authors also showed that chronic treatment of STZ-diabetic rats reduces proteinuria and renal inflammation. In fact, increased glomerular permeability to albumin can be seen in rats given a chronic infusion of ET-1 for 2 weeks without the development of hypertension, an effect that can be reversed by ET_A antagonist treatment.[26] These studies suggest a direct, dynamic influence of ET-1 on glomerular permeability characteristics that seem to be related to direct effects on glomerular podocytes. This idea is further supported by studies in humans with nondiabetic proteinuric renal disease showing that acute administration of an ET_A antagonist reduces proteinuria within one hour.[7]

CONCLUSIONS

There is little question now that the renal endothelin system plays a critically important role in the control of fluid–electrolyte balance, and therefore, in blood pressure regulation. The localized action of the renal ET system explains how what has been considered the most potent vasoconstrictor can also produce vasodilation and facilitate the excretion of salt and water. Although human kidneys have similar ET-1 production and distribution of ET receptors, there have been no studies to determine the intrarenal actions of endogenous ET-1. In one study examining the influence of ET-1 infusion on renal function, however, the dose used produced a significant degree of renal vasoconstriction and reduced GFR, so any potential influence of ET_B receptors to promote natriuresis would have been prevented.[16] Clearly, the factors that regulate the production of ET-1, receptor expression,

and activity in the human kidney remain to be elucidated, especially in the setting of high dietary salt intake typical of the Western diet.

Chapter 201

Neurohypophyseal Peptides

Joseph G. Verbalis

ABSTRACT

The most prominent physiological function of the neurohypophyseal peptides vasopressin (VP) and oxytocin (OT) is maintenance of water homeostasis. The VP V2 receptor subtype (V2R) is responsible for VP-induced antidiuresis via changes in collecting duct water permeability. This process is initiated by V2R ligand binding in collecting duct principal cells, leading to increased intracellular cAMP levels and fusion of aquaporin-2 (AQP2)-containing intracytoplasmic vesicles with the apical plasma membranes of the principal cells, a process that increases water permeability by increasing the number of water-conducting pores in the apical membrane. Data in animals and man have implicated renal effects of OT in pathological antidiuresis, primarily via crossreactivity at V2R at high plasma OT concentrations. In contrast, the natriuretic effects of OT seem to occur at physiological plasma concentrations of OT and can be blocked by OT-specific antagonists, likely as a result of OT receptor (OTR)-ligand binding in the macula densa.

BRIEF HISTORY AND OVERVIEW OF THE NEUROHYPOPHYSEAL PEPTIDES

As described in the Brain Peptides section of this handbook, the neurohypophyseal hormones vasopressin (VP) and oxytocin (OT) are nonapeptides consisting of a 6-amino-acid ring with a cysteine to cysteine bridge, and a 3-amino-acid tail. Some forms of these nonapeptides have existed throughout the evolutionary species from amphibia and reptiles to birds and mammals, and in all species their most prominent physiological function is participation in the maintenance of water homeostasis (although the target organ may vary, from skin to bladder to kidney[2]). It is assumed that OT and VP derive from a single ancestral gene that is expressed in the lamprey and hag fish as only a single gene and hormone, vasotocin, which consists of a ring identical to oxytocin and a tail identical to vasopressin.[2] All mammals synthesize and secrete both OT and arginine VP with the exception of the pig; in the pig a lysine is substituted for arginine in position 8 of vasopressin, producing lysine VP.

Similar to other peptide hormones, VP is synthesized as part of a prohormone, including a midmolecule neurophysin and a carboxy-terminal glycopeptide, named *copeptin*. For OT, the peptide products are the nonapeptide and a neurophysin but not glycopeptide. At the physiologic pH of plasma, there is no binding of either OT or AVP to their respective neurophysins, so each peptide circulates independently in the blood stream. Although each neurophysin and copeptin circulate in plasma, no biological functions have ever been demonstrated for these peptides. Therefore, this chapter will focus exclusively on the actions of VP and OT in the kidney; effects at other organs, and specifically the reproductive functions of OT and the vascular and metabolic actions of VP, are covered elsewhere in this handbook.

BODY FLUID HOMEOSTASIS

Because the most important homeostatic function of VP is the maintenance of normal body water stores, the renal effects of VP that serve to accomplish this function can best be appreciated and understood within the context of the overall body mechanisms that regulate body fluid homeostasis. The maintenance of normal water balance in humans is achieved principally through an integration of thirst, VP secretion, and renal responsiveness to VP. Plasma osmolality is maintained within narrow limits by osmotically regulated VP secretion and thirst. Despite large variations of water intake, the osmolality of body fluids in healthy individuals is maintained within a relatively narrow range (275–295 mOsm/kg H_2O). To maintain plasma osmolality at such a constant level, VP secretion must vary in response to relatively small changes in plasma osmolality, which is achieved through the activation of the osmoreceptors located in the anterior hypothalamus.

The primary stimulus for VP release is an increase in plasma osmolality. There are individual variations in the osmotic threshold, or set point, for VP release, probably reflecting variations in the sensitivity of individual

osmoreceptor cells. At all plasma osmolalities below this set point, plasma VP is suppressed to low or undetectable levels. Above this set point, secretion of the hormone increases in direct proportion to the increasing plasma osmolality. Therefore, with plasma hypoosomolality, VP is suppressed and urine osmolality is maximally dilute (*diuresis*), while with plasma hyperosmolality, VP levels increase and the urine is progressively more concentrated (*antidiuresis*). The sensitivity of this response can be appreciated by noting that an increase in plasma osmolality of only 1% leads to an increase in plasma VP of 0.4–0.8 pg/mL, a concentration sufficient to significantly increase urinary concentration and decrease urine flow, whereas maximum antidiuresis occurs at a plasma VP concentration of only 5 pg/mL.[27] In general, the osmotic threshold for thirst is approximately 5–10 mOsm/kg H_2O above that for VP release. This allows the kidney to primarily regulate body water homeostasis in response to very small changes in plasma osmolality, whereas thirst is only activated by larger and more threatening osmotic perturbations to maintain total fluid balance by the ingestion of additional fluid.

In addition to changes in plasma osmolality, VP secretion is also stimulated by hypotension and volume depletion, mediated largely by baroreceptors located in the cardiac atria and large arteries. By contrast to the extremely sensitive osmotic regulation of VP secretion, a reduction in effective circulating volume of approximately 10–15% is required before a significant VP response occurs. VP is also released in response to other nonosmotic stimuli such as nausea, pain, hypoxia, hypercapnia, hypoglycemia, physical exercise, and various medications. Although nonosmotic secretion of VP is not involved with normal body fluid homeostasis, such secretion is of importance because the renal effects of VP are the same regardless of the stimulus that caused secretion of the hormone, leading to potential disturbances in water homeostasis from inappropriate antidiuresis.[4]

VASOPRESSIN AND OXYTOCIN RECEPTORS

Three known receptor subtypes mediate the peripheral actions of VP. They are classified according to the second messenger system to which they are coupled. The vasopressin V1a (V1aR) and V1b (V1bR) receptors are linked to the phosphoinositol signaling pathway, with intracellular calcium acting as the second messenger. In contrast, the vasopressin V2 receptors (V2R) are linked to the adenylate cyclase signaling pathway with intracellular cAMP acting as the second messenger.[33] The V1aR subtype is ubiquitous and is present on vascular smooth muscle cells, hepatocytes, and platelets where it mediates vascular constriction, glycogenolysis, and platelet aggregation, respectively. V1aR also seems to be the major AVP receptor subtype found within the brain, where it presumably mediates central effects of this peptide. The V1bR subtype is found predominately in the anterior pituitary, where it mediates adrenocorticotropin release in concert with corticotropin releasing hormone. The V2R subtype is present predominately in the kidney, where it mediates free water reabsorption. In addition, there is now evidence indicating the presence of extrarenal V2R in the endothelium that are involved in the secretion of von Willebrand factor and factor VIIIc.[17] In contrast to vasopressin, only one oxytocin receptor (OTR) has been identified. Similar to the V1aR and V1bR, the OTR is coupled to the phosphoinositol signaling pathway, with intracellular calcium acting as the second messenger.[13] The OTR subtype is present predominantly in breast and uterine tissue, with lesser expression in the brain, kidney, and heart.[13]

LOCALIZATION OF VASOPRESSIN AND OXYTOCIN RECEPTORS IN THE KIDNEY

V2R Expression

V2R is the predominant neurohypophyseal receptor expressed in the kidney, apropos its crucial role in the urinary concentrating process. Prominent expression has been found by autoradiography,[19] immunohistochemistry,[12] and receptor mRNA expression[21] throughout all portions of the collecting duct (cortical, outer, and inner medullary), the connecting segment, the distal convoluted tubule, and the thick ascending limb of the loop of Henle.

V1aR Expression

High levels of V1aR expression have also been found in the renal medulla by autoradiography,[31] Western analysis,[24] and receptor mRNA in situ hybridization histochemistry.[21] However, in contrast to the V2R, the V1aR is localized predominantly among the medullary interstitial cells and vascular elements of the vasa recta rather than the collecting ducts; sparser labeling is found in the renal cortex, but not in the glomeruli.

OTR Expression

In the adult rat, OTR expression by receptor autoradiography occurs predominantly in the macula densa cells of the juxtaglomerular apparatus, with a lesser degree of expression in the medulla on the loops of Henle of juxtamedullary nephrons.[30] The cortical OT binding sites express higher selectivity for OT than AVP compared with the medullary sites, which may be due to binding of OT to medullary V2R. Estrogen treatment of ovariectomized rats induced OTR mRNA expression in the outer stripe of the outer medulla and increased expression in macula densa cells.[22] The induction of outer stripe OTR mRNA expression by

estradiol was blocked by the antiestrogen, tamoxifen, but was not significantly affected by high levels of circulating oxytocin.[22]

RENAL EFFECTS OF VASOPRESSIN

The primary renal response to increased circulating VP is an increase in water permeability of the kidney collecting tubules, leading to antidiuresis. Although an increase in solute reabsorption (primarily urea, but also sodium) occurs as well, the total solute reabsorption is proportionally much less than water. Consequently, a decrease in urine flow and an increase in urine osmolality occur as secondary responses to the increased net water reabsorption. With refinement of radioimmunoassays for VP, the unique sensitivity of this hormone to small changes in osmolality, as well as the corresponding sensitivity of the kidney to small changes in plasma VP concentrations, have become apparent.[27] Although some debate still exists with regard to the exact pattern of osmotically stimulated AVP secretion, most studies to date have supported the concept of a discrete *osmotic threshold for VP secretion* above which a linear relationship between plasma osmolality and VP concentrations occurs. The slope of the regression line relating VP to plasma osmolality can vary significantly across individual human subjects, in part because of genetic factors. In general, each 1 mOsm/kg H_2O increase in plasma osmolality causes an increase in plasma VP from 0.4 to 0.8 pg/ml. The renal response to circulating VP is similarly linear, with urinary concentration that is directly proportional to VP levels from 0.5 to 4–5 pg/ml, after which urinary osmolality is maximal and cannot increase further despite additional increases in VP levels. Thus, changes of ≥1% in plasma osmolality are sufficient to cause significant increases in plasma VP levels with proportional increases in urine concentration, and maximal antidiuresis is achieved after increases in plasma osmolality of only 5–10 mOsm/kg H_2O (2–4%) above the threshold for VP secretion.

However, even this analysis underestimates the sensitivity of this system to regulate free water excretion for the following reason: Urinary osmolality is directly proportional to plasma VP levels as a consequence of the fall in urine flow induced by the VP, but urine volume is inversely related to urine osmolality. Thus, an increase in plasma VP concentration from 0.5 to 2 pg/ml has a much greater relative effect to decrease urine flow than does a subsequent increase in VP concentration from 2 to 5 pg/ml, thereby further magnifying the physiological effects of small initial changes in plasma VP levels [28] (Fig. 1). The net result of these relations is a finely tuned regulatory system that adjusts the rate of free water excretion accurately to the ambient plasma osmolality via small changes in pituitary VP secretion. Further, the rapid response of pituitary VP secretion to changes in plasma osmolality coupled with the short half-life of VP in human plasma (10–20 minutes) enables this regulatory system to adjust the renal water excretion to changes in plasma osmolality on a minute-to-minute basis.

Over the last decade, the cellular mechanisms responsible for this exquisitely sensitive mechanism for renal water conservation have been elucidated after identification of the aquaporin family of water channels by Agre et al.[7] Renal concentrating ability is determined primarily by proximal water reabsorption, the corticopapillary osmotic gradient, and VP-mediated changes in collecting duct water permeability, all of which involve molecular water channels of the aquaporin family. Four major aquaporin water channels are expressed in the renal tubules.[18] Aquaporin-1 (AQP1) is primarily responsible for the high constitutive water permeability of the proximal tubules and thin descending limbs of the loop of Henle. Aquaporin-3 (AQP3) and aquaporin-4 (AQP4) are expressed in the basolateral membrane of collecting duct principal cells, and confer this epithelial membrane with high water permeability. The most unique water channel is aquaporin-2 (AQP2), which is expressed exclusively in renal collecting duct principal cells and whose activity is largely regulated by VP. VP induces changes in collecting duct water permeability via both short-term and long-term effects that regulate renal aquaporin synthesis and function.[18]

Short-term regulation of renal aquaporins is associated with increases in water permeability within a few minutes of VP exposure, an effect that is rapidly reversible. VP triggers this response by binding to the V2R in the collecting duct principal cells and increasing intracellular cAMP levels by activating adenylyl cyclase. The increase in collecting duct water permeability is a consequence of fusion of AQP2-containing intracytoplasmic vesicles with the apical plasma membranes of the principal cells, a process that increases apical water permeability by markedly increasing the number of water-conducting pores in the apical plasma membrane.[18] Dissociation of VP from the V2R allows intracellular cAMP levels to decrease, and the water channels are reinternalized into the intracytoplasmic vesicles thereby terminating the increased water permeability. By virtue of the subapical membrane localization of the AQP2-containing vesicles, they can be quickly "shuttled" into and out of the membrane in response to changes in intracellular cAMP levels. This mechanism therefore allows minute-to-minute regulation of renal water excretion through changes in ambient plasma VP concentrations. Long-term regulation of collecting duct water permeability represents a sustained increase in collecting duct water permeability in response to prolonged high levels of circulating VP. This response requires at least 24 hours to elicit and is not as rapidly reversible. This conditioning effect results largely from the ability of vasopressin to induce large increases in the abundance of AQP2 and AQP3 water channels in the collecting duct

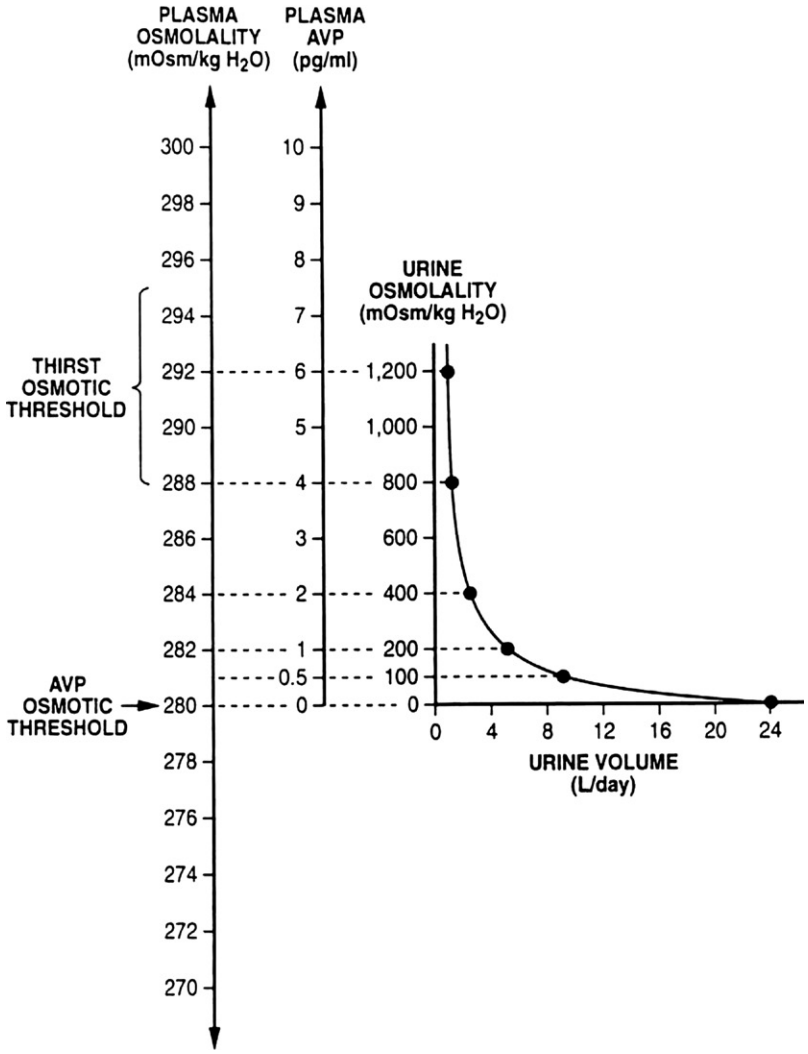

FIGURE 1 Relationship of plasma osmolality, plasma AVP concentrations, urine osmolality, and urine volume in humans. Note that the osmotic threshold for AVP secretion defines the point at which urine concentration begins to increase, but the osmotic threshold for thirst is significantly higher and approximates the point at which maximal urine concentration has already been achieved. Note also that because of the inverse relation between urine osmolality and urine volume, changes in plasma AVP concentrations have much larger effects on urine volume at low plasma AVP concentrations than at high plasma AVP concentrations.

principal cells.[9] Greater total expression of the number of AQP2 and AQP3 water channels, when combined with the short-term effect of vasopressin to shift AQP2 into the apical plasma membrane, allows the collecting ducts to achieve higher water permeabilities during conditions of prolonged dehydration, thereby further enhancing urine concentrating capacity in response to equivalent levels of VP.

In addition to these effects on water permeability of the collecting duct cells to regulate the degree of antidiuresis in response to plasma VP levels, VP also acts to enhance the other major factor regulating renal concentrating ability, namely, establishment and maintenance of the corticopapillary osmotic gradient that is the determinant of maximal urine concentration. VP-dependent reabsorption of sodium into the renal interstitium in the thick ascending limb of the loop of Henle loop is regulated by the V2R in this region of the nephron via upregulation of the Na–K-2Cl cotransporter expression in the outer medulla,[16] and also V2R-mediated increased expression of the epithelial sodium channel (ENaC) in the distal convoluted tubule.[3] Similarly, VP causes increased expression of the UT-A1 urea transporter in rats, either directly or indirectly via effects at V2R in the inner medulla of the kidney.[29] Thus, each of these factors in addition to AQP2 regulation can contribute to the achievement of maximal urinary concentration in response to chronic VP stimulation via long-term upregulation of the countercurrent multiplication system that is responsible for the generation of the corticopapillary osmotic gradient.

In contrast to the well-understood effects of VP acting at V2R receptors in the kidney, much less is understood about the effects of the V1aR that are also clearly expressed in the kidney. Early studies suggested that V1aR acted at the collecting duct principal cells to antagonize the V2R effects of VP by virtue of increasing intracellular Ca^{2+} by phosphoinositide hydrolysis[5] and/or stimulating synthesis and release of prostaglandins such as PGE_2 and nitric oxide. However, subsequent results have implicated V2R in many of these effects,[10,15] and although some *in vitro* studies have suggested the presence of functional V1aR activity in isolated collecting tubules, no studies to date have conclusively shown expression of V1aR in collecting duct principal cells. Alternatively, in view of the localization of V1aR in the renal cortical and medullary microcirculation combined with results indicating that VP reduces renal medullary blood flow,[8] it is reasonable to postulate an intrarenal hemodynamic effect for VP actions at kidney V1aR. Studies using reverse transcription-polymerase chain reaction and Western blot analyses confirm that V1aR mRNA and protein, but not V2R mRNA and protein, are present in isolated cortical and medullary vasculature.[24] Thus, VP effects at V1aR are probably responsible for the vasoconstrictor actions on renal medullary blood flow.[8]

The physiological ramifications of this effect are multiple, but it has been suggested that regulation of the descending vasa recta microcirculation is a determinant of Na^+ and water excretion, and possibly also the development of hypertension.[8,23] Results support the idea that regulation of descending vasa recta blood flow occurs via the actions of multiple vasoactive substances on the contractile pericytes surrounding these vessels.[23] Substances known to reduce descending vasa recta blood flow via vasoconstriction include angiotensin II, vasopressin, endothelins, norepinephrine, acetylcholine, and adenosine (via adenosine A1R); substances known to increase descending vasa recta blood flow through vasodilatation include nitric oxide, prostaglandin E_2, bradykinin, acetylcholine, and adenosine (via adenosine A2R).[23] The complexity of this regulation is illustrated by the observation that some stimuli activate opposing systems. For example, both angiotensin II and VP have been shown to stimulate nitric oxide production in the kidney,[20,25] which may serve to counterbalance the otherwise unopposed vasoconstrictive effects of these hormones. Decreases in vasa recta blood flow would have the effect of maximizing the corticopapillary concentration gradient, whereas increases in vasa recta flow would enhance a washout of the solutes that establish this gradient. Thus, VP acting at V1aR in the vasa recta and/or the intramedullary pericytes would complement the effects of VP acting at V2R in the nephron to produce maximally concentrated urine by limiting blood flow into the inner medulla.

RENAL EFFECTS OF OXYTOCIN

Because OT has been associated primarily with reproductive functions, studies of the renal effects of OT have been much more limited. However, abundant results in animals and man have implicated renal effects of OT in pathological antidiuresis, and in rats in physiological natriuresis.

Antidiuretic effects of OT were first suggested by cases of hyponatremia in females infused with OT for induction of labor or induced abortion. Studies of OT infusion to normal subjects confirmed the antidiuretic effects of OT infusions,[1] and other studies suggested an antidiuretic potency of OT approximately 1/200 that of VP. Subsequent studies in Brattleboro rats indicated that the limited urinary concentrating abilities in this animal with genetic absence of VP synthesis result from OT effects in the kidney.[11] Early studies did not differentiate whether these effects on urinary concentration resulted from the effects of OT at the OTR, or from crossreactivity of OT at V2R. Subsequent *in vitro* studies using isolated collecting ducts from rats indicate that the antidiuretic effects of OT could be blocked by administration of V2R-specific antagonists, consistent with OT crossreactivity at V2R to explain the antidiuretic effects of high concentrations of plasma OT.[6]

In contrast to the antidiuretic effects of OT, the natriuretic effects of this peptide seem to occur at physiological concentrations of plasma OT,[34] and are blocked by OT-specific antagonists.[35] Initial studies suggested that OT-induced natriuresis may result from stimulation of atrial natriuretic peptide (ANP) secretion form the cardiac atria.[14] However, subsequent studies have indicated that the natriuresis produced by low doses of OT involves a nitric oxide mechanism, unlike ANP-induced natriuresis, and therefore probably represents a direct effect of OT at the OTR on cells of the macula densa,[32] presumably by altering the set point of glomerular–tubular feedback mechanism. However, similar natriuretic effects have not been observed in human studies, suggesting that this represents a species-specific effect of OT.[1,26]

Chapter 202

Peptides, Sex, Diabetes, and the Kidney

Michaele B. Manigrasso and Christine Maric-Bilkan

ABSTRACT

Diabetic nephropathy is characterized by a complex interaction between metabolic and hemodynamic factors that activate common second messenger signaling pathways leading to the production of several locally active growth factors and peptides that contribute to the development of renal injury. Unlike nondiabetic renal diseases that predominantly affect men, diabetic renal disease affects women and men similarly. This loss of the female sex as a protective factor against renal disease in the setting of diabetes has been attributed to the reduction in estrogen levels. Further, men with diabetes also exhibit an imbalance in sex hormone levels, mainly characterized by the loss of testosterone. Experimental studies have shown that estrogens and androgens, via interacting with locally active peptides, such as angiotensin II, contribute to the development and progression of renal disease. These observations show that estrogens and androgens have a role beyond reproduction and are important contributors to diabetic nephropathy.

INTRODUCTION

Diabetes is the leading cause of end-stage renal disease (ESRD) in the Western world and is associated with increased cardiovascular risk, high morbidity, and mortality.[30] With the increasing prevalence of diabetes mellitus worldwide, the prevalence of ESRD is also likely to steadily increase despite the advancements in the clinical management and treatment of the disease. Thus, ESRD resulting from diabetes, that is, diabetic nephropathy, remains a significant economic and health burden.

Diabetic nephropathy is characterized by a complex interaction between metabolic and hemodynamic factors that activate common second messenger signaling pathways leading to the production of a number of locally active growth factors and peptides that contribute to the development of renal injury. One of the most important vascoative peptides, and certainly the most studied in the context of diabetic nephropathy is angiotensin II (Ang II). However, other peptides and growth factors, such as endothelin, also play an important role in the development and progression of diabetic renal injury. This review will focus on the contribution of these peptides, especially via their interaction with estrogens and androgens in mediating cellular processes that contribute to diabetic nephropathy.

Although ESRD affects both men and women, there is an intriguing gender disparity in the prevalence of ESRD with respect to its cause. Specifically, the incidence of ESRD resulting from causes other than diabetes (e.g., hypertension) is significantly lower in premenopausal women compared with that in age-matched men.[24] After the onset of menopause, this gender disparity is largely diminished and the incidence of ESRD due to hypertension dramatically increases in women. These observations lead to the belief that it is the loss of estrogens associated with menopause that contributes to this increase in the incidence of ESRD in postmenopausal women. But in contrast to ESRD resulting from hypertension in which premenopausal women are relatively protected, women with either type 1 or type 2 diabetes are just as likely to develop ESRD as men regardless of their age and menopausal status.[26] Studies from this and other laboratories have gone on to show that women with type 1 or type 2 diabetes are characterized by reduced levels of circulating estradiol,[20] which could possibly explain why women with diabetes seem to be less protected from developing renal disease compared with nondiabetic women. Experimental studies using rodent models of diabetic renal disease have shown that treatment with 17-β estradiol (E_2) attenuates the disease development and progression,[21] suggesting that estrogens may regulate biological processes that are adversely regulated and contribute to diabetic renal disease. Indeed, several studies have examined some of the mechanisms by which estrogens may regulate cell proliferation, apoptosis, and extracellular matrix (ECM) metabolism,[10] all of which are important contributors to diabetic renal disease. Further, studies have shown that estrogens exert their actions in the kidney by interacting with the locally active vasoactive peptides, including Ang II.[19]

Similar to women, men with either type 1 or type 2 diabetes exhibit an imbalance in sex hormones levels, in particular low testosterone, which correlates with the decline in renal function.[22] Experimental studies have shown that supplementation with testosterone, to levels of those observed in nondiabetic animals, protects the kidney.[34] Specifically, testosterone obviates ECM metabolism and promotes apoptosis in the diabetic kidney contributing to the development of glomerulosclerosis and tubulointerstitial fibrosis.[11] Similar to estrogens, studies show that the effects of testosterone are mediated via interaction with vasoactive peptides such as Ang II and endothelin.[19] This review will summarize our current understanding of the contribution of sex hormones, both estrogens and androgens, via their interaction with locally active peptides and growth factors, in the pathophysiology of diabetic nephropathy.

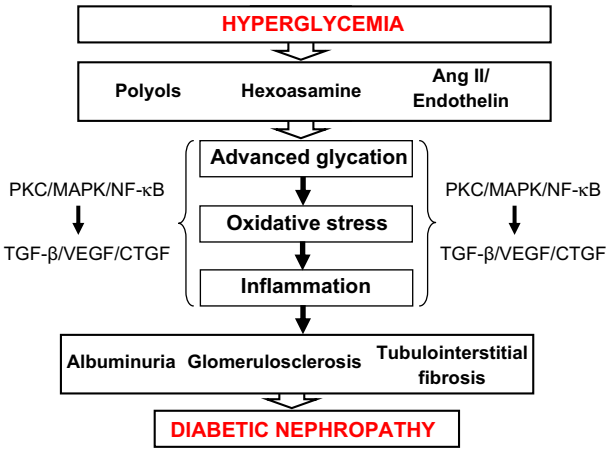

FIGURE 1 Interaction between vasoactive peptides, estrogens, and androgens in modulating metabolic and hemodynamic pathways in the pathophysiology of diabetic nephropathy.

ETIOLOGY OF DIABETIC NEPHROPATHY

Diabetic nephropathy is manifested clinically in a sequence of stages beginning with initial glomerular hyperfiltration, glomerular hypertrophy, and microalbuminuria. Elevated mean arterial pressure (MAP), which is common in patients with diabetic nephropathy, further exacerbates the disease progression to proteinuria, nodular glomerulosclerosis and tubulointerstitial injury and a decline in glomerular filtration rate (GFR), eventually leading to ESRD.[30]

Diabetic nephropathy develops as a result of an interaction between several metabolic and hemodynamic factors. These factors all activate common intracellular signaling pathways which, in turn, trigger the production of numerous growth factors, peptides and cytokines that contribute to the development of renal injury. In particular, chronic hyperglycemia, which is characteristic of diabetes mellitus, activates nonenzymatic glycation and oxidative stress, polyol pathway, and hexosamine flux.[6] Chronic hyperglycemia also dysregulates renal hemodynamics via activating a number of vasoactive peptides including members of the renin–angiotensin system (RAS) and endothelin.[15] These vasoactive peptides then activate common second messenger signaling pathways including protein kinase C (PKC) and MAP kinase (MAPK), and transcription factors such as nuclear factor-κB (NF-κB). These second messenger pathways are involved in regulating the expression of genes of a number of growth factors and cytokines including transforming growth factor-beta (TGF-β), vascular endothelial growth factor (VEGF), connective tissue growth factor (CTGF), etc., all of which have been implicated in the development of albuminuria, glomerulosclerosis, and tubulointerstitial fibrosis associated with diabetic nephropathy.[4] This complex interaction between metabolic and hemodynamic pathways in the etiology of diabetic nephropathy is summarized in Figure 1.

PEPTIDE REGULATION OF RENAL FUNCTION IN THE DIABETIC KIDNEY

The Role of the Ang II in Diabetic Nephropathy

The initial understanding of the role of the RAS in the pathophysiology of diabetic nephropathy was complicated by the observation that circulating levels of Ang II, one of the main effector molecules of the RAS, were unaltered in both type 1 and type 2 diabetes.[33] However, angiotensin-converting enzyme (ACE) inhibitors (which inhibit the conversion of ANG I into the biologically active peptide Ang II) such as enalapril and lisinopril, clearly offer renoprotection in both experimental models of diabetic nephropathy and in humans.[28] After the discovery of specific tissue RASs, including the kidney, it was clear that despite no differences in circulating Ang II concentrations, the renal Ang II levels are elevated in the setting of diabetes[18] and that blocking its formation may be an effective treatment of diabetic nephropathy. Until about a decade ago, most of the known biological actions of Ang II were believed to be mediated via the Ang II AT_1 receptor subtype. Thus, in addition to ACE inhibition, AT_1 receptor subtype blockade (ARB) has become a common and effective treatment for diabetic nephropathy. Further, in recent years, both clinical trials and experimental studies have reported the superiority of the combination therapy of ACE inhibition and ARB over either treatment alone in diabetic nephropathy.[23]

As indicated above, for decades, the AT_1 receptor subtype has been believed to mediate most, if not all, of the known

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

biological effects of Ang II, despite the observation that another receptor, namely, AT_2, has also been identified. However, in the past 15 years, emerging evidence suggests that the AT_2 receptor has just as important role in the diabetic kidney as does the AT_1 receptor. It is now believed that the AT_1 and AT_2 receptors mediate opposing effects of Ang II in the kidney. Specifically, activation of AT_1 receptors leads to renal vasoconstriction, sodium retention, cell proliferation, and ECM synthesis,[35] whereas activation of AT_2 receptors leads to vasodilatation, natriuresis, and inhibition of cell proliferation.[14] Other actions of Ang II in the diabetic kidney include stimulation of differentiation and proliferation of monocytes and macrophages via increasing monocyte chemoattractant protein-1 (MCP-1), ostepontin, and RANTES expression. These actions of Ang II have mainly been attributed to stimulation of a number of profibrotic cytokines such as TGF-β, VEGF and CTGF as well as activation of downstream signaling pathways involving PKC and NF-κB leading to the development of glomerulosclerosis and tubulointerstitial fibrosis.[13]

The Role of the Endothelin in Diabetic Nephropathy

Several studies show that the endothelin system is important in the pathophysiology of chronic kidney disease, including diabetes, and that endothelin levels correlate with serum creatinine and the degree of albuminuria in patients with diabetic nephropathy. Multiple factors have been reported to increase renal endothelin-1 levels, including cytokines, growth factors, and sex hormones.[3] As discussed in other chapters of this book, endothelins are potent vasoconstrictors with proinflammatory, promitogenic, and profibrotic properties in many target organs, including the kidney. In the context of diabetic nephropathy, most of the biological actions of endothelins are mediated by endothelin-1, which exerts its renal actions through its two receptor subtypes, the ET_A and ET_B. Studies show that selective ET_A receptor antagonists and combined ET_A/ET_B receptor antagonists attenuate hypertension, renal vasoconstriction, inflammation, proteinuria, glomerulosclerosis, and tubulointerstitial fibrosis in experimental models of diabetic nephropathy.[9] Although hyperglycemia-associated inflammation and fibrosis are mediated via both ET_A and ET_B receptors, vasoconstrictor actions of endothelin-1 seem to be mediated via ET_A receptors. In addition to increased synthesis of the ligand itself, diabetic nephropathy is associated with increased ET_A receptor expression. Some of the actions of endothelin-1 in the diabetic kidney include promoting ECM matrix protein synthesis involving the MAPK and PKC signaling pathways, mesangial cell proliferation, constriction of cortical and medulary vessels, and inhibition of sodium and water reabsorption.[25] Collectively, these observations suggest that inhibiting the expression and actions of endothelins may be a beneficial treatment of diabetic nephropathy.

ESTROGEN–PEPTIDE INTERACTIONS IN THE DIABETIC KIDNEY

Although estrogen is generally thought of in the context of reproduction, studies, especially in the past several years, have shown that estrogens play an important role in mediating biological functions beyond that of the reproductive system. With respect to the kidney, several studies show that estrogens, E_2 in particular, modulate cellular processes that are involved in the pathophysiology of diabetic nephropathy. Experimental studies using the streptozotocin (STZ)-induced diabetic rat show that E_2 attenuates glomerulosclerosis and tubulointerstitial fibrosis via reducing collagen type I and type IV synthesis, increasing expression of matrix metalloproteinases (MMPs), and by inhibiting apoptosis of mesangial cells and podocytes involving the PI3 K-AKT signaling cascade.[12] Further, E_2 decreases the expression of growth factors and cytokines, such as TGF-β, VEGF, and CTGF, all of which stimulate abnormal cell growth, ECM metabolism and contribute to vascular dysfunction associated with renal disease. At least in the kidney, all of these functions have mainly been ascribed to activation of the estrogen ERα receptor. Until recently, all the biological effects of estrogens have been thought to be mediated via binding to the classical estrogen nuclear ERα and ERβ receptors. More recently, a novel seven-transmembrane, G-protein-coupled estrogen receptor (GPR30) has been identified;[31] however, the importance of activation of the GPR30 receptor by estrogens in the kidney is currently unclear.

Estrogens tonically downregulate renal AT_1R in the Dahl salt-sensitive rat kidney,[16] increase the expression of renal AT_2Rs,[2] and reduce renal ACE and Ang II levels.[5] Studies in the rats containing the mouse DBA/Ren-2 transgene show that E_2 attenuates the hypertensive response to infusion with Ang II via shifting the vasoconstrictor/vasodilator balance.[5] These effects add to the protective effects of estrogens via suppressing the activity of the renal RAS. Although the direct interaction between estrogens and the RAS in the pathophysiology of diabetic nephropathy has not been fully explored, studies suggest that ACE inhibition in women with type 1 diabetes is associated not only with the decline in blood pressure, but also a reduction in GFR. Further, the renal blood flow responses to Ang II infusion are negatively correlated with estrogen levels, with the higher levels predicting a blunted response.[8] These observations support the notion that estrogens may regulate renal function both directly and via modulating the expression and activity of the RAS. Figure 2 summarizes the known interactions between estrogens and

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

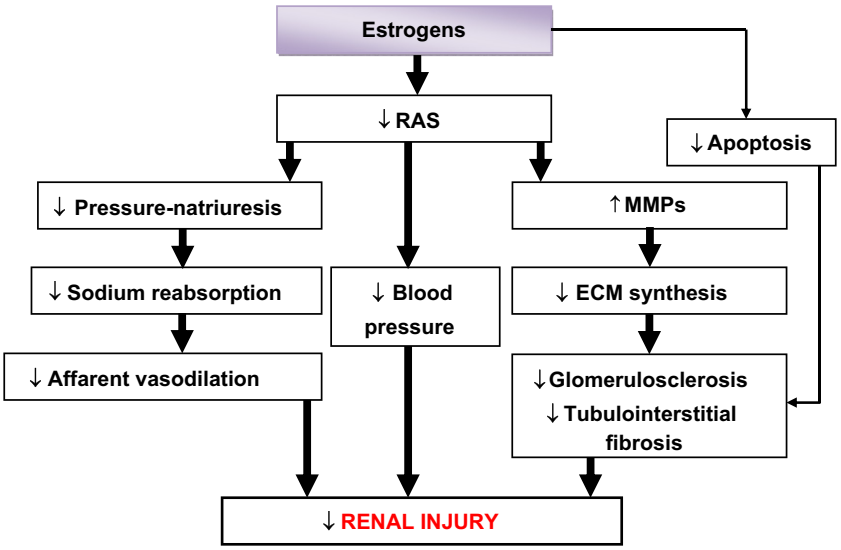

FIGURE 2 Interaction between estrogens and the RAS in modulating metabolic and hemodynamic pathways in the pathophysiology of nondiabetic and diabetic renal injury.

the RAS in the kidney: please note that the current data indicate that the effects of estrogens in the nondiabetic and diabetic kidney are similar.

There is a growing body of evidence suggesting that metabolites of E_2, such as 2-methoxyestradiol (2-ME) and 2-hydroxyestradiol (2-OHE), mediate the beneficial effects of E_2 but without the feminizing side effects. Treatment with 2-OHE attenuates proteinuria in chronic puromycin aminonucleoside nephropathy[32] and attenuates the development of obesity, metabolic syndrome, and vascular and renal dysfunction in obese ZSF1 rats. In mesangial cells, 2-ME and 2-OHE inhibit mitogenesis and ECM synthesis via estrogen-receptor-independent mechanisms. However, no study to date has examined the effects of 2-OHE in diabetic nephropathy and the mechanisms of their action in the diabetic kidney remain largely unexplored. Preliminary data from our laboratory show that 2-OHE is renoprotective in an experimental model of hypertension-accelerated diabetic nephropathy via reducing albuminuria and tubulointerstitial fibrosis (unpublished observations). Further, we have evidence to show that these effects of 2-OHE in the diabetic kidney may be mediated via regulation of the expression of the components of the RAS (unpublished observations); however, further studies are needed to fully understand the importance of the interaction between estrogen metabolites and the RAS in the pathophysiology of diabetic nephropathy.

Collectively, these studies clearly indicate that estrogens have a beneficial effect in the kidney; however, it should be pointed out that all these described effects of estrogens are observed only in the females. Although no study to date has examined the effect of estrogens in the male diabetic kidney, there is reason to believe that these effects may differ in the two sexes, but why? As mentioned above, diabetes is associated with an imbalance in sex hormone levels. Specifically, in the females, diabetes is characterized by decreased estrogen levels alongside increased testosterone levels. In contrast, in the males, diabetes is associated with decreased testosterone and increased circulating estradiol levels. Thus, it seems that in the females, the loss of estrogen may contribute to the loss of the female sex as a protective factor against renal disease and that estrogen supplementation is renoprotective. However, given that estrogen levels are elevated in males with diabetes, it is conceivable that, in the males, estrogens may contribute to the development and progression of diabetic nephropathy. Indeed, experimental studies from our laboratory show that inhibition of estrogen synthesis in diabetic males may be renoprotective, suggesting that estrogens may promote renal injury in the setting of diabetes. Future studies are warranted to fully examine the renal effects of estrogens in both males and females with diabetic renal disease.

ANDROGEN–PEPTIDE INTERACTIONS IN THE DIABETIC KIDNEY

Similar to estrogens, the actions of testosterone are best understood in the context of reproduction; however, studies over the past decade have shown that these classic actions of testosterone may be involved in modulating functions in peripheral organs, including the kidney. It is well known that testosterone provides a negative biofeedback mechanism on the hypothamlamus-pituitary axis to inhibit gonadotropin secretion. Other pituitary hormones such as growth hormone (GH) and insulin-like growth factor-I (IGF-I) may promote diabetic renal disease. Studies have

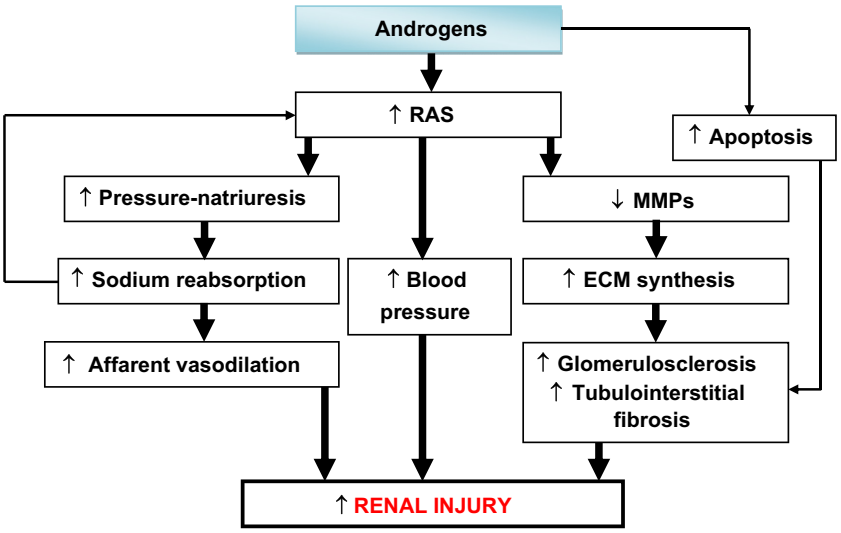

FIGURE 3 Interaction between androgens and the RAS in modulating metabolic and hemodynamic pathways in the pathophysiology of nondiabetic renal injury.

shown that there is a direct correlation between GH and IGF-I activity and an increase in renal hypertrophy and glomerulosclerosis in experimental models of diabetic renal disease.[7] The peak in testosterone, GH and IGF-I levels during puberty suggests that these hormones may promote the development of diabetic renal disease, as diabetic end-organ complications, including diabetic nephropathy, rarely develop before puberty. Therefore, alterations observed in sex hormone levels that occur with puberty may be a contributing factor to the onset and increased rate of progression of diabetic nephropathy. Corroborating this evidence is the observation that GH concentrations are elevated in adolescents with type 1 diabetes compared with that of healthy non-diabetic individuals and there is a correlation between GH and microalbuminuria along with decreased GFR.[27] In contrast to plasma levels of IGH-I, which are elevated in diabetic patients, renal levels of IGF-I are decreased, suggesting that local production and biological metabolism of IGF-I may possibly be more important in determining the renal effects of this peptide.

The effects of testosterone in the kidney are best understood in the context of blood pressure regulation. It has been documented that androgens can directly stimulate the expression and activity of the components of the renal RAS in experimental models of hypertension, leading to increases in blood pressure and sodium retention. Namely, plasma renin activity is lowered after castration in the male spontaneously hypertensive (SHR) rat and elevated in ovariectomized SHR females after supplementation with testosterone.[29] Similarly, renal angiotensinogen mRNA levels decrease after castration and increase after supplementation with exogenous testosterone, suggesting androgens also directly regulate angiotensinogen levels. Further, this increase in angiotensinogen substrate may partially explain the increase in renin observed in males. In the hypertensive mRen(2) Lewis rat, ACE activity is higher in males than in females and androgens increase ACE activity. Treatment with an ACE inhibitor, enalapril, reduces blood pressure in SHR male and testosterone-supplemented ovariectomized females, supporting the notion that androgens play a role in the development of hypertension by stimulating RAS expression and activity. Although the exact mechanisms underlying androgen-driven hypertension are not completely understood, the currently accepted hypothesis is that testosterone causes a rightward shift in the pressure-natriuresis curve via enhancing proximal tubular reabsorption leading to decreased sodium delivery to the macula densa. This consequently stimulates renin release and tubuloglomerular feedback-mediated afferent vasodilation, which, in combination with the increase in arterial pressure, results in glomerular hypertension and renal injury. With respect to the interaction between androgens and the RAS in the context of diabetic nephropathy, very few studies have examined this relationship either in experimental models or humans (Fig. 3). What is known is that ACE inhibition in men with type 1 diabetes reduces arterial pressure, but only females show a reduction in GFR.[8] This suggests that ACE inhibition is more effective in reducing renal injury associated with early diabetes in women than men, possibly because of the testosterone-stimulated increase in other components of the RAS. Clinical trials examining the efficacy of inhibitors of the RAS in patients with diabetic nephropathy have yielded conflicting findings with respect to the differences in men and women, with some studies showing that ARBs and ACE inhibitors are more effective in females while others reporting the opposite. However, very few studies

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

have examined the direct interaction between the inhibitors of the RAS and sex hormones in diabetic nephropathy, and drawing any conclusions from these observations would be risky. Thus, the summary of the known interactions between androgens and the RAS depicted in Figure 3 only applies to the nondiabetic kidney.

In addition to the interactions between androgens and the RAS, testosterone inhibits endothelial production and vasodilator action of nitric oxide in obese fa/fa Zucker diabetic rats [1] and enhances the platelet aggregation and the TXA2-endothelin-1 receptor crosstalk in this experimental model of type 2 diabetes.[1] Further, endogenous androgens regulate the systemic and renal microvascular response to endothelin-1. In addition to growth factors and sex hormones, insulin also stimulates both the production and action of endothelin-1 in both experimental animals and in humans. Furthermore, clinical studies have shown that testosterone reduces insulin sensitivity, whereas testosterone replacement reduces insulin resistance and improves glycemic control in hypogonadal men with type 2 diabetes.[17] The mechanisms by which testosterone improves insulin sensitivity in men is likely due to a combination of effects on multiple organs and may involve reduction of the production of inflammatory cytokines (such as TNF-α and IL-6) which promote insulin resistance and diabetic renal injury.

Interestingly, although most of the above studies examining the effects of androgens on renal function have been performed in experimental models of nondiabetic renal disease, in the setting of diabetes, testosterone seems to exert opposite effects. Specifically, castration in experimental models of hypertension-associated renal injury improves renal structure and function, in the male STZ-induced diabetic rat, castration actually contributes to the progression of diabetic renal disease.[34] Further, supplementation of testosterone to physiological levels observed in nondiabetic improves albuminuria, glomerulosclerosis, tubulointerstitial fibrosis, and TGF-β protein expression associated with diabetes.[34] These observations suggest that the mechanisms by which androgens exert their actions in the kidney differ under normo- and hyperglycemic conditions.

Collectively, these observations suggest that androgens play an integral role in the development and progression of hypertension and renal injury, in both nondiabetic and diabetic conditions. Although most of the studies investigating the role of androgens in pathological conditions have been directed at males, the role androgens play in the development of renal disease in females warrants further investigation. This statement is based on the observation that diabetic females exhibit increase in testosterone levels that correlate with the decline in renal function, suggesting that testosterone may contribute to the development of diabetic nephropathy in females. Further, the interplay between androgens and locally active peptides, such as angiotensin, endothelin-1, etc., also requires further investigation to better understand the mechanisms involved in the development and progression of diabetic renal disease.

SUMMARY AND PERSPECTIVES

Clinical and experimental studies show that diabetes is a state of imbalance in sex hormone levels. Specifically, males exhibit low testosterone and elevated estradiol levels, whereas females exhibit low estradiol and elevated testosterone levels. Both estrogens and androgens, despite being considered sex hormones, play an active role in mediating renal function in the setting of diabetes. Although the mechanisms by which sex hormones exert their actions in the kidney need to elucidated, studies to date point to estrogens and androgens modulating the expression and activity of locally active peptides, such as Ang II and endothelin. We conclude that therapies that include sex hormones in conjunction with blocking of the actions of the classical pathways involved in the development and progression of renal injury may be an effective, sex-specific treatment for diabetic nephropathy.

Chapter 203

Prolactin

Willis K. Samson

ABSTRACT

Prolactin, a large peptide produced in and secreted from lactotrophs of the anterior pituitary gland, traditionally has been considered a reproductive hormone in man. In submammalian species, however, it plays an important role in osmoregulation. Recently, prolactin receptors have been described in mammalian kidney and the peptide seems to be produced there as well. Prolactin has been shown to exert natriuretic, diuretic, and kaliuretic actions by decreasing Na+, K+-ATPase activity in the proximal convoluted tubule. This effect requires interaction with renal dopamine D-1 receptors. Thus, it may be that instead of acting as an endocrine hormone (of pituitary origin), locally produced prolactin exerts direct, paracrine actions in the nephron leading to important changes in sodium and potassium excretion.

Because prolactin (PRL) was considered by most endocrinologists to be primarily a hormone associated with reproductive function, for years the prevailing editorial commentary obstructed attempts to understand the physiologic relevance of the consistent findings that receptors for the peptide were localized to nonreproductive tissues, including kidney. Yet in submammalian species, a clear role was indicated for the peptide in fluid and electrolyte homeostasis. What has emerged from years of sporadic interest in the possible renotropic actions of PRL is a body of evidence that suggests little significance in humans of pituitary-derived peptide; however, much promise still exists for renal actions of endogenous PRL, in particular PRL produced within the kidney acting in a local, paracrine, fashion to control tubular function. These effects would not have been observed in the human studies published to date, but were in fact predicted by not only the comparative studies in lower species but also some groundbreaking work in unique animal models.[12,19,26,31,33] Numerous excellent reviews of the roles played by PRL in fishes, birds, and other species have been published,[5,21,23] and those reviews will not be recapitulated here. Instead, the evidence for actions of PRL in the mammalian kidney will be highlighted.

CLASSICAL PRODUCTION SITE AND ACTIONS OF PROLACTIN

As reviewed by several recognized experts in the field,[3,4] PRL is produced primarily in the anterior pituitary gland where it is both stored and released as the mature 199 amino acid polypeptide after removal from the prohormone of a 28 amino acid signal peptide. It circulates as both a 23-kDa protein and, after enzymatic cleavage and reduction of one of its disulfide bonds in a variety of tissues sites, a 16-kDa, biologically active fragment.[2,9] In fact, several of the nontraditional actions of PRL have been ascribed to this 16-kDa fragment.[1,3,8,10] In the pituitary gland, PRL is produced in a unique population of cells, termed lactotrophs, because of the primary action of the protein in the mammary gland to stimulate milk production.[28] This "hallmark" action of PRL, together with its effects on corpus luteum function in the ovary,[3,28] formed the basis of the predominant view that PRL was a "reproductive" hormone, one associated primarily with female reproductive function. Why then do males make, store, and release PRL from the anterior pituitary gland? Why is the PRL gene transcribed and protein produced in extrapituitary sites? Why then are receptors for the protein found in numerous tissues sites other than the ovary and mammary gland?

PROLACTIN RECEPTORS

Prolactin receptors belong to the class 1 cytokine receptor superfamily that includes receptors for a wide variety of peptides (e.g., interleukins, erythropoietin, leukemia inhibiting factor, and the hormone leptin). As reviewed by Kelly et al.,[4] the PRL receptor itself exists in at least three major isoforms, all splice variants of the same gene product. They share homology in the extracellular, amino-terminal domain, and in the single chain transmembrane portion, but differ in the length of their cytoplasmic C-terminal tails. The extracellular domain establishes the homology to the cytokine receptors and is approximately 200 amino acids in length. The intracellular domains of the receptor contain not only the sequences necessary for appropriate signal transduction but also those responsible for receptor internalization.

Ligand binding to the PRL receptor results in stimulation of the tyrosine kinase activity of JAK2 (Janus kinase 2) and, except in the case of the short form isoform, receptor phosphorylation and subsequent activation of Stat proteins

Handbook of Biologically Active Peptides. http://dx.doi.org/10.1016/B978-0-12-385095-9.00203-7

Copyright Elsevier 2024

(signal transducer and activator of transcription proteins), in particular Stat5.[4] Interactions of the activated Stat proteins with DNA binding sites account for the specificity of the genomic effects of PRL. Signaling via the mitogen activated protein kinase (MAPK) pathway has also been identified and an interaction with the epidermal growth factor (EGF) family of receptors suggested. Within the kidney, evidence for an interaction of the PRL receptor with the dopamine, D-1 receptor has been shown,[12] an effect that determines the renal actions of the hormone.

As stated above, the primary actions of PRL were for a long time considered to be in mammary gland and ovary, tissues containing abundant receptors for the protein. However, a much broader distribution of PRL receptors has been cataloged in what were largely unexpected sites including brain, adrenal gland, bone, adipocytes, liver, pancreas, gastrointestinal tract, a variety of lymphoid tissues, and kidney.[4] Not surprisingly, the pharmacologic effects of PRL have now been described in those tissues as well, opening the possibility that PRL is not just a hormone of reproduction but instead one with diverse biologic potential. Best characterized to date are the actions of PRL in immune cells, bone, brain, and pancreas.[3,4] Some of those actions may be a reflection of circulating PRL, while others may require local production of the peptide, as in the case of the potential renal actions.[33]

PROLACTIN AND OSMOREGULATION

PRL plays a significant role in osmoregulation in species exposed to harsh environments.[4,21,28] Indeed, the protein is an important protective factor in fish in both the fresh and sea-water environments and in the transition between those two osmotic conditions. The importance of PRL in osmoregulation in fish has been reviewed by Manzon[23] and its role in birds and amphibians described.[5,28,31] Evidence for a role in osmoregulation in mammals has also accumulated and indeed the presence of PRL receptors in the mammalian kidney detailed.[16,27,33] However, most clinically based studies have failed to present a clear picture of PRL effects in humans and only some of the animal trials have been able to at least partially explain the possible similarity of PRL actions in mammals with those observed in submammalian species. What has been missing perhaps has been an appreciation for the importance of locally produced PRL as opposed to circulating, pituitary-derived peptide.

PROLACTIN RECEPTORS IN THE MAMMALIAN KIDNEY

Already in the 1980s[27] it was known that high affinity PRL binding could be seen in rat kidney membrane preparations (medullary and cortical fragments) and that maximal binding was present in epithelial cells of the glomerulus and proximal tubule as identified by autoradiography. Faint but detectable labeling was observed in tubule cells of the cortical and medullary nephron as well. That work extended the original observations of Marshall et al.[24] that showed by Scatchard analysis the presence of PRL binding activity in rat kidney. The proximal tubule site of autoradiographic PRL labeling suggested an action of the peptide on sodium handling in the kidney; however, the original article[24] failed to show a significant effect of uninephrectomy or salt loading on PRL binding in the kidney. Similarly, serum PRL levels failed to be significantly altered by manipulation of osmolality in several studies.[25]

With the cloning of the mammalian PRL receptors much more was learned about the potential roles played by circulating or locally produced PRL in renal function. *In situ* hybridization histochemistry reveals the presence of both the short and long forms of the PRL receptor in rat kidney. Unlike in the other tissues (e.g., adrenal, spleen, thymus, skin, and heart) where the long receptor isoform predominates, the short form is more abundantly detected in kidney with highest signal found in the glomeruli and in the tubules of the outer medulla.[29] This was later confirmed by Freemark et al.[16] by reverse transcription-polymerase chain reaction, which also showed the relative increased levels of short versus long isoform of the PRL receptor in fetal rat kidney. The same group of investigators[32] extended those initial studies with a combination of *in situ* hybridization histochemistry, immunhistochemistry, and radioligand binding studies that showed the presence of PRL receptors in fetal rat kidney by day 19–20 of gestation. On day 20, PRL binding is best observed in cortical and subcortical renal tubules. In human fetal kidney, PRL receptor immunoreactivity is detected at embryonic day 52 in tubules and at gestational day 96 in tubules and collecting ducts.[15] Staining is particularly intense on the luminal surfaces of the tubules and ducts. No immunoreactivity was observed in glomeruli. The luminal localization of PRL receptors was confirmed in murine kidney,[33] in particular in the proximal tubule and the parietal epithelium of Bowman's capsule, where mRNA encoding PRL itself also is detected raising the possibility of local actions of endogenously produced PRL within the kidney. This is further implied by the failure of fetal growth restriction to alter renal PRL receptor message in the face of suppressed synthesis and secretion of PRL in the pituitary gland.[30]

RENAL PRODUCTION OF PROLACTIN

How would PRL access its apparent binding sites on the luminal epithelium of the tubule? Certainly, circulating PRL of pituitary origin may be filtered through the glomerulus. An arteriovenous gradient of PRL across the human kidney[11] has been described suggesting either removal by filtration and metabolism by the kidney;[13] however, micropuncture

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

studies describing the concentrations of PRL in tubular urine are lacking. It is clear that at least in the mouse[33] PRL mRNA and protein can be detected in luminal epithelial cells of the proximal tubule. In addition, those cells also express the message for Pit-1, a transcription factor known to be important in the regulation of PRL gene expression,[4] further suggesting significant, local production of the peptide.

RENAL ACTIONS OF PROLACTIN

Although there is clear consensus that PRL receptors exist in kidney, there is little agreement in the literature concerning the potential renal actions of the peptide. This may be a result of differing experimental protocols or the use of heterologous peptide preparations. The lack of agreement may also be a result of the commonly held belief that all PRL effects in kidney would be a result of peptide delivered by the general circulation. This may not be the case and a unique isoform of PRL may in fact be the effective agent.

Horrobin et al.[17] injected semipurified sheep PRL intramuscularly into five male volunteers. In addition to a long-lasting malaise, they observed a decrease in urine volume and urinary sodium and potassium excretion that was matched by increased plasma sodium and osmolality. The volunteers also expressed a sensation of thirst. The absolute purity of the peptide preparation could not at the time be assured and thus contamination with other anterior lobe hormones, as well as the neurohypophysial peptides, oxytocin and vasopressin, could not be ruled out. That human study was designed to mirror work by Lockett et al.[20] in which antinatriuretic, antidiuretic, and antikaliuretic effects of purified PRL preparations were observed in conscious rats, in the absence of demonstrable actions on glomerular filtration rate. Thus tubular effects to increase sodium reabsorption were the first suggested actions of PRL.

The decreased urine volume observed in human volunteers led many to speculate that PRL is a unique antidiuretic agent. This was further suggested by the observation in rats that ovine PRL infusions reduce the diuresis and natriuresis of an intravenous saline load.[22] However, that same year, a report appeared, which suggested that the antidiuretic effect of PRL resulted from occupancy of the vasopressin (AVP) receptors in kidney.[14] Indeed, Clapp and colleagues have elegantly shown that prolactin administered into the brain or systemically promotes AVP, and oxytocin, release.[35]

In the absence of AVP (Brattleboro rats or Sprague Dawley rats fluid loaded to decrease endogenous AVP secretion), recombinant mouse PRL exerts antinatriuetic and antidiuretic effects. However, when AVP is present, the action is diuretic. These excellent studies show several important shortcomings of earlier work: the use of recombinant material obviating the potential for contamination with other renotropic factors, the use of species-specific peptide, and the separation of the potentiative effects of PRL on AVP actions. The study[26] does not, however, isolate the problem of identifying the actions of circulating (pituitary origin) versus locally produced peptide.

It also does not address the possibility that prolactin of renal origin may exert actions in differing nephron segments than that administered systemically. In fact, more recent convincing evidence for a natriuretic action[12] in proximal convolutes tubule (PCT) is opposed by earlier work[6] indicating an antinatriuretic effect in medullary ascending limb (MAL) and distal convoluted tubule (DCT). Indeed, although prolactin decreases Na+, K+-ATPase activity in PCT,[19] it seems to increase the activity in MAL and DCT.[6]

The physiologic relevance of a PCT site of action of prolactin produced within the kidney is beginning to gain support. Not only does prolactin decrease Na+, K+-ATPase activity there, it signals through activation of protein kinase A, protein kinase C, and phosphorylation of cellular proteins (including Na+, K+-ATPase) and via heterologous recruitment of the dopamine, D-1 receptor.[12] Dopamine, acting via the D-1 receptor, is a potent natriuretic agent and interactions between dopamine and other natriuretic agents (e.g., atrial natriuretic factor) resulting from heterologous recruitment of the D-1 receptor. Crambert et al.[12] take their argument one step further by showing that prolactin fails to alter Na+, K+-ATPase activity in SHR rats, a strain that displays a blunted natriuretic response to dopamine.

THE JURY IS STILL OUT ON THE RENAL ACTIONS OF PROLACTIN

Despite abundant suggestive evidence for renotropic actions of PRL, these still have not been conclusively shown to exist. Perhaps the approach taken has led to the confusion. Almost all the studies described in the literature focus on PRL of pituitary origin as the potential renotropic agent. Now that it is known that the gene for PRL is expressed in kidney[33] and that PRL receptors are expressed on the luminal epithelium of the renal tubule,[15] attention should be focused on the potential for PRL of renal origin to act in the tubule to alter sodium and water handling. Micropuncture studies using homologous, recombinant peptide should be conducted to include infusion of PRL into the tubular fluid.

Continued investigation of the functional significance of the prevalence of the short form of the prolactin receptor in kidney[16] is needed. Is the presence of this form of the receptor in medullary nephron segments the reason why the action of PRL in MCT and DCT[6] differs from that in PCT?[12,19] Clearly, the heterodimerization of the long form of the PRL receptor with the dopamine D-1 receptor is an important interaction leading to changes in Na+, K+-ATPase activity[12,19] Is it possible that the predominance of the short form of the PRL receptor in more distal nephron segments

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

is acting as a dominant negative, blocking the dimerization observed in more proximal elements? Indeed, Tan and Walker[34] present convincing evidence in HEK-293 cells that increased short form to long form ratios interrupt signaling of PRL, by prevention of homodimerization (of the long form). Increased expression of the short form of the receptor also reduces expression of the long form. Thus, in distal tubule, the apparent dominant negative action of the receptor short form may interrupt dopamine signaling and lead to the opposite effect on sodium handling as that observed in the proximal tubule. This hypothesis deserves further study.

The potential actions of PRL variants in the kidney also need to be further examined. For example, the effect of glycosylated PRL or the smaller 16-kDa isoform should be examined. In particular, the 16-kDa form may hold promise. This is the posttranslationally modified form of PRL that is created by enzymatic cleavage followed by reduction of the disulfide bridge between amino acids 58 and 174. The resultant 16-kDa isoform is poorly recognized by the classical PRL receptors[9] but does express unique biologic activities, including antiangiogenesis and antitumorigenesis.[8,10,16] Clearly, this modified form of PRL may be produced in kidney, where the necessary cathepsin-D-like enzymes and reductases are present,[2] and it also may play a role in the local regulation of sodium and water transport.

HAVE TRANSGENE METHODS CLARIFIED THE ISSUE?

Two excellent models for the study of the potential renotropic actions of PRL have been developed, the PRL[18] and the PRL receptor[4] knockout mice. Recognizing that embryonic gene deletion may not uncover the physiologic relevance of a protein that plays, along with other unique proteins that may compensate for its deletion, a role in renal function, these models if properly studied may provide insight into the tubular actions of 23- or 16-kDa PRL. Likewise, the availability of a modified PRL homolog with antagonistic activity[7] may well explain the confusion of the natiuretic/antinatriuretic or diuretic/antinatriuretic effects of PRL, and may clarify the potential role played by endogenous PRL in mammals that seems to be predicted by the important osmoregulatory actions of the peptide in submammalian species.

Chapter 204

Renin–Angiotensin System

Minolfa C. Prieto, Alexis A Gonzalez, Ryousuke Satou, Hiroyuki Kobori and L. Gabriel Navar

ABSTRACT

Renal angiotensin (Ang) II is regulated independently of the systemic renin–angiotensin system. Intrarenal Ang II concentrations are higher in renal interstitium and proximal tubular compartments than in the circulation. The transcript for angiotensinogen (AGT) is in proximal tubule cells and for renin in juxtaglomerular and collecting duct cells. Secretion of their proteins increases intratubular formation of angiotensin peptides. Ang II is internalized via AT_1R into renal endosomes. When inappropriately stimulated, Ang II augments synthesis and secretion of AGT in proximal tubules and renin in collecting ducts, which increase further intrarenal Ang II and cause hypertension. Ang II has pleiotropic actions on cortical and medullary blood flow, vascular tone of afferent and efferent arterioles, mesangial cell function, and sensitivity of the tubuloglomerular feedback mechanism via the activation of AT_1R. AT_2R and Ang III partially oppose these actions. Ang II also regulates sodium transport in proximal and distal nephrons via the activation of luminal and basolateral AT_1R.

INTRODUCTION

The contribution of the intrarenal renin–angiotensin system (RAS) to the regulation of renal function is unique because renal functional, and transport alterations caused by angiotensin II (Ang II) influence overall sodium balance and cardiovascular status and thus contribute to blood pressure regulation. When inappropriately stimulated, an enhanced intrarenal RAS markedly influences renal function by acting on vascular and tubular components causing the development and maintenance of hypertension and associated cardiovascular dysfunction.[12,18–20,33]

This chapter covers the intrarenal RAS, the formation of several angiotensin peptides by various enzymes, and the characterization of angiotensin receptors including AT_{1a}, AT_{1b}, and AT_2 for Ang II and Ang III, and the Mas receptor for Ang 1–7. In addition, we describe some newly discovered aspects of the intrarenal RAS including the regulation of proximal tubule angiotensinogen (AGT), collecting duct renin, and the renin/(pro)renin receptor.

DISTRIBUTION OF ANGIOTENSINOGEN, RENIN, (PRO)RENIN RECEPTORS, ANGIOTENSIN CONVERTING ENZYMES, AND ANG TYPE 1 RECEPTORS IN THE KIDNEY

All components of the RAS are present in the kidney and are compartmentalized to the tubular and interstitial networks. Because kidney Ang II tissue concentrations are greater than can be explained by the concentrations delivered in the arterial blood flow, it is generally acknowledged that most of the Ang II in the intrarenal components is generated locally from AGT delivered to the kidney as well as that locally produced by proximal tubule cells. The presence of abundant sources of renin, AGT, and angiotensin-converting enzyme (ACE) in the kidney provides an environment conducive to high levels of Ang II synthesis.[19,21]

Angiotensinogen

AGT, the only known substrate for renin, is a 60-kD glycoprotein synthesized and released from the liver, and cleaved in the circulation to form the biologically inactive, Ang I (Fig. 1). In addition, renal AGT mRNA and protein are localized to proximal tubule cells indicating that much of the intratubular Ang II is derived from locally formed and secreted AGT. AGT is regulated by an amplification mechanism such that AGT mRNA and protein are stimulated by Ang II, which maintains or increases the production of Ang II in Ang II-dependent hypertension. Producing its metabolites intracellularly and secreting them into the tubule lumen, AGT is taken up by megalin-dependent endocytosis and is then secreted into the tubular lumen.[12,19,24] More recent studies have evaluated the molecular mechanisms responsible for the regulation of AGT expression and synthesis in proximal tubular cells.[21] Activation of AT1 receptors stimulates intrarenal NF-κB, which is a key factor in the augmentation of AGT expression in proximal tubule cells.[1,20] The activation of NF-κB by Ang II leads to the stimulation

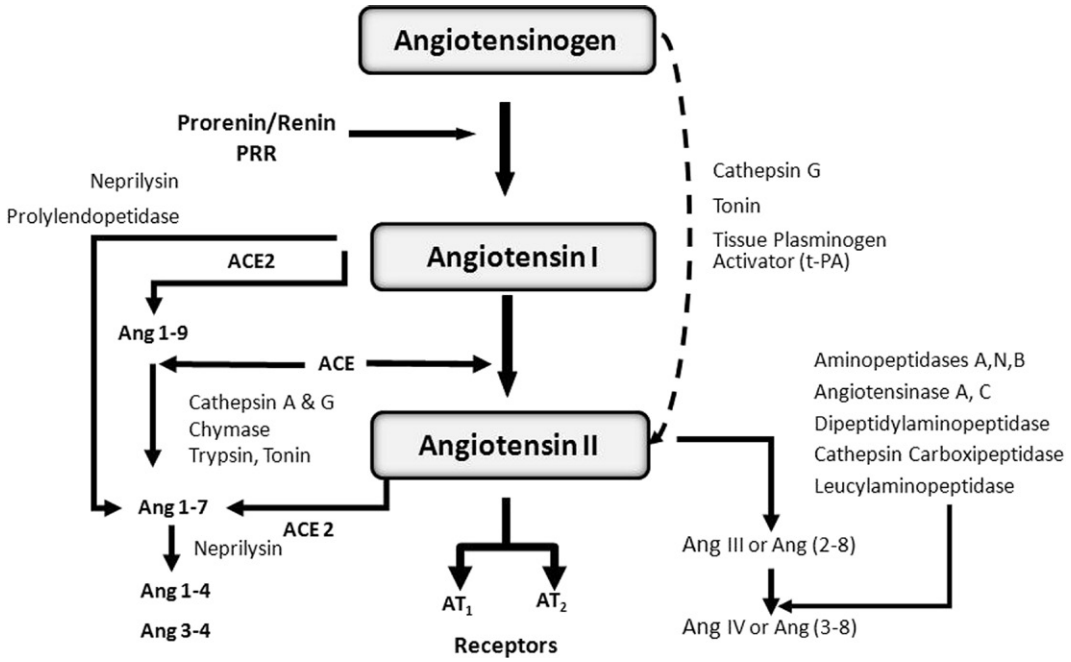

FIGURE 1 Intrarenal renin–angiotensin system cascade. Known and postulated enzymatic pathways responsible for formation and metabolism of angiotensin peptides.

of intrarenal proinflammatory cytokine expressions such as interleukin-6, contributing to the increase in AGT expression via activation of a JAK-STAT pathway.[29] Therefore, Ang II increases intrarenal AGT levels via both direct and indirect mechanisms mediated by activated NF-κB and the JAK-STAT pathway. By contrast, tumor necrosis factor α, which is also an Ang II-induced proinflammatory factor in the kidney, suppresses AGT expression by increasing p50/p50 complex in proximal tubular cells.[30] This inhibitory action on NF-κB provides a counterregulatory influence limiting the magnitude of Ang II-induced AGT augmentation in renal proximal tubular cells, which may explain why higher doses of Ang II infusion in mice fail to augment intrarenal AGT levels.[20]

Proximal tubule AGT concentrations in anesthetized rats are in the range of 300 nM, which greatly exceeds the free Ang I and Ang II tubular fluid concentrations. Because of its molecular size, it is unlikely that much plasma AGT filters across the glomerular membrane, further supporting the concept that proximal tubule cells secrete AGT directly into the tubule.[12] In response to chronic Ang II infusions there is an augmentation of AGT mRNA leading to increased synthesis and secretion with some of the secreted AGT spilling over to the distal nephron segments as reflected by increased urinary AGT excretion.[13] Under conditions of elevated salt intake combined with chronic Ang II infusion, the urinary AGT excretion response is elevated to much greater levels than those seen in Ang II-infused rats fed a normal salt diet.[14] By contrast, normal rats fed a high salt diet exhibit urinary AGT excretion rates similar to those observed in rats fed a normal salt diet. Thus, during chronic Ang II infusion, salt-sensitive hypertension develops and high salt paradoxically stimulates intrarenal RAS activity, as reflected by exacerbation of the urinary AGT despite inhibition of plasma renin activity.[14] Formation of Ang I and II in the tubular lumen subsequent to AGT secretion is probable because some renin is filtered and/or secreted from juxtaglomerular apparatus (JGA) cells.[12] Once Ang I is formed, conversion readily occurs because there is abundant ACE associated with the proximal tubule brush border.[32] Intact AGT in urine reflects its presence throughout the nephron and, to the extent that renin and ACE are available along the nephron, substrate availability supports continued Ang I generation and Ang II conversion in distal segments.[19,25]

Renin and (Pro)renin Receptor

Renin, synthesized by the JGA cells, is the primary source of both circulating and intrarenal renin levels. Juxtaglomerular apparatus cells secrete renin into the renal interstitium, thus providing a stimulus for the local generation of Ang I, and this secreted active form contains 339–343 amino acid residues after proteolytic removal of the 43 amino acid residue at the N-terminus of prorenin. Circulating active renin and prorenin are derived mainly from the kidney; and circulating prorenin is taken up by some tissues where it may contribute to the local synthesis of angiotensin peptides. The only well-established role of

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

renin is to cleave Ang I from AGT. However, the recently cloned (pro)renin receptor ((P)RR) binds renin or prorenin, thus enhancing renin activity and fully activating the biologically inactive prorenin peptide, which leads to an increase in the catalytic efficiency of Ang I formation from AGT. Activation of the (P)RR by renin or prorenin also directly elicits intracellular signals that stimulate ERK1/ERK2 and downstream pathways.[22]

There is growing awareness of the possible roles of renin in other intrarenal structures where renin has been localized. Renin producing cells have a unique origin that allows their abundance along the afferent arteriole to be regulated by various stimuli. ACE inhibition induces a recruitment of cells in afferent arterioles beyond the JGA even though they were not expressing the renin gene in the basal state.[31] Positive renin immunoreactivity has also been observed in the cells of glomeruli and in proximal and distal tubular segments. More recently, increased attention has been focused on the presence of renin mRNA and protein expression in distal nephron segments, specifically in the principal cells of connecting tubules and collecting ducts, suggesting local formation and secretion into the distal tubular fluid. Renin synthesis in principal cells of collecting ducts is further increased by chronic infusions of Ang II.[25,26] Rats chronically infused with Ang II for 13 days show a suppression of plasma renin activity but increases in urinary prorenin content and renin excretion.[16] In addition, the urinary renin and prorenin protein levels, examined by Western blot, are augmented about 10-fold in Ang II-infused rats. Concomitant AT1R blockade with candesartan prevents increases in both urinary and tissue renin and in prorenin levels. Although there is marked suppression of plasma renin activity, increased renin synthesis by CD cells and secretion into the luminal fluid lead to increased urinary levels of renin and prorenin.[16]

The presence of renin in distal nephron segments provides the requisite pathway for Ang I generation from proximally delivered AGT.[25,26] Renin synthesis is augmented in the principal cells of connecting tubules and cortical and medullary collecting ducts of chronic Ang II-infused rats and mice, Cyp1a1Ren2 transgenic rats, and in both kidneys of two-kidney one clip Goldblatt hypertensive rats.[9,25,26] The AT1R via a PKC pathway directly mediates the stimulation of renin synthesis in rat inner medullary collecting duct because inhibition of PKC with calphostin C prevents the Ang II-mediated increases in renin transcript and prorenin protein levels in rat inner medullary collecting duct (IMCD) cells while activation of PKC with phorbol 12-myristate 13-acetate increases renin expression to the same extent as Ang II.[7] Further, renin activity and renin and prorenin protein levels are increased in the urine of these rats[6] indicating that both renin and prorenin are secreted by the collecting duct cells into the lumen of distal nephron segments and are also augmented in chronic Ang II-infused hypertensive rats. The discovery of the (P)RR provides new insights regarding its possible role in a setting of activated intrarenal RAS. The (P)RR is expressed in the kidneys[6] particularly in mesangial cells, podocytes, and intercalated type A cells of distal nephron segments.[2,6,11] Chronic infusion of Ang II for 14 days in Sprague–Dawley rats increases renal (P)RR transcript levels and augments the soluble form of the (P)RR, s(P)RR.[6] The augmentation of s(P)RR in the urine of Ang II hypertensive rats suggests that s(P)RR can bind renin and prorenin secreted by the principal collecting duct cells and can catalyze additional formation of Ang I. The existence of an inducible and functional form of s(P)RR in the renal medulla and in the urine of chronic Ang II-infused rats reflects increased s(P)RR in collecting duct tubular fluid and further supports the potential role of this soluble form to enhance intratubular renin activity. Thus, the interaction between the (P)RR and renin in the lumen of the collecting ducts may contribute substantially to facilitate intratubular formation of Ang I in hypertension.

Angiotensin-Converting Enzymes

As in other organs, ACE is located on endothelial cells throughout the vasculature. ACE is also on membranes of both proximal and distal nephron segments with the greatest abundance found on the brush border of proximal tubules, particularly in the S3 segment.[21,32] Marked upregulation of ACE in the brush border occurs in kidneys from Goldblatt hypertensive rats and Ang II infused hypertensive rats.[32] Humans predominantly express ACE in the brush border of proximal tubular segments with very little ACE expression on vascular endothelial cells or in the vasculature of the glomerular tuft. The lower renal vascular endothelial expression in humans helps explain the much lower Ang I to Ang II conversion rates that have been reported for human kidneys as compared with that of other species. In rats, ACE activity is present in tubular fluid throughout the nephron except in the distal tubule, with activity higher at the initial portion of the proximal tubule, decreasing toward the distal nephron, and increasing again in the collecting ducts and urine. Therefore, intratubular Ang II formation may occur not only in the proximal tubule but also beyond the distal convoluted tubule. Renal tissue ACE activity is critical to maintain the steady-state Ang II levels in the kidney. The presence of ACE only in the kidney is sufficient to increase kidney Ang II levels and promote the development of hypertension in response to chronic Ang I infusions.[8] Tissue-ACE knockout mice exhibit 80% lower intrarenal Ang II levels compared with wild-type mice.[3]

ACE2, which acts on Ang II to form Ang 1–7 or on Ang I to form Ang 1–9 (Fig. 1), is a membrane-associated and secreted enzyme expressed predominantly on endothelium,

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

but highly restricted in humans to heart, kidneys, and testes.[21] Ang 1–7 may serve as an endogenous antagonist of the Ang II induced actions mediated via AT_1 receptors and changes in ACE2 activity could affect the balance of Ang peptides found in the kidney. This probably explains the elevated Ang II levels in the ACE2 knockout mice.[28] Collectrin, a novel homolog of ACE2 has been identified in mouse, rat, and human. Both ACE2 and collectrin have tissue-restricted expression in the kidney. Collectrin is localized on the luminal surface and in the cytoplasm of collecting duct cells, and its mRNA is expressed in the renal collecting ducts cells while ACE2 is present throughout the endothelium, in proximal tubular epithelial cells and in medullary tissue.[21] In Ang-II-dependent hypertension, intrarenal ACE is increased, but ACE2 levels are decreased leading to another mechanism maintaining increased Ang II levels.[26]

Intrarenal Angiotensin II Receptors

Ang II receptors are widely distributed in various regions and cell types of the kidney. Two major categories of Ang II receptors, AT_1 and AT_2, have been described, pharmacologically characterized and cloned.[18,21] As depicted in Figure 2, most of the Ang-II-mediated hypertensinogenic actions are generally attributed to the AT_1 receptor.[5,18] In rodents, there are two AT_1 receptor subtypes, with the AT_{1a} being the predominant subtype in all nephron segments, while the AT_{1b} is more abundant in the glomerulus.[18,21] In mature kidneys, AT_{1a} receptors have been localized to the renal microvasculature in cortex and medulla, smooth muscle cells of afferent and efferent arterioles, thick ascending limb of the loop of Henle, proximal tubular apical and basolateral membranes, mesangial cells, distal tubules, collecting ducts, and macula densa cells. The afferent arteriole has both AT_{1a} and AT_{1b} receptors, whereas the efferent arteriole primarily expresses AT_{1a} receptors.[10] The essential role of the AT_{1a} receptor in mice is apparent from studies showing that 2-kidney, 1-clip (2K1C) Goldblatt hypertension does not develop in AT_{1a} knockout mice.[4]

Vascular and tubular receptors respond differently during high Ang II states.[18] High Ang II levels associated with a low salt diet decrease glomerular AT_1 receptor expression but increase proximal tubular AT_1 receptor levels. Glomerular AT_1 receptors and AT_{1a} receptor protein are reduced in both clipped and contralateral kidneys of 2K1C Goldblatt and of 2 kidney-1-wrap hypertensive models and in kidneys of Ang II infused rats.[18] In the TGR(mRen2) harboring the mouse renin2 gene, AT_1 receptor binding is increased in vascular smooth muscle of afferent and efferent arterioles, JGA, glomerular mesangial cells, proximal tubular cells, and renomedullary interstitial cells suggesting that the upregulation of AT_1 receptors contributes to the pathogenesis of hypertension in these rats. In Ang II infused rats studied with *in vitro* autoradiography, there are differential responses with significant decreases in glomeruli and inner stripe but not in proximal tubules.[18]

The AT_2 receptor is highly expressed in human and rodent kidney mesenchyme during fetal life and decreases dramatically after birth. AT_2 receptors have been localized to the glomerular epithelial cells, proximal tubules, collecting ducts, and parts of the renal vasculature of the adult rat. AT_2 receptor activation is believed to counteract AT_1 receptor

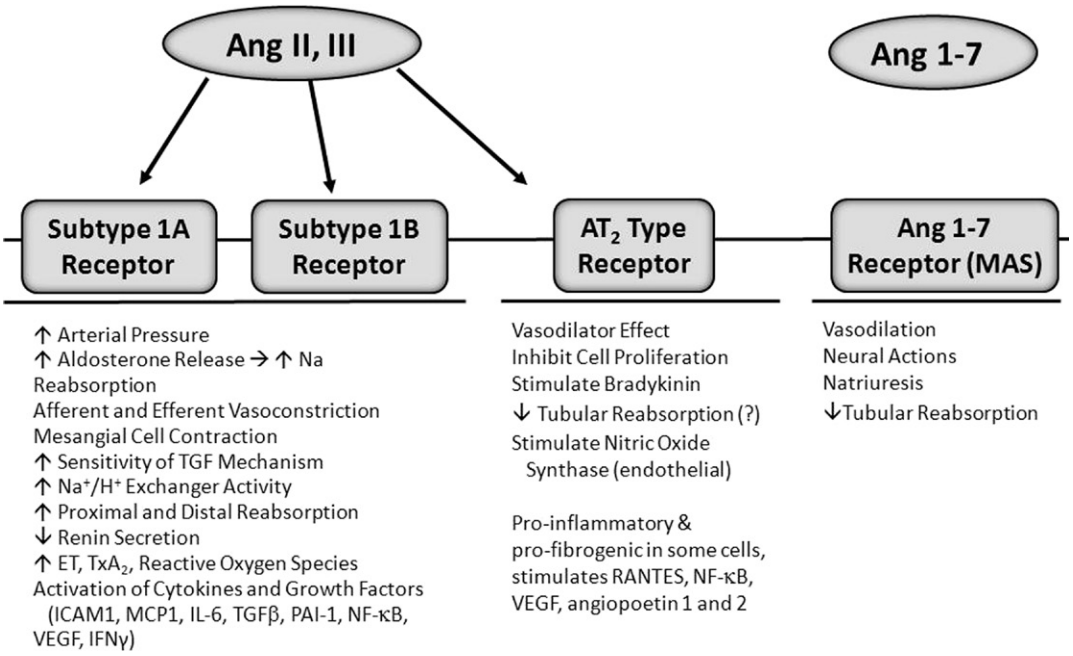

FIGURE 2 Major Ang II receptor subtypes and their renal actions.

effects by stimulating the formation of bradykinin and nitric oxide leading to increases in interstitial fluid concentration of cyclic guanosine monophosphate (cGMP). AT_2 receptor activation influences proximal tubule sodium reabsorption either by a cell-membrane-receptor-mediated mechanism or via an interstitial nitric-oxide-cGMP pathway.[17,18]

INTRARENAL LEVELS OF ANGIOTENSIN II

Interstitial Angiotensin II

Intrarenal Ang II is not distributed in a homogeneous fashion but is compartmentalized in both a regional and segmental manner.[19] Medullary Ang II levels are higher than cortical levels in normal rats and increase further in Ang II infused hypertensive rats.[18] Within the cortex, there is distribution of Ang II in the interstitial fluid, tubular fluid, and intracellular compartments. The interstitial and intratubular compartments contribute to the disproportionately high intrarenal Ang II levels. Ang II concentrations in interstitial fluid are much higher than the plasma concentrations with values in the range of 3–5 pmoles/mL.[19] Renal interstitial fluid Ang II levels increase further in hypertensive rats infused with Ang II for 2 weeks. The high renal interstitial values indicate local regulation of Ang II formation in the renal interstitial compartment and an enhancement of interstitial Ang II production in Ang II dependent hypertension.[12]

Tubular Ang II

As shown in Figure 3, proximal tubule fluid concentrations of Ang I and Ang II are also much greater than the plasma concentrations and have been found to be in the range of 5–10 pmoles/ml.[19] In perfused tubules, where the contribution resulting from glomerular filtration is prevented, Ang II concentrations are similar to those in nonperfused tubules indicating that the proximal tubule secretes Ang II or a precursor into the proximal tubule fluid. In addition to AGT, proximal tubule cells have renin that can act on AGT to generate Ang I. Evidence that renin is augmented in the urine of chronic Ang II-infused rats also indicates secretion of renin by the collecting duct cell into the tubular lumen[16] and provides a pathway for Ang I generation from proximally delivered AGT, leading to concentrations of Ang II in distal tubular fluid in the picomolar range.[34]

Intracellular Angiotensin II

Ang II is internalized via AT_1–receptor-mediated endocytosis and endosomal accumulation of Ang II in intermicrovillar clefts and endosomes is increased further in Ang II infused hypertensive rats.[35] AT_1 receptor blockade prevents the endosomal accumulation even though plasma Ang II increases. The presence of Ang II in renal endosomes indicates that some of the internalized Ang II remains intact and contributes to the total Ang II content measured in tissue homogenates.[35] Endocytosis of the Ang II-AT_1 receptor complex is required for the full expression of functional responses coupled to the activation of signal transduction pathways, but the full extent of the functions exerted by intracellular Ang II has not been determined.[15] In Ang-II-dependent hypertension, a higher fraction of the total kidney Ang II is internalized into intracellular endosomes consisting of both light endosomes and intermicrovillar clefts via an AT_1-receptor-mediated process. AT_1 receptor blockade prevents the augmentation of intracellular Ang II.[35]

Our understanding of the functions of internalized Ang II remains incomplete. Ang II may be recycled and secreted to exert further actions by binding to Ang II receptors on the cell membranes. Ang II may also act on cytosolic receptors to activate intracellular signaling mechanisms.[15] Ang II may also migrate to the nucleus to exert genomic effects.[21] Nuclear binding sites of the AT_1 subtype in renal cells have been reported. Because Ang II exerts a positive stimulation on AGT mRNA and protein production, intracellular Ang II may have genomic actions to regulate AGT or renin mRNA expression in proximal tubule cells either directly or via NF-κB.[1,21,30]

BIOLOGICAL ACTIONS OF INTRARENAL ANG II

In view of the near ubiquitous distribution of Ang II receptors in the various structures of the kidney, it is not surprising that Ang II exerts pleiotropic effects at multiple levels within the kidney. As shown in Figure 2, the actions of Ang II span both cortical and medullary, vascular and tubular and can be stimulatory or inhibitory.[18] At the level of the vasculature, Ang II exerts important direct and indirect effects to regulate vascular tone of the afferent and efferent arterioles and of the mesangial cells.[17] Ang II also regulates afferent arteriolar tone through its influence on the tubuloglomerular feedback mechanism with elevated Ang II levels increasing the sensitivity of the feedback mechanism, thus regulating the amount of filtrate that escapes the proximal nephron and enters the distal nephron segments. In the postglomerular circulation, Ang II regulates both the cortical and medullary capillary blood flow and helps to regulate the relative blood flowing to the medullary tissues through its control of the tone of the pericytes.[17]

Interestingly, although Ang II constricts both afferent and efferent arterioles, the mechanisms are different. The afferent arteriolar constrictor responses to Ang II involve activation of L-type Ca^{++} channels to provide sustained Ca^{++} entry and vasoconstriction.[17] By contrast, efferent arterioles of normal rats do not vasodilate or vasodilate much less in response to L-type Ca^{++} channel blockers and the vasoconstrictor effects of Ang II are not blocked by L-type Ca^{++} channel blockers. Rather, T-type channels have greater functional significance in regulating the efferent arteriolar constrictor responses to Ang II.[17] T-type Ca^{++} channel blockers markedly attenuate the efferent vasoconstrictor responses to Ang II. Storage operated Ca^{++} channels in efferent and afferent arterioles are also activated by Ang II. Thus, although both afferent and efferent arterioles respond to Ang II, the mechanisms for Ca^{++} entry and the activation pathways are different. These differences may be attributable to the differential abundance of AT_{1A} and AT_{1B} receptors on the afferent and efferent arterioles.[10]

Virtually, all aspects of the filtration and tubular reabsorptive processes are influenced by Ang II. Ang II directly regulates the glomerular filtration coefficient with high Ang II concentrations reducing and low levels or blockade of AT_1 receptors increasing the filtration coefficient.[17,18] At the level of the proximal tubule, Ang II binds to receptors at both the apical and basolateral membranes, stimulating the activity of the sodium/hydrogen exchanger and the sodium bicarbonate co-transporter, thereby exerting an important influence on net proximal reabsorption rate.[18] Transport mechanisms in the proximal tubule, loop of Henle, and distal nephron segments are also influenced by Ang II.[18,27,34]

Under conditions in which the activity of the RAS is stimulated and greater amounts of AGT are secreted from the proximal tubule, the locus of influence shifts to include the distal nephron segments where the interaction between the (P)RR and renin/prorenin may contribute substantially to increase intrarenal and intratubular formation of Ang II (Fig. 4).[7,20] The *in vivo* demonstration that increased urinary Ang II concentrations in mice infused chronically with Ang II enhance distal sodium reabsorption[34] emphasizes further the importance that renin and the (P)RR may have in the distal nephron segments contributing to the increases in intratubular Ang II formation. Ang II stimulates the sodium/hydrogen exchanger and the sodium chloride cotransporter in distal tubules, and the amiloride sensitive sodium channel in principal cells of connecting tubules and collecting duct segments.[20,23] This enhanced stimulatory effect allows the kidney to have maximum capability to conserve sodium by markedly decreasing fractional sodium reabsorption.[34] At the whole kidney level, this is manifested as a marked suppression of the pressure natriuresis relationship. Ang II also regulates acid base balance through its effects on the Na^+/H^+ exchanger as well as by influencing the activity of the H^+ ATPase in intercalated cells.[2] Collectively, the actions of Ang II allow the kidney to maximize sodium conservation without compromising its ability to regulate its many other functions.

CONCLUDING COMMENTS AND PERSPECTIVE

Recent findings have stimulated interest in the molecular mechanisms regulating the various components of the intrarenal RAS and particularly the interstitial, intracellular, and intratubular concentrations of Ang II and related peptides. Intratubular and interstitial Ang II levels are regulated independently of the circulating Ang II and exert powerful actions via the stimulation of AT1 receptors on the vascular, glomerular, and tubular structures to provide a synchronous cascade of effects contributing to the ability of the kidney to retain >99% of the filtered sodium. From a functional perspective, the effects of Ang II on proximal nephron reabsorption as

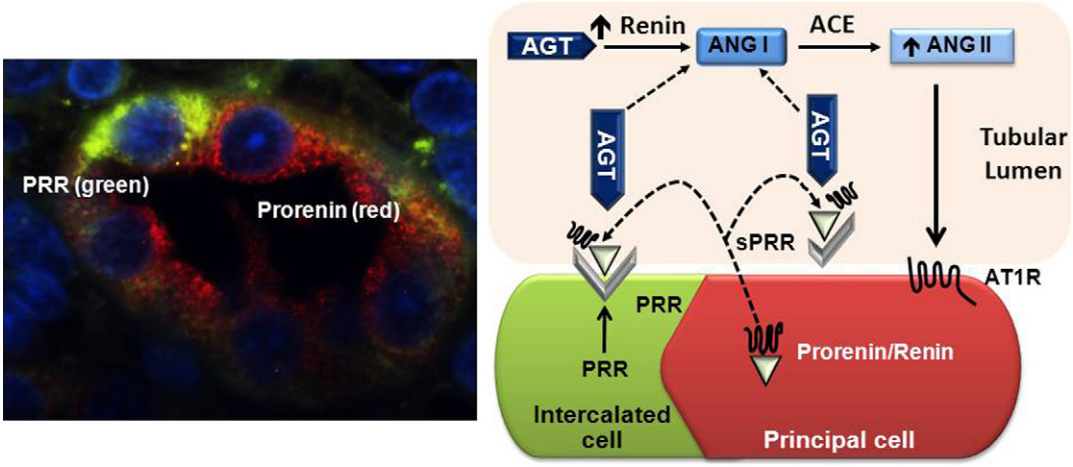

FIGURE 4 Renin and (pro)renin receptor interaction in the collecting duct. Prorenin and renin stimulation in the principal cells of the collecting ducts may increase Ang I formation in the tubular lumen and increase Ang II generation. The presence of (pro)renin receptor at the surface of the intercalated cells along with its soluble form in the tubular lumen increases the catalytic efficiency for renin to form Ang I. In addition, the pro(renin) receptor bound to the membrane of the intercalated cells may anchor prorenin secreted by the principal cells to reduce the washout of prorenin or renin into the urine. ANG—angiotensin; AGT—angiotensinogen; AT1R—angiotensin II type 1 receptor; PRR—(pro)renin receptor; sPRR—soluble form of the (pro)renin receptor; ACE—angiotensin converting enzyme. well as on distal nephron transport function, coupled with the associated actions of elevated aldosterone levels, markedly increase the sodium retaining capability of the kidney. When activated in a physiologically appropriate setting under conditions of volume contraction or salt deficient states, these actions can be life saving. When inappropriately maintained or augmented, however, these effects contribute to the development and maintenance of hypertension. Further, the sustained increases in intrarenal Ang II in a setting of hypertension can lead to progressive renal injury, cell proliferation, and fibrosis associated with activation of several major cytokines and growth factors.[12,33]

Chapter 205

Adrenomedullin

Stefan Hippenstiel, Andreas C. Hocke, Norbert Suttorp
and Bettina Temmesfeld-Wollbrück

ABSTRACT

Pulmonary diseases or involvement of the lung during severe systemic illness significantly contribute to mortality worldwide. In particular, acute or chronic inflammation of the lung impairs vital gas exchange thereby causing life-threating diseases. Adrenomedullin (AM) is a 52-amino-acid peptide expressed throughout the body and induced at sites of inflammation. AM may possess anti-inflammatory and protective effects in the lung, with extensive binding in the lung vasculature. *In vivo* studies provide considerable evidence that AM may improve acute lung injury (ALI), a severe condition with extensive mortality. Studies in humans and animal models indicate that the peptide reduces pulmonary arterial hypertension. Further, in chronic lung disease models of lung fibrosis or emphysema, AM application improved critical markers of the diseases. Overall, AM seems to be an innovative and promising pharmaceutical molecule for treatment of important lung diseases causing serious human illness.

INTRODUCTION

Exchange of gas in vertebrates takes place in the lung. In a human being, via the tracheobronchial tree, >10.0001 of air each day reach the alveolus, a filigree structure essentially consisting of lung epithelial type I and type II cells as well as endothelial cells. Passive diffusion of oxygen or carbon dioxide over the alveolar barrier guarantees blood gas homeostasis.

Several acute or chronic lung diseases are characterized by the perturbation of the alveolar structure and function finally leading to impaired vital gas exchange in the lung. Acute lung inflammation in pneumonia or severe acute lung injury (ALI) is accompanied by the perturbation of the alveolar barrier resulting, for example, from lung edema formation and the infiltration of inflammatory cells during the host pathogen defense.[19] Subsequent proinflammatory mediator production and release of toxic metabolites and proteases by invading polymorphonuclear leukocytes finally cause damage to the alveolar wall with lung edema formation. A critical step is the failure of endothelial barrier function allowing for interstitial and subsequent intraalveolar fluid flux.[19]

In more chronic inflammation of the lung, rarefication of the alveolar structure and/or thickening of the alveolar wall with fibrosis of lung tissue takes place.[27] Finally, independently of the initial cause of the disease, reduced gas diffusion will lead to deleterious oxygenation failure. Further, these processes may be accompanied by diseases such as pulmonary artery hypertension or pulmonary perfusion mismatch, which furthermore aggravate the pathology. These chronic changes not only disturb lung function, they also may induce remote organ dysfunction. In pulmonary arterial hypertension, for example, the blood pressure increase subsequently causes right ventricular heart dysfunction.

Because despite extensive research, all these diseases show high mortality worldwide, it is of outmost importance to find innovative interventional strategies targeting the central pathophysiological processes. This chapter will show that AM, referred to as the amidated mature form of the peptide, is an attractive pharmacological candidate for the treatment of inflammatory pulmonary diseases. AM is a 52-amino-acid peptide belonging to the calcitonin gene-related peptide family, which was first isolated by Kitamura et al. from a human pheochromocytoma in 1993.[16] For details regarding its discovery, gene structure, and processing please see the AM chapters in several sections of the book.

AM EXPRESSION AND CLEARANCE IN THE LUNG

AM is expressed in human lung cells including lung vascular endothelial cells.[17] Intraperitoneal exposure of rats to lipopolysaccharide (LPS) of gram-negative bacteria increases the immunoreactivity of AM in the lung.[2] The authors showed increased AM expression in ciliated epithelium, endothelium, and alveolar type I cells, but they did not prove the specificity of the staining and identified cells based solely on their morphological characteristics.

In another study, AM expression was analyzed in a rat model of combined LPS exposure and acute normobaric hypoxia (9% O_2).[1] The combination of hypoxia and LPS treatments overcomes AM expression observed after each treatment alone. Using *in situ* techniques, AM expression was documented in inflammatory cells within blood vessels, in lung parenchyma, and bronchiolar epithelial cells.[1]

The report of Nishikimi et al.[25] was the first indicating that the lung may be a target for AM in humans. The authors presented results derived from human subjects in which they show reduced AM plasma concentrations in the aorta compared with that of the pulmonary artery. This observation in humans was verified by Hirayama et al.[11] Further, application of the AM receptor antagonist hAM(22–52) in rats causes an increase of AM liberated by lungs, which could not be attributed to the alterations of AM transcription.[4] High expression of AM receptors, consisting of calcitonin-receptor-like receptor (CRLR) and receptor activity modifying protein (RAMP) 2 was noted in the lungs of normal mice and human lung cells including lung vascular endothelial cells.[17] Notably, the high capture of AM in the lung vasculature is highlighted by the suggestion to use AM derivatives as innovative molecules for molecular imaging of lung microcirculation.[9]

AM IN MODELS OF ACUTE LUNG INFLAMMATION

The most severe forms of lung inflammation are ALI and acute respiratory distress syndrome (ARDS).[19] ARDS is the more severe form of the disease, defined by acute onset, bilateral infiltrates on chest radiographs, pulmonary artery occlusion pressure <18 mmHg (if measured or absence of clinical signs of left atrial hypertension), and <200 mmHg ratio of partial pressure of oxygen in arterial blood (PaO_2) to the fraction of inspired oxygen (FiO_2).[19]

The acute inflammation of the lung in ALI/ARDS is caused by primary pulmonary activation (e.g., bacterial pneumonia, inhalation trauma) or systemic inflammatory syndromes (e.g., sepsis). Despite the primary cause, the initial phase of ALI/ARDS is characterized by a severe oxygenation defect, reduced lung compliance, bilateral pulmonary infiltrates, endothelial and epithelial cell injury, subsequent edema formation in interstitium and airspaces, inactivation of surfactant, and neutrophil sequestration and migration in lung.[19] Effective mechanical ventilation with low tidal volume is the standard therapy. However, despite high mortality ranging from 30 to 80%, currently there is no pharmaceutical therapy for ALI/ARDS available.[19] Because there are many different causes, such as bacteria-related pneumonia, massive blood transfusion, peripheral organ reperfusion, or thermal trauma that induce ALI/ARDS, a potential effective pharmaceutical treatment has to show its efficiency in various models of injury.[19]

Intratracheal instillation of the cell wall component lipopolysaccharide (LPS) of Gram-negative bacteria is a widely used experimental model of ALI/ARDS simulating direct injury of the lung. Itoh et al. continuously infused AM in the left jugular vein via implanted osmotic minipumps and induced ARDS 2 h later by the intratracheal application of 1 mg/kg LPS.[13] AM reduced the total protein and albumin levels in bronchoalveolar lavage (BALF) and normalized histological findings. Reduced cleavage of caspase-3 was noted in alveolar wall cells in AM-treated animals suggesting that AM reduces apoptosis of lung cells in this model. Further, the authors noted decreased numbers of total cells and neutrophils accompanied by lower levels of TNF-α and CINC in the BALF.[13] AM also reduces total protein and albumin levels in BALF.

The massive recruitment of polymorphonuclear leukocytes into the alveolar space is an integral part of the acute inflammation of the lung in pneumonia and ALI/ARDS.[19] In the lung, these cells liberate highly reactive oxygen radicals which directly injure the alveolar compartment. Hydrogen-peroxide infusion into blood-free perfused and ventilated rabbit lungs was used to mimic a granulocyte attack of the lung.[10] The application of a single bolus of 0.1 nmol/L ADM 15 min before infusion of hydrogen peroxide reduces the hydrogen-peroxide-related increase in lung capillary filtration coefficient, indicating endothelial barrier stabilization in AM-treated lungs.[10]

Besides leukocyte-derived radicals, hyperoxia is known to induce oxidative stress-related lung injury. In a rat model of hyperoxia-induced ALI/ARDS, Tao et al. tested the effect of AM administered by osmotic minipumps.[28] After the start of AM infusion, the animals were exposed to >95% oxygen for 72 h. Histological examination revealed that AM remarkably improves lung injury score, reduces the infiltration of inflammatory cells, as well as edema formation. The AM infusion increases glutathione peroxidase and superoxide dismutase activities suggesting that AM strengthened the anti-inflammatory capacity of the lung. Along those lines, the authors showed reduced lipid hydroperoxide formation, nuclear factor-kappa B activity, and less inflammatory mediator release (IL-6, KC, MMP-9).[28]

Severe systemic infection (sepsis) is a leading cause of ALI/ARDS and severe lung pneumonia may cause sepsis.[19] The combination of sepsis and ALI/ARDS is characterized by high mortality in man. The pathogen *Staphylococcus aureus* is frequently isolated in septic patients. These bacteria express the highly potent pore-forming α-toxin. To study septic shock related ALI/ARDS in rats, we used central venous infusion of α-toxin.[29] In this model, α-toxin infusion induces a mortality of 50% within 5 h, accompanied by depression of arterial blood pressure, cardiac index, renal failure, and massive systemic endothelial hyperpermeability. In the lung, ALI/ARDS was indicated by pronounced edema formation and albumin extravasation.[29] One hour

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

after the start of central venous α-toxin infusion, therapeutic AM (24 μg/kg per hour) was applied via the peripheral tail vein.[29] After 6 h, AM reduced mortality from 53% to 7%, stabilized arterial blood pressure, increased cardiac index, reduced renal failure, and normalized endothelial barrier function in the lung and other affected organs.[29]

Remote organ damage of the lung is a frequently observed clinical problem in, for example, severe burn or ischemia-reperfusion injury. In severe burn, remote oxidant-induced organ injury with increased lipid peroxidation and generalized tissue inflammation in uninjured organs occurs within hours of injury. The effect of AM administration on burn-induced remote organ damage was investigated in rats.[12] The authors treated rats with subcutaneous application of AM 10 min before burn insult covering 30% of total body surface area. Rats were sacrificed 24 h after the burn insult. AM treatment reduced lipid peroxidation, tissue neutrophil infiltration, oxidant generation in analyzed organs, including the lung. In particular, malondialdehyde and myeloperoxidase activities were reduced in AM-exposed animals compared with that in -treated controls.[12]

Like massive burns, ischemic bowel disease is known to induce remote organ damage including the lung associated with high mortality, Dwivedi et al. hypothesized that the administration of AM and its binding protein (AMBP-1) would have protective effects on intestinal ischemia-reperfusion-related ALI/ARDS in rats.[5] They induced intestinal ischemia-reperfusion by clipping the superior mesenteric artery for 90 min. On release of the clamp, the animals were treated with AM/AMBP-1 for 30 min via a femoral vein catheter. After 4 h, the authors examined lung water content, morphologic changes, and granulocyte myeloperoxidase activity as well as TNF-α and IL-6 expression. In this model, AM/AMBP-1 reduces lung injury, including edema formation, histopathologic changes, myeloperoxidase activity, and cytokine levels in the lung.[5] Comparable results regarding reduced lung tissue injury were presented by the same group in models of obstructive jaundice[32] and gut ischemia and reperfusion injury[34] in rats.

In ALI/ARDS, mechanical ventilation (MV) is a life-saving treatment without alternatives.[19] However, although ventilation strategies have been optimized over the years, even minimal MV-induced physical forces on lung tissue may evoke ventilator-induced lung injury (VILI).[6] VILI is characterized by pulmonary inflammation with liberation of cytokines, recruitment of leucocytes to the lung, increased lung permeability, and surfactant dysfunction finally resulting in the deterioration of pulmonary gas exchange. We tested the hypothesis that AM application would be an adjuvant pharmacological strategy to reduce VILI.[20] Mice were treated with AM, and lung permeability, local and systemic inflammation and markers of distal organ function were assessed after 2 or 6 h of mechanical ventilation with 100% oxygen and protective or moderately injurious ventilator settings, respectively. In this experimental system, AM dramatically reduces lung permeability in VILI in mice, leading to improved oxygenation. AM attenuates leucocyte infiltration in the lung and prevents the increase in lactate and creatinine levels in mice ventilated with high tidal volumes. Importantly, AM protects against VILI even when treatment is initiated 2 h after the beginning of mechanical ventilation in the 6-h VILI mouse model.[20]

AM AND PULMONARY ARTERIAL HYPERTENSION

Pulmonary arterial hypertension (PAH) is characterized by a progressive rise in pulmonary artery pressure and pulmonary vascular resistance with limited dysfunction of the left ventricle.[7] Conditions that result in PAH are heterogeneous and seemingly unrelated and the pathogenesis is poorly understood. Nevertheless, there is an imbalance between vasoconstrictive or proliferative and vasodilatory or antiproliferative mediators in the lung vasculature leading to the proliferation of endothelial and smooth muscle cells, as well as increased extracellular matrix deposition. Finally, the end result is a reduction and/or obliteration of luminal space in the pulmonary vasculature.[7]

Two studies in humans suffering from PAH published by Nagaya et al. provide direct evidence that AM may be an attractive pharmaceutical agent to reduce pulmonary arterial pressure. Intravenous infusion of 0.05 μg/kg/min AM was tested in 13 patients with precapillary pulmonary hypertension.[24] Besides a strong increase in cardiac index, a 32% decrease in pulmonary vascular resistance and a 4% reduction in mean pulmonary arterial pressure were noted.[24] In a second study, the effect of inhaled AM on pulmonary hemodynamics and exercise capacity was determined in 11 patients with idiopathic pulmonary arterial hypertension.[22] Inhalation of 10 μg/kg body weight aerosolized AM produced a 13% decrease in mean pulmonary arterial pressure and reduced pulmonary vascular resistance about 22% without affecting systemic arterial pressure or heart rate. This was accompanied by an increase in peak oxygen consumption.[22] Overall, these pilot studies indicate that AM may have beneficial effects on pulmonary hemodynamics and exercise capacity in patients with pulmonary arterial hypertension.

These results obtained in humans are supported by several animal studies. In three studies, administration of monocrotaline in rats was used as a model.[8,23,33] Monocrotaline induces vascular endothelial cell damage, medial thickening of the muscular pulmonary arteries, and neomuscularization of the nonmuscular distal arteries, leading to pulmonary hypertension and right ventricular hypertrophy. Continuous infusion of monocrotaline-exposed rats with AM via an osmotic minipump for 21 days reduces

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

the increase in right ventricular systolic pressure and the ratio of right ventricular weight to body weight observed after monocrotaline treatment.[33] Further, medial thickening of the pulmonary artery is reduced in AM-treated rats. Harada-Shiba et al. tested the effect of a nonviral gene delivery system of intratracheal administration of polyplex nanomicelles formulated with a therapeutic plasmid of the human AM gene in monocrotaline-exposed rats.[8] Gene transfer of AM by this approach notably increases pulmonary human AM mRNA levels and significantly reduces right ventricular pressure.[8] In a third study with the monocrotaline model, isolated circulating endothelial progenitor cells (EPC) were nonvirally transfected with plasmid DNA of AM and intravenously administered.[23] Transplantation of AM DNA-transduced EPC reduces pulmonary hypertension in monocrotaline-exposed rats and these animals show an increased survival rate.[23]

A severe increase of pulmonary arterial pressure could also be induced by surfactant depletion in newborn piglets. In these animals, Kandler et al. analyzed the effect of aerosolized AM on pulmonary arterial pressure in the presence of the nitric-oxide synthase inhibitor L-NAME.[14] Aerosolized AM reduces mean pulmonary artery pressure, increases oxygenation of the animals without influencing mean systemic arterial pressure.

Finally, experiments in mice with hypoxia-associated pulmonary vascular remodeling also indicate the protective effect of AM on PAH.[18] In AM+/− mice, hypoxia induces significantly greater media wall thickness of the pulmonary arteries and shows enhanced production of pulmonary reactive oxygen species compared with AM+/+ mice. Interestingly, the administration of both exogenous AM and of a superoxide dismutase mimetic normalizes pulmonary vascular media wall thickness and oxidative stress in the lung.[18]

AM AND CHRONIC LUNG DISEASE

Idiopathic pulmonary fibrosis (IPF) is a fatal interstitial lung disease characterized by inexorable, chronic-progressive fibrosis with limited treatment options. A mouse model of bleomycin-induced lung injury was used to test the effect of daily intraperitoneal AM injection.[3] Compared with solvent-exposed animals, AM-treated mice show reduced lung damage and inflammation. In particular, myeloperoxidase activity, the expression of cytokines, of transforming growth factor beta, as well as of nitric-oxide synthase is reduced in AM-treated mice. In addition, reduced activity of nuclear enzyme poly (ADP-ribose) polymerase is indicated by lower poly (ADP-ribose) formation.[3]

In contrast to fibrosis, pulmonary emphysema is defined as abnormal permanent enlargement of airspaces distal to terminal bronchioles. As for IPF, there is no effective treatment that prevents the progression of this disease or even restores normal lung function. In a mouse model, elastase was injected to induce destruction of the alveolar wall. AM administration by osmotic minipumps inhibits the increase in lung volume, static lung compliance, and mean linear intercept in mice exposed to elastase.[21] Importantly, even when AM administration is started 25 days after elastase injection, AM slightly, but significantly attenuates the increase in mean linear intercept, in lung volume and in static lung compliance. By using chimeric mice in which the bone marrow is reconstituted with GFP-positive cells, the authors further show that AM infusion increases the number of GFP-positive cells in the alveolar walls and of GFP/cytokeratin double-positive cells.[21] Hence, it is hypothesized that AM would promote lung regeneration by increasing the number of bone-marrow-derived alveolar epithelial cells.

In addition to emphysema, bronchopulmonary dysplasia (BPD) is characterized by alveolar simplification and abnormal distal airspace enlargement. After intranasal administration of the AM antagonist AM22–52 in rat pubs, decreased lung capillary density, impaired alveolar development and reduced septal counts are detected.[31] Using a model for arrested lung vascular and alveolar growth (oxygen-induced BPD), the study shows that AM attenuates arrested lung angiogenesis and alveolar development. Interestingly, reduced pulmonary hypertension was noted, indicated by decreased right ventricular hypertrophy and pulmonary artery medial wall thickness.[31]

AM—MODE OF ACTION IN THE LUNG

The mechanisms by which AM act in the lung may be as diverse as the diseases mentioned above and can only be briefly highlighted in this chapter.

In acute inflammation of the lung, protection of lung alveolar barrier is a critical point. AM reduces actin–myosin-based endothelial cell contraction and stabilizes endothelial cell–cell contacts thus preventing deleterious edema formation.[10,29,30] Protective lung vascular effects are also mediated by reducing cell apoptosis and the influence of AM on the liberation of vasoactive mediators such as nitric oxide.[5,12,13,18,20,24,33] Increased expression and activity of antioxidative enzymes such as gamma–glutamate–cysteine ligase, glutathione peroxidase, and reductase in AM-exposed lung cells may protect against oxygen radicals-related injury.[15] AM suppresses increase of reactive oxygen species by inhibiting the reduction of glutathione levels in hypoxia/reoxygenation injury. Further, the peptide maintains total and active reduced thioredoxin levels under such conditions in lung cells.

Taking into account that surfactant malfunction is observed in severe lung inflammation, the AM-related increase in the secretion of phosphatidylcholine, the predominant component of pulmonary surfactant, by type II lung alveolar epithelial cells may be protective, too.[26] Besides these effects, numerous

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

reports show that AM reduces the expression of proinflammatory mediators and influences the liberation of growth factors. How bone-marrow-derived alveolar epithelial cells contribute to the lung protective effects needs further investigation in the different models of disease discussed.[21]

CONCLUSIONS

Acute and severe lung inflammation, pulmonary hypertension, emphysema, and lung fibrosis cause tremendous mortality worldwide. In some of the diseases mentioned little or no effective pharmaceutical therapy is available. Thus, there is high medical need for innovative therapies for these important lung diseases. The human endogenous peptide AM has beneficial effects on key aspects of these ailments. Because the available results show a low-risk profile for the use of AM in humans and AM is already given to humans by several application modes, clinical proof-of-concept studies using this peptide in appropriate lung diseases are highly warranted. Nevertheless, there are still large gaps in knowledge regarding AM. For example, signaling mechanisms of AM are still obscure, and most of the complex pathways positively affected by AM in general and even in a particular lung disease are unknown. There are only limited results available about the long-term use of AM and it would be of great interest to understand mechanisms of its beneficial effects. Results from existing *in vitro* and animal studies should be applied wherever possible in human material to substantiate the rationale for the use of AM in humans. Overall, AM seems to be a promising candidate for pharmaceutical therapy of lung diseases.

Chapter 206

Endothelin-1

Karen A. Fagan, Natalie N. Bauer and Ivan F. McMurtry

ABSTRACT

Endothelin-1 is a 21-amino acid peptide with diverse biological activity that has been implicated in numerous lung diseases. ET-1 is a potent regulator of smooth muscle tone, a mitogen, and an inflammatory mediator that may play a key role in diseases of the airways, pulmonary vasculature, and inflammatory lung diseases, both acute and chronic. This chapter will focus on the biology of ET-1 and its role in lung disease.

INTRODUCTION

Endothelins 1, 2, and 3 (ET-1, -2, and -3) are peptides of much interest in the last several decades. Our laboratory and that of Highsmith's identified an endothelial cell-derived peptide vasoconstrictor, which was later sequenced and cloned by Yanagisawa in 1988.[15,17,23,33] Since then, endothelins have been implicated in both normal lung homeostatic pathways and acute and chronic lung diseases. This chapter focuses on the role of endothelins (especially ET-1) in a wide variety of lung disorders, including diseases of the airways and pulmonary vasculature, lung tumors, the acute respiratory distress syndrome, and pulmonary fibrosis.

ENDOTHELIN GENES, CELLULAR DISTRIBUTION, SYNTHESIS, RECEPTORS, AND REGULATION

The endothelins are a family of three distinct isoforms 21 amino acid peptides long (ET-1, -2, and -3). The ET-2 and -3 isoforms differ from ET-1 by 2 and 6 amino acids, respectively, and share significant homology especially at the carboxy terminus with sarafotoxins a–e. The gene for ET-1 is located on chromosome 6, ET-2 on chromosome 1, and ET-3 on chromosome 20.[3] Endothelin-1 is the most abundant isoform. In the normal lung, ET-1 primarily localizes to vascular endothelium, airway and vascular smooth muscle cells, and, to a lesser degree, the epithelium. ET-1 can also be measured in the plasma. ET-2 has similar functions as ET-1 but is found in the myocardium, kidney, and placental tissues primarily. ET-3 circulates in plasma and is also found in the CNS, gastrointestinal tract, lung, and kidney.

All three endothelins are synthesized as preprohormones and then posttranslationally processed to active peptides. For ET-1, the 212-amino acid protein (preproET-1 or ppET-1) is proteolytically cleaved by endopeptidases to big ET-1 (39 amino acids called proET-1 or pET-1), which has 1% the biologic activity of ET-1. pET-1 is then cleaved by the metalloendoprotease endothelin converting enzyme (ECE) to the 21-amino acid peptide. ECE is found in many cell types in the lung, including endothelium, epithelium, and alveolar macrophages. ET-1 is not stored in the cell but is processed and transported through the cell in vesicles resulting in directional secretion of ET-1 toward the interstitium and smooth muscle (80%) and away from the luminal surface of the airway or vessel. This directional secretion allows ET-1 to act in a paracrine or autocrine manner on neighboring cells while secretion into the circulation allows ET-1 to act as a hormone.[10]

There are two primary human endothelin receptors known. Endothelin A (ETA) and B (ETB) receptors are members of the seven transmembrane, G protein-coupled rhodopsin superfamily. The ETA and ETB receptor genes are located on chromosomes 4 and 13, respectively.[2,26] ETA has the highest affinity for ET-1, but all three have equal affinity for ETB receptor. In the lung, ETA receptors are found on vascular and airway smooth muscle cells, whereas ETB receptors are found on the endothelium.[5,21] The ETB receptor mediates clearance of ET-1 from the circulation primarily in the lung and also in the kidney and liver.[9]

ETA and ETB receptor activation on smooth muscle cells leads to vasoconstriction, whereas ETB receptor activation causes bronchoconstriction. Endothelial cell activation of ETB receptors may lead to vasodilation by increasing nitric oxide (NO) production. ETA receptor activity primarily mediates the mitogenic and inflammatory modulator functions of ET-1. Binding of ET-1 to its receptor results in coupling of cell-specific G proteins that activate or inhibit multiple intracellular signaling events. The varied effects of ET-1 receptor activation depend on the G protein and signal

Copyright Elsevier 2024

transduction pathways active in the cell of interest. A growing number of receptor antagonists exist with variable selectivity for one or both receptor subtypes.[22]

ET-1 is primarily transcriptionally regulated by stimuli including shear stress, hypoxia, cytokines lipopolysaccharides, and multiple growth factors (TGFβ, PDGF, EGF, etc) that induce transcription of ET-1 mRNA and secretion of protein. ET-1 itself may also increase ET-1 expression through autocrine activity. Additionally, some stimuli may enhance preproET-1 mRNA stability, leading to increased and sustained ET-1 expression. The number of ETA and B receptors is also cell specific and regulated by a variety of growth factors. The complex regulation of ET-1 expression, cell-specific receptor expression, and receptor-mediated cell signaling contribute to lung disease in a variety of ways.[11]

AIRWAY DISEASES

In the airway, ET-1 is localized primarily to the bronchial smooth muscle with low expression in the epithelium. However, multiple cellular subsets of the epithelium secrete ET-1 including mucous cells, serous cells, and Clara cells with ET-1-binding sites are found on bronchial smooth muscle, alveolar septae, endothelial cells, and parasympathetic ganglia. ET-1 expression in the airways is in large part regulated by inflammatory mediators.

All three endothelins cause bronchoconstriction in intact airways, with ET-1 being the most potent, while denuded bronchi constrict equally to all three endothelins suggesting considerable modulation of ET-1 effects by the epithelium. The majority of ET-1 binding sites on bronchial smooth muscle are ETB receptors. ETA antagonists fail to inhibit bronchoconstriction, whereas ETB agonists augment this activity. Cultured airway epithelium secretes equal amounts of ET-1 and -3, which have equivalent affinity for the ETB receptor, and thus, bronchoconstriction could be mediated by both endothelins.[10]

Inhibition of cyclooxygenase or blockade of histamine or leukotriene receptors has no effect on bronchoconstriction suggesting that, despite the ET-1-stimulated release of these bronchoconstrictors, ET-1-mediated bronchoconstriction is a direct effect of activation of the ET receptors (ETB most importantly). ETA-mediated bronchoconstriction may also be important after ETB receptor desensitization or denudation of the airway epithelium, as may occur during airway inflammation and the late, sustained airway response to inhaled antigens. Interestingly, heterozygous ET-1 knockout mice, with a 50% reduction in ET-1 peptide, have airway hyperresponsiveness but not remodeling, suggesting that the decrease in ET-1 modulates bronchoconstriction activity by a functional mechanism, possibly by decreasing basal NO production.[10]

Asthma is characterized by bronchoconstriction and hyperreactivity with influx of inflammatory cells, mucous production, edema, and airway thickening and ET-1 may have important roles in each of these processes. Although ET-1 causes immediate bronchoconstriction, it also increases bronchial reactivity to inhaled antigens and influx of inflammatory cells, increased cytokine production, airway edema, and airway remodeling. Inhibition of ETA receptors or combined ETA and B receptor blockade leads to decreased airway inflammation in antigen-challenged animals, suggesting that the proinflammatory effects of ET-1 in the airway are mediated by ETA receptors.[11] Inflammation-induced ET-1 secretion may also act in an autocrine or paracrine fashion (or as a hormone released from peripheral mononuclear cells), via the ETA receptor, to increase transepithelial potential difference and ciliary beat frequency, and to exert mitogenic effects on airway epithelium and smooth muscle cells contributing to airway remodeling.[24,10]

ET-1 immunostaining and in situ hybridization for ET-1 in asthmatic airways is increased and correlates with asthma symptoms. In asthmatic patients, there is also a relative increase in ETB vs. ETA receptor expression in the airway, which may contribute to increased bronchoconstriction. Children with asthma have increased circulating levels of ET-1, whereas adults have normal levels between attacks but during acute exacerbations, elevated serum ET-1 correlate inversely with airflow measurements and decrease with treatment. Similarly, bronchoalveolar lavage (BAL) ET-1 in asthmatics is increased to concentrations that may cause bronchoconstriction and inversely correlates with FEV1.[25] Importantly, treatment of asthma with steroids and/or beta-adrenergic agonists decreases BAL ET-1.[10] Polymorphisms in the ET-1 and ETB receptor genes have been associated with asthma.[24,32,35]

Smoking is associated with increased ET-1 concentrations, but chronic obstructive pulmonary disease (COPD), in the absence of hypoxemia or pulmonary hypertension, is not associated with increased circulating ET-1. Also, smokers have impaired ET-1-mediated vasodilation, which correlates with bronchial hyperresponsiveness and may contribute to pulmonary hypertension (and the systemic vascular effects of smoking).[10] In cystic fibrosis (CF), sputum ET-1 levels are increased and may promote neutrophil activation and chemotaxis. *Pseduomonas* infection in non-CF-related bronchiectasis is associated with increased ET-1.[34]

ET-1 has also been implicated in the pathogenesis of *bronchiolitis obliterans* (BO) characterized by dysregulated repair and formation of proliferative, collagen-rich tissue obliterating the normal small airway anatomy. The proinflammatory and mitogenic properties of ET-1 in the airways has led to speculation that ET-1 may be involved in the formation of the lesion. *In vivo* gene transfer of ET-1 to the airway epithelium using the hemagglutinating virus of Japan (HVJ) in rats results in pathologic changes in the distal airways identical to those seen in human BO specimens.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

These changes do not result from nonspecific effects of the HVJ itself but can be attributed to the presence of the ET-1 gene, which is localized to the airway epithelium, hyperplastic lesions, and alveolar cells.[31]

PULMONARY VASCULAR DISEASE

Pulmonary arterial hypertension (PAH) is a fatal disease characterized by vasoconstriction, pulmonary vascular remodeling, and right heart failure. Human PAH is characterized by progressive increases in pulmonary vascular resistance and pulmonary vascular remodeling including formation of the complex plexiform lesion. PAH is classified as idiopathic, heritable, or associated with a variety of other conditions such as connective tissue diseases, human immunodeficiency virus, portal hypertension, hemolytic anemias, schistosomiasis, and congenital heart disease. Pulmonary hypertension (PH) can result from cardiac disease, chronic lung disease, recurrent pulmonary thromboemboli, and a variety of miscellaneous conditions. PH is distinguished from PAH by the arteriopathy and the clinical course. In humans, circulating ET-1 is increased in PAH or PH related to other cardiopulmonary disease. Concentrations are highest in patients with idiopathic PAH. Because the lung is the major source for clearance of ET-1 from the circulation, increased arteriovenous ratios as seen in PAH suggest either decreased clearance or increased production in the lung. ET-1 is also increased in the small resistance arteries and the plexiform lesions in lung tissue of patients with PAH.[10]

ET-1 has been implicated as a mediator in many of the pulmonary vascular changes seen in PAH. In the pulmonary circulation, ET-1 is found in endothelial cells and to a lesser extent the vascular smooth muscle cells. The endothelium secretes ET-1 primarily to the basolateral surface of the cell. ET-1 secretion may be increased by a variety of stimuli including cytokines, catacholamines, and physical forces such as shear stress, and decreased by NO, prostaglandins, and oxidant stress.

The distribution of receptors has important implications in understanding ET-1 regulation of vascular tone as activation of ET-1 receptors leads to both vasodilation and vasoconstriction depending on cell type and receptor. In the whole lung, ETA receptors are the most abundant and are localized to the medial layer of the arteries, decreasing in intensity in the peripheral circulation. ETB receptors are also found in the media of the pulmonary vessels, increasing in intensity in the distal circulation.[29]

In the pulmonary circulation, ET-1 can act as both a vasodilator and vasoconstrictor. The overall effect of ET-1 on vascular tone depends on both the dose and the preexisting tone in the lung. Low dose ET-1 administration during acute hypoxic vasoconstriction will result in transient pulmonary vasodilation while higher or repetitive doses cause vasoconstriction after an initial, brief vasodilation. The vasodilating activities of ET-1 are the result of ETB-mediated nitric oxide production in endothelial cells. Both ETA and ETB receptors acting on vascular smooth muscle mediate ET-1-induced vasoconstriction. In the normal lung, ET-1 causes vasoconstriction by the activation of ETA receptors in the large, conducting vessels of the lung. In the smaller, resistance vessels of the lung, ETB receptors in the media predominate and are responsible for the ET-1-induced vasoconstriction, especially when tone is increased.[27]

The importance of ET-1 in the pathogenesis of PH has also been studied in several models of PH. In the chronic hypoxic PH models, plasma and lung tissue ET-1 is increased after exposure to hypoxia.[29] Treatment with either ETA or ETA and B combined receptor antagonists attenuates the development of hypoxic PH by decreasing vasoconstriction and vascular remodeling.[6] ET-1 is increased in fawn-hooded rats that develop severe PH when raised under conditions of mild hypoxia and in monocrotaline-treated rats that develop PH.[13,30] In both these forms of pulmonary hypertension, the increase in ET may be contributing to increases in vascular tone and to vascular remodeling. Rats that are deficient in the ETB receptor have increased susceptibility to hypoxic PH.[19] Interestingly, transgenic mice overexpressing the human preproET-1 gene, with modestly increased lung ET-1 levels (35–50%), do not develop pulmonary hypertension under normoxic conditions or an exaggerated response to chronic hypoxia.[18]

Several ET-1 receptor antagonists have demonstrated clinical benefit in patients with pulmonary arterial hypertension. The mixed ETA and B receptor antagonist, bosentan, was the first receptor antagonist to demonstrate improvement in patient exercise tolerance, leading to approval of this drug for the treatment of pulmonary arterial hypertension in many parts of the world. ETA selective antagonists, sitaxsentan and ambrisentan, have also shown clinical effectiveness. Ambrisentan is approved for clinical use in many parts of the world. Sitaxsentan, which was approved in many countries (excluding the United States), was withdrawn from the market owing to hepatotoxicity concerns. Long-term follow-up of patients treated with endothelin receptor antagonists suggests an overall improvement in survival compared with historical controls.

LUNG TRANSPLANTATION AND REJECTION

ET-1 has been implicated as an important factor in ischemia–reperfusion injury at the time of transplant and in acute and chronic rejection of the allograft.[16] ET-1 concentration is after perfusion of the donor allograft in the recipient, increasing 3-fold within minutes and remains high for 12 hours after transplantation, declining to near normal levels within 24 hours. Circulating ET-1 correlates with increased

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

pulmonary vascular resistance occurring about 6 hours after transplantation, suggesting that ET-1 may be responsible for the vasoconstriction. This activity may also be associated with the ischemia–reperfusion injury that is the leading cause of early postoperative graft failure and death. BAL ET-1 in lung allografts is also increased several fold and remains elevated up to 2 years posttransplant. Importantly, increased BAL ET-1 is found in the transplanted lung as compared with the native lung in patients receiving single lung transplants. However, ET-1 in BAL fluid does not correlate with episodes of infection or rejection. The source of ET-1 in lung allografts is uncertain with several reports suggesting that it is derived from alveolar inflammatory cells and/or from *de novo* expression in the airway epithelium.[10]

Rejection of the allograft is an important clinical problem. Acute rejection is manifested by diffuse infiltrates, hypoxia, airflow limitation and may lead to respiratory insufficiency and death. In some species, BAL ET-1 levels correlate with acute rejection, whereas in humans, acute episodes of rejection are not associated with further increases in BAL ET-1. Chronic, long-term rejection of allografts, manifested as bronchiolitis obliterans, is the major cause of morbidity and mortality in long-term lung transplant survivors. The etiology of BO is unclear but may be related to repeated episodes of acute rejection, chronic low-grade rejection, or organizing pneumonia. As discussed earlier, an increase in allograft ET-1 may contribute to BO. Importantly, in single lung transplant recipients, BAL ET-1 is increased in the transplanted lung but not the native lung.[10]

PULMONARY MALIGNANCIES

ET-1 may play a role in the development of lung cancer and metastasis to the lung. ET-1 has been implicated in a wide variety of human cancers including prostatic, colorectal, breast, lung, bladder, etc. The importance of ET-1 on tumor growth and survival may lie in its effects on cell survival, mitogenic effects, angiogenesis, and metastatic potentiation. ET-1 stimulates cell proliferation in several tumor cells including prostate, ovarian, and cervical. This proliferation can be inhibited by blockade of the ETA but not ETB receptors suggesting an autocrine function of ET-1 in promoting tumor growth. Several signaling pathways have been implicated most notably the activation of epidermal growth factor receptors (EGFRs). Inhibition of ETA decreased EGFR activation, whereas inhibition of EGFR with gefitinib decreased ET-1 activation of downstream targets. ET-1 has also been implicated in promoting cell survival through the activation of the ETA receptor. ETA activation increased antiapoptotic pathways such as AKT and indeed may contribute to chemotherapeutic resistance observed in several cancer cell lines. These observations suggest the potential of inhibitors of ET-1 receptors, notably the ETA receptor, as a therapeutic tool in the treatment of cancer.[4]

Tumor angiogenesis is necessary for continued growth of the tumor beyond the limits of oxygen diffusion. The growth of vessels into the tumor is also important to metastatic potential of the tumor. ET-1 may play an important role in angiogenesis and tumor growth and survival through induction of VEGF expression and sprouting of new vessels into the tumor and surrounding tissue. This effect is further enhanced by hypoxia (as may be seen in tumors that are expanding rapidly) by ET-1 potentiation of HIF1alpha potentiation of VEGF expression. Inhibition of the ETA receptor inhibits the upregulation of VEGF. Because metastasis is dependent on neovascularization, ET-1 may also be an important mediator of this phenomenon. Tumor invasion is also frequently accompanied by epithelial-to-mesenchymal transition (EMT). ET-1 has been implicated in EMT possibly through downregulation of E-cadherin and beta-catenin as well as upregulation of metastasis-related proteinases (MMPs).[4,7,8]

ET-1 is increased in lung tumors compared to surrounding normal lung tissue. Immunoreactivity was found in pulmonary adenocarcinomas and squamous cell tumors and much less in small cell and carcinoid tumors. In situ hybridization also shows a similar pattern of ET-1 mRNA expression in nonneuroendocrine tumors.[14] ETA receptors are increased in small cell tumors, adenocarcinomas, and large cell tumors, while ETB receptors are expressed primarily in adenocarcinomas and small cell tumors although to a level below normal surrounding lung. ET-1 and ETA receptors are notably found in the cells that comprise the tumor vasculature as well as in the cancer cells derived from epithelium.[4,10] Additionally, ECE, which converts big ET-1 to ET-1, the committed step in ET-1 biosynthesis, is also found in human lung tumors but not in adjacent normal lung. ET-1 expression in lung tumors is also correlated with VEGF levels and a poorer prognosis in non-small-cell lung tumors. Exhaled ET-1 levels may also serve as a biomarker of non-small-cell cancer and may be an early noninvasive test for lung cancer.[4]

Inhibition of ET-1 in cancer is a promising therapeutic approach. Inhibition of ET-1 production through inhibition of ECE is one approach. Targeted, selective inhibition of ETA vs. ETB receptors is another. ETA selective receptor inhibitors are of particular interest despite the clinical trial of zibotentan in prostate cancer that was terminated for lack of efficacy (www.clinicaltrials.gov).

ACUTE RESPIRATORY DISTRESS SYNDROME (ARDS)

Lung injury results in increased circulating ET-1, BAL ET-1, and lung tissue ET-1. In humans, ET-1 levels are increased in sepsis, burns, disseminated intravascular coagulation, acute lung injury, and ARDS and correlate with a poorer

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

outcome with multiple organ failure, increased pulmonary arterial pressure, increased airway pressure and decreased PaO_2/FiO_2, while clinical improvement correlates with decreased in ET-1 levels. The arteriovenous ratio for ET-1 is increased in patients with ARDS but it is not clear if this results from increased secretion of ET-1 in the lungs or decreased clearance.[20] Additionally, in patients who succumb to ARDS, there is a marked increase in tissue ET-1 immunostaining in vascular endothelium, alveolar macrophages, smooth muscle, and airway epithelium, compared with lungs of patients who died without ARDS.[1]

ARDS is characterized by the presence of inflammatory cells in the lung. Since ET-1 may act as an immune modulator, an increase in ET-1 may contribute to lung injury by inducing expression of cytokines including TNF and IL-6 and 8. These cytokines may in turn stimulate the production of many inflammatory mediators leading to lung injury. Additionally, ET-1 activates neutrophils and increases neutrophil migration and trapping in the lung.

Another hallmark of ARDS is disruption and dysfunction of the pulmonary vascular endothelium leading to accumulation of lung water. Infusion of ET-1 raises pulmonary vascular pressure, but it is uncertain if ET-1 by itself increased pulmonary protein or fluid transport in the lung.[28] Impaired alveolar fluid clearance may result from ET-1 activation of the endothelial ETB receptor raising the potential therapeutic utility of mixed ETA and ETB receptor antagonists in patients with ARDS.

PULMONARY FIBROSIS

Pulmonary fibrosis is the final outcome for a variety of lung injuries. After injury to the alveolar wall, inflammatory cells are recruited, inflammatory mediators are released, and then decreased with resolution. Occasionally, the reparative phase becomes disordered resulting in progressive fibrosis.

ET-1 in the lung may be important in the initial events in lung injury by activating neutrophils to aggregate and release elastase and oxygen radicals, increasing neutrophil adherence, activating mast cells, and inducing cytokine production from monocytes. Among the many cytokines induced by ET-1 that are important in mediating pulmonary fibrosis are CCN2, TGFβ, and TNFα. ET-1 is also profibrotic by stimulating fibroblast replication, migration, contraction, and collagen synthesis and secretion while decreasing collagen degradation. Additionally, ET-1 enhances the conversion of fibroblasts into contractile myelofibroblasts. ET-1 also increases fibronectin production by bronchial epithelial cells. Lastly, ET-1 has mitogenic effects on vascular and airway smooth muscle. Thus, ET-1 may play an important role in the initial injury and eventual fibrotic reparative process of many inflammatory events in the lung.[10,12]

Several lines of evidence regarding the importance of ET-1 in human pulmonary fibrosis are available. Plasma and BAL ET-1 levels are increased in idiopathic pulmonary fibrosis. Additionally, lung biopsies from patients with idiopathic pulmonary fibrosis have increased ET-1 immunostaining in airway epithelial cells and type II pneumocytes, which correlates with disease activity. ECE is also increased. Scleroderma is commonly associated with pulmonary hypertension and pulmonary fibrosis. Plasma and BAL ET-1 is increased in these patients, but it is unclear if the presence of either pulmonary hypertension or pulmonary fibrosis increases these levels further. BAL fluid from patients with scleroderma increased the proliferation of cultured lung fibroblasts, which was inhibited by ETA receptor antagonist. This suggests that the ET-1 in the airspace may be contributing significantly to the fibrotic response. Additionally, an increase in ET-1 binding has been reported in lung tissue from patients with scleroderma associated with pulmonary fibrosis. Pulmonary inflammatory cells also seem to be primed for ET-1 production because cultured alveolar macrophages from patients with scleroderma and lung involvement secrete increased amounts of ET-1 in response to stimulation with LPS. Collectively, these observations suggest that augmented ET-1 release may contribute to and perpetuate the inflammatory process.[10,12]

Bleomycin-induced pulmonary fibrosis in animals is associated with increased ET-1 expression in alveolar macrophages and epithelium. The increase in ET-1 precedes the development of pulmonary fibrosis. The use of ET-1 receptor antagonists has had mixed results in limiting the development of bleomycin-induced fibrosis. Pulmonary fibrosis was reported in mice that overexpress human ET-1.[18] These mice are known to develop progressive nephrosclerosis in the absence of systemic hypertension. The transgene is localized throughout the lung with the strongest expression in the bronchial wall. In the lung, the mice develop age-dependent accumulation of collagen and accumulation of CD4+ lymphocytes in the perivascular space. This observation suggests that an increase in lung ET-1 alone may play a causative role in the development of pulmonary fibrosis.

Several clinical trials of ET-1 receptor antagonists in patients with pulmonary fibrosis have yielded mixed results with some suggesting a decrease in disease progression with others failing to show a clinical effect.

CONCLUSIONS

Since its discovery, much evidence has accumulated regarding the biologic activity of ET-1 and its potential role in lung disease. The development of ET receptor antagonists has helped elucidate the role of ET-1 in lung disease and future studies will continue to clarify the role of endothelins in health and disease.

Chapter 207

Kinin Receptors

Sébastien Talbot, James Chi-Jen Lin and Réjean Couture

ABSTRACT

Kinin B1 and B2 receptors (B1R and B2R) are involved in lung inflammation and pulmonary diseases. An emerging role for kinin B1R is proposed in the onset and chronicity of cigarette smoke (CS)-induced lung inflammation and interstitial diseases. B1R can be an IL-1β downstream emphysematous mediator expressed on lung fibroblasts, neutrophils, and parenchymal epithelial cell types I and II. Oxidative stress is another factor operating through the transcriptional nuclear factor NF-kB pathway to enhance B1R expression induced by CS. Through a positive feedback loop, B1R may amplify and perpetuate oxidative stress by enhancing NADPH oxidase activity and thereby promoting chronic lung inflammation and diseases. The detrimental effects of B1R activation include several interactive mechanisms, notably neutrophil infiltration and activation, chemokine and cytokine expression, release of matrix metalloproteinases, and excessive extracellular matrix and collagen formation that lead to airway tissue remodeling and lung fibrosis. Hence, kinin receptor antagonists are expected to become therapeutic in lung inflammation and pulmonary diseases.

INTRODUCTION

Inflammation is a common pathological feature of chronic lung diseases such as lung fibrosis and chronic obstructive pulmonary disease (COPD). Lung fibrosis is characterized by overgrowth of active lung fibroblasts and excessive deposition of extracellular matrix (ECM) within the alveolar septa, which appear to be thicker than the normal ones. The pathological descriptions for COPD include bronchitis, narrowed small airways resulting from airway wall remodeling and corrupted alveoli, that is, emphysema. For both diseases, excessive inflammatory cells appear in the airway lumen and in the disorganized parenchyma. They are involved in a complex inflammatory cascade by releasing cytokines and matrix metalloproteinases,[6,30] which in turn contribute to chronic disease development.[3] Animals exposed to lung inflammation inducers, such as cadmium and cigarette smoke (CS), develop both lung fibrosis and emphysema, two diseases of opposite pathological outcomes.

Acute CS exposure increases the quantity of inflammatory cells and inflammatory mediators in bronchoalveolar lavage fluid (BALF) and pulmonary parenchyma.[31] The expression of inflammatory mediators is associated with ECM breakdown products,[7] which can become an endogenous source of inflammatory inducers leading to chronic inflammation.[21] Thus, CS exposure complicates the networks between inflammatory mediators, inflammatory cells, and parenchymal tissues, which can disturb the physiological role of inflammation in the process of tissue repair. Because of the involvement of such complicated networks, it has been difficult to highlight the inflammatory or pathological effects of CS on pulmonary parenchyma, where fibrosis and emphysema actually occur. We have developed and validated a model using rat lung slices, to study the parenchymal responses to acute CS exposure.[19] In this model, blood supply is absent and the effect of inflammatory cells can be reduced to minimum. We found that kinin B1 receptor (B1R) but not kinin B2 receptor (B2) can be induced in the parenchymal cells by CS exposure, which strongly suggests that B1R might be involved in the CS-associated pulmonary inflammation and interstitial diseases.

KININS

Kinins belong to a group of 9–11 amino acid peptides, including bradykinin (BK), kallidin (KD or Lys-BK), T-kinin (only in rat) and their active metabolites, des-Arg^9-kinins.[11] BK and KD are generated after the proteolytic cleavage of their respective precursors, high-molecular-weight kininogen (HMWK), and low-molecular-weight kininogen (LMWK), by plasma and tissues serine proteases named kallikreins. These peptides undergo rapid metabolic degradation by amino-, carboxy-, and endopeptidases found in tissues and biological fluids.[18] The most physiologically relevant enzymes are kininase I (carboxypeptidases N and M), which remove arginine^9 from kinins to produce active metabolites, neutral endopeptidase 24.11 (enkephalinase), which cleaves the C-terminal dipeptide (Phe–Arg) and pentapeptide (Phe–Ser–Pro–Phe–Arg) from BK, and kininase II (also named angiotensin-I-converting

Copyright Elsevier 2024

enzyme or ACE), which acts as dipeptidyl carboxypeptidase to remove the C-terminal dipeptide, Phe–Arg. Further, ACE cleaves the C-terminal dipeptide Ser–Pro of BK (1–7) to produce BK (1–5), which is the final metabolite of BK and des-Arg^9-BK. T-kinin and KD are also subjected to transformation into BK by aminopeptidases M and P (Figure 1). (See the Peptide Biosynthesis/Processing section of the book.)

KININ RECEPTORS

Kinin receptors denoted as B1 (B1R) and B2 (B2R) have been cloned in several species, belong to the superfamily of G-protein-coupled receptors (GPCR), and preferentially signal through the Gαq/11 and Gαi subunit.[18] The preferential agonists of B2R are BK and Lys-BK (KD), while their metabolites, des-Arg^9-BK and Lys-des-Arg^9-BK, are the preferred endogenous ligands for B1R. Pharmacological sensitivities of kinin receptors vary among species. For instance, human and rabbit B1R show a higher sensitivity to ligands with N-terminal Lysine residue (i.e., Lys-des-Arg^9-BK) contrary to the mouse/rat receptor (i.e., des-Arg^9-BK). Kinin receptors are primarily linked to phospholipase C, phosphoinositide and mitogen-activated protein kinase (MAPK) pathways.[18] B2R can also activate protein tyrosine kinases, phosphatases, phospholipase A_2, and phospholipase D in some cellular systems.[10,18]

KININ RECEPTORS EXPRESSION

The B2R is widely and constitutively expressed in the whole body and mediates most of the physiological responses to kinins. In contrast, the B1R is weakly expressed in healthy tissues,[10] and its expression is enhanced after exposure to proinflammatory cytokines (IL-1β, TNF-α), bacterial endotoxins, and oxidative stress.[10] B1R expression is regulated by MAPK and the transcriptional nuclear factor κappa B (NF-κB).[18,25] A transcriptional regulatory site for NF-κB is found in the promoter region of human and rat B1R gene and specific NF-kB blockers prevent B1R upregulation *in vitro* and *in vivo*.[18]

As a general rule, the constitutive kinin B2R has been associated with acute inflammation, while the inducible B1R seems to play a greater role in the chronic phase of inflammation.[11,27] Consistently, on agonist stimulation, the B2R shows much faster rates of internalization and desensitization than B1R.[18]

ROLE OF KININ RECEPTORS IN AIRWAYS

Thus far, it is known that the stimulation of B2R with BK in airways promotes acute inflammation, bronchoconstriction, cholinergic and sensory nerve stimulation, mucus secretion, cough, and microvascular leakage leading to edema.[16,17,19] B2R-induced bronchoconstriction is mediated by increased intracellular calcium influx, PKC and PLC activation, the

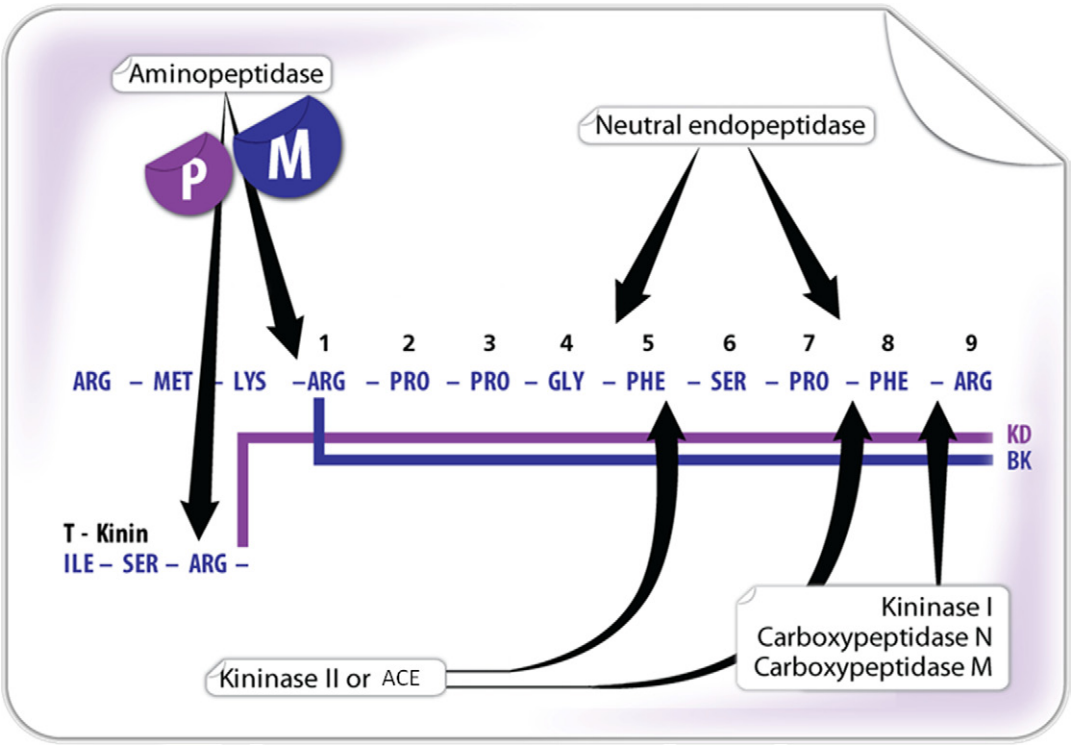

FIGURE 1 Kinins and their metabolites under the action of amino- endo- and carboxy-peptidases.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

release of prostanoids, and activation of sensory C-fibers in normal or inflammatory conditions. Kinins generated during the allergic response cause an activation of sensory nerves to release tachykinins in guinea-pig airways contributing to antigen-induced bronchoconstriction. NO release accounts for B2R-induced vasodilatation in airways microcirculation. Under noninflamed conditions, B1R agonists have no effect on airways in human and animal species both *in vitro* and *in vivo*.

CONTRIBUTION OF IMMUNE CELLS TO AIRWAY INFLAMMATION INDUCED BY KININ RECEPTORS

Peripheral immune cells including neutrophils, eosinophils, leukocytes, and mast cells exert a critical role in airway diseases and chronic lung inflammation.[3] The group of P. Sirois at Sherbrooke University has reported two salient findings: (1) untreated and ovalbumin-sensitized rat BALF cells express functional B2R, yet functional B1R is expressed only in BALF cells of ovalbumin-sensitized and challenged mice; (2) sephadex bead-induced guinea-pig lung inflammation increases BALF cells (neutrophil, eosinophil, and macrophage), an effect prevented by B1R and B2R antagonists. In 1996, the group of E. Whalley reported that B1R and B2R agonists cause human PMN elastase release favoring endothelial cell monolayer permeability. This suggests a role for kinin receptors in inflammation-induced lung permeability and edema. These findings suggest that both B1R and B2R may enhance airway leukocyte infiltration in inflammatory states.

KININ RECEPTORS IN LUNG FIBROSIS AND AIRWAY TISSUE REMODELING

Evidence suggests that BK may play a role in airway tissue remodeling and lung fibrosis. BK enhances alpha-smooth muscle actin expression, fibroblast proliferation, and collagen production through MAPK (p-ERK 1/2) in human lung fibroblasts.[32] Also, BK stimulates the release of the matrix metalloproteinase-2 via B2R and endogenous prostaglandins in guinea-pig tracheal smooth muscle cells. The stimulation of the constitutively expressed B1R in human embryonic lung fibroblasts increases mRNA levels of connective tissue growth factor (4 h) and alpha1 (1) collagen (20 h), suggesting the involvement of B1R in fibrogenesis. Interestingly, expression of B1R is found in the fibrous tissue of patients with pulmonary sarcoidosis, whereas it is nondetectable in normal human lungs. B1R is also found on the basement membranes of bronchopulmonary cells and the surrounding fibrous stroma in transbronchial biopsies taken from patients with interstitial lung disease associated with progressive systemic sclerosis. Moreover, B1R activation induces chemotaxis of human neutrophils and enhances the release of neutrophil metalloproteinase, which leads to lung extracellular matrix (ECM) destruction and accumulation.[6]

KININ RECEPTORS IN LUNG INFLAMMATION INDUCED BY CIGARETTE SMOKE EXPOSURE

Herein, we summarize the current knowledge regarding the expression and pathological function of kinin receptors in lung inflammation induced by CS exposure. Acute (24 h) exposure to cigarette smoke condensate (CSC) increases the expression of B1R (but not that of B2R)

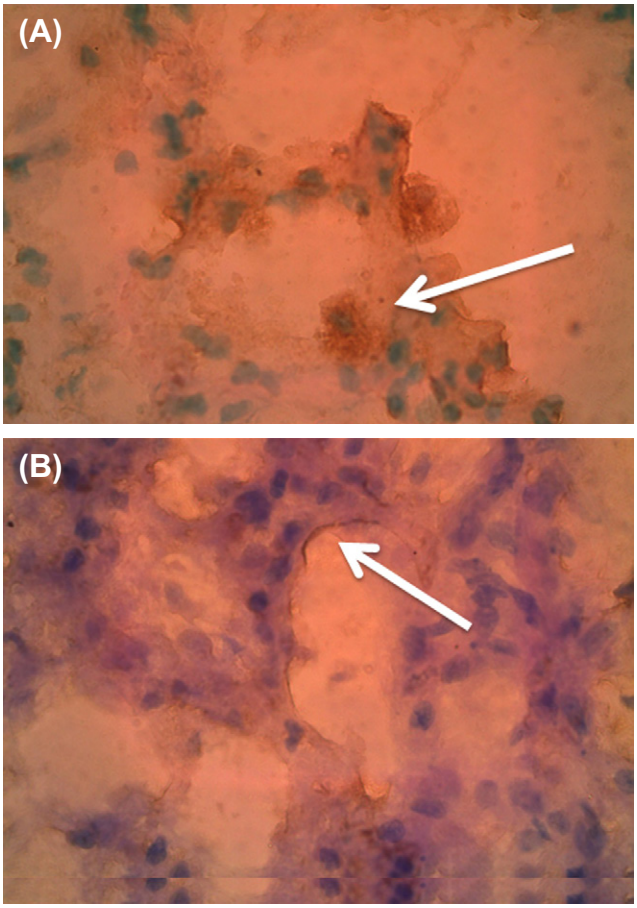

FIGURE 2 Cultured rat lung slices freshly isolated were exposed for 24 h to CSC (5 μg/ml), as described elsewhere.[19] After fixation in 4% paraformaldehyde for 30 min at room temperature, lung slices (20 μm thick coronal sections) were permeabilized in PBS containing 0.2% Triton X-100 (30 min) and exposed to rabbit anti-rat B_1R antibody (1:500; 120 min),[19] washed, incubated with biotin-conjugated antirabbit secondary antibody (1:300; 60 min), washed and incubated with horseradish peroxidase (HRP)-conjugated streptavidin antibody (1:300; 60 min). After final washing, sections were incubated with PBS 0.05% 3,3'-Diaminobenzidine (DAB) + 0.015% H_2O_2 (5 min) for revelation. Nucleus (blue) was counterstained by incubating slides in Mayer's hematoxilin solution (5 min). Slides were coverslipped using DPX mountant (Fluka) and examined under an inverted microscope. Positive B1R staining (brown) is seen on (A) type II pneumocytes (great alveolar cells), according to the large/cuboidal (arrowed) morphology of stained cells, and (B) type I pneumocytes (simple squamous alveolar cells), according to the thin/stretched (arrowed) morphology of stained cells. Magnification = 400×. Pictures are representative of a minimum three slices per rat from three different rats. See color plate 55.

through a mechanism involving oxidative stress, IL-1R and the NF-κB pathway in cultured human alveolar epithelial cell line (A549)[28] and in *ex vivo* rat lung slices.[19] Moreover, rats exposed to inhaled CS for a period of 6 weeks show increased expression of kinin B1R in the trachea.[19] We have further identified that the particulate phase but not the vapor phase of CS is more responsible for B1R induction (see also Lin et al. (2012) *Toxicology*). Interestingly, nicotine enhances kinin-receptor-mediated tracheal contraction in mice through inducing the expression of B1R and B2R.[33] The stimulation of B1R, after its induction by CSC, enhances the production of superoxide anion through NADPH oxidase in human alveolar epithelial cells (A549).[28] Although the exact significance of this finding remains to be confirmed in preclinical studies, it is suggested that B1R can amplify and perpetuate the oxidative stress and promote inflammation and human lung diseases associated with CS.[28]

A more accurate localization of kinin B1R is mandatory to further determine its pathological role in human lung diseases associated with CS. *Ex vivo* rat lung slices represent a unique model to address this issue by immunohistochemistry, considering that lung slices maintain not only the 3-dimensional lung parenchyma structure but also cell–cell and cell–matrix interactions. This *ex vivo* model has been considered a standard tool for approaching lung inflammation and disease.[24] Using such a model, we found specific B1R immunostaining in the alveolar type I and type II pneumocytes of the rat lung slices treated with CSC (Figure 2). Using confocal microscopy and a selective B1R fluorescent agonist,[29] the presence of B1R in lung slices exposed to CSC has been confirmed on lung epithelial cells (Figure 3) and infiltrating neutrophils (Figure 4).

The expression of B1R on neutrophils and the absence of neutrophil migration to inflamed tissues in B1R knockout mice[2] suggest a role for B1R in infiltration of neutrophils in lung tissues after CS exposure. The expression of B1R by parenchymal epithelium after exposure to CS is also relevant as alveolar epithelial cells play a critical role in the generation of lung diseases.[1] CS is a major risk factor in the development of various lung diseases, including pulmonary emphysema and pulmonary fibrosis,[14] COPD, and lung cancer.[34] The mechanisms of these diseases include alterations in alveolar epithelial cells, which are essential in the maintenance of normal alveolar architecture and function. After exposure to CS, alterations in alveolar epithelial cells increase epithelial permeability, decrease surfactant production, and cause an inappropriate production of inflammatory cytokines and growth factors. Ultimately, CS causes the death of alveolar epithelial cells by oxidative stress.[1,31,34] CS contains and generates various ROS and reactive nitrogen species that damage alveolar epithelial cells. Apoptosis of alveolar epithelial and endothelial cells contributes to the pathogenesis of pulmonary emphysema.[12]

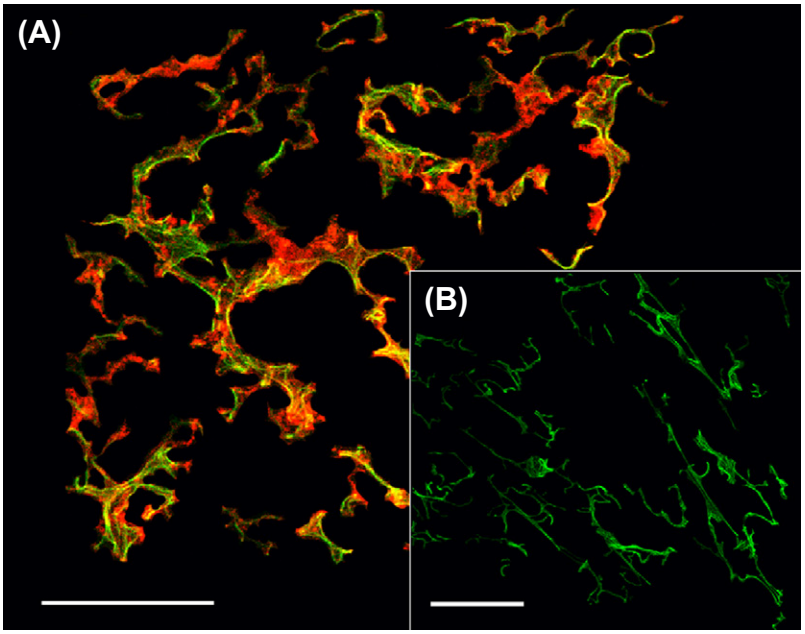

FIGURE 3 Rat lung slices treated with 5 μg/ml CSC (A) or vehicle (B) for 24 h were exposed to [N^{α}-Bodipy]-des-Arg^9-BK, a specific fluorescent ligand for B1R[29] and to Anti-EpCAM (1:1000), a specific antibody against epithelial cells (Abcam, Cambridge, MA; stock number: AB68892). The experimental protocol for confocal microscopy is described elsewhere.[29] The B1R fluorescent dye is red (ext: 550 nm/em: 570 nm) and Anti-EpCAM dye is green (ext: 505 nm/em: 515 nm). Colocalization between B1R and epithelial cells is shown in yellow. Scale bar = 100 μm, magnification 20×. Confocal pictures are representative of a minimum four slices per rat from three different rats. See color plate 56.

The inducible nitric oxide synthase and peroxynitrite are closely related to CS-induced emphysema and pulmonary hypertension.[26] Knowing that the B1R is induced in lung alveolar epithelial cells by CSC and that B1R activation enhances oxidative stress, it is tempting to suggest that B1R may contribute to CS-induced alveolar dysfunction, remodeling, and cellular death.

To further define the downstream mechanism of B1R activation in lung inflammation, we performed a series of PCR arrays to assess changes in expression levels of 86 chemokines and cytokines genes in the presence of des-Arg^9-BK (10 μM, 30 min) in rat lung slices pre-exposed to CSC (5 μg/ml, 4 h). The mRNA expression ratio of selected genes was evaluated against the mean of five housekeeping genes (Rplp1, Hprt1, Rpl13a, Ldha, and β-actin). Des-Arg^9-BK increased mRNA levels of TNF-α (4.6-fold), IL-3 (35.4-fold), Cx3CL1 (31.3-fold), and IL-11 (14.5-fold), but decreased mRNA levels of CCL11 (−21.4-fold), CCL25 (−9.4-fold), Pf4 (−8.1-fold), CCL6 (−4.5-fold), Mif (−1.7-fold), IL-15 (−1.2-fold), IL-4 (−10.7-fold), and CCL22 (−10.2-fold) without affecting the expression of IL-2rg (0.4-fold) and that of the 74 others. Results of the qPCR array were confirmed with a standard qPCR on two target genes, which are among the mostly affected by CSC. Results reveal that the B1R agonist reduces by 76% IL-4 mRNA expression level, while it increases by 930% Cx3CL1 mRNA expression. Moreover, the B1R agonist enhances mRNA expression of its own receptor by 310%, as previously described in human lung fibroblasts[25] (Figure 5).

An important feature of pulmonary inflammation implies the adhesion and transmigration of polymorphonuclear (PMN) cells toward the lung alveolar epithelial cells. The contact is generally mediated by inflammatory mediators. NO and mast cell mediators serve to modulate PMN responses within the microcirculation and interstitium. In addition, many cytokines can act uniquely to alter epithelial adhesive interactions with PMN. Potent inhibitors of PMN-epithelial interactions include interferon-γ (IFN-γ) and IL-4,

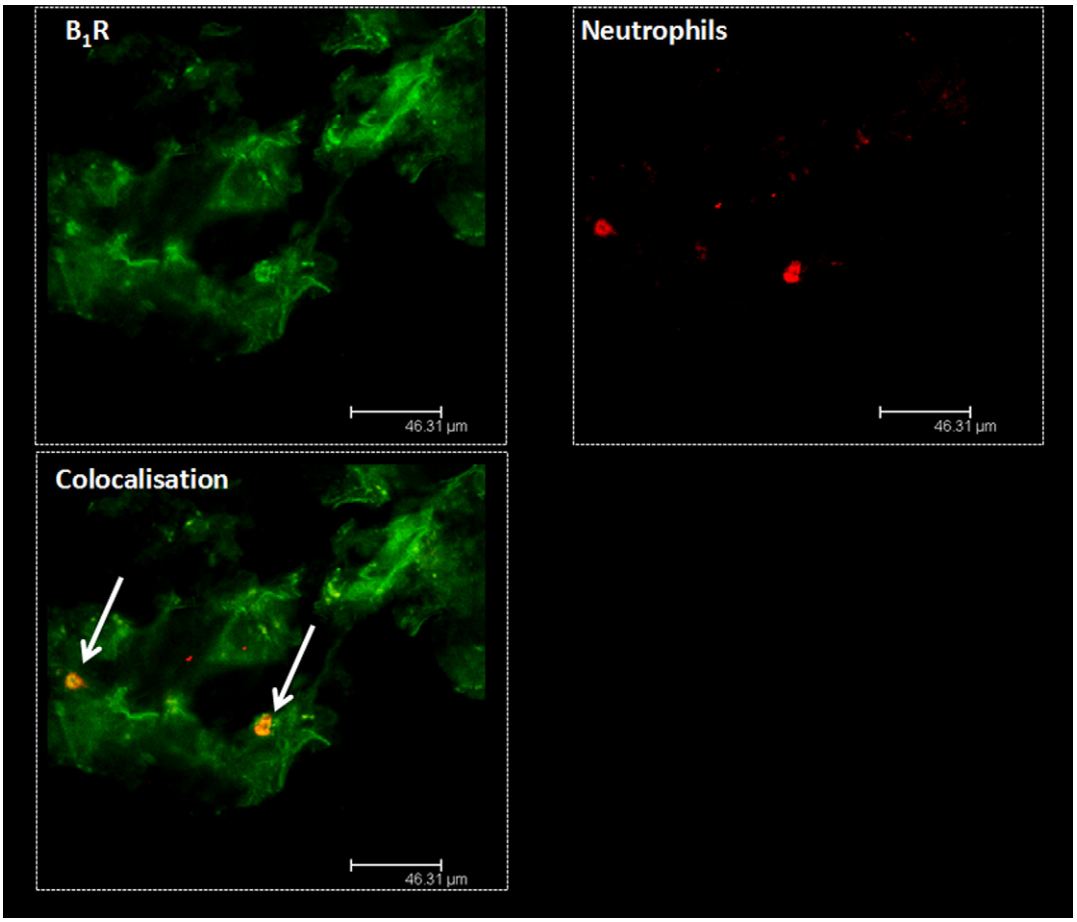

FIGURE 4 Rat lung slices treated with 5 μg/ml CSC for 24 h were exposed to [N$^{\alpha}$-Bodipy]-des-Arg^9-BK, a specific fluorescent ligand for B1R[29] and to Antineutrophil elastase, a specific antibody against neutrophil (1:1000) (Abcam, Cambridge, MA; stock number: AB21595). Colocalization between B1R and infiltrating neutrophils in yellow is indicated by two arrows in the bottom panel. The fluorescent ligand for B1R is green (ext: 505 nm/em: 515 nm) and the Antineutrophil elastase dye is red (ext: 550 nm/em: 570 nm). Scale bar = 46.31 μm. FIGURE 5 Rat lung slices were exposed to CSC (5 μg/ml, 4 h)[19] and then to des-Arg^9-BK (10 μM, 30 min) or its vehicle. The mRNA expression ratios between B1R, IL-4, CX3CL1, and 18S were evaluated using qRT-PCR as described elsewhere[19] and presented as the mean ± S.E.M from six slices/group of two different experiments. Significant comparison to vehicle is indicated by $*P<0.05$.

whereas IL-1, LPS, and TNF-α strongly modulate PMN endothelial interactions.[3] In both cases, modulation at least in part result from expression of new surface proteins. Generally, enhanced PMN adhesion/activation is followed by tissue destruction as observed in COPD and emphysema.[3]

However, the chemokine CX3CL1 (Fractalkine) is a membrane-bound adhesion molecule or a circulating glycoprotein acting through the CX3CR1 receptor. To be liberated in an active form, Fractalkine has to be cleaved by the tumor necrosis factor-[alpha]-converting enzyme to exhibit chemotactic activity for monocytes, natural killer cells and T cells.[5] CX3CR1−/− mice display impairment in the recruitment of immune cells to the inflamed lung.[15] The duo CX3CR1-CX3CL1 may play a role in the sustained recruitment of immune cells in the pathogenesis of CS-induced emphysema.[20] As described above, immune cells and particularly neutrophil migration/activation is an important feature of emphysema and COPD related to CS. Consequently, the enhanced expression of CX3CL1 and the reduction of cytokine expression (e.g., IL-4) by B1R agonist suggest that B1R may contribute to disease onset and disease chronicity in CS-induced lung inflammation.

CONCLUSIONS

1. Growing evidence gathered mainly in animal models suggest a strategic role for kinin receptors in pulmonary and airway inflammatory diseases. An emerging role for B1R is proposed in the onset and chronicity of CS-induced lung inflammatory diseases. IL-1β and TNF-α are pro-inflammatory cytokines involved in CS-induced lung

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

inflammation.[4,7,13] Both are also critical mediators in the pathogenesis of CS-induced emphysema.[8,9] Our results suggest that B1R can be an IL-1β downstream emphysematous mediator expressed in the parenchyma. CS is a potent oxidative stress inducer,[1,23,31] and the oxidative stress is confirmed to be another factor for CSC-induced B1R expression in addition to IL-1β.[28]

2. CS-associated lung inflammatory diseases can be mediated by neutrophils through B1R activation. In addition to neutrophils, activating B1R expressed in type II pneumocyte and lung fibroblasts can stimulate the release of chemotactic cytokines and chemokines for neutrophil infiltration.[16,17] Our new findings also suggest that type I pneumocyte can express B1R and therefore be another cell type mediating neutrophil infiltration.
3. Activation of B1R in human epithelial cells (A549) enhances ROS production through NADPH oxidase.[28] Genetic deletion of NADPH oxidase enhances susceptibility to CS-induced lung inflammation and emphysema in mice.[35] However, sustained CS exposure may result in persistent inflammatory cells infiltration through B1R activation leading to ECM breakdown, which in turn can cause further chronic lung inflammation.[22] Even though the inflammatory and pathological influence of B1R activation in parenchymal epithelial cells has not yet been fully characterized, it is clear that B1R involves neutrophil infiltration and activation. We therefore propose B1R as a biomarker of CS-associated lung diseases.

Chapter 208

PACAP

Mario Delgado

ABSTRACT

In this chapter, I focus on the expression and functions of the pituitary adenylate cyclase-activating polypeptide (PACAP) and its receptors in different areas and structures of the respiratory system. Numerous studies indicate that PACAP is an endogenous regulator of the airway and lung functions, with predominant roles in bronchodilation, pulmonary vascular relaxation, airway inflammation, and mucus secretion. PACAP emerges as a promising candidate for the development of therapies for the treatment of human respiratory pathological conditions such as asthma, primary pulmonary hypertension, bronchitis, and emphysema.

DISCOVERY, STRUCTURE, AND SYNTHESIS OF PACAP

As its name indicates, the pituitary adenylate cyclase-activating polypeptide (PACAP) was originally isolated from the ovine hypothalamus by Dr. Arimura's group in 1989 based on its capacity to stimulate cAMP production in cultures of rat anterior pituitary cells.[19] After the initial isolation of the peptide, its sequencing revealed a C-terminally-amidated polypeptide of 38 amino acids, named PACAP38, which contained an internal cleave-amidation site GKR at position 28. One year later, the same group isolated from the same hypothalamus extracts another peptide able to stimulate adenylate cyclase activity in cells of adenohypophysis, which corresponded to the N-terminal 27 residues of PACAP38, which they called PACAP27.

Based on their sequence and structure, both forms of PACAP belong to a family of structurally related peptide hormones that include secretin, glucagon, growth hormone releasing factor, glucagon-like peptides-1 and -2, helodermin, gastric inhibitory peptide, and vasoactive intestinal peptide (VIP, which shows ~70% identity with PACAP27). The amino acid sequences of the various members of the PACAP family are depicted in Fig. 1A. It is assumed that this superfamily of peptides resulted from the duplication of a common ancestral gene, which then diverged extensively. The structure and sequence of PACAP27 have been highly conserved during the evolution. PACAP27 sequence (the biologically active region of PACAP) is identical in mammals, lizards, frogs, and fishes, and it only changes in one residue in chick and tunicates, suggesting that PACAP must play important physiological roles.

PACAP, like other members of this family, has a secondary structure characterized by long α-helical structure at the C terminus. PACAP27 is proposed to have an initial N terminus sequence of eight amino acid residues, probably with disordered structure, followed by two helical segments at residues 9–20 and 22–26, connected by a region of undefined structure that confers mobility to the molecule.[31] The conformation of PACAP38 mirrors that of PACAP27 and the C-terminal (28–38) extension exhibits a short helix connected by a flexible hinge to the 1–27 region.

PACAP27 and PACAP38 are synthesized from the same precursor molecule (preproPACAP), which also contains a PACAP-related peptide called PRP (Fig. 1B). PACAP38 is the predominant molecular form in the brain and almost all the peripheral tissues (for instance, PACAP27 represents 10% of total PACAP in the brain and 30% in the colon). The occurrence of different proportions of the two peptides in various tissues could be due to the existence of different processing enzymes of the PACAP precursor. The preferential expression of PACAP38 in most organs could be because of the higher metabolic stability of PACAP38 versus PACAP27. The discovery of PACAP and PRP sequences on the same gene suggests that both peptides are cosynthesized in the same tissues. However, PACAP and PRP are not always found in the same cell, suggesting that alternative processing of the nuclear precursor RNA or differential protein processing may occur, resulting in cells expressing either PACAP or PRP.

After its isolation, PACAP was rapidly identified in the central and peripheral nervous system and has since been recognized as a widely distributed neuropeptide [reviewed in Ref. 31]. PACAP was initially localized in hypothalamic neurons that project toward the median eminence and terminate in the capillary loops of the hypothalamo–pituitary

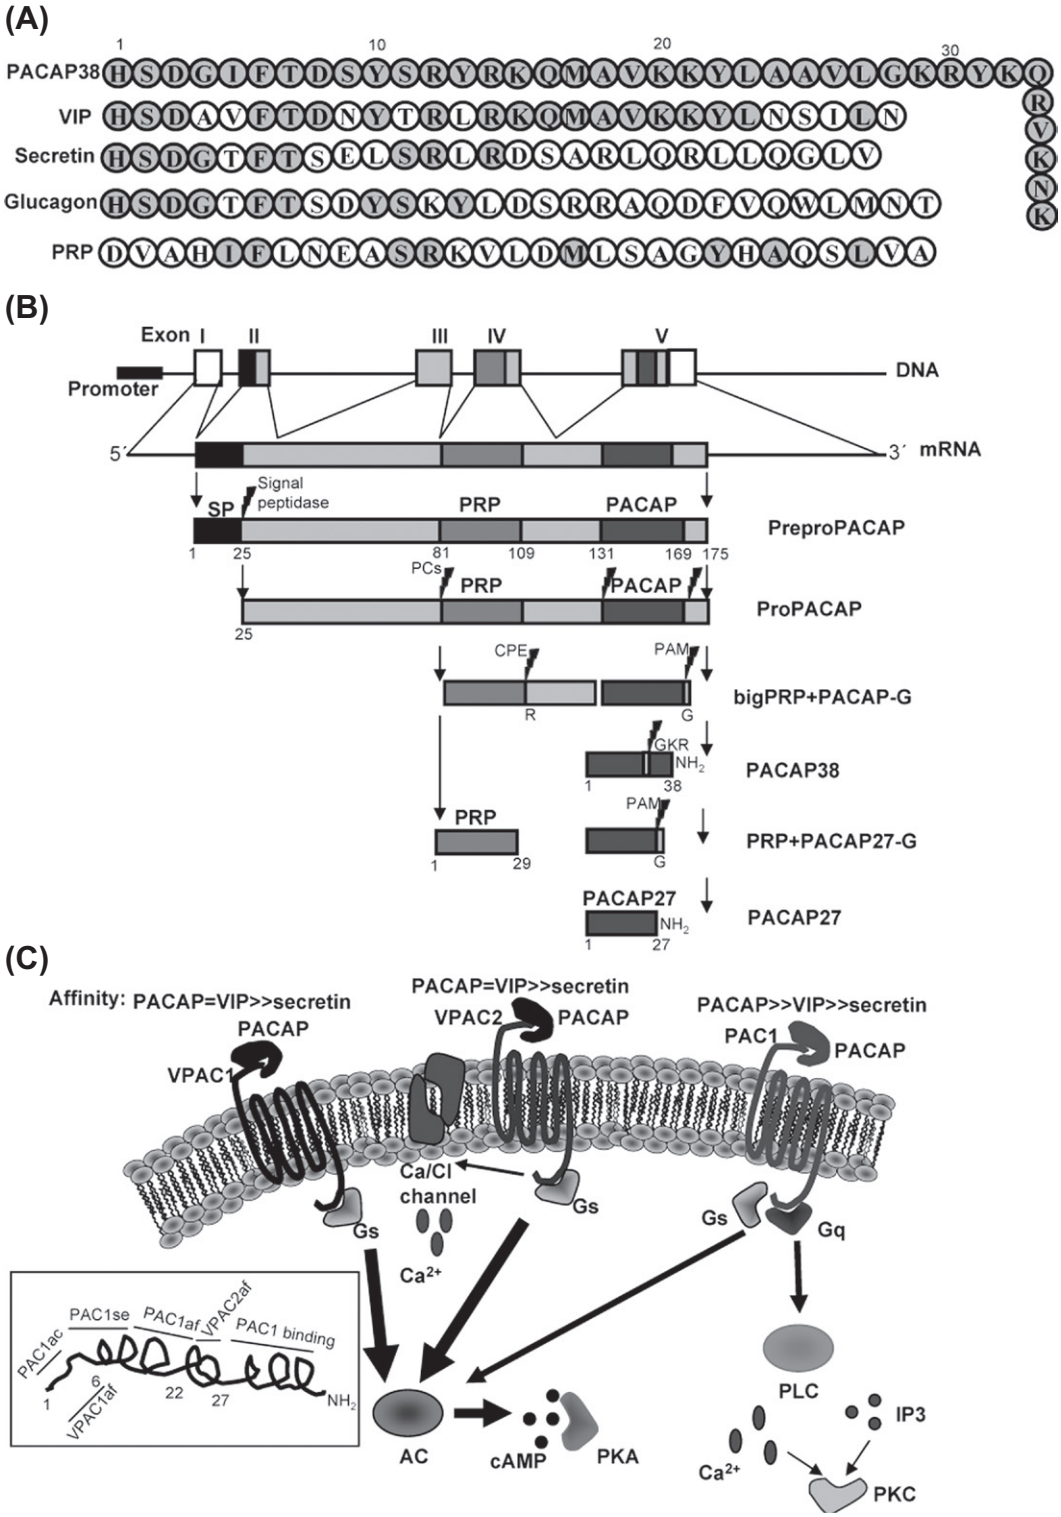

FIGURE 1 PACAP sequence, gene, and receptors. A. Sequence of PACAP and related peptides of the family. PACAP27 shows 68% identity with VIP. B. PACAP gene structure (DNA and RNA): the human PACAP gene, located on chromosomal region P11 of the chromosome 18, contains five exons, each encoding a distinct functional domain on the protein precursor or its mRNA. Investigation of the promoter activity has revealed that PACAP is constitutively expressed and that transcription of the gene can be enhanced by cAMP, phorbol diester, thyroid-specific transcription factor-1, glucocorticoids, progesterone, and PACAP itself. Both forms of PACAP are synthesized from a precursor molecule (preproPACAP), which also contains PACAP-related peptide (PRP). The 175-amino acid preproPACAP is metabolized by a signal peptidase in the endoplasmic reticulum to yield the 151-amino acid pro-PACAP. Pro-PACAP is cleaved by various prohormone convertases (PCs) to a glycine-extended PACAP-G ($PACAP_{125–155}$) and a large intermediate precursor of PRP

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

portal system. Moreover, PACAP is substantially expressed by neurons in several extrahypothalamic brain areas, including cerebral cortex, thalamus, hippocampus, striatum, substancia nigra, nucleus accumbens, locus ceruleus, and pineal gland.[31] PACAP-containing fibers are also found in the periphery in many organs and tissues, including the heart, genital organs, eye, pancreas, adrenal gland, urinary and gastrointestinal tracts and lymphoid tissues (thymus, spleen, and duodenal mucosa), frequently associated with sensory and parasympathetic neurons.[31] Besides neurons, many endocrine, immune, and germ cells also produce PACAP under different physiological and pathological situations.[31]

Within the lung, PACAP-containing nerve fibers have been detected in the respiratory tract of different mammalian species, including man.[11,27,29,32] In the human upper-respiratory tract, PACAP immunoreactivity is found in nerve fibers in close association with blood vessels and glandular structures.[11] In other mammals, nerve fibers with PACAP are found close to small bronchioles and in bronchi beneath the epithelium, among bundles of smooth muscle cells of the bronchial wall, around blood vessels, penetrating the pulmonary arterial smooth muscle bundles, and in seromucous glands.[3,20,27,29,32] As is observed in other peripheral organs, PACAP immunoreactivity mainly colocalizes with VIP in cholinergic nerve fibers in the lung.[29]

PACAP RECEPTORS AND SIGNALING

PACAP27 and PACAP38 elicit their biological actions through binding to a subset of specific membrane receptors belonging to the large family B of G protein-coupled receptors (GPCRs) [reviewed in Ref. 31]. These receptors share a common molecular architecture, consisting of seven transmembrane-spanning domains, which are linked to one another by three extracellular (EC1, EC2, and EC3) and three intracellular (IC1, IC2, and IC3) loops, a long amino-terminal extracellular domain, and an intracellular carboxyl terminus. To date, three types of receptors that can interact with PACAP have been cloned (Fig. 1C). Due to the high homology that exists between PACAP and VIP, these receptors are shared by the two peptides. According to the International Union of Pharmacology nomenclature the VIP/PACAP receptors have been classified as follows: VPAC1 (also known as VIP1, VIP/PACAP type II, or PVR 2) and VPAC2 (also known as VIP2, VIP/PACAP type III, or PVR 3). Both receptors bind VIP and PACAP with equal affinity ($K_d \approx 1$ nM) and activate primarily the adenylate cyclase pathway. The PAC1 (also known as VIP/PACAP type I receptor, or PVR 1) shows a high affinity for PACAP-27 and PACAP-38 ($K_d \approx 0.5$ nM), but a much lower affinity for VIP ($K_d > 500$ nM). This PACAP-preferring receptor activates both adenylate cyclase and phospholipase C and exists in at least 8 different variants that result from alternative splicing of a single transcript and inclusion or exclusion of one or two cassettes, the hip and hop cassettes, which are involved in the differential coupling to second messengers.

VPAC1 is expressed in the brain (especially in the cerebral cortex and hippocampus) and in peripheral tissues such as liver, lung (see below), and intestine, and immune cells. VPAC2 has been localized in brain (especially the thalamus and suprachiasmic nucleus, and at lower levels in the hippocampus, brainstem, spinal cord, and dorsal root ganglia) and in a number of peripheral tissues, including the pancreas, skeletal muscle, lung, heart, kidney, adipose tissue, testis, stomach, and in smooth muscle of blood vessels and of the gastrointestinal and reproductive tracts. PAC1 has been detected predominantly in the brain (olfactory bulb, thalamus, hypothalamus, dentate gyrus of the hippocampus and cerebellum), the adrenal medulla, the anterior pituitary, testis and macrophages.[31]

In general, PACAP receptors in the respiratory system share the same molecular basis of ligand–receptor interaction as in other cells and tissues. Analysis of binding studies at different levels of the respiratory tract indicates the presence of a single class of type II binding sites that show the same affinity for VIP as for both forms of PACAP, and the absence of type I binding sites (selective for PACAP).[14,31] Type II binding sites are localized in acini and excretory ducts of submucosal glands of the trachea and in the lung.[9,14,28] Most of the studies of expression confirmed these initial findings. VPAC1 and VPAC2 receptors have been previously detected in rat and human lung by Northern blot, RT-PCR, Western blot and in situ hybridization

(big-$PRP_{81–110}$). Big-PRP is then cleaved by carboxypeptidase-E like enzymes (CPE) to PRP, and PACAP38G is metabolized and amidated in C-terminus by peptidyl glycine α-amidating monooxygenase (PAM) enzymes to PACAP38. Finally, the internal GRK motif in PACAP38 can be cleaved and amidated to generate PACAP27. C. Three receptors for PACAP, belonging to family B1 of the G protein–coupled receptors, have been described: $VPAC_1$ and $VPAC_2$, which show high affinity for both forms of PACAP and VIP, and PAC_1 that shows selective affinity for PACAP. The three receptors are coupled to Gαs proteins, increase the levels of cAMP through the activation of adenylate cyclase (AC), and activate the PKA pathway. In addition, PAC1 is coupled to the activation of phospholipase C (PLC), elevation of intracellular calcium and phosphoinositides (In3P), and subsequent activation of PKC. Finally, VPAC2 is also coupled to a membrane calcium/chloride channel. The inset represents the schematic secondary structure of PACAP38 with indications of the domains responsible for recognition (PAC1af), activation (PAC1ac), and selectivity (PAC1se) for the different PACAP receptors.

histochemistry. VPAC1 mRNA is highly expressed in the epithelium of large bronchi, whereas VPAC2-R mRNA is present in small terminal bronchioles.[2,30] VPAC1 have been also located by immunohistochemistry in smooth muscle of pulmonary veins, airway epithelium from the trachea to the respiratory bronchioles of rat and human lungs.[2] Moreover, immunohistochemical and gene expression methods indicate that VPAC1 and VPAC2 are present in resident and infiltrating immune cells, including macrophages, lymphocytes and dendritic cells, in the lungs of rodents and humans, especially in inflammatory situations.[2,15] Although PAC1 has been detected in human and rat lungs at mRNA (by RT-PCR) and protein (by immunoblotting of lung membranes), the immunohistochemical methods have failed to identify PAC1 in the respiratory system and the autoradiographycal studies of PACAP27 binding indicate that the putative PACAP receptors were not the PAC1 receptor subtype.[30] This apparent contradiction can be understood in terms of a low density of the PAC1 in lung that makes it difficult to visualize immunostaining because of the relatively low sensitivity of the immunohistochemical method. Alternatively, the expression of PAC1 in the lung could be solely due to the PAC1 expressed by monocytes, macrophages and dendritic cells present in lung in normal and pathological situations.[15,31]

In summary, until the tissue localization of PAC1 is confirmed, VPAC1 and VPAC2 seem to be the major PACAP receptors expressed in the respiratory system. Because these receptors show similar affinities and selectivity for PACAP and VIP, one could assume that most of the effects described for VIP in the respiratory system (see the chapter written by Dr. S. Said in this book section) may be also attributed to PACAP.

BIOLOGICAL ACTIONS AND PATHOLOGICAL IMPLICATIONS

The widespread distribution of PACAP and its receptors is correlated with its involvement in a large variety of biological activities (see Ref. 31 and other chapters in this book for references), especially acting as a highly potent vasorelaxant factor in several tissues, including the gut, eye, brain, and testis. PACAP also acts as a neuromodulator in the brain and has been proposed to be associated with the "visceral forebrain system" that influences and temporarily overrides brainstem control of cardiovascular, respiratory, and gastrointestinal functions. Thus, PACAP increases cardiac output, induces bronchodilatation and smooth muscle relaxation, and regulates secretory processes (saliva and gastric acid) in the gastrointestinal tract and gastric motility. In the endocrine system, PACAP releases prolactin, luteinizing hormone, adrenocorticotrophin, somatostatin, and growth hormone from the pituitary and regulates the release of insulin and glucagon in the pancreas. It also acts on the exocrine pancreas to increase the bicarbonate output. PACAP also promotes analgesia, hyperthermia, learning, and behavior; has neurotrophic effects (modulating cell proliferation and migration and promoting cell survival and differentiation); and regulates bone metabolism, circadian rhythms, embryonic development, and the inflammatory and immune responses.

Regarding the respiratory system, the pattern of expression of PACAP within lungs and respiratory airways suggests a clear role for this peptide in secretory activities and in the regulation of smooth muscle tone of bronchi and pulmonary blood vessels. Thus, different studies have demonstrated that PACAP acts as a potent bronchodilator, a relaxant of tracheal smooth muscle and of pulmonary arteries, a stimulator of airway mucus secretion, and a modulator of the inflammatory response in airways (Fig. 2).

PACAP as a Bronchodilator and a Tracheal Relaxant

Strong evidence in various species indicates that PACAP causes relaxation of tracheal smooth muscle,[1,4,10,35] promotes bronchodilation,[16] and increases nasal airway resistance.[12] Depending on the experimental conditions, different nonexcluding mechanisms have been proposed for the relaxant activities of PACAP on airway smooth muscle, involving direct and indirect actions of smooth muscle cells. Most of the studies implicate the activation of the cAMP/PKA pathway[1,10] and the cAMP-mediated activation of calcium-dependent potassium channels. Others have demonstrated the involvement of nitric oxide/cGMP[26] and carbon monoxide as indirect mediators in the relaxant activities of PACAP.[13] However, another study showed in tracheal strips that most of the effect of PACAP depends on the presence of the airway epithelium and is independent of nitric oxide production. Shigyo and collaborators[27] demonstrated that suppression of smooth muscle contraction by PACAP occurs at a prejunctional level, by decreasing the release of acetylcholine from vagal nerve termini innervating the smooth muscle bundles of the trachea and by blocking the excitatory nonadrenergic noncholinergic component of the vagal nerve in the main bronchi. The bronchodilatatory effect of PACAP was confirmed *in vivo* in a model of histamine-induced pulmonary resistance in anesthetized guinea pigs.[25] Interestingly, the bronchodilatory effect of inhaled PACAP38 lasted much longer than that of VIP or PACAP27,[25] presumably because of a greater resistance to endopeptidase-mediated degradation of PACAP38 versus VIP or PACAP27, a hypothesis that was sustained by *in vitro* studies with precontracted bronchial smooth muscle segments from humans or precontracted tracheal rings from guinea pigs. In fact, more stable PACAP27 analogs, generated by substitutions of various amino acids of naive peptide, showed long-lasting dilatory effects on

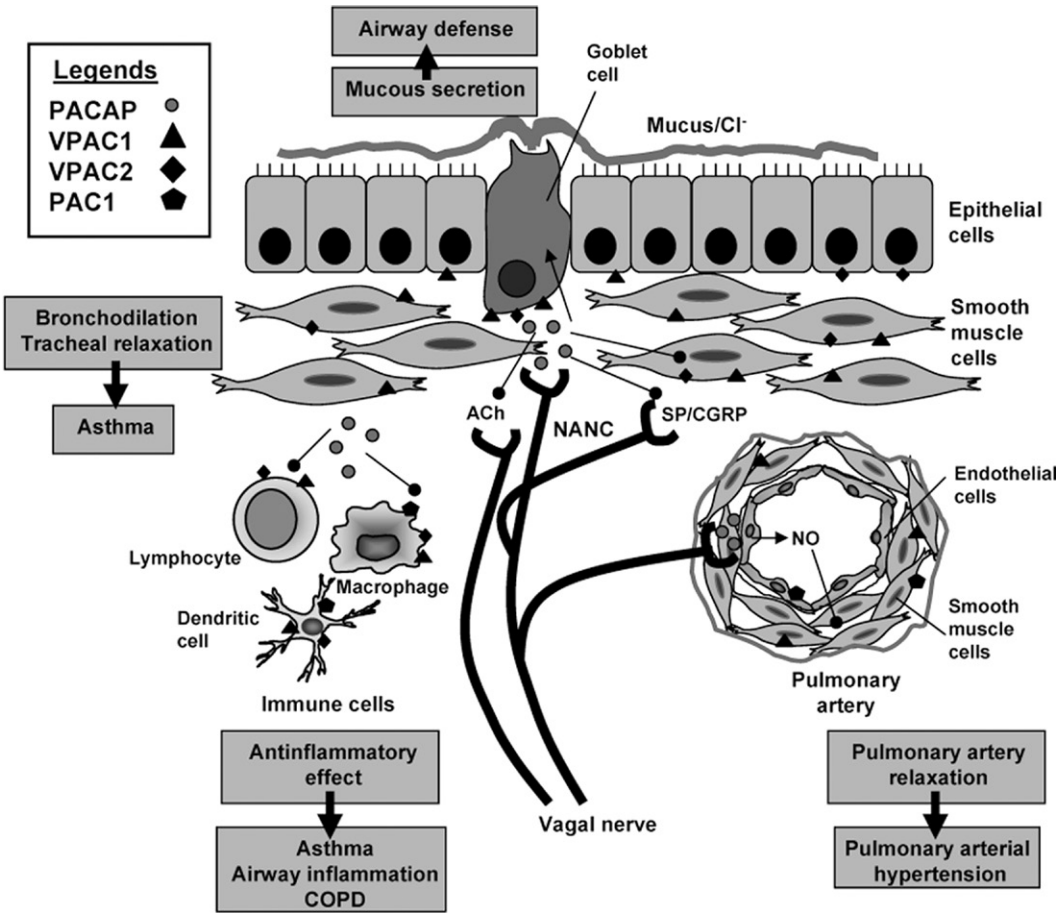

FIGURE 2 Functions and expression of PACAP and its receptors in the respiratory system. ACh, acetylcholine; COPD, chronic obstructive pulmonary disease; NANC, nonadrenergic noncholinergic terminal nerves; NO, nitric oxide.

human bronchi.[35] Based in their bronchorelaxant properties, various works have described the beneficial effects of VIP and stable VPAC1/VPAC2 agonists in models of asthma and chronic obstructive pulmonary disease (see the chapter written by Dr. Said in this book section). Although PACAP could exert similar actions to VIP in these conditions, through VPAC1 and VPAC2, the effect of PACAP through its selective receptor PAC1 is not clear. Although mice deficient for PACAP and PAC1 show higher bronchial hyperreactivity in various models of chronic asthma, this phenotype seems to be mainly dependent on the antinflammatory action of the PACAP–PAC1 signaling on immune cells (see below).

PACAP as a Relaxant on Pulmonary Artery

Similar to its effect on other tissues, PACAP has shown potent relaxant activities on pulmonary arteries from human, primates and guinea pigs *in vitro* and in anesthetized cats *in vivo* (reviewed in Ref. 16). This effect seems to be mediated through the induction of nitric oxide in the endothelial cells, because PACAP failed to induce vasorelaxation in the presence of inhibitors of endothelial nitric oxide synthase or in pulmonary arteries denudated of endothelium. This is an interesting finding because PACAP acts as vasodilator in an endothelial-independent manner in other arteries (i.e., aorta or coronary arteries) (reviewed by Ref. 31), and VIP induced vasodilatation in pulmonary artery segments acting on smooth muscle cells independently of the presence of intact endothelium. Although it needs further investigation, these findings hypothesize that PACAP and VIP act in pulmonary vasorelaxation through different receptors localized in different cells/localization. VIP has been proven to be efficient in the treatment of primary pulmonary hypertension in humans.[24] Moreover, patients suffering from pulmonary hypertension exhibit reduced levels of VIP in serum and lung and increased expression of VPAC1 and VPAC2. Similarly, in piglets, overcirculation-induced pulmonary hypertension decreased VIP and increased VPAC1 expressions in pulmonary arterial smooth muscle, although neither PACAP nor PAC1 expression significantly changed.[32] On the other hand, mice deficient in VIP developed features of pulmonary arterial hypertension in normoxia, with right ventricular hypertrophy and pulmonary vascular remodeling (see the chapter of Dr. Said in this book section). As far as I

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

know, no data exist about the phenotype of PACAP-deficient mice regarding pulmonary hypertension, although deficiency of PACAP leads to breathing defects and sudden neonatal death,[34] because PACAP may control breathing by acting on carotid bodies and via the respiratory centers in the central nervous system.[34] However, PAC1-deficient mice suffer from pulmonary hypertension leading to severe right heart failure and death,[23] suggesting that PACAP signaling through PAC1 seems to play a crucial role in the maintenance of normal pulmonary vascular tone during early postnatal life, despite the scarcity of PAC1 expression on the respiratory system.

Effects of PACAP on Airway Mucous Secretion

Although some controversy exists, some evidence indicates that PACAP could contribute to the natural airway defense against pathogens by regulating mucous and electrolyte secretion by submucosal glands and epithelial goblet cells. Wagner et al.[33] clearly demonstrated that PACAP and VIP are potent stimulators of mucous secretion in isolated rat trachea, with an order of potency of PACAP27 > VIP > PACAP38. In contrast, Liu et al.[17] described in ferret trachea that VIP caused a modest increase in mucus secretion, whereas both forms of PACAP failed to significantly increase secretion. Discrepancies between both studies could be due to the different experimental designs used or to the fact that the main source of mucus in rat trachea is the goblet cells and in ferret trachea is the submucosal glands. Interestingly, VIP, PACAP38 and PACAP27 (in this order of potency) suppressed cholinergic mucous secretion in ferret trachea, although they did not affect acetylcholine-induced mucous secretion.[17] This suggests a prejunctional regulation of cholinergic neuronal secretion by the three neuropeptides, as previously described for the relaxant activity of PACAP on tracheal smooth muscle cells.[27] However, VIP and PACAP27, but not PACAP38, increased the secretion of chloride by human bronchial epithelial cells by inducing the chloride channel CFTR (cystic fibrosis transmembrane conductance regulator).[6] This effect seems to be mediated by VPAC1, although this finding does not explain the lack of effect by PACAP38. In conclusion, PACAP seems to play an important role in airway secretion and the clearance of pathogens, a hypothesis that is in agreement with the antimicrobial activities recently described for VIP and PACAP.

Effects of PACAP on Airway Inflammatory Responses

PACAP has lately emerged as a potent antinflammatory and immunomodulatory factor that acts at various levels (reviewed in Ref. 5). PACAP is produced by immune cells, mainly T lymphocytes, especially under inflammatory conditions, and different immunocompetent cells, including macrophages, monocytes, lymphocytes, and dendritic cells express VPAC1, VPAC2, and PAC1.[5] Through interaction with these receptors, PACAP deactivates macrophages and dendritic cells, inhibiting the production of a plethora of inflammatory and cytotoxic mediators, including tumor necrosis factor-α, IL-6, IL-12, IL-1β, prostaglandin E2, nitric oxide, and various chemokines.[5] A growing body of literature describes the protective effect of VIP in airway inflammatory disorders (see the chapter written by Dr. Said in this book section), although few works, especially *in vitro*, have addressed the effect of PACAP in this scenario. Because PACAP seems to exert its immunomodulatory actions in other tissues/organs mainly through VPAC1,[5] mimicking the effects of VIP, one could assume that PACAP must share with VIP the same prominent role in lung protection under inflammatory conditions. In a model of septic shock, where the lung is one of the major affected organs, systemic injection of PACAP significantly reduced leukocyte infiltration and disseminated coagulation in the lung, and consequently decreased mortality due to sepsis.[5] In agreement, PAC1-deficient mice were more susceptible to suffer sepsis, with the lung especially affected.[18] Similarly, in a model of allergic chronic asthma induced by ovoalbumine infusion, treatment with a PAC1-specific agonist resulted in significant amelioration of airway inflammation, and PAC1-deficient mice showed markedly increased lung inflammatory markers.[8] However, lung function, measured by airway hyperresponsiveness, was affected neither by the PAC1-agonist nor in the PAC1-deficient mice.[8,23] This suggests that PACAP signaling through PAC1 plays a major role in the regulation of the inflammatory response in the respiratory system but not against bronchoconstriction. In agreement with this hypothesis, PACAP-deficient mice showed the same bronchial hyperreactivity to carbacol inhalation than did wild-type mice, but they were more susceptible to bronchoconstriction in conditions of lung inflammation.[8] Moreover, PACAP-deficient mice showed increased inflammatory markers in airways after exposure to bacterial endotoxin.[8]

Effects of PACAP on Proliferation and Apoptosis

Numerous studies indicate that PACAP is a cytoprotective factor in various cells and tissues subjected to different injuries, acting at multiple levels on proliferation, differentiation and survival (discussed in various sections of this book). In the respiratory system, the effect of PACAP on cell proliferation and survival is diverse. As in other cell types, PACAP inhibits, in a VPAC2-dependent manner, apoptotic death of alveolar cells induced by chronic exposure to cigarette-smoke extracts, which is attractive for the treatment of conditions such chronic obstructive pulmonary disease and other lung inflammatory disorders.[22] Similarly, PACAP acts as a protective factor against glutamate

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

cytotoxicity in the lung by reducing oxidant and apoptotic activities.[31] On the other hand, PACAP inhibits the proliferation of pulmonary smooth muscle cells, an effect that could contribute to the amelioration of asthma and other pulmonary obstructive disorders.[31] Contrary to its effects on the proliferative response of smooth muscle cells and other cell types, PACAP induces the growth of human lung tumor cells (small lung cancer and non-small lung cancer), through a mechanism that depends of VPAC1 and PAC1, induction of cAMP and calcium and activation of mitogen-activated protein kinase and the oncongenes fos, myc and jun.[21] Contrarily, VIP inhibited the proliferation of both types of lung cancer cells (see the other chapters of this book). Interestingly, a VIP hybrid with capacity to block VPAC1, VPAC2 and PAC1 inhibited the growth of several human lung cancer lines,[21] whereas treatment with this VIP hybrid or with VIP inhibited proliferation of human lung cancer cells in a xenograft system and reduced the number of blood vessels in tumors (see the chapter written by S. Said in this book section). However, PACAP27 induced the production of vascular endothelial growth factor by human lung cancer lines and the potential of promoting neovascularity in tumors.[21]

CONCLUSIONS

The findings reviewed here clearly indicate that PACAP is an endogenous regulator of airway and lung functions, with predominant roles in bronchodilation, pulmonary vascular relaxation, inflammation, and mucus secretion. Because PACAP38 has higher stability and improved pharmacokinetics than VIP, PACAP38 emerges as an attractive candidate for the treatment of pulmonary disorders where VIP has shown effectiveness such as pulmonary arterial hypertension and sarcoidosis. Although inhalation of PACAP in healthy humans was shown to be safe,[7] caution should be exercised in its use in patients, in view of the growth-promoting activities showed by PACAP on lung cancer cells. In any case, elucidation of the role of PAC1 as a preferring PACAP receptor in the normal physiology and pathology of airways and lung should increase the interest of pharmaceutical companies in the development of nonpeptide analogs of PAC1 for the treatment of asthma, pulmonary hypertension, bronchitis, and emphysema.

Chapter 209

VIP

Sami I. Said, Valerie Chappe and Sayyed A. Hamidi

ABSTRACT

The neuropeptide vasoactive intestinal peptide (VIP) is widely distributed in the central and peripheral nervous systems and is expressed in all pulmonary structures, including airway epithelial cells, airway and pulmonary vascular smooth muscle cells, secretory glands, and immune and inflammatory cells. VIP actions in the lung, mediated predominantly by the adenylyl cyclase–cAMP pathway and by receptors shared with PACAP, include relaxation of airway and vascular smooth muscle and inhibition of their proliferation, modulation of inflammatory and immune responses, protection against cell injury, and stimulation of water and electrolyte transport. Strong evidence suggests that physiological roles of VIP in the lung include cotransmission of airway and pulmonary vascular smooth muscle relaxation, modulation of immune and inflammatory responses, and guarding against the pathogenesis of bronchial asthma, pulmonary hypertension, and CFTR dysfunction in cystic fibrosis. Therefore, it seems probable that VIP has strong therapeutic potential in a variety of clinical disorders.

HOW WAS VIP DISCOVERED?

In 1967, as a pulmonary physician in Richmond, Virginia, I (S.I.S.) wondered why serious acute events in the lung, such as severe pneumonia and the Acute Respiratory Distress Syndrome (ARDS), are often complicated by systemic hypotension. One possibility that appealed to me was that injured lung tissue releases into the circulation one or more vasodilator compounds. Preliminary experiments confirmed that supernatants of lung extracts, when injected into other animals, reduced systemic arterial blood pressure. This hypotension was not fully explained by the presence in lung extracts of the then-known vasodilators histamine, prostaglandins, and kallikreins, suggesting that one or more vasodilator peptides contributed to the phenomenon.[16]

To seek validation of this explanation, and identification of such a peptide, I decided to spend a sabbatical year at the Karolinska Institute, in Stockholm, Sweden, with Professor Viktor Mutt, a leading peptide biochemist, as my guide and mentor.

Although we soon confirmed the presence of strong vasodilator activity in extracts of porcine lung, isolation of a pure peptide with this property was progressing too slowly, because of the difficulty in securing sufficient quantities of fresh lungs.[22] Although lung extracts were in short supply, extracts of upper small intestine were plentiful in Viktor's laboratory, because he was preparing the gastrointestinal hormones secretin and cholecystokinin on a large scale. One day, as I wished we were searching for our peptide in the intestine instead of in the lung, I recalled that both upper intestine and lungs originated from the same embryonic bud, the foregut, and decided to look for vasodilator activity in intestinal extracts. The search proved fruitful, culminating in the isolation of the "vasoactive intestinal peptide," so named because, at that point, we did not know whether it also existed outside the intestine or whether it had any other biological activity. During its purification, the dominant biological activity of VIP was closely associated with that of secretin.[23,24] Reading the original articles on the discovery of secretin, I noted that Bayliss and Starling observed some "vasodepressor" activity in the secretin-containing preparations, which they attributed to the presence of an unidentified compound that, in all likelihood, was VIP!

Soon after VIP became available in pure form, its amino acid composition and sequence were identified,[12] and it was successfully synthesized, by Miklos Bodanszky.[1] After the development of a radioimmunoassay for the measurement of VIP content in plasma and tissues, and reports that the "watery diarrhea" or "pancreatic cholera" syndrome was attributable to excessive production of VIP by certain tumors, we began to receive biological samples from around the country and abroad, from patients suspected of having that disorder. Those assays revealed that the highest levels of VIP were associated with neurogenic tumors, especially neuroblastomas.[21] In addition, analysis of neuroblastoma cell lines showed them to be rich in immunoreactive VIP. As I looked into the biology of these cells, I learned that they share many features with normal neurons, so I wondered whether VIP could also be produced by normal neurons.

With neurologist colleagues, we searched for the peptide in the human brain and peripheral nerves and found it to be widely and selectively present. VIP was thus rediscovered as a neuropeptide and a probable neurotransmitter.[27]

VIP IS A MEMBER OF A FAMILY OF PEPTIDES[24]

VIP is a 28-amino acid residue peptide (Fig. 1) that belongs to a family of structurally and functionally related peptides, including secretin, glucagon, gastric inhibitory peptide or glucose-dependent insulinotropic peptide (GIP), the peptide with N-terminal histidine and C-terminal isoleucine amide (PHI) and its counterpart in human tissues, the peptide with N-terminal histidine and C-terminal methionine amide (PHM), corticotropin-releasing hormone (CRH), growth hormone-releasing hormone (GHRH), sauvagine, urotensin I, helodermin, and the pituitary adenylate cyclase-activating polypeptides (PACAP), with which VIP shares the greatest degree of homology (Fig. 2).

TISSUE DISTRIBUTION AND CELLULAR LOCALIZATION

The expression of VIP in different cells and organs has been defined by immunofluorescence, radioimmunoassay, and more recently, by measurement of VIP mRNA. In the brain, the peptide is found in the highest concentrations in the cerebral cortex, suprachiasmatic nucleus, hippocampus, amygdala, and striatum, but it is also present in the midbrain periaqueductal gray and the sacral spinal cord. In the peripheral nervous system, VIP is localized in the sympathetic ganglia, the vagus nerve, predominantly motor nerves such as the sciatic nerve, and nerves supplying exocrine glands, blood vessels, and nonvascular smooth muscle.[3–5,25]

In the lungs, VIP-containing nerve fibers and nerve terminals are principally localized in the smooth muscle layer of the airways from the trachea through the small bronchioles, around submucosal mucous and serous glands, and in the walls of both pulmonary and bronchial arteries. Immunoreactive VIP is also present in neuronal cell bodies forming microganglia that provide a source of intrinsic innervation of pulmonary structures. In addition to its neuronal localization, VIP is richly present in the immune system, including inflammatory cells such as mast cells, eosinophils, and B and T lymphocytes.

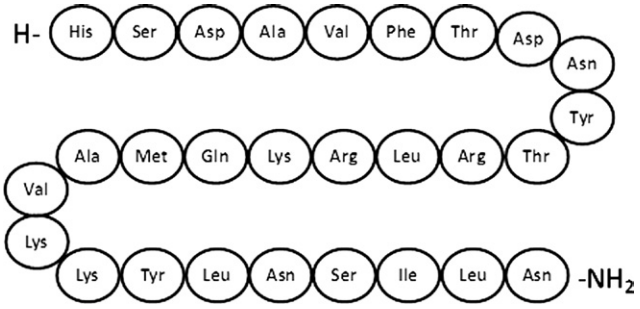

FIGURE 1 Amino acid sequence of VIP.

COLOCALIZATION WITH OTHER PEPTIDES AND NEUROTRANSMITTERS

VIP coexists with acetylcholine in most cholinergic neurons, both central and peripheral. In exocrine glands, this colocalization serves the dual functional advantages of promoting both blood flow and glandular secretion. VIP may also be colocalized with other peptides, including PHI (or PHM, its human counterpart), peptides that are synthesized from the same precursor molecule, and substance P. Other neurotransmitters that may coexist with VIP include nitric oxide (nitric oxide synthase) and the excitatory transmitter glutamic acid.

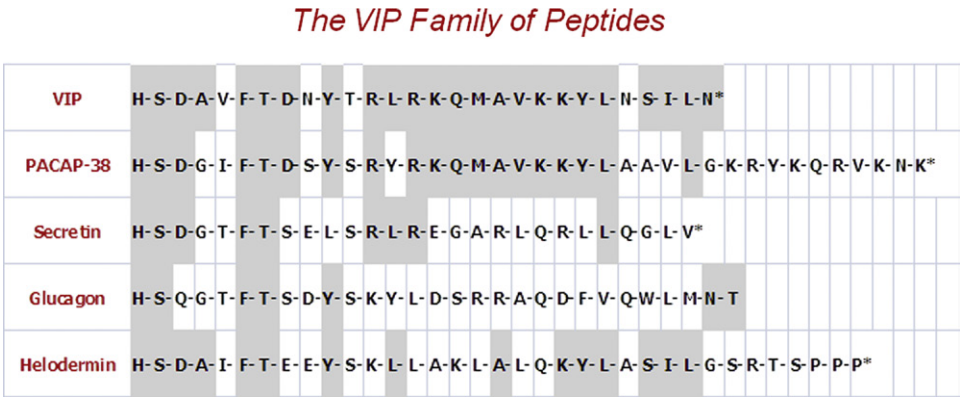

FIGURE 2 Some members of the VIP family of peptides. Amino acid homologies are noted by shading.

BIOLOGICAL ACTIONS IN THE LUNG

Airways

Airway Smooth Muscle Tone[5,6,11,15,17]

VIP relaxes airway smooth muscle, both *in vitro* and *in vivo*, in guinea pigs, rats, mice, rabbits, dogs, and humans. VIP also counteracts airway smooth muscle contraction induced by a variety of bronchoconstrictor agents, including histamine, prostaglandin F2α, kallikrein, leukotriene D4, neurokinin A, serotonin, and endothelin (Fig. 3). Relative to most other bronchodilators, VIP-induced airway relaxation is longer lasting and is unaffected by blockade of adrenergic or cholinergic receptors or of cyclooxygenase activity. In limited trials in human asthmatics, however, VIP, given by inhalation, is generally less effective than expected in relieving bronchoconstriction, probably because of its degradation by proteases in airway secretions.

Airway Smooth Muscle Proliferation

VIP inhibits human airway smooth muscle proliferation,[9] an action that is potentially beneficial in reducing airway remodeling, which contributes to increased airway resistance in bronchial asthma.

Tracheobronchial Secretion

VIP stimulates water and ion transport in canine tracheal epithelium and may also promote macromolecular secretion. The coexistence of VIP and acetylcholine in cholinergic neurons brings together the blood flow-promoting and secretion-promoting effects of VIP and acetylcholine, respectively.

Pulmonary Circulation[6,13,15,20]

VIP dilates the vessels supplying the nose, upper airways, trachea, and bronchi, as well as pulmonary vessels. As a pulmonary vasodilator, VIP is more potent than isoproterenol, acetylcholine, or prostacyclin, and its action is independent of endothelium. Given intravenously in sufficient concentrations, VIP reduces both pulmonary and systemic vascular resistance. Delivered as an aerosol, however, it acts as a selective pulmonary vasodilator. As with airway smooth muscle, VIP suppresses human pulmonary vascular smooth muscle proliferation, a major feature of pulmonary hypertensive disease.

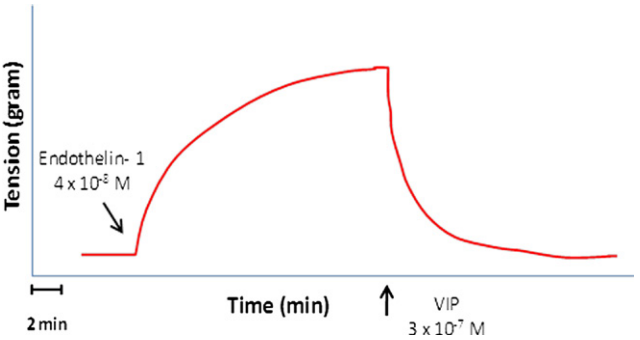

FIGURE 3 VIP as a tracheal smooth muscle relaxant. Isolated strip of guinea pig trachea was strongly contracted in response to endothelin 1. Application of VIP promptly and completely restored tracheal tension to resting level.

Immune and Inflammatory Responses[2,28,30]

VIP modulates several aspects of the immune and inflammatory responses: (1) It has a moderate inhibitory effect on antigen-induced release of histamine from guinea pig lung. Because the peptide is normally present in mast cells, the peptide may act as a natural modulator of mast-cell degranulation, an important mechanism underlying acute asthmatic and anaphylactic reactions. (2) VIP also modulates T-cell activation and inhibits the expression of proinflammatory cytokines (TNF-α, IL-6, IL-12, IL-18) and chemokines (e.g. RANTES); inducible nitric oxide synthase (*i* NOS), and proteases (MMP-2 gelatinase), while upregulating the expression of anti-inflammatory cytokine IL-10 and promoting the generation of tolerogenic dendritic and regulatory T-cells.

Anti-Injury and Cell-Protective Effects[18,19,30]

Acting by a number of actions, VIP prevents or attenuates acute lung injury in a variety of experimental models. These actions include antiapoptotic, prosurvival effects that are mediated by 3 complementary and synergistic mechanisms: Inhibition of the activation of caspases, key effectors of apoptosis; upregulation of the antiapoptotic protein bcl2; and suppression of cytoplasmic translocation of cytochrome c, a critical step in mitochondrial-mediated apoptosis.

RECEPTORS AND SIGNAL TRANSDUCTION PATHWAYS

Specific, high-affinity receptors for VIP have been identified in membrane preparations of normal lungs and human lung tumor cells. These receptors, localized immunocytochemically and by the increased cyclic (c)AMP levels resulting from activation by VIP, exist in a variety of pulmonary cells. Molecular and pharmacologic studies have led to the identification, characterization, and cloning of at least three receptors for VIP and the related PACAP peptides (see the chapter in this section of the book by Mario Delgado). These receptors, known as VPAC receptors, belong to a distinct family of seven transmembrane-domain receptors coupled to G proteins. The three VPAC receptors are VPAC1 and VPAC2, both of which respond to VIP and PACAP with

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

comparable affinity, and PAC1, which has greater affinity for PACAP than for VIP.

The actions of VIP are mediated principally by adenylyl cyclase stimulation and cAMP production. VIP biosynthesis itself is promoted by higher cAMP levels, and thus, the peptide is potentially capable of stimulating its own generation. In some VIP actions, additional second messengers and signal transduction pathways are involved, for example, phospholipase C activation in the case of the PACAP-preferring PAC 1 receptor.

Some actions of VIP, such as the relaxation of airway and vascular smooth muscle cells, are mediated partly by NO, released from neurons or smooth muscle cells. Through its activation of a constitutive NOS in neural elements and smooth muscle, leading to activation of cytosolic guanylyl cyclase, VIP can stimulate intracellular cyclic GMP formation. The contribution of neuronal NOS to VIP-induced relaxation of the trachea was examined in neuronal NOS-knockout mice and estimated to account for a significant proportion of the relaxation. It is now believed that both NO and carbon monoxide (CO) mediate VIP-induced relaxation of airway, gastrointestinal, and other smooth muscle. The combined activation of cyclic AMP and GMP pathways ensures greater smooth muscle relaxation, inhibition of mitogenesis, and smooth muscle cell proliferation.[26]

PHYSIOLOGICAL ROLES

The physiological significance of VIP is suggested by 3 lines of evidence:

1. It is widely present, in a conserved structure, throughout the animal kingdom.
2. Deletion of the VIP gene alters the expression of almost 27% of all other genes.
3. VIP KO mice express the phenotypes of at least 4 disorders, which are correctable with VIP.[7]

Deletion of the VIP gene results in (i) bronchial asthma, manifested by airway hyperresponsiveness and airway inflammation; (ii) pulmonary arterial hypertension, with vascular remodeling, right ventricular hypertrophy, and perivascular inflammation; (iii) cystic fibrosis (CF)-like features, including dysfunctional CFTR, associated with structural abnormalities in the lung and gastrointestinal tract; and (iv) increased susceptibility to death from endotoxemia.

Several lines of evidence suggest the following physiological roles for VIP, with special reference to the lungs:

1. Mediation of vascular and nonvascular smooth muscle relaxation: Together with NO and CO, VIP is a cotransmitter of neurogenic, noncholinergic, nonadrenergic smooth muscle relaxation.
2. Modulation of smooth muscle cell proliferation.
3. Modulation of inflammatory responses.
4. Modulation of immune responses and promotion of immune tolerance.
5. Enhancement of cell survival, and defense against injury and apoptosis: VIP exerts these effects by attenuating inflammation and reducing apoptotic cell death. For example, VIP protects lung cells against oxidant stress resulting from: xanthine + xanthine oxidase, paraquat, excitotoxicity (glutamate toxicity), and ischemia-reperfusion injury; as well as platelet-activating factor and endotoxin lipopolysaccharide.
   In addition, VIP also protects neuronal cells against injury, as by oxidants, for example, H_2O_2 and glutamate; as well as by envelope protein of HIV, nutrient or nerve growth factor deprivation, tetrodotoxin, and β-amyloid (Aβ). Further, as discussed in the chapter by Paul Gressens, VIP promotes embryonic brain growth and differentiation.
6. Stimulation of water and electrolyte transport: Among the earliest biological actions of VIP to be recognized is its ability to promote water and electrolyte transport. This is true for Cl^- in bronchial and intestinal epithelium, and for HCO_3^- in pancreatic secretion.

As earlier mentioned, mice lacking the VIP gene express CF-like pathophysiological features, and the role of VIP in the pathogenesis and possible modulation of the human disease is further discussed later. Finally, excessive stimulation of H_2O/Cl^- transport, in the presence of VIP-secreting tumors (VIPomas), results in the "watery diarrhea syndrome."

VIP IN THE PATHOGENESIS AND MODULATION OF PULMONARY DISEASE

Bronchial Asthma[17,31]

A close link between VIP deficiency and the pathogenesis of asthma is suggested by 3 sets of findings:

1. VIP-immunoreactive nerves are absent in airways of a group of severely asthmatic subjects who died accidentally.
2. Mice with targeted deletion of the VIP gene exhibit airway hyperresponsiveness and histopathologic features of airway inflammation.
3. As an airway smooth muscle cell relaxant, with anti-inflammatory and antiproliferative activities, VIP is well qualified to counteract the pathophysiological features of bronchial asthma, including airway constriction, hyperresponsiveness, airway inflammation, and, in severe cases, smooth muscle proliferation.

Despite its demonstrated effectiveness in animal models *in vivo*, however, the results of several clinical trials in asthmatics are less impressive than anticipated. The inhalation

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

route would seem to be ideally suited for delivering VIP to asthmatics. Unfortunately, success of this approach seems to be limited by degradation of the inhaled peptide by peptidases in airway secretions. This problem may be solved by either of 2 alternate solutions, neither of which has been put to the test in clinical trials: (a) Instead of VIP itself, use a VIP-like analog that is more resistant to enzymatic degradation, such as the C-terminally extended helodermin (Fig. 2) or (b) combining VIP with one or more enzyme inhibitors that are particularly effective against VIP-selective peptidases, notably dipeptidyl peptidase (DPP IV) and neutral endopeptidase (enkephalinase).

Pulmonary Arterial Hypertension (PAH)

Strong experimental evidence and 2 clinical studies suggest a useful therapeutic potential for VIP in PAH:

1. As noted above, in the absence of the VIP gene, mice express a PAH phenotype, with pulmonary vascular remodeling, inflammation, and right ventricular hypertrophy.[29] RT-PCR arrays in these mice show the upregulated expression of pathways that promote vasoconstriction, smooth muscle and collagen proliferation, and inflammation, together with the downregulation of key pathways that promote vasodilation, and suppress vascular proliferation, including endothelial NOS (eNOS) and prostacyclin (PGI_2).
2. VIP relaxes pulmonary vascular smooth muscle cells *in vitro* and *in vivo*.[26] Further, it suppresses pulmonary vascular smooth muscle cell proliferation, and corrects pulmonary vascular remodeling, inflammation, and RV pathology in experimental PAH induced by (a) VIP gene deletion in mice, (b) monocrotaline in rats (Fig. 4), and (c) chronic hypoxia in mice.
3. In patients with Idiopathic Pulmonary Hypertension (IPAH), serum VIP concentrations are below normal, and VIP-containing nerves are absent in pulmonary arterial walls, whereas VIP receptors VPAC1 and VPAC2 are upregulated in pulmonary arterial smooth muscle cells.[13]

Lung Cancer

VIP suppresses the growth of small-cell lung cancer cells in culture and in athymic nude mice *in vivo*.[10] These results suggest that VIP may offer an effective and less toxic alternative to conventional chemotherapy in the management of this highly malignant form of cancer, but no clinical trials have been conducted to validate this possibility.

Acute Lung Injury (ALI) and Related Conditions[19,30]

1. VIP protects the lungs and airways in at least 13 experimental models (Table 1). This protection is attributable to a combination of anti-inflammatory, antioxidant, and antiapoptotic properties.
2. Based on these encouraging data, a phase I clinical trial of VIP, funded by the Orphan Drug Program of the FDA, was conducted in 8 patients with relatively severe ARDS, with or without Multiorgan Dysfunction Syndrome (MODS), in the setting of sepsis. VIP was given by continuous iv infusion, for 6 or 12 h. The study confirmed the safety of the peptide under these conditions: of the 8 patients, only 2 died, with neither death being drug related. A follow-up, multicenter clinical trial to evaluate efficacy is being planned.

Inflammatory and Autoimmune Diseases[2]

Based on its anti-inflammatory and immune-modulating properties, VIP has undergone early trials in a number of clinical disorders and experimental models of such disorders, including pulmonary sarcoidosis, COPD, rheumatoid arthritis, experimental autoimmune encephalomyelitis, inflammatory bowel disease, and type I diabetes. It is still too early to draw firm conclusions from these studies.

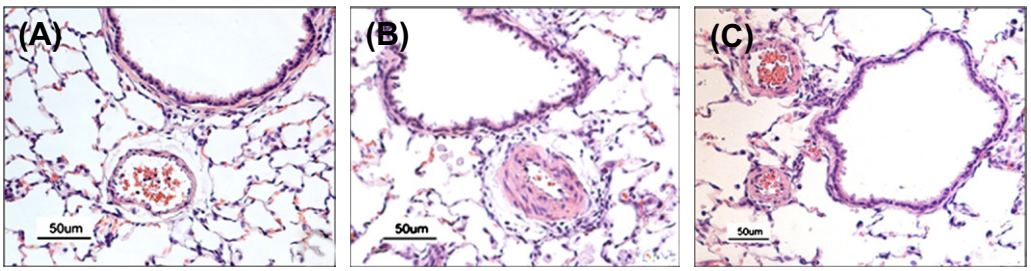

FIGURE 4 VIP corrects pulmonary vascular and RV pathology in monocrotaline (MCT)-induced PAH in rats: (A) H&E section of normal control lung, showing alveoli, bronchus, and small PA. No evidence of inflammation or vascular thickening. (B) Lung section 3 weeks after injection of MCT, showing vascular thickening and inflammatory cell infiltrates. (C) 3 weeks after VIP treatment, almost complete reversal of MCT-induced pathology. See color plate 58.

11. Cobra venom factor
12. Endotoxemia
13. Excitotoxicity (NMDA receptor activation)

VIP and the NFAT Transcription Factor

In considering the role of VIP in disease, it is important to keep in mind the relationship of VIP to transcription factor nuclear factor of activated T-cells (NFAT). Activation of calcineurin–NFAT signaling is triggered by increased concentration of intracellular Ca^{2+}, which leads to dephosphorylation (i.e. activation) of the phosphatase enzyme calcineurin (Fig. 5). In its resting, inactive state, this enzyme is located in the cytosol; on activation, it enters the nucleus to act on its target genes.

In addition to T-cell activation, activation of this pathway results in inflammation, smooth muscle cell contraction and proliferation, and autoimmune responses. Inhibition of calcineurin-mediated effects, as by cyclosporine A and the peptide VIVIT, can prevent organ transplant rejection. With special reference to VIP, mice lacking the VIP gene show activation of NFAT, and strong evidence suggests that VIP is a physiological modulator of this pathway.

CYSTIC FIBROSIS (CF)

CF, a fatal autosomal recessive disease, is characterized by abnormal ion transport across epithelia, viscous secretions, chronic bacterial infections, and airway inflammation. Over 25 years ago, we first observed that normal skin had a rich network of VIP-immunoreactive nerves around sweat gland acini and ducts, in contrast to absent or minimal VIP innervation of CF sweat glands. We wondered (1) whether deficient VIP innervation is responsible for the chloride ion abnormality in CF; and (2) to what extent is VIP involved in the pathogenesis, or possible correction, of CF pathology?[8]

We now know that the basic molecular defect in CF is a deficiency or absence of the cystic fibrosis transmembrane conductance regulator (CFTR) from the apical membrane of epithelial cells, due to mutations in the CFTR gene.

CFTR and Its Mutations

The most common (>90%) mutation in CF, a deletion of phenylalanine 508 (ΔF508), causes improper folding of the CFTR protein, resulting in its retention in the endoplasmic reticulum and proteosomal degradation. Major CF research efforts are devoted to the attempt to rescue ΔF508-CFTR defective trafficking to restore normal epithelial function. We have investigated the potential rescue and stability at the cell membrane of ΔF508-CFTR, by VIP treatment, in human nasal epithelial cells JME/CF15, derived from a patient with this homozygous mutation. When the cells, maintained at 37 °C, are treated with VIP for 1 or 2 h, mature ΔF508-CFTR proteins are observed: Immunostaining confirms localization at the cell membrane, and functional assays confirm that CFTR-dependent chloride secretion has been restored after VIP treatment. In these cells, which express the VPAC1 receptor, we found that VIP-dependent rescue of ΔF508-CFTR trafficking is mediated by the PKA-dependent signaling pathway, whereas membrane stability by prolonged VIP treatment involves the Gαq and PKCε signaling cascade. Evidence from airway cells thus shows that the VIP mechanisms of regulating CFTR activity involve both PKA and PKC signaling in a synergistic manner to rescue defective trafficking of mutant CFTR, activate CFTR gating through direct phosphorylation of its regulatory domain, and most importantly, stabilize CFTR channels at the cell surface by reducing their internalization rate, thus *optimizing CFTR-dependent secretions.*

In Vivo Confirmation of the Role of VIP[14]

As earlier mentioned above, VIP knockout mice express several features of the absence of the VIP gene, including an asthma-like phenotype, a PAH phenotype, and increased vulnerability to endotoxemia. In addition, they also show CF-like pathological changes: the lungs show significant lymphocyte accumulation, increased airway secretion, alveolar thickening, and edema; the pancreas also shows increased secretion, and inflammatory cell infiltrates around the ducts. These pathological changes could be reversed, close to a wild-type phenotype, by treatment with VIP (15 μg) intraperitoneally, every other day, for 3 weeks. In this model, whereas normal control tissues show CFTR predominantly at the apical membrane of epithelial cells, CFTR distribution in VIP KO tissues is mainly observed intracellularly. VIP treatment restores strong CFTR membrane localization, confirming the important role of chronic

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

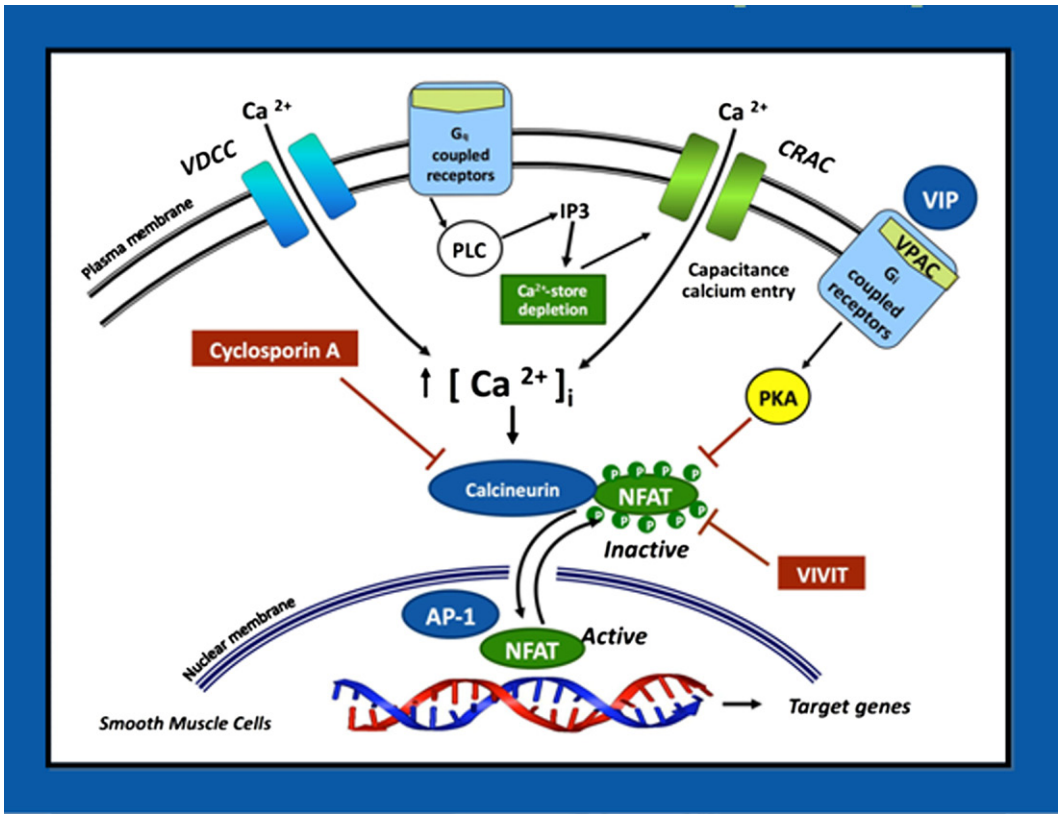

FIGURE 5 Calcineurin–NFAT signaling and its inhibition by VIP. In resting cells, NFAT resides in the cytoplasm, where it is maintained in a phosphorylated, inactive state. Stimulation of cell-surface receptors coupled to phospholipase C (PLC) results in calcium mobilization, initially from intracellular stores, followed by influx of Ca^{2+} through specialized voltage-dependent Ca^{2+} channels (VDCC) and Ca^{2+} release-activated Ca^{2+} channels (CRAC). On activation by Ca^{2+}, the phosphatase calcineurin dephosphorylates NFAT, triggering its activation and nuclear translocation. In the nucleus, NFAT interacts with other transcription factors, including activator protein (AP)-1, to stimulate gene expression. When NFAT is rephosphorylated, it is exported back to the cytoplasm. The immunosuppressive drug cyclosporin A inhibits calcineurin interactions with all its substrates, whereas VIVIT selectively inhibits NFAT activation. VIP seems to inhibit this pathway, but its mechanism of action is yet to be determined. IP3: inositol-1,4,5-triphosphate. See color plate 59.

VIP exposure tin maintaining CFTR channels at the membrane, and for exocrine epithelial tissues integrity. We conclude that inflammation and damage observed in VIP KO tissues can be attributed, at least in part, to the lack of CFTR-dependent secretions that ultimately depend on VIP stimulation, both for acute and long-term regulation of CFTR function. These observations also provide evidence of the molecular link between early observations of deficient VIP-containing fibers innervation of epithelial layers of exocrine organs in CF tissues and the absence of CFTR-dependent secretions.

The results set VIP, or its analogs, as a potential candidate for the treatment of CF as it corrects many features of this disease including its molecular basis. Ivacaftor, an investigational drug targeting the second most common CFTR genetic mutation, G551D, found in 4–5% of CF patients, boosts lung function in patients with CF with that mutation. If the ongoing studies with VIP are equally successful, the result could be an even bigger prize.

Chapter 210

Antiopioid Peptides

Ji-Sheng Han

ABSTRACT

The first demonstration in 1979 of an antiopioid peptide and prediction of the existence of other endogenous antiopioid peptides in the central nervous system have prompted extensive research endeavors exploring and identifying these peptides during the past 3 decades. Several peptides that fall into this category include cholecystokinin, neuropeptide FF, Tyr-MIF-1-related peptides, nociceptin/orphanin FQ, and several others. Hypothetically, they are collectively viewed as a negative feedback system to antagonize the excessive activation of the opioid receptors induced by the repeated administration of opiates or excessive release of opioid peptides. From a practical point of view, the blockade of the antiopioid peptides may have clinical implications for the treatment of intractable pain.

INTRODUCTION

Numerous pharmacological and behavioral studies have demonstrated a potent antagonizing effect of the antiopioid peptides on various forms of opioid analgesia after systemic, intracerebroventricular (ICV), or intrathecal (IT) injection. Most of these antiopioid peptides also contribute to the development of tolerance to opioid analgesia. At the cellular level, cholecystokinin (CCK) receptors may colocalize with opioid receptors in the same neurons,[16] which provides an anatomical basis for direct interactions between CCK and opioid systems at the receptor and postreceptor levels.

Although MIF-1 was the first peptide described to have antiopioid activity,[14] CCK has been the most thoroughly studied. This peptide, therefore, is mainly reviewed in this chapter regarding its antiopioid action, followed by a summation of three other antiopioid peptides (neuropeptide FF, NPFF); nociceptin/orphanin FQ (N/OFQ); and the Tyr-MIF-1 (Tyr-Pro-Leu-Gly-NH_2)-family of peptides, as well as mention of some more recently described ones.

REGULATION OF OPIOID ANALGESIA BY CCK

CCK, a member of the gastrin family of peptides, is present in the central nervous system (CNS) mainly in the form of a carboxy-terminal octapeptide (CCK-8). Faris et al.[6] in 1983 first reported that CCK, when administered systemically or perispinally, antagonized opiate analgesia. The antiopioid action of CCK was afterward confirmed and characterized in a large number of pharmacological and behavioral studies. For instance, the ICV or IT administration of CCK-8 suppressed morphine analgesia in rats.[8,10] Apparently, CCK-8 possesses the ability to antagonize morphine analgesia at both the supraspinal and spinal levels. Acupuncture and electroacupuncture (EA) have been documented to release endogenous opioid peptides in the CNS and thus produce strong analgesia.[9] Like morphine analgesia, EA-induced analgesia was substantially attenuated by ICV or IT injection of CCK-8. Thus, CCK-8 exerts its influence over analgesia induced by both exogenous and endogenous opioids in an inhibitory fashion.

The antagonizing effect of exogenous CCK on morphine suggests that endogenous CCK may act physiologically as an opioid antagonist to dose dependently suppress opioid analgesia. Indeed, previous studies[28] have shown that the CCK receptor antagonist proglumide or MK329 (L364,718) when given by the ICV, IT, or systemic route potentiated various forms of analgesia produced by morphine and endogenous opioids and seemed to reverse tolerance to morphine analgesia. Active immunization against CCK also resulted in a potentiation of morphine analgesia. In addition, the antiserum against CCK could reverse tolerance to EA analgesia. Even clinical placebo-induced analgesia, which may be opioid in nature, was potentiated by proglumide. These results suggest that in response to upregulated opioidergic activities the endogenous CCK system can act as a negative feedback control to return pain sensitivity to its basal level. Because neither proglumide nor CCK-8 antiserum produced measurable analgesia in the absence of morphine, the endogenous CCK system does not seem to be tonically active in affecting basal pain perception.

Two subtypes of CCK receptors have been identified: CCKA (A for alimentary) receptors, predominantly located in the periphery, and CCKB (B for brain) receptors, in the CNS. These 2 receptors are now designated as CCK1 and CCK2. Results from a large number of pharmacological

Copyright Elsevier 2024

studies support the concept that the central type CCKB receptor, rather than the peripheral type CCKA receptor, is primarily responsible for the antiopioid effect of CCK. The CCKB subtype-selective antagonist L365,260, L740,093, or CI988 readily mimicked the effect of the non-subtype-selective CCK receptor antagonists and CCK antiserum in augmenting morphine- and EA-induced analgesia and preventing tolerance to morphine analgesia.[3,28] In mice lacking CCKB receptors, morphine induced a significantly stronger antinociceptive effect as compared with that in wild-type animals.[27] Noticeably, the role of CCKB receptor in modulating opioid analgesia varies with different opioid receptor subtypes. Wang XJ et al. have shown that the CCKB receptor plays a significant role in antagonizing the analgesia mediated by μ- and κ-opioid receptors, with a minimal influence over the δ-opioid receptor-mediated analgesia.[28]

CCK GENE EXPRESSION IN RESPONSE TO OPIOID ANALGESIA

CCK mRNAs and CCK-like immunoreactive materials are broadly distributed in the CNS. Generally, substantial overlap in the anatomical distribution of CCK, endogenous opioid peptides and their receptors exists in the brain and spinal cord, providing an anatomical basis for the interaction between the two systems. Alterations in CCK peptide gene expression in the CNS were investigated in rodents exposed to opioids or that had developed tolerance to opioid or EA analgesia. Zhou et al. reported that the basal levels of CCK mRNAs were elevated in the whole brain of rats rendered tolerant to repeated injections of morphine.[28] The increased levels of CCK mRNAs suggest an accelerated synthesis of CCK peptides in the brain at the transcription level, probably leading to enhanced CCK activity. As a compensatory response, enhanced CCK activity could then engage in counteracting the analgesic effect of opioids. The results from the pharmacological studies previously described support this notion. In line with this, ICV injection of CCK antisense RNA to the rat to knock down the biosynthesis of CCK in the CNS has been shown to increase the analgesic effect induced by EA or low dose morphine, and changed low responder rats to morphine and EA analgesia into high responders.[23]

The region-specific increase in CCK mRNAs was also investigated by in situ hybridization. Pu et al. found that CCK mRNA levels were elevated in the amygdala in morphine-tolerant rats. Moreover, the increase in CCK mRNA levels in the amygdala kinetically corresponded well with the development of tolerance to morphine. Thus, CCK in the amygdala may play a functional role in regulating morphine tolerance. This was substantiated by the finding that the CCKB receptor antagonist locally injected into the amygdala augmented the analgesic effect of systemic morphine.[28]

The periaqueductal gray (PAG) of the midbrain represents another strategic site in the CNS where CCK-8 can exert its antiopioid action.[26] The reduction of cellular levels of CCK-8 through an antisense approach converted low responder rats into high responders to morphine and EA analgesia, and delayed the development of analgesic tolerance to prolonged EA stimulation or repeated morphine administrations.[23] Similarly, the CCK receptor antagonist injected into the PAG reversed tolerance to morphine analgesia.[26] These results demonstrate a strong antagonizing effect of endogenous CCK-8 in the PAG on opioid analgesia.

Ding and Bayer revealed that chronic treatment with morphine increased CCK mRNA levels and CCK immunoreactive peptides in the hypothalamus, the spinal cord, and the brainstem, areas known to be involved in opioid analgesia.[28]

THE ROLE OF CCK IN THE DEVELOPMENT AND MAINTENANCE OF CHRONIC PAIN

The analgesic effect of morphine varies in different pain states. Patients or experimental animals with neuropathic pain after injury to the nervous system usually respond poorly to opioids. This poor response may be related to the antiopioid action of CCK. Hokfelt and his group have conducted a series of studies showing that axotomy caused an upregulation of CCK and CCKB receptor mRNAs in rat dorsal root ganglion neurons. The CCKB receptor antagonist CI988 was able to reverse the reduction of morphine analgesia in axotomized rats. CI988 could also reverse the lack of effect of IT morphine in alleviating neuropathic pain like symptoms in rats after complete or partial peripheral nerve injury. Thus, insensitivity to opioid analgesia in rats with nerve injury may result from enhanced CCK and CCK receptor expression.[28]

In a rat experiment, ligation of the sciatic nerve or microinjection of CCK into the brainstem rostral ventral medulla (RVM) results in the production of hyperalgesia of the hind paw, an indication of the neuropathic pain. This neuropathic pain seems to require the activity of a subset of RVM neurons that are distinguished by coexpression of the mu opioid receptor (MOR) and cholecystokinin type 2 receptor (CCK2). Lesion of these RVM neurons significantly shortened the duration of the hyperalgesia, suggesting that RVM CCK is involved in the maintenance of neuropathic pain.[34]

In addition to the opioid/CCK interaction in the CNS, it may also occur in the periphery. In diabetic rats, the antinociceptive effect of local injection of morphine in the second phase of the formalin test was about twofold less than that in nondiabetic rats. Pretreatment with proglumide

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

enhanced the antinociceptive effect of morphine, suggesting that in diabetic rats, CCK exerts a tonic antagonistic role on peripheral morphine antinociception.[25]

The psychic component plays an important role in the maintenance of chronic pain. It is well recognized that placebo analgesia is mediated by opioid mechanisms. Little is known on the mechanisms of nocebo hyperalgesia. Benedetti et al. studied verbally induced nocebo effects using experimental ischemic arm pain in healthy volunteers. They found that the nocebo hyperalgesia can be completely abolished by proglumide, suggesting a CCK-ergic mechanism.[1]

CCK RELEASE IN RESPONSE TO OPIOID ANALGESIA

The extracellular level of CCK under different conditions determines its potency of modulating opioid action. Through *in vivo* microdialysis technique in freely moving and conscious animals combined with radioimmunoassay, Gustafsson et al. found that the basal CCK level was usually below or close to the detection limit of the radioimmunoassay in the normal rat spinal cord. The normal extracellular CCK levels could be markedly elevated by depolarization caused by perfusion of the microdialysis probe with Krebs–Ringer solution containing a high concentration of potassium. In addition to depolarization, morphine is a potent stimulator for facilitating CCK release. When injected intravenously or applied topically on the spinal cord, morphine significantly increased CCK in the dialysate. Because the release of CCK by morphine was sensitive to naloxone blockade, opioid receptors are believed to mediate the morphine-induced CCK release. CCK-8 was also detectable in the cerebrospinal fluid (CSF) of rats with a normal range of 14.4–15.1 fmol/ml. EA stimulation resulted in a naloxone-sensitive increase in CCK-8 levels in the CSF. This increase lasted for at least 6 h. Such a long-lasting increase in CCK-8 release may require a parallel increase in biosynthesis of the peptides as already noted.[28]

The mechanism(s) underlying the opioid facilitation of CCK release are unclear. There is evidence that opioid receptors may facilitate the formation of inositol 1,4,5-phosphate (IP3) through their coupling to phospholipase C. Because IP3 is a strong stimulator of intracellular Ca^{2+} release, the activation of opioid receptors may lead to a Ca^{2+}-dependent CCK release, although it needs to be proven experimentally. It can be argued that the CCK release may not be mediated by a direct action of opioids because generally opioids exert an inhibitory modulation for a given cellular activity. The ability of opioids to facilitate CCK release can therefore be explained by a disinhibitory mechanism. It is possible that both direct and indirect mechanisms mediate CCK release by opioids.

Using an electrophysiological approach, Heinricher et al. showed that, although morphine activated the OFF cell and inhibited the ON cell simultaneously in the RVM, microinjection of CCK within the RVM selectively prevented opioid activation of OFF cells, without affecting the suppression of spontaneous ON-cell firing by morphine.[12]

CCK–OPIOID INTERACTIONS IN PHYSIOLOGICAL FUNCTIONS OTHER THAN PAIN

The extensive presence of CCK in the CNS implies that its function may not be limited to the perception and the control of pain. A role for CCK in the induction and persistence of anxiety and major depression seems to be conspicuous. Hebb et al. summarized that there appears to be an intricate balance between the anxiety-provoking and memory-enhancing effects of CCK on the one hand, and the anxiolytic and amnesic effects of opioid peptides on the other hand.[11]

Gospic et al. tried to observe whether CCK and opioids can modulate the processing of other external signals, for example, visual stimuli-induced emotional experience. The results showed that the CCKB receptor agonist pentagastrin (0.1 μg/kg) increased the rating of unpleasantness for both neutral and unpleasant pictures, whereas the mu opioid receptor agonist remifentanil (0.0625 μ/kg) increased the pleasantness rating for the neutral pictures.[7]

The CCK/opioid interaction seems critical for maintaining maternal behavior during lactation. In contrast to the general expectation, morphine inhibits maternal behavior, whereas CCK restores it. The PAG was found to be the critical brain site responsible for this interaction.[17]

CELLULAR AND MOLECULAR MECHANISMS FOR CCK–OPIOID INTERACTIONS

The cellular and molecular mechanisms underlying the CCK antiopioid action are poorly understood. At the receptor level, Wang et al. have observed that CCK-8 reduced the ligand binding affinity to μ- and κ-opioid receptors. Considerable colocalization of CCK receptors in the dorsal horn neurons of the spinal cord with μ-opioid receptors seems to provide a morphological basis for this receptor–receptor interaction in the same neuron.[33] At the postreceptor level, crosstalk between CCK and opioid-receptor-associated signaling pathways may exist, and the activation of CCK receptor-derived signaling cascades has been found to affect the intracellular calcium availability downstream to opioid receptor activation assessed by electrophysiological[16] and neurochemical approach.[28]

CCK AS MEDIATOR OF OTHER PEPTIDES WITH ANTIOPIOID EFFECT

Yoshikawa et al. have recently identified two peptides with antiopioid activities. Enterostatin (APGPR)[22] was found in the gastrointestinal tract and brain as an anorectic pentapeptide. ICV injection to the mice inhibited morphine-induced analgesia. This effect could be antagonized by lorglumide and LY225910, antagonists for CCK1 and CCK2 receptors, respectively. Because APGPR did not have affinity for CCK receptors, it was postulated that the antianalgesic effect of APGPR may be mediated by CCK release. Another peptide was rapakinin, Arg-Ile-Tyr.[30] It is a vasorelaxing, antihypertensive, and anorexigenic peptide derived from rapeseed napin. ICV administration of rapakinin to mice inhibited the analgesic effect of morphine. This antiopioid activity seemed to be mediated by the CCK2 receptor, because it was blocked by LY225910, an antagonist of the cholecystokinin CCK2 receptor, but not by lorglumide, an antagonist of the CCK1 receptor. Moreover, the antiopioid activity of rapakinin was also found to be blocked by CAY10441, an antagonist of the prostaglandin (PG) IP receptor. Further studies revealed that rapakinin showed antiopioid activity via the activation of the PGI(2)-IP receptor system followed by the CCK2 receptor system.

These two examples can be taken to show the complicated interaction between biologically active peptides in modulating the opioid/antiopioid interaction, modulating body functions related with pain and pleasure.

REGULATION OF OPIOID ANALGESIA BY NPFF

NPFF (FLFQPQRFamide, F8Famide, Phe-Leu-Phe-Gln-Pro-Gln-Arg-Phe-NH_2) is another important endogenous octapeptide that possesses CCK-like antiopioid action.[34] NPFF and NPFF receptors are densely distributed in the CNS, especially in the spinal dorsal horn and the PAG, areas important in opioid-mediated pain modulation.

ICV injection of NPFF reduced the analgesic effect of systemic morphine, whereas NPFF antisense oligonucleotides (ICV) decreased tolerance to morphine analgesia. Electrophysiological studies also showed an antagonizing effect of NPFF on μ-opioid receptor-mediated inhibition of the dorsal horn neuronal activity evoked by C-fiber stimulation.[28] These results indicate a significant role played by NPFF at the supraspinal level in antagonizing opioid analgesia.

Several brain areas have been identified as important sites for the NPFF-opioid interaction.[28] Local infusion of NPFF into the hippocampus reduced the electrophysiological response of hippocampal neurons to opioids. The NPFF analogs when injected into the nucleus raphe dorsalis also suppressed the antinociceptive effect of morphine. Other central sites where application of NPFF or NPFF analogs produced antiopioid action include the ventral tegmental area (VTA) of the midbrain and the parafascicular nucleus. In contrast to the supraspinal antiopioid effect, IT injection of NPFF produced antinociceptive effect and/or a potentiation of morphine analgesia.

The receptor of NPFF can be divided into two types: NPFF(1) and NPFF(2). The NPFF(2) receptor is mainly distributed in the CNS, especially in brain areas related to pain perception, such as the dorsal horn of the spinal cord, the parafascicular and the dorsolateral nuclei of the thalamus nucleus. However, recent studies have shown that ICV injection of specific agonists for type 1 (NPVF) and type 2 (dNPA), respectively, produced the same antiopioid actions on the antinociceptive effect of systemic morphine as the authentic peptide NPFF, suggesting that the two receptors have a similar effect in this action.[5] Kersanté et al. also studied whether NPFF antagonizes the rewarding effect of opiates. Results showed that systemic morphine-induced elevation of dopamine and serotonin metabolites within the nucleus accumbens (NAc) can be inhibited by NPFF administered into the VTA, suggesting that NPFF in the VTA can also antagonize the rewarding effect of opiates in the mesolimbic dopamine system.[15]

Develliers et al. noted that remarkable similarities in several key antiopioid actions are noted between CCK and NPFF. First, the two peptides when applied alone cause no significant pronociceptive effect; rather they exert a dose-dependent antagonism of opioid-induced analgesia. Second, like CCK and CCK receptors, NPFF and NPFF receptors strategically overlap with the opioid receptor distribution in many brain regions related to pain perception and modulation. Finally, opioids can increase NPFF gene expression and NPFF release. Thus, the NPFF system, like the CCK system, can be upregulated and mobilized to exert its antiopioid action in response to enhanced opioidergic transmission.[28]

REGULATION OF OPIOID ANALGESIA BY NOCICEPTIN/ORPHANIN FQ

N/OFQ and its regulatory role in pain modulation are discussed by Calo in another chapter in this section of the book. The available results show that nociceptin has a complex pharmacology in rodents, eliciting either an antiopioid/hyperalgesic action or analgesic effect depending on the dose, testing paradigm, and brain regions surveyed.

ICV injection of nociceptin blocked the supraspinal antinociception produced by the injection of all three opioid receptor subtypes (μ, δ, and κ)-selective agonists administered via the same route.[18] Nociceptinergic terminals are located in the PAG, and intra-PAG injection of nociceptin

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

attenuates morphine analgesia, indicating the PAG as a site for nociceptin to antagonize opioid actions. Recent studies showed that nociceptin also antagonizes analgesia induced by nonopioid substances such as paracetamol[21] and serotonin (5-HT). Therefore, it is not only an antiopioid peptide but may also be an antianalgesic peptide.

In contrast to its supraspinal effect, IT nociceptin showed no antagonistic effect against antinociception induced by IT or systemic injection of morphine. In fact, nociceptin *per se* produced an antinociceptive effect in the spinal cord.[24] Recent findings revealed that IT injection of a specific nociceptin receptor agonist UFP-112 produced long-lasting antinociceptive effects that could be reversed by an NOP receptor antagonist J-113397 but not by a classic opioid receptor antagonist naltrexone. IT injection of inactive doses of UFP-112 in combination with a small dose of morphine produced significant and long-lasting antinociceptive effects without increasing the adverse effects such as scratching responses.[13]

Yuan et al. showed that the continuous use of high doses of morphine accelerated the release and biosynthesis of nociceptin in rat brain, which antagonizes the analgesic effect of opioids and promotes the development of morphine tolerance. Besides, administration of the nociceptin or synthetic agonist Ro 64–6198 can block the rewarding effects of cocaine, morphine, amphetamines, and alcohol in various behavioral models of drug reward and reinforcement, such as conditioned place preference and drug self-administration. Addiction to multiple abused drugs (polydrug addiction) is now very common, and no satisfactory pharmacotherapies are yet available. In this sense, the NOP receptor may serve as a target for drug abuse medications.[31]

The mechanisms underlying the antiopioid effect of nociceptin are not clear. Rady and Fujimoto[20] pointed out that the antianalgesic action of nociceptin is mediated by spinal PGE2 and attenuated by IT PGD2 or indomethacin. At the cellular level, μ-opioid receptor-mediated inhibition of calcium currents can be antagonized by nociceptin applied at the same neuron.[32] At the circuitry level, nociceptin, which profoundly inhibits all three classes of RVM neurons (ON, OFF, and neutral), blocks the opioid activation of OFF cells and interferes with opioid antinociception.[12]

REGULATION OF μ-OPIOID SYSTEMS BY MIF-1, TYR-MIF-1, AND TYR-W-MIF-1

The first endogenous peptide to show antiopioid properties was reported by Kastin et al. in 1979 with MIF-1 (Pro-Leu-Gly-NH_2).[14] Two more related endogenous brain peptides, Tyr-MIF-1 and Tyr-W-MIF-1 (Tyr-Pro-Trp-Gly-NH_2), were later also shown to have antiopioid activity. These peptides show inhibitory actions not only against endogenous opioid activity but also against several pharmacological effects of morphine, including antinociception,[14] hypothermia, and inhibition of guinea pig ileum contractions. Their antiopioid properties seem to be mediated by μ-opioid receptors because these peptides show low, but significant, affinity and very high selectivity for μ-opioid receptors. Correlating with their affinity to μ-opioid receptors, their inhibitory effects against morphine are relatively weaker than those of traditional μ-opioid receptor antagonists, such as naloxone or CTOP.[28]

Yehuda et al. revealed that these peptides show an inverted U-shaped dose–response curve for the inhibition of morphine-induced pharmacological effects. As expected, most of these peptides later were reported to have agonistic properties for μ-opioid receptors in several experimental paradigms, including analgesia[29] and electrically stimulated guinea pig ileum contraction. Their agonistic effects are completely attenuated by μ-opioid, but not δ- and κ-opioids, receptor antagonists. Moreover, the potencies of their agonistic effects are relatively lower than those of morphine. The evidence clearly suggests that these peptides are partial agonists for μ-opioid receptors with relatively low intrinsic activity and affinity, although effects at the Tyr-MIF-1 receptor itself may be involved. Physiologically, these peptides may biphasically, both negatively and positively, control the μ-opioid system as a partial agonist. Bocheva et al. reported that IP injection of Tyr-MIF-1 peptides (all in a dose of 1 mg/kg i.p.) in the male Wistar rats reduced morphine-induced analgesia using the paw-pressure (PP) and the tail-flick (TF) tests, and also the immobilization stress-induced antinociception using the PP test. Doses as low as 0.01 mg/kg have also be effective in studies of the antiopioid effects of these small peptides in rodents, and MIF-1 significantly reduced the effects of morphine in a clinical study in men. The results suggest that overall, Tyr-MIF-1 peptides can manifest themselves as functional antiopioid peptides.[2]

CONCLUSIONS

Mollereau et al.[34] noted that CCK and NPFF produce an antiopoid effect via cellular mechanisms, whereas N/OFQ, showing antiopioid effects in the brain and proopioid effects in the spinal cord, seems to act via circuitry-induced mechanism. Antiopioid effects have also been reported for MSH (melanocortin—see the chapter in Brain Peptides section), TRH, complement 3a, angiotensin II, enterostatin, and rapakinin, the effects of last two being mediated through CCK. Although there has been much progress since the first description of antiopioid effects of peptides in 1979 with a member of the Tyr-MIF-1 family of brain peptides,

elucidation of the opioid-modulating effects of peptides such as the ones described here should stimulate novel means to alleviate pain and treat opioid abuse.

Chapter 211

Casomorphins/Hemorphins

Fred Nyberg, Anna Carlsson and Mathias Hallberg

ABSTRACT

In addition to classical opioid compounds with their N-terminal Tyr-Gly-Gly-Phe sequence, atypical opioid peptides typified by their N-Terminal Tyr-Pro are derived by the partial hydrolysis of endogenous existing functional proteins and are mainly produced in peripheral tissues and body fluids. The β-casomorphins and the hemorphins are formed through the hydrolysis of the milk protein β-casein and hemoglobin, respectively. They are less potent compared with the classical opioid peptides but share most of their typical effects. Among the atypical endogenously produced opioid active peptides are the β-casomorphins and hemorphins. Their concentrations in body fluids greatly exceed those of β-endorphin and the enkephalins. This chapter gives a brief review about past and current research on the β-casomorphins and hemorphins regarding the mechanisms for their release, their distribution, their biological actions, and their pathophysiological roles.

INTRODUCTION

The endogenous opioids are derived from at least three genetically distinct systems giving rise to several active peptides, including β-endorphin, the dynorphins, and the enkephalins. The active structures in these peptides are all typified by their N-terminal Tyr-Gly-Gly-Phe tetrapeptide sequence. However, atypical opioid active peptides containing the Tyr-Pro dipeptide residues in their N-terminal sequence have been identified and characterized. These so-called atypical endogenously produced opioid active peptides share most of their typical effects with the classical opioid peptides. Originally, the β-casomorphins and the hemorphins were isolated from enzymatically treated bovine milk and blood, respectively. Later they were identified as naturally occurring compounds present in high concentrations in human plasma and cerebrospinal fluid.

DISCOVERY OF THE β-CASOMORPHINS AND THE HEMORPHINS

Soon after the discovery of opioid receptors in mammalian brain, the presence of endogenous compounds acting on these receptors were identified and found to be present in the central nervous system (CNS) and also in peripheral tissues and in a variety of body fluids. Interestingly, most opioid peptides, which are present in the CNS, have also been identified in the cerebrospinal fluid (CSF).[22] The CNS distribution of the well-known β-endorphin, enkephalins, dynorphins, and endomorphins are described in other chapters in this section of this book.

The presence of opioid active material in bovine milk was originally reported by Brantl et al.[1] They isolated a peptide fragment from an enzymatic digest of the milk protein β-casein. This fragment exhibited binding affinity for opioid receptors and was shown to produce opioid effects in the guinea-pig ileum assay (GPI assay). Because of this and its origin, the isolated peptide was named β-casomorphin. Sequence analysis of β-casomorphin revealed that the structure of this compound diverges from that of the classical endogenous opioids, in that the milk-derived peptide contains a Pro residue next to the N-terminal Tyr (Table 1). In subsequent studies, β-casomorphin was found to exist in bovine plasma[34] as a naturally occurring compound in both truncated and extended forms of the first isolated entity and also in human body fluids. For instance, β-casomorphin-8-like immunoreactivity was measured in human plasma,[15,23] in human CSF,[22,23] and in human milk.[29]

The β-casomorphins are fragments of the bovine β-casein sequence 60–68 and in sheep, water buffalo, and human whey, they are found in analogous positions. In human β-casein the casomorphin unit also resides in the sequence 60–68. Moreover, the human β-casomorphin differs from its bovine analog by having a Val-Glu instead of Pro-Gly in positions 4–5 (Table 1). An analog, β-casomorphin-4 amide (named morphiceptin, Table 1) isolated from a commercial hydrolysate of bovine casein, appears as a highly potent and μ-opioid receptor (MOP) receptor selective peptide.[3] Further, opioid active peptides in milk lacking the Tyr-Pro sequence in their N-terminal have also been found. Among these are the Arg-Tyr-Leu-Gly-Tyr-Leu-Glu sequence from bovine α-casein, the whey protein-derived α-lactorphin (Tyr-Gly-Leu-Phe), and β-lactorphin (Tyr-Leu-Leu-Phe). These last peptides behave as MOP receptor agonists but exhibit much weaker potency than that of the β-casomorphins.

TABLE 1 The Amino Acid Sequence of β-Casomorphins, Hemorphins, and Related Peptides

Peptide	Amino acid sequence
β-Casomorphin-5 (bovine)	H-Tyr-Pro-Phe-Pro-Gly-OH
β-Casomorphin-7 (bovine)	H-Tyr-Pro-Phe-Pro-Gly-Pro-Ile-OH
β-Casomorphin-8 (bovine)	H-Tyr-Pro-Phe-Pro-Gly-Pro-Ile-Pro-OH
β-Casomorphin-5 (human)	H-Tyr-Pro-Phe-Val-Glu-OH
β-Casomorphin-7 (human)	H-Tyr-Pro-Phe-Val-Glu-Pro-Ile-OH
β-Casomorphin-8 (human)	H-Tyr-Pro-Phe-Val-Glu-Pro-Ile-Pro-OH
Morphiceptin	H-Tyr-Pro-Phe-Pro-NH_2
Hemorphin-4 (human)	H-Tyr-Pro-Trp-Thr-OH
Hemorphin-7 (human)	H-Tyr-Pro-Trp-Thr-Gln-Arg-Phe-OH
LVV-Hemorphin-4	H-Leu-Val-Val-Tyr-Pro-Trp-Thr-OH
LVV-Hemorphin-6	H-Leu-Val-Val-Tyr-Pro-Trp-Thr-Gln-Arg-OH
LVV-Hemorphin-7	H-Leu-Val-Val-Tyr-Pro-Trp-Thr-Gln-Arg-Phe-OH
Valorphin	H-Val-Val-Tyr-Pro-Trp-Thr-Gln-OH
Spinorphin	H- Leu-Val-Val-Tyr-Pro-Trp-Thr-OH
Endomorphin-1	H-Tyr-Pro-Trp-Phe-NH_2
Endomorphin-2	H-Tyr-Pro-Phe-Phe-NH_2

The first report on the hemorphins also came from Brantl and coworkers.[2] This time they isolated and determined the sequence of an opioid active tetrapeptide (Tyr-Pro-Trp-Thr) from bovine blood treated with gastrointestinal enzymes. From a computer search, this peptide was identified as fragment 34–37 in the β-chain of bovine hemoglobin. In analogy with β-casomorphin, this tetrapeptide was named hemorphin-4, and it was also found to reside in positions 35–38 of the β-, k-, ∂-, and ε-chains of human hemoglobin. During the past decades, many opioid active peptides containing the Tyr-Pro-Trp-Thr core have been identified and characterized (Table 1). The existence of naturally occurring peptides containing the hemorphin-4 sequence in humans was reported in 1991.[10] In subsequent studies, similar structures in human CSF[11] and plasma[12] were found. All these hemorphin structures (LVV-hemorphin-6, LVV-hemorphin-7, and hemorphin-7) shown to retain biological activity were found to exhibit affinity for opioid receptors. Among other fragments containing the hemorphin-4 sequence shown to be released from the β-chain of hemoglobin are peptides given the names valorphin[7] and spinorphin (Table 1).

THE FORMATION OF β-CASOMORPHINS AND HEMORPHINS

In contrast to the classical opioid peptides, the pathways for the formation of the atypical opioids β-casomorphins and hemorphins are not yet fully clarified. For instance, although the enkephalins or dynorphins are formed within and released from neurons in which their precursors are processed the atypical opioids are not necessarily formed at the site of their precursor production. Prestages or intermediately processed entities of both β-casomorphins and hemorphins have been identified in the circulation[12,23] and CSF.[11,23] Extended forms of β-casomorphin-8 were found both in the CSF[23] and in the blood.[15,23] Therefore, the release of β-casomorphins from β-casein was suggested to occur stepwise. In CSF, a radioimmunoassay (RIA)-active component chromatographically characterized as β-casomorphin-8 was identified in addition to a larger sized RIA-active congener.[22,23] In plasma and milk, the β-casomorphin-8-like RIA activity was mainly derived from a structure that is of a larger size than the octapeptide.[23] However, in a later study, the presence of β-casomorphin-8 in milk from a patient with postpartum psychosis was confirmed.[29]

The presence of large fragments of the β-chain of hemoglobin containing the hemorphin sequence in human pituitaries[10] and plasma[12] was believed to indicate that the blood protein subunit is processed or degraded in sequential steps. It was thus suggested that a chymotryptic-like cleavage at the Phe^{41}–Phe^{42} bond in the β-chain was followed by a similar cleavage to generate LVV-hemorphin-7,[24] which can be further hydrolyzed by exopeptidases to yield smaller hemorphin peptides.[17] Further, the role of macrophage proteolytic complexes in the hemorphin generation has been investigated. When hemoglobin was exposed to rat liver lysosomes a rapid release of hemorphin-related peptides including hemorphin-7, LVV-hemorphin-7, and VV-hemorphin-7 was observed.[9]

RECEPTOR SELECTIVITY AND ITS MODULATION

Like most of the atypical opioid peptides containing the Tyr-Pro dipeptide in their N-terminal sequence, the β-casomorphins and the hemorphins show binding preference for the MOP receptor,[1,2,10] The peptides seem to act agonistically on this opioid receptor subunit as shown by means of the GTPγS assay. Their opioid activity was also confirmed in the GPI –bioassay.[1,8,10] Although these peptides are found

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

endogenously in quite high amounts, their agonistic actions on opioid receptors are comparatively weak. For instance, compared with β-endorphin, the affinity of the hemorphins for the MOP receptor is about 500-fold lower. Interestingly, two more recently discovered opioid peptides, endomorphin-1 and endomorphin-2,[35] with a structure (Table 1) similar to that of hemorphin and β-casomorphin, respectively, exhibit a very high potency to stimulate the MOP receptor.

Studies have also indicated that the β-casomorphins may act on non-opioid sites. For example, the bovine pentapeptide was shown to induce behavioral effects in the rat, which was not completely reversed by appropriate doses of naloxone.[14]

In recent years, studies have revealed that LVV-hemorphin-7 may act as an endogenous ligand for the insulin-regulated aminopeptidase (IRAP)/AT4 receptor in the brain.[20] The AT4 receptor was originally defined as the specific, high-affinity binding site for angiotensin (ang) IV (Val-Tyr-Ile-His-Pro-Phe), a bioactive fragment derived from Ang II. Ang IV is known to be released from both Ang I and Ang II. In addition to Ang IV, the hemoglobin fragment LVV-hemorphin-7 exhibits high binding affinity to the IRAP/AT4 receptor.[25] Both LVV-hemorphin-7 and Ang IV are competitive inhibitors of this enzyme activity and do not serve as substrates of the IRAP.[13] Moreover, central administration of LVV-hemorphin-7 enhances learning and memory capabilities in normal rodents and reverses memory deficits observed in animal models of amnesia.[13] The presence of high-affinity binding sites for this peptide was observed in the brain, including areas such as the hippocampus that are involved in memory processing.

BIOLOGICAL ACTIONS AND FUNCTIONAL RELEVANCE OF THE β-CASOMORPHINS AND HEMORPHINS

Like other endogenous opioid peptides, the β-casomorphins and hemorphins retain several effects related to opiates. These include analgesic effects and effects on respiration, constipation, sedative effects as well as effects on various behaviors. Analgesic effects of the β-casomorphins have been demonstrated in animals subjected to intracerebral injections of the peptides.[9] Likewise, in an animal model for phasic nociception (tail-flick assay), both hemorphin-4 and hemorphin-5 produce a dose-related and naloxone-reversible antinociceptive effect in the mice.[5]

Specific Actions and Functions of the β-Casomorphins

The β-casomorphins have been shown to produce effects in the gastrointestinal tract. For instance, β-casomorphin-7 markedly induces mucus release in the rat jeujenum,[33] an effect leading to the protection of the mucosa. The effect, which is dose dependent, is reversible by naloxone. It was suggested that the peptides from dairy products provide dietary prospects for improving gastrointestinal protection.[33] Given orally, the β-casomorphins influence postprandial metabolism by stimulating the secretion of insulin and somatostatin and take part in the regulation of postprandial gastrointestinal endocrine function.[30] Also, the β-casomorphins and their derivatives prolong gastrointestinal transit time and are useful in the treatment of diarrhea.[6] The β-casomorphins also affect hypoxia. Studies on the effects of β-casomorphins on immediate and delayed changes in electrocardiography (ECG) in female rats subjected to acute hypobaric hypoxia during pregnancy were performed.[19] Hypoxia induces alterations in the structure of the EKG that reflect development of arrhythmias and conduction disturbances. Intranasal administration of β-casomorphin-7 to pregnant female rats promotes recovery from acute hypoxia and normalized the EKG in the posthypoxic period.

Studies examining the ability of β-casomorphins to induce various behaviors have been reported.[14,25] The effect on rotational behavior in rat of β-casomorphins (bovine and human origin) was compared with that produced by three reference compounds, morphine, D-ala^2-D-leu^5-enkephalin, and U50,488H, ligands for MOP, DOP, and KOP types of opioid receptors, respectively. In this assay, the bovine β-casomorphin-5 seems to be more potent than a human analog (β-casomorphin-4).[14] The effects of both morphine and bovine β-casomorphin-5 in producing rotational behavior are partly antagonized by naloxone.

With respect to their functional relevance, it has been speculated that the β-casomorphins may be involved in the interplay between mother and child during lactation. Studies dealing with these milk-derived peptides have been directed to both mothers and infants. At term pregnancy, β-casomorphin-8 is elevated in both plasma and CSF, and this elevation further increases six months later in the puerperal period.[23] Interestingly, there is a positive correlation between plasma and CSF concentrations and CSF levels of the peptide. This indicates that β-casomorphin crosses the breast parenchyma–blood barrier into plasma and subsequently penetrate the blood–brain barrier to reach the CNS. It was suggested that the peptide may have a function in maternal behavior.[23] Further, the studies suggested that the milk-derived opioid also may reach the brain of the infant. Using a peptide extraction procedure combined with high-performance liquid chromatography and RIA, Pasi et al. [26] detected rostrocaudally increasing levels of immunoreactive β-casomorphin-8 in functionally relevant brain areas including mesencephalon, pons cerebri, and medulla oblongata. Indeed, it has been discussed that the β-casomorphins also may affect the child during lactation and it has been assumed that the milk opioids may induce sedation.

Specific Actions and Functions of the Hemorphins

Several actions have been studied with regard to the hemorphins. They affect blood pressure,[21] produce anti-inflammatory effects,[24] and affect the immune system.[22] The effect of hemorphin-7 on inflammatory processes is probably mediated through its action on the MOP receptor. Using a blister model of inflammation in the rat hind footpad local administration of the heptapeptide inhibits the acute but not chronic peripheral inflammatory response.[24] The effects are reversible by naloxone. The vasoconstrictive effect may result from the ability of the peptides to inhibit angiotensin converting enzyme (ACE). A potent inhibitory effect on ACE has been shown for hemorphin-7 and its N-terminal extensions LVV-hemorphin-7 but also for LVV-hemorphin-4 and –6.[17] Thus, the hemorphins not only interact with ACE but also with the previously mentioned IRAP/AT4 receptor, again showing a coupling to the angiotensin system.

The hemorphins induce the release of β-endorphins in the pituitary or hypothalamus,[24] and in humans a concomitant enhancement of hemorphin-7 and β-endorphin was observed after a completed marathon run[12] and in patients subjected to open-heart surgery.[24] In the case of marathon runners, a significant positive correlation between the plasma concentrations of hemorphin-7 and β-endorphin was observed. This relationship suggests a link between the heptapeptide and β-endorphin as later found in studies of patients undergoing open-heart surgery using a heart-lung machine.[24] During this treatment, which continues for several hours, the red blood cells are lysed as a result of their mechanical contact with the instrument and hemoglobin is released into the arterial blood flow and degraded by enzymes to generate hemorphins. Indeed, RIA-detectable hemorphin-7 is increased in the arterial blood flow with time but not in the jugular venous bulb. By contrast, the concentration of RIA-active β-endorphin in the arterial blood did not change during surgery but was significantly increased over time in blood collected from the venous bulb.[24] It is known that patients subjected to cardiopulmonary bypass generally have a sense of well-being during the first postoperative day and this could be explained by the released peptides, which may reach brain nuclei associated with reward and produce euphoria through their actions on opioid receptors.

IMPLICATION OF β-CASOMORPHINS AND HEMORPHINS IN PATHOPHYSIOLGY

There are still limited studies on the β-casomorphins and hemorphins in relation to pathophysiology. The β-casomorphins have been suggested to be involved in the mechanism underlying childhood autism[25] and apnea in relation to sudden infant death (SID).[28] A review article highlighted the possible link between β-casomorphins and SIDs in the context of the passage of these peptides through the gastrointestinal tract and the blood–brain barrier.[32] Thus, it was suggested that in infants predisposed to respiratory apnea because of abnormal autonomic nervous system development and respiratory control mechanisms, milk-derived opioid peptides such as the β-casomorphins might be one of the etiological factors for the SID syndrome.[28] Another aspect studied in relation to β-casomorphins is their possible role in psychomotor development in infants. It has been suggested that breast feeding may have an advantage over feeding with cow milk for the development of infants during their first year of life.[16] Thus, increased plasma concentrations of both bovine and human immunoreactive β-casomorphin were observed mainly during the first 3 months of life. High levels of basal peptide activity were observed in breast-fed infants with a normal muscle tone and psychomotor development. Contrarily, increased basal levels of bovine β-casomorphin were detected in infants fed with cow milk, and these individuals showed a heightened muscle tone and a delayed psychomotor development.[16] This finding was considered to give support for the idea that bovine β-casomorphin may influence the infant's psychomotor development.[16]

The β-casomorphins have also been implicated in allergic reactions. In a study of breast-feeding women having a history and clinical manifestation of food allergy, the levels of β-casomorphin-5 and -7 were measured in their colostrum and milk and compared with those assessed in healthy age-matched breast-feeding controls.[31] The results from this study show that the peptide concentrations in colostrum and milk of these groups of women exhibit a diverse profile with highest levels of the opioid peptides in colostrums of healthy women followed by a rapid decrease in their mature milk, whereas the levels in women with food allergy remained constant during lactation. It was suggested that the content of the β-casomorphins in their milk could serve as an indicator of allergic conditions in the lactating women.[31]

Further, studies have implicated β-casomorphin-like peptides in postpartum psychosis.[18] In fact, the presence of high levels of β-casomorphin-8 in milk from a patient with postpartum psychosis has been reported.[29] A more recent study has indicated that the levels of β-casomorphin in plasma and milk samples are elevated in women with mastitis and that there is a relationship between this complication and the prevalence of postpartum psychosis (Righard, Carlsson, and Nyberg, unpublished data).

As mentioned above, the hemorphins have been found at high levels within the central and peripheral nervous systems. In addition to opioid-receptor binding, hemorphins have many effects on the renin–angiotensin system, including the inhibition of ACE[17] and IRAP/AT4 receptor binding.[20]

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

However, only a few studies have examined the role of hemorphins in pathophysiology. A study[27] of hemorphins in Alzheimer's disease (AD) and control brains measured the levels of both LVV- and VV-hemorphin-6 and -7 by quantitative MALDI-TOF mass spectrometry. The authors found that LVV-hemorphin-6 and total hemorphin levels are elevated in AD temporal neocortex but not in the hippocampus, occipital lobe, or frontal lobe. They suggested that the observed elevation of hemorphins could reflect a vascular abnormality resulting from cerebral amyloid angiopathy associated with both neurodegenerative disease and aging.[27] Increased concentrations of hemorphins in the circulatory system, also mentioned above, have been seen under certain physiological[4] and clinical conditions, such as hemodialysis and during open-heart surgery.[24] Finally, during the past few years it has been reported that the serum concentrations of hemorphins in patients with diabetes are reduced.[8] Some studies have attempted to investigate the biochemical mechanisms that may underlie this anomaly through studying the influence of hemoglobin glycation on hemorphin generation.[8] Another aspect of the involvement of hemorphins in pathophysiology arises from the observations that their N-terminal extensions LVV-hemorphin-7 and VV-hemorphin-7 may interact with IRAP/AT4 receptors. Effects mediated through these sites are involved in cognitive function. Thus, the extended hemorphins may constitute a group of compounds suitable for the development of new therapeutic agents, which may be used for various cognitive disorders.[13]

CONCLUDING REMARKS

Although the past decades have seen much progress in opioid peptide research, there are comparatively few studies directed to the atypical opioid peptides, like β-casomorphins and hemorphins, and their role in physiology or pathophysiology. They are produced in relatively high amounts, but their weak activity on opioid receptors may have resulted in less attention. However, currently, the β-casomorphins seem to be receiving new interest regarding their role in allergic reactions[31] and in apnea related to SID.[32] The hemorphins have become very attractive compounds since their link to the renin–angiotensin system was discovered.[13] Therefore, it is probable that both these peptide systems will receive renewed interest in the years to come.

Chapter 212

Endomorphins

Hirokazu Mizoguchi, Tsukasa Sakurada and Shinobu Sakurada

ABSTRACT

Endomorphins are highly selective endogenous μ-opioid peptides discovered in mammalian brain in 1997. Endomorphins have several identical pharmacological and physiological characters, as well as identical sequence structures, with other endogenous opioid peptides and μ-opioid receptor agonists. Interestingly, endomorphin-1 and endomorphin-2, which have only one difference in the amino acid residue at position 3, show some characteristic differences from each other in their pharmacological and physiological effects. In this chapter, we describe the pharmacological and physiological characteristics of endomorphins, with emphasis on their differences.

DISCOVERY OF ENDOMORPHINS

Since the discovery of opioid receptors, neuroscientists have searched for their endogenous ligands. The search led to the discovery of enkephalins, endorphins, and dynorphins in the 1970s. The three families of opioid peptides contain a common N-terminal amino acid sequence, Tyr-Gly-Gly-Phe. The enkepkalins ([Met^5]enkephalin and [Leu^5]enkephalin) are the endogenous ligands for δ-opioid receptors and dynorphins (dynorphin A, dynorphin B, α-neoendorphin, and β-neoendorphin) are the endogenous ligands for κ-opioid receptors. β-Endorphin binds μ-opioid receptors and δ-opioid receptors equally. These compounds can also bind μ-opioid receptors, but they display relatively low selectivity and efficacy at the μ-opioid receptors. Before 1997, no mammalian opioid peptide that exhibited both high affinity and selectivity for μ-opioid receptors was identified. As a peptide with opioid-related activity in the central nervous system, Tyr-Pro-Trp-Gly-NH_2 (Tyr-W-MIF-1), which was isolated from bovine and human brain and contains the same structure at the N-terminus (Tyr-Pro-aromatic amino acid) with casomorphin, shows high selectivity for μ-opioid receptors, but its affinity for μ-opioid receptors is relatively low.[34] Based on this information, the peptide with the highest affinity and selectivity for μ-opioid receptors was searched from the 20 peptides that have a common N-terminal sequence Tyr-Pro-Trp-X and whose amino acid at the fourth position was substituted by the possible natural amino acids. Among the 20 peptides tested (Tyr-Pro-Trp-X-NH_2, X: Phe, Leu, Ile, Met, Val, Pro, Gln, Trp, Cys, Thr, Tyr, Asn, Ser, Ala, Gly, Arg, Lys, His, Asp, Glu), Tyr-Pro-Trp-Phe-NH_2 showed a highest affinity and selectivity for μ-opioid receptors. This peptide showed very potent analgesia after intracerebroventricular and intrathecal administration.[33] Moreover, specific μ-opioid receptor antagonists reversed the pharmacological effects of this peptide in both *in vitro* and *in vivo* experiments. Zadina and colleagues generated a specific antibody against this peptide that showed no crossreactivity for >40 opioid or nonopioid peptides and used it in combination with HPLC to screen extracts of bovine brain for immunoreactivity. After multiple purification steps, the immunoreactive fraction was applied to automated Edman degradation, and this yielded two peptide sequences, Tyr-Pro-Trp-Phe-NH_2 and Tyr-Pro-Phe-Phe-NH_2. Both peptides showed a high affinity and selectivity for μ-opioid receptors and pharmacological effects as μ-opioid receptor agonists. Because these peptides are the first endogenous mammalian peptides to have a high affinity and a clear specificity for μ-opioid receptors (see below), they were named endomorphin-1 (Tyr-Pro-Trp-Phe-NH_2) and endomorphin-2 (Tyr-Pro-Phe-Phe-NH_2).[33] Interestingly, the structure of endomorphins is different from those of traditional endogenous opioid peptides, which have a common N-terminal sequence, Tyr-Gly-Gly-Phe. Unlike other endogenous opioid peptides, however, the precursors or its cording DNAs for endomorphins have not yet been identified, although it has been already been 15 years since their discovery. Therefore, the biosynthesis for endomorphins is still unknown, although Ronai and colleagues have provided evidence of de novo biosynthesis of endomorphin.[10,11,19]

DISTRIBUTION OF THE ENDOMORPHINS IN THE CENTRAL NERVOUS SYSTEM

Soon after the discovery of endomorphins, the distribution of the endomorphin-2-like immunoreactive neurons was shown in the central nervous system. The endomorphin-2-like

immunoreactive fibers are present in the superficial layers of spinal dorsal horn and medulla oblongata.[12,13] The dorsal horn of the spinal cord is an important site for nociceptive transmission. It constitutes the first relay station for incoming somatosensory information and contains many neurotransmitters, such as substance P and glutamate. This region contains the highest densities of both μ-opioid receptors and endomorphin-2-like immunoreactivity. Mechanical disruption of the primary afferent neurons by dorsal rhizotomy dramatically diminished the endomorphin-2-like immunoreactivity.[12] Similarly, chemical disruption of primary sensory afferent neurons by the neurotoxin capsaicin eliminated its staining in the dorsal horn. These results provide direct evidence that endomorphin-2-like immunoreactive fibers may originate from the dorsal root ganglion, which contains the endomorphin-2-like immunoreactive neuronal perikarya.

The μ-opioid receptors are expressed in the primary afferent neurons that terminate in the superficial layers of the spinal dorsal horn.[1] Based on the distribution and physiological function of μ-opioid receptors, two major mechanisms for producing μ-opioid receptor-mediated analgesia have been proposed: presynaptic inhibition of neurotransmitter release from primary afferent neurons and postsynaptic hyperpolarization of excitatory neurons. μ-Opioid receptor agonists are known to regulate the release of glutamate, substance P, and calcitonin gene-related peptide from primary afferent neurons. Endomorphin-2 also modulates release of these excitatory neurotransmitters presynaptically.[29] Endomorphin-2-like immunoreactivity is present in dense-core vesicles in the terminals of primary afferent neurons at the spinal dorsal horn[25] and endomrphin-2 may be released from the primary afferent neurons by stimulation of the dorsal roots. The morphological demonstration and synaptic relationship provides evidence that endomorphin-2 may functionally work as a neurotransmitter and/or neuromodulator regulating pain processes.

Although both endomorphin-1- and endomorphin-2-like immunoreactivity are present in most areas of the central nervous system, several differences in their distribution and density were observed. Endomorphin-2-like immunoreactivity is more prevalent in the spinal cord and lower brain stem, whereas endomorphin-1-like immunoreactivity is more widely and densely distributed throughout the brain than endomorphin-2-like immunoreactivity.[13] However, very limited regions in the central nervous system contain endomorphin-1-like immunoreactive cell bodies. Like the endomorphin-2-like immunoreactive neuronal perikarya, the endomorphin-1-like immunoreactive neuronal perikarya are found in the dorsomedial hypothalamic nucleus and arcuate hypothalamic nucleus. The endomorphin-1-like immunoreactive neuronal perikarya are also present in ventromedial hypothalamic nucleus and the nucleus of solitary tract.

In the telencephalon, a dense plexus of endomorphin-1- and endomorphin-2-like immunoreactive nerve fibers are seen in the nucleus accumbens, septum, substantia innominata and the bed nucleus of the stria terminalis.[13,25] Endomorphin-1-like immunoreactivity is also very evident in the cortex, the dorsal lateral septal nucleus, and nucleus of the vertical limb of the diagonal band of Broca. The distribution of endomorphin-2-like immunoreactivity closely parallels that of endomorphin-1-like immunoreactivity, but its contribution to the telencephalic structures is much smaller.

In general, endomorphin-1-like immunoreactivity is extensively present in hypothalamic structures. Endomorphin-1-like immunoreactive fibers are detected in the organum vasculosum lamina terminalis, the median preoptic nuclei, and posterior hypothalamic nuclei. Other regions containing relatively large numbers of endomorphin-1-like immunoreactive fibers include the lateral preoptic area, anterior hypothalamic area, lateral hypothalamic area, ventromedial hypothalamic nucleus, dorsal hypothalamic area, dorsomedial hypothalamic nucleus, arcuate nucleus, and ventral premammillary and supramammillary nuclei. Endomorphin-2-like immunoreactivity is also widely distributed in hypothalamic structures. However, unlike endomorphin-1-like immunoreactive fibers, endomorphin-2-like immunoreactive fibers are infrequently detected in hypothalamic regions outside the regions containing endomorphin-2-like immunoreactive cell bodies.

In the midbrain, endomorphin-1-like immunoreactive fibers, and endomorphin-2-like immunoreactive fibers, are detected in the superior and inferior colliculii, periaqueductal gray, dorsal raphe nucleus, laterodorsal tegmental nucleus, ventral tegmental area, and the substantia nigra pars reticularis. However, in the lower brain stem, most of the endomorphin-1-like immunoreactive fibers are spread over different parts of the locus coeruleus and the parabrachial nucleus, in which the endomorphin-2-like immunoreactive fibers are intensely observed. The principal sensory nucleus of the trigeminal, the nucleus of the spinal trigeminal tract, and the nucleus of the solitary tract also contain some endomorphin-1-like immunoreactive fibers but at lower density than the endomorphin-2-like immunoreactivity.

RECEPTOR SELECTIVITY AND ITS MODULATION

The receptor selectivities of endomorphins have been well established. As Zadina and his colleagues described when they firstly reported the existence of endomorphins in mammalian brain, endomorphins show very high affinity and selectivity for μ-opioid receptors.[33] The affinity of endomorphin-1 to μ-opioid receptors mimics that of the selective μ-opioid receptors agonist [D-Ala^2,N-MePhe^4,Gly-ol^5]enkephalin (DAMGO), and its selectivity for μ-opioid receptors is >4000 times and 15,000 times

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

higher than those for δ-opioid receptors and κ-opioid receptors, respectively. However, the affinity of endomorphin-2 to μ-opioid receptors is approximately 2 times lower than that of DAMGO, but its selectivity for μ-opioid receptors is still >13,000 times and 7000 times higher than those for δ-opioid receptors and κ-opioid receptors, respectively. The extremely high affinity and selectivity of endomorphins for μ-opioid receptors have been confirmed in the membrane preparations obtained from several brain regions and spinal cord in mice and rats.[8] With high affinity and selectivity to the μ-opioid receptors, in addition to some biological action mimicking traditional μ-opioid receptor agonists, endomorphins were predicted to be the long-sought endogenous μ-opioid peptides.[33] Interestingly, endomorphins are the only endogenous opioid peptides to show high receptor selectivity, whereas other endogenous opioid peptides show selectivity to multiple opioid receptors.

Because opioid receptors are coupled with Gi/Go protein, the intrinsic activity of opioid receptor agonists has been preferentially evaluated in the [^{35}S]GTPγS binding assay. Like other μ-opioid receptor agonists, both endomorphin-1 and endomorphin-2 produce marked increase in the [^{35}S]GTPγS binding in membrane preparations obtained from several brain regions and spinal cord in mice and rats.[8] The endomorphin-induced increase in [^{35}S]GTPγS binding is completely eliminated by the co–incubation with selective μ-opioid receptor antagonists but not δ-opioid receptor and κ-opioid receptor antagonists.[17] Consistent with their selectivity to opioid receptors, G-protein activation induced by endomorphins is selectively mediated by μ-opioid receptors. In fact, the endomorphin-induced increase in [^{35}S]GTPγS binding is completely abolished in the membrane preparation obtained from μ-opioid receptor knockout mice.[15] The maximal increase in [^{35}S]GTPγS binding by endomorphins (the intrinsic activities of endomorphins) is approximately half that of DAMGO, an μ-opioid receptor full agonist.[8,17] Moreover, the maximal increase in [^{35}S]GTPγS binding by the μ-opioid receptor full agonists, DAMGO and β-endorphin, is partially attenuated by coincubation with high concentrations of endomorphins.[2,16] The evidence clearly suggests that endomorphins, as well as morphine and fentanyl, are partial agonists for μ-opioid receptors. It is of interest to note that endomorphins are the only endogenous opioid peptides to have a partial agonistic property, whereas other endogenous opioid peptides are full agonists for their respective opioid receptors.[2,35] The physiological role of endomorphins may be somewhat different from that of other endogenous opioid peptides.

BIOLOGICAL ACTIONS OF ENDOMORPHINS

Like other endogenous opioid peptides or selective μ-opioid receptor agonists, endomorphins have a variety of biological actions. As expected, a major biological action of endomorphins is their remarkable antinociceptive effect. After intrathecal and intracerebroventricular injections, endomorphins show as potent antinociception as the other endogenous opioid peptides [Met^5]enkephalin, [Leu^5]enkephalin, and dynorphin A.[24] The antinociception induced by both endomorphin-1 and endomorphin-2 is mediated by μ-opioid receptors. However, their antinociceptive effects are characteristically somehow different. The antinociception induced by endomorphin-2, but not endomorphin-1, is attenuated by the μ_1-opioid receptor antagonist naloxonazine,[21,24] whereas the antinociception induced by endomorphin-1, but not endomorphin-2, is attenuated by the recently identified μ_2-opioid receptor antagonist D-Pro^2-Tyr-W-MIF-1.[31] These results clearly suggest that the antinociception induced by endomorphin-1 and endomorphin-2 is characteristically distinct from each other, and selectively mediated through μ_2- and μ_1-opioid receptors, respectively. This theory is additionally supported by the evidence that the antinociception induced by endomorphin-1 and endomorphin-2 is selectively attenuated by the μ_2-opioid receptor antagonist D-Pro^2-endomorphin-1 and the μ_1-opioid receptor antagonist D-Pro^2-endomorphin-2, respectively, but not vice versa.[23] Moreover, endomorphin-2-induced antinociception is attenuated by 3-methoxynaltrexone, which is a heroin-sensitive and morphine-insensitive antagonist, suggesting that endomorphin-2 has selectivity to multiple μ-opioid receptors, including the μ_1-opioid receptor and other μ-opioid receptor as a third party of the μ-opioid receptor, but not to the μ_2-opioid receptor.[21] More interestingly, the antinociceptive effect of endomorphin-2, but not endomorphin-1, is mediated by δ-opioid and κ-opioid receptors in addition to the μ-opioid receptor,[22] even though endomorphin-2-induced antinociception is completely abolished in the μ-opioid receptor knockout mice.[15] This controversial result is shown by the ability of endomorphin-2 to lead to the release of other endogenous opioid peptides, [Met^5]enkephalin and dynorphin A, by its stimulation of μ-opioid receptors.[22] β-Endorphin is another endogenous opioid peptide known to release [Met^5]enkephalin.[30] However, at present, endomorphin-2 is the only endogenous opioid peptide, which releases endogenous κ-opioid peptides. Like other endogenous opioid peptides, the duration of endomorphin-induced antinociception is short-lived, and completely disappears within half an hour.[15,24] Unfortunately, enzymatic degradation of endomorphins cannot explain this phenomenon. The process of enzymatic degradation of endomorphins by enzymes identified in the cerebrospinal fluid and central nervous systems has already been described.[20,27] The enzymatic degradation of endomorphins in cerebrospinal fluid, like that described earlier for the related peptide Tyr-MIF-1 (Tyr-Pro-Leu-Gly-NH_2), proceeds more slowly than that of other endogenous opioid peptides, and it requires >2 h to degrade endomorphins.[20,27]

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

The identical character of endomorphins on acute tolerance may help to explain their short-lived effects. As is well known, a single injection of opioid receptor agonists leads to a short-lived desensitization to the same agonists, the so-called acute tolerance effect, and the time course of acute tolerance is identical to the receptor to which the agonist binds. Unlike the traditional μ-opioid receptor agonist, DAMGO, whose acute antinociceptive tolerance shows up 3 h after the treatment and lasts for 6 h, the acute antinociceptive tolerance to endomorphins rapidly develops within half an hour and disappears by 3 h.[32] The rapid development of the acute antinociceptive tolerance to endomorphins may be involved in its short-lived antinociceptive effect.

The other traditional biological activities of μ-opioid receptor agonists, including rewarding effect, locomotor enhancement, inhibition of gastrointestinal transit, cardiovascular depression, and respiratory depression, have also been described for endomorphins. Like other μ-opioid receptor agonists, both endomorphin-1 and endomorphin-2 produce potent inhibition of gastrointestinal transit[7] and cardiovascular depression[8] with similar efficacy. Both endomorphin-1 and endomorphin-2 also produce respiratory depression; however, an approximately 12 times higher dose of endomorphin-1 is required to produce the respiratory depression in comparison with endomorphin-2.[5] The difference in the sensitivity for respiratory depression may be caused by the different distribution of endomorphin-1 and endomorphin-2-containing neurons. Although endomorphin-1-like immunoreactivity and endomorphin-2-like immunoreactivity both densely distribute in areas associated with respiratory function such as the nucleus tractus solitarius and the parabrachial nucleus, endomorphin-2-like immunoreactivity is more prominent than endomorphin-1-like immunoreactivity in the ventrolateral nucleus tractus solitarius and external medial parabrachial nucleus, which are the most crucial regions for respiratory regulation.[13] Regarding the rewarding effect and locomotor enhancement, endomorphin-1 and endomorphin-2 show more significant differences from each other. Endomorphin-1, and other traditional μ-opioid receptor agonists, produces a remarkable rewarding and locomotor-enhancing effect in a dose-dependent manner.[3,18] By contrast, endomorphin-2 shows a bell-shaped dose-response curve for the rewarding and locomotor-enhancing effects, and prominently produces an aversive rather than rewarding effect.[4,18] As is well known, the rewarding and locomotor-enhancing effects of μ-opioid receptor agonists are mediated by the disinhibition of mesolimbic and nigrostriatal dopaminergic neurons via the activation of μ-opioid receptors located on the GABAergic neurons in the ventral tegmental area and substantia nigra, respectively.[18] In the terminal of mesolimbic and nigrostriatal dopaminergic neurons on the nucleus accumbens and striatum, respectively, dynorphinergic neurons are localized to inhibit the release of dopamine. Unlike endomorphin-1 and other traditional μ-opioid receptor agonists, endomorphin-2 has a characteristic pharmacological ability to release dynorphin A.[22] The release of dynorphin A in the nucleus accumbens and striatum may be involved in the lack of the remarkable rewarding effect and locomotor-enhancing effect of endomorphin-2. In fact, endomorphin-2 shows a remarkable rewarding effect when dynorphin A is blocked by the use of its antiserum.[18]

PATHOPHYSIOLOGICAL IMPLICATIONS OF ENDOMORPHINS

The pathophysiological roles of endomorphins still have not been well characterized. However, the functional changes induced by endomorphins in several pathological conditions may be helpful. In a neuropathic pain state induced by sciatic nerve ligation, endomorphin-2-like immunoreactivity is dramatically decreased in the superficial layer of dorsal horn.[26] This evidence strongly suggests that endomorphin-2 may regulate the transmission of nociceptive stimuli in the spinal cord, and the reduction of endomorphin-2-containing neurons may be associated with the nerve ligation-induced neuropathic pain. By contrast, endomorphin-2-like immunoreactivity in the periaqueductal gray matter is greatly increased by spinal nerve ligation.[28] Taken together with the evidence that endomorphin-2 is particularly more effective than morphine in nerve ligation-induced neuropathic pain, endomorphin-2 in the periaqueductal gray matter may be involved in the regulation of the pain sensation induced by nerve injury via activation of the descending pain control system.

In peripheral inflammation, especially knee joint inflammation induced by adjuvant, endomorphin-1-like immunoreactivity is greatly increased in the synovium of the knee joint.[14] The increase of endomorphin-1-like immunoreactivity is also observed in the synovium of adjuvant-inflamed paws.[9] At present, the increased endomorphin-1-like immunoreactivity is limited to the peripheral tissues. Unlike endomorphin-2, which seems to control pain sensation in the central nervous system, endomorphin-1 may control painful inflammation in the peripheral tissues.

The endomorphins are the only endogenous opioid peptides identified as partial agonists.[16] The other endogenous opioid peptides are all full agonists for their respective receptors. Theoretically, a high dose of partial agonists can partially attenuate the effect of full agonists working on the same receptors. As expected, endomorphins partially attenuate the effects of β-endorphin, another endogenous μ-opioid peptide.[16] In the specific physiological condition in which the μ-opioid system is overstimulated, endomorphins may prevent excessive stimulation of the μ-opioid receptor by β-endorphin by a negative feedback mechanism in

tissues in which endomorphins and β-endorphin are colocalized.

CONCLUDING REMARKS

A growing body of evidence indicates some differences between endomorphin-1 and endomorphin-2. Overall, the pharmacological characteristics of endomorphin-1 are relatively close to those of the traditional μ-opioid receptor agonists, whereas endomorphin-2 has several differences in its pharmacological characteristics from other μ-opioid receptor agonists. There are >30 subclasses of μ-opioid receptors in mice based on the splice variants of μ-opioid receptor mRNA.[6] The differences in their pharmacological and physiological character may be revealed by the different selectivity of endomorphins for μ-opioid receptor subclasses and by the different colocalization of endomorphins and their preferred μ-opioid receptor subclasses.

Chapter 213

Evolution of the Opioid System

Dan Larhammar, Görel Sundström and Robert M. Dores

ABSTRACT

Evolutionary analyses suggest that the vertebrate ancestor had a single opioid peptide precursor gene and a single opioid receptor gene. The two genome doublings before the origin of gnathostomes generated two more peptide precursor genes. A fourth copy probably arose by a local gene duplication. The sequences diverged and became the precursors for endorphin (POMC), enkephalin, dynorphin, and nociceptin/orphanin. The ancestral receptor gene was quadrupled in the same events to give the receptors called delta, kappa, and mu and the nociceptin/orphanin receptor. Subsequently, certain ligand–receptor preferences have evolved. A third genome doubling in the ancestor of teleost fishes generated additional copies. For instance, the zebrafish has one additional delta receptor gene and three additional peptide precursor genes. Thus, the opioid system had already considerable complexity at an early stage in vertebrate evolution and expanded further in the teleost fish lineage but remained constant in most tetrapods.

PEPTIDE FAMILY

Soon after the seminal discoveries in the 1970s that subsets of neurons in the central nervous system of mammals have receptors that bind opiates,[26] peptides with the ability to bind to these receptors were purified from brain tissue, namely Met-enkephalin and Leu-enkephalin.[13] Subsequently, additional opiate receptor-binding peptides (opioids) were identified, including β-endorphin, α-neoendorphin, and dynorphin (for a review see Ref. 9). A unifying feature of these peptides is the presence of the N-terminal motif YGGF called the opioid core sequence. Later, an opioid-like peptide named nociceptin or orphanin was identified,[18,28] which has the modified core motif FGGF in mammals and chicken, while in teleost fishes, it still has the original YGGF motif.[30] In this chapter, nociceptin will from an evolutionary point of view be considered a member of the opioid peptide family. Beyond this core motif, each peptide has a distinct C-terminal sequence giving sizes that range from five for the enkephalins to >30 amino acid residues for β-endorphin.[9] Unlike many other biologically active peptides, the opioid peptides do not have a C-terminal amide.

Cloning of the opioid peptides revealed that they are generated from large and complex precursors (Fig. 1). The peptide β-endorphin was found in the same precursor as the one encoding the pituitary hormone ACTH and additional nonopioid peptides.[20] This precursor has been named POMC for proopiomelanocortin. Enkephalin and dynorphin were found to be generated from separate precursors, each of which encodes multiple opioid peptides.[9] The nociceptin precursor has 1–2 opioid-like peptides depending on species.[30]

In the precursors, the opioid sequences are flanked by sets of paired basic amino acids (i.e. KR, RR, RK, KK), except for a few of the sequences in some species.[9,30] Each precursor has a cleavable signal peptide for transfer into the endoplasmic reticulum during synthesis, followed by an N-terminal part containing a cysteine-rich region with 4 cysteines in POMC and 6 cysteines in the other three precursors at conserved positions. Apart from these shared features, the precursor proteins share only limited and patchy amino acid sequence identity.

Four Propeptide Genes

Proenkephalin is the common precursor for the pentapeptides Met-enkephalin and Leu-enkephalin and two C-terminally extended forms of Met-enkephalin, as well as three additional opioid core motifs (Figs 1 and 2).[22] The seven opioid sequences in this precursor are designated A through G, and the positions of some of these sequences coincide with the positions in the other precursors. In addition to mammals (for review, see Ref. 11), proenkephalin has been cloned and characterized or predicted from genome sequences in several nonmammalian tetrapods and bony fishes[9,30] and in a cartilaginous fish.[17]

Prodynorphin in mammals encodes three opioid core motifs, named α-neoendorphin, dynorphin A, and dynorphin B.[15] Amphibians and teleost fishes have two additional

FIGURE 2 Amino acid sequence alignment for the opioid peptides in placental mammals.

opioid peptides corresponding to positions B and C in proenkephalin[1,9] (Fig. 1).

The POMC precursor contains β-endorphin at its C-terminus that seems to correspond to opioid site E or F in Fig. 1. Shorter cleavage products containing part of the β-endorphin sequence have been purified and named α- and γ-endorphin, but the β form is the predominant peptide that can bind to opioid receptors. The melanocortin-related peptides ACTH, α-MSH (which constitutes the beginning of ACTH), β-MSH, and γ-MSH,[20] and in cartilaginous fish δ-MSH,[2] are encoded between the cysteine-rich region and β-endorphin. The melanocortin peptides all have the core amino acid motif HFRW, and these ligands activate the melanocortin receptors, a distinct family of G protein-coupled receptors (GPCR).[4] POMC has been characterized in representatives of all the major classes of vertebrates.[8]

The nociceptin precursor in mammals contains only a single opioid-like peptide, nociceptin itself,[12,23,24] whereas in teleost fishes, this is preceded by another peptide with a slightly modified core sequence, FGGF (as in the nociceptin peptide in mammals but not in fish).[30] Possibly, the two fish peptides correspond to positions E and F with the latter one being the nociceptin present in mammals. It has also been proposed that a relic YGGF motif is present C-terminally to the nociceptin peptide; this sequence is YLGM in chicken and some fishes, YLVL in placental mammals.[30]

Propeptide Comparisons

The vertebrates that possess all four propeptides span the groups of Actinopterygians (ray-finned fishes) and Sarcopterygians (flesh- or lobe-finned fishes) (Fig. 3). Among Chondrichthyes (sharks, rays, and chimaeras), it has so far been possible to identify proenkephalin, prodynorphin and POMC. In lampreys, two POMC homologs exist, but no additional propeptides have yet been published.

The number of opioid core motifs that were present in the ancestral precursor at the time of its quadruplication in early vertebrate evolution is difficult to deduce because, as for the various MSH peptides, some copies of the core motif may have been added and others may have been lost[7] in the different genes and in different lineages. With the exception of POMC, the other three precursors contain two or more opioid core motifs, indicating that the ancestral precursor may have had at least two, possibly more. POMC probably lost all opioid core motifs except the one in β-endorphin coincident with the insertion of the region encoding one or more MSH motifs. A single intron in the corresponding position and in the same reading frame of all four opioid precursor genes further emphasizes their shared evolutionary ancestry.

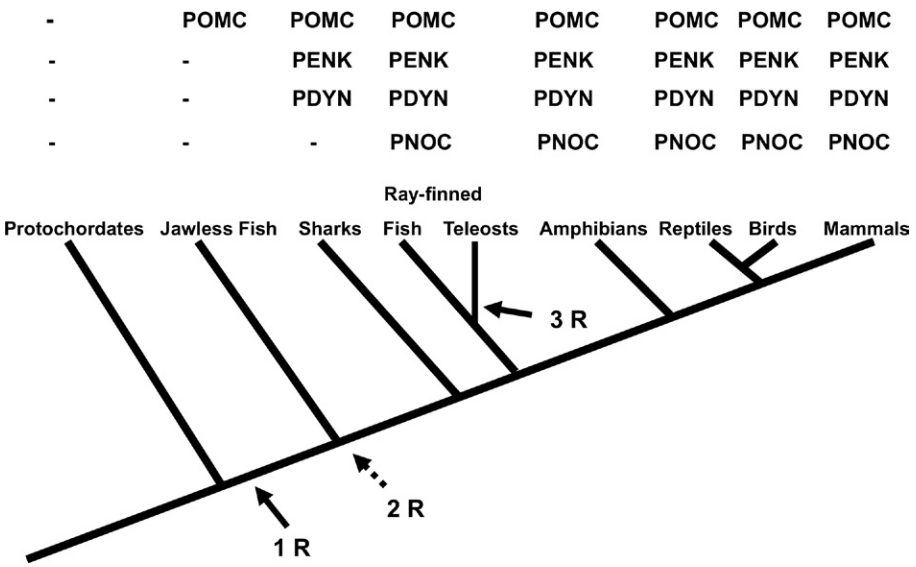

FIGURE 3 Phylogenetic distribution of the opioid peptide precursors. The three arrows mark the three major genome doublings. The time point for 2R (dashed arrow) relative to the divergence of the jawless fishes is still uncertain. The ray-finned fish branch is divided into teleosts (that underwent 3R) and other ray-finned fishes. Some teleost fishes have duplicates of some of the opioid precursor genes due to 3R. The protochordates consist of urochordates (tunicates) and cephalochordates (lancelets).

Interestingly, the propeptides contain a number of potential dibasic cleavage sites that are not used for proteolytic cleavage, resulting in the presence of dibasic motifs in both mature dynorphins and mature nociceptin (and ACTH). It may be speculated that the absence of cleavage at dibasic sites could have resulted from either amino acid changes elsewhere in the propeptide that reduce the efficiency of cleavage at the dibasic sites, or from altered specificity or expression of the processing enzymes, primarily prohormone convertases 1 and 2.

The genome doubling that took place in the ancestor of teleost fishes[14] has resulted in additional duplicates of some of the propeptide genes.[30] For instance, zebrafish has duplicates of both proenkephalin, pronocicpetin and POMC. The latter two are duplicated also in medaka and three-spined stickleback, two other teleost fish species whose genomes have been sequenced. The duplicates generally display high sequence conservation, but β-endorphin has diverged considerably in the POMCb gene in medaka and stickleback where the core opioid motif YGGF has changed to NGSF and NGST, respectively, but has remained intact in zebrafish. Also the ACTHb peptide has changed considerably in the three fishes, whereas α-MSHb differs in only a single position. The barfin flounder *Verasper moseri* has a third POMC gene[31] that probably resulted from a recent duplication. Sturgeons and paddlefish have two copies of POMC, presumably as a result of their independent tetraploidizations. In lampreys, duplicates of the POMC gene have been identified, both of which display partial degeneration[32]: one has been named POC and can generate ACTH and a variant of β-endorphin but has lost the ability to make α-MSH and β-MSH. The other copy is called POM and can give rise to the MSH peptides and a distinct version of β-endorphin. POC and POM are expressed in distinct parts of the hypothalamus. The frog *Xenopus laevis* has undergone a recent tetraploidization that probably explains its duplicate genes for POMC, proenkephalin, and prodynorphin.

Anatomical studies have shown that in mammals an individual neuron will express only one precursor-coding gene.[16] As a result, distinct enkephalinergic, dynorphinergic, and endorphinergic circuits can be identified in the mammalian CNS. Regarding the additional duplicates of the propeptide genes that exist in teleost fishes, it is still largely unknown to what extent the duplicates differ from each other with regard to anatomical and temporal expression, as well as propeptide processing and receptor affinity and efficacy of the mature peptides.

Given the sequence similarity between the opioid peptides, it is not surprising that each one may bind to more than one of the different receptor types but with different affinities (Fig. 4). In mammals, the enkephalins have the highest affinity for the δ receptor (OPRD), the dynorphins for the K receptor (OPRK), and β-endorphin for the μ receptor (OPRM), but each category displays some affinity also for the other receptor types. Nociceptin, by contrast, with its FGGF motif in mammals and chicken, is selective for the nociceptin receptor. Even zebrafish nociceptin with the ancestral YGGF motif does not bind appreciably to the other opioid receptors.

Invertebrate Opioid System?

Several studies published in the 1980s reported opioid-like immunoreactivity in invertebrates as detected by antisera raised to the mammalian opioid peptides. Some of the reports described opioid-like peptide sequences and even two complete POMC sequences for invertebrates have been published, one of them also cloned as cDNA. However, there was no proof with appropriate control experiments that the POMC gene was present in the genome of this invertebrate. Also an opioid receptor sequence has been reported for an invertebrate, but its nucleotide sequence was almost identical to the human sequence and therefore probably resulted from contamination. No opioid propeptides or receptors have yet been identified in any invertebrate genome project, not even deuterostome invertebrates such as the tunicate *Ciona intestinalis*, the lancelet *Branchiostoma floridae*, or the sea urchin *Strongylocentratus purpuratus*.[30] Also melanocortin receptors are still unknown outside the vertebrates.

RECEPTORS

The opioid receptors were discovered by Pert and Snyder in 1973[26] before the first endogenous opioid peptides were characterized,[13] and it soon became apparent that distinct receptor types exist in mammals. The receptors were named using the initial Greek letter for certain characteristic features, namely, μ (mu) for the morphine-preferring receptor, K (kappa) for the ketocyclazocine-binding receptor, and δ (delta) for the receptor found in vas deferens. Clones for all three receptors were reported in mammals in 1992–1993, and a fourth receptor was identified by sequence similarity and therefore called opioid receptor-like.[19] Subsequently, a peptide was discovered that bound to this receptor, nociceptin/orphanin, hence leading to the name NOP for nociceptin receptor belonging to the opioid receptor family. The genes encoding the four receptors in mammals have been named OPRD1, OPRK1, OPRM1, and OPRL1. All the four genes have two introns in the corresponding positions, supporting origin from the same opioid receptor ancestor. The overall identity among the three opioid-binding receptor types in mammals is in the range 55–58%, while the NOP receptor is slightly more divergent displaying 48–49% identity to the other three. The transmembrane regions of the receptors are more highly conserved than the loops and the termini, as is usually the case for GPCRs.

Subtypes of some of the receptors have been reported in mammals and probably result from alternative splicing and possibly also posttranslational modifications or interactions with other proteins or dimerization.[6] Detailed studies of the mouse gene for the μ receptor have shown that in addition to the three major coding exons that are conserved between the four receptor types, numerous splice variants also can be detected.[25] Many of these seem to result in prematurely truncated receptors that probably fail to be expressed at the cell surface, but several variants exist that differ in the length of the cytoplasmic tail and result in different coupling efficiency.[25] The physiological importance of these splice variants and their conservation between species are still largely unexplored.

The four opioid receptor genes that have been identified in mammals have also been found in other tetrapods including chicken,[10] the rough-skinned newt *Taricha granulosa*[3] and the frog *Silurana/Xenopus tropicalis*[10] (Figs 5 and 6). In teleost fishes, homologs of all four receptors are present in all species whose genomes have been sequenced.[10] Furthermore, duplicates have arisen in the teleost-specific tetraploidization like for some of the propeptide genes as shown in the phylogenetic tree in Fig. 6: an extra copy of the δ receptor gene was identified in zebrafish and three-spined stickleback and a duplicate K receptor gene was found in medaka, three-spined stickleback and the green spotted

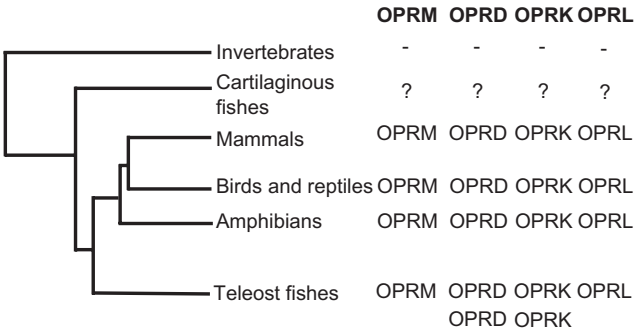

FIGURE 5 Phylogenetic distribution of opioid receptors mu (OPRM), delta (OPRD), kappa (OPRK), and the nociceptin receptor (OPRL). The question marks indicate that four partial receptor sequences have been found in a cartilaginous fish (the elephant shark), but it is still unclear whether they are orthologs (species homologs) of the four subtypes found in tetrapods. Note that duplicates of delta and kappa receptors have been found in some teleosts.

pufferfish (*Tetraodon nigroviridis*). However, no duplicates were found for the μ receptor or the NOP receptor in any of these species.

Opioid receptor-like sequences have also been identified in the sequenced genome of a holocephalan cartilaginous fish, the elephant shark *Callorhinchus milii*.[10] However, it was not possible to say if these partial sequences correspond to the four opioid receptor types found in mammals.

Comparison of the receptor sequences between tetrapods and teleost fishes show that no striking insertions or deletions have taken place, indicating strong conservative evolutionary pressure. Binding studies with opioid peptides have been performed to cloned receptors in the rough-skinned newt[3] and in zebrafish.[5,29] It was noted in these studies that the newt receptors seem to have less stringent ligand selectivity than the mammalian receptors.

EVOLUTION OF THE OPIOID SYSTEM

The four propeptide precursors have arisen from a single ancestral gene in early vertebrate evolution as shown by similarities in precursor organization (Fig. 1), the conserved cysteine cluster, and a single conserved intron. The species distribution of the propeptides shows that the duplications took place before the origin of gnathostomes (Fig. 3).

Likewise, the four receptor types originated from a single ancestral receptor as supported by two conserved introns in the coding region of all four genes. The phylogenetic tree based on sequence comparisons (Figs 5 and 6) supports duplications in early vertebrate evolution, as for the propeptide genes.

An additional type of evidence that can be used to deduce duplication mechanisms and time points is the chromosomal locations of genes. Gene families that expanded in early vertebrate evolution often have their members on different chromosomes, and each chromosomal region contains members from the same set of gene families. Usually, the genomes of tetrapods have four related such chromosomal regions with similar repertoires of genes. This is a result of the two tetraploidizations or genome doublings that took place in early vertebrate evolution before the radiation of the gnathostomes.[21,27] Subsequently, a third tetraploidization happened in the ancestor of teleost fishes.[14]

The four opioid propeptide genes are located on three chromosomes that share members from several other gene families that display similar sequence-based phylogenetic trees. This suggests that all of these families were duplicated at the same time as part of a large block of genes or an entire chromosome. The exception is the fourth gene, POMC, which is located in the same chromosomal region as the pronociceptin gene. This may be the result of a local gene duplication as suggested in Fig. 7A.[30] More complicated (less parsimonious) evolutionary scenarios are also conceivable.

The four opioid receptor genes display an even better match with the double tetraploidization scheme, because all four share neighboring gene families that have similar phylogenetic relationships. Thus the opioid receptor expansion coincided with the opioid propeptide duplications.

One important aspect of duplication by chromosome doubling is that large gene regions including regulatory elements such as promoters and even distant enhancers are included in the duplication. This means that the daughter genes will initially share the same regulation. Gradually, the regulatory elements and the coding regions may diverge, leading to distinct roles of the gene duplicates. They may evolve either novel functions (neofunctionalization) or more specialized functions (subfunctionalization). This mode of

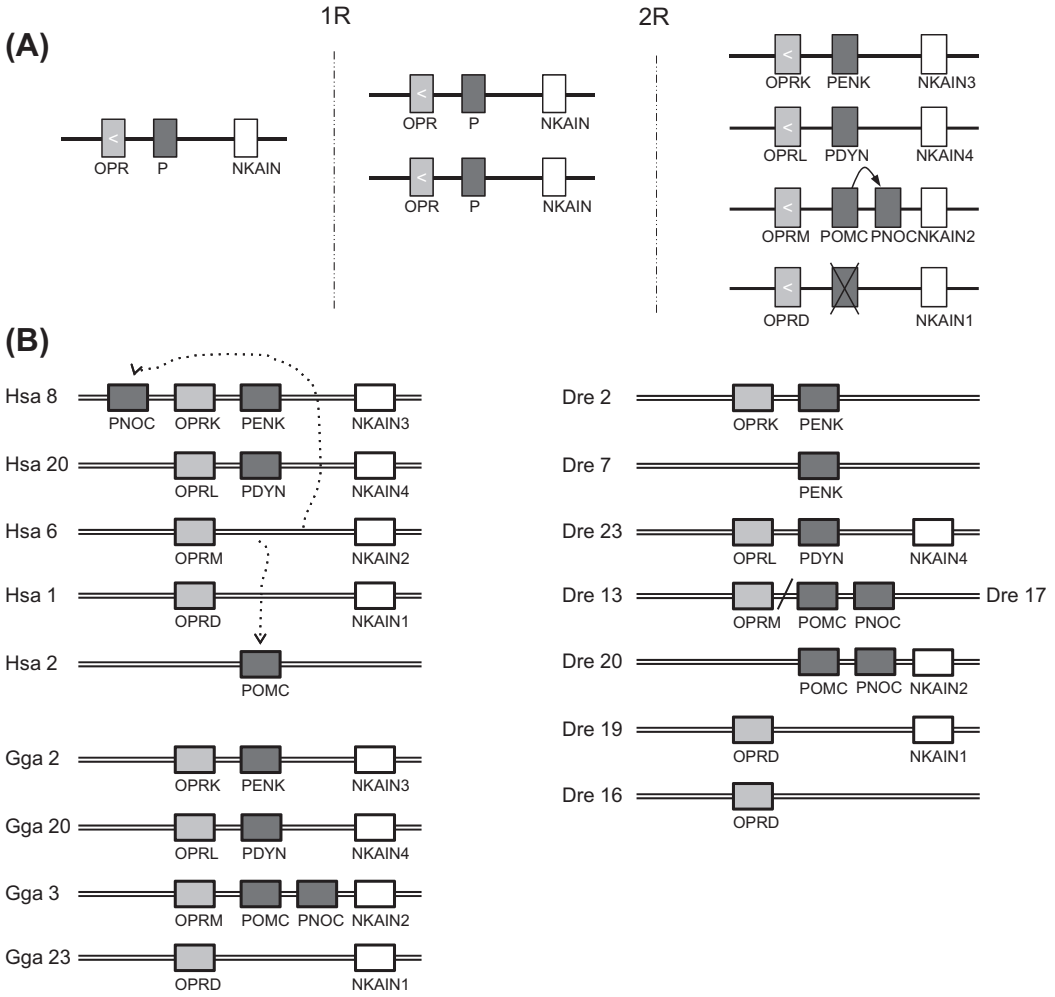

FIGURE 7 (A) A parsimonious duplication scheme for the opioid precursor and receptor genes found in the vertebrates, as explained by the two rounds of chromosome duplication in early vertebrate evolution. PENK stands for proenkephalin, PDYN for prodynorphin, and PNOC for pronociceptin. This chromosomal segment also contains numerous other gene families that were duplicated simultaneously, one of which is included in the figure, namely, NKAIN (Na+/K+ transporting ATPase interacting). The cross marks a gene that was lost. More complicated schemes are conceivable. (B) Chromosomal locations of the opioid precursor and receptor genes in chicken (Gga for *Gallus gallus*), human, and zebrafish (Dre for *Danio rerio*). The dashed arrows show translocations that have taken place in the lineage leading to *Homo sapiens*, as deduced from comparisons with several other vertebrates. The zebrafish genome has a duplicate set of chromosomal regions as a result of the teleost fish genome doubling. The figure was modified from Ref. 30.

duplication explains why considerable functional overlap may exist for the duplicates. Duplications that happen locally on the same chromosome, by contrast, do not necessarily include all of the flanking regulatory elements of a gene and may immediately result in distinct expression pattern of the duplicated gene.

Probably, the duplicated propeptides and receptors specialized rather quickly because all duplicates seem to have been retained in all vertebrate lineages investigated. Not only do the opioid propeptides and receptors seem to have duplicated concomitantly twice in early vertebrate evolution and again in the teleost ancestor, it also seems that the ancestral propeptide gene and the ancestral receptor gene were located in the same chromosomal region (Fig. 7). This suggests that their gene expression may once have been coregulated. However, after the tetraploidizations, there have been several translocations so any such coregulation seems to have faded. Furthermore, the peptide-receptor preferences that exist today in mammals do not agree with colocalization of the genes. For instance, proenkephalin and the K receptor are encoded on the same chromosome in both human, chicken, and zebrafish, but the preferred ligand of this receptor is dynorphin, which is encoded on a different chromosome (Fig. 7).

Because long periods of time have passed since the vertebrate classes diverged from one another, it might be expected that peptide-receptor preferences may differ between evolutionary lineages. Therefore it is probably important to investigate this in each species that is being studied. It is also possible that the physiological roles of the various

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

opioid peptides and receptors may have drifted differently in the evolutionary lineages. It will be very interesting to learn how the different components contribute differentially in distantly related vertebrates to pain regulation, reward mechanisms, metabolism, and the many other functions of the opioid system.

CONCLUDING REMARKS

Thus, both the opioid peptides and the opioid receptors can be traced back to a single ancestral gene in early vertebrate evolution that underwent genome quadruplication. However, beyond this point there is still no firm evidence for an opioid system. Likewise, the melanocortin system seems to be a vertebrate innovation with the insertion of melanocortin peptide(s) in POMC and the emergence of MC receptors. The genomes of representatives for the two major cyclostome lineages, lampreys and hagfishes, will hopefully shed further light on the origin of the opioid and melanocortin systems.

The expansion of the opioid system in early vertebrate evolution probably resulted in rapid specialization of the genes, because four propeptide genes and four receptor genes are still expressed in all tetrapod classes. Teleost fishes have received additional copies of both propeptide and receptor genes and thus display even greater opioid complexity.

Chapter 214

Exorphins

Masaaki Yoshikawa

ABSTRACT

Exorphin is a term suggested by Zoiudrou for opioid peptides derived from proteins of exogenous origin such as milk or plant. Many peptides having opioid activities have been shown to be released from proteins other than the classical precursor proteins for endogenous opioid peptides. Most of these exogenous opioid peptides have a Tyr residue at their amino termini. However, they differ from the typical endogenous ones by the absence of the enkephalin sequence. Such a typical opioid peptides are released from various proteins of animal and plant origin. Exorphins in the true sense may be those from plant proteins since those from animal proteins may function as endogenous peptides under certain conditions. Nevertheless, in this chapter, a typical opioid peptides of both plant and animal origin are described. Exogenous opioid peptides are classified into 2 groups based on whether they contain Tyr-Pro sequence, and they are subdivided into 4 groups.

OPIOID PEPTIDES DERIVED FROM PLANT PROTEINS

Gluten Exorphins

By using the mouse vas deferens (MVD) assay, Zioudou found opioid activity in the enzymatic digests of wheat gluten.[35] We isolated four opioid peptides, Gly-Tyr-Tyr-Pro-Thr (gluten exorphin-A5), Gly-Tyr-Tyr-Pro (gluten exorphin-A4), Tyr-Gly-Gly-Trp-Leu (gluten exorphin-B5), and Tyr-Gly-Gly-Trp (gluten exorphin-B4), from the pepsin–thermolysin digest of wheat gluten.[6] All of these were rather selective for the δ-receptor. Their IC_{50} values in the MVD assay were 60, 70, 0.017, and 3.4 μM, respectively. Gluten exorphins-A5, -B5, and -B4 were also released by the action of pepsin and pancreatic elastase.[3] Large amounts of des-Gly[1]-gluten exorphin-A5 (Tyr-Tyr-Pro-Thr) showing marginal δ-opioid activity in MVD assay: (IC_{50} = 800 μM) were also found in the same digest. Gluten exorphin-A5 sequence was found 15 times in the primary structure of high-molecular-weight glutenin. However, gluten exorphin-A5 is released from only one of these sites (-SGYYPTS-) by the action of pepsin and pancreatic elastase. The Tyr[3] in gluten exorphins-A5 is absolutely essential for the activity, whereas Tyr[2] can be replaced with Phe. Therefore, gluten exorphin-A could be classified as opioid peptide containing Tyr-Pro.

Among gluten exorphins, gluten exorphin-B5, which corresponds to [Trp[4]]-[Leu]-enkephalin, showed the most potent δ-opioid activity in the MVD and δ-receptor binding assays. However, in most *in vivo* assays, gluten exorphin-A is weaker than gluten exorphin-B probably because of susceptibility to peptidases. In a single trial passive avoidance experiment with step-through cages, gluten exorphin-A5 stimulated acquisition of memory after oral administration at doses of 300 mg/kg.[19] However, gluten exorphin-B5 was ineffective at the same dose. Gluten exorphins-A5 and -B5 stimulated postprandial insulin secretion after oral administration at a dose of 30 and 300 mg/kg, respectively, in rats.[3] In contrast, gluten exorphin-B5 is reported to stimulate prolactin secretion after intravenous administration at a dose of 3 mg/kg in rats.[2]

Another opioid peptide Tyr-Pro-Ile-Ser-Leu was isolated from the pepsin–chymotrypsin–trypsin digest of wheat gluten. This peptide was named gluten exorphin-C.[5] Gluten exorphin C was slightly selective for δ-receptor. Its IC_{50} value in the MVD assay was 13.5 μM. It should be noted that the Tyr-Pro sequence in gluten exorphin C was not followed by an aromatic amino acid, which has been believed to be essential for the opioid activity but by an aliphatic amino acid.

We found the Tyr-Pro-Leu-Gly-Gln sequence in the primary structure of wheat gliadin as an analog of Tyr-Pro-Leu-Gly-NH_2 (Tyr-MIF-I), and synthesized it. The peptide was rather selective for the μ-receptor because it exhibited opioid activity in the guinea-pig ileum (GPI) assay (IC_{50} = 7 μM) as did Tyr-MIF-I, an antiopioid peptide.[7] We named it gluten exorphin D.

Based on homology to β–casomorphin-7, Tyr-Pro-Gln-Pro-Gln-Pro-Phe sequence found in α-gliadin was synthesized and named gliadorphin.[8] Although the peptide did not exhibit opioid activity in the MVD assay, its binding to human peripheral lymphocytes was blocked by naloxone and an enkephalin derivative.

Rubiscolins

Ribulose bisphosphate carboxylase/oxygenase (Rubisco) is a key enzyme in photosynthesis catalyzing corbondioxide fixation. Rubisco is ubiquitus for photosynthetic organisms and is regarded as the most abundant protein on earth., From a nutritional point of view, the large subunit of Rubisco has an exceptionally ideal composition of essential amino acids among plant proteins. Therefore, plant Rubisco is expected to be a large source of food protein in the future. We found the Tyr-Pro-Leu sequence, which satisfies the requirements for opioid activity as described above, in the conserved region in the large subunit of plant Rubisco. We then synthesized the corresponding sequences, Tyr-Pro-Leu-Asp-Leu-Phe and Tyr-Pro-Leu-Asp-Leu. Both peptides were active in the MVD assay; IC_{50} values were 24.4 and 50 μM, respectively.[26] We named them Rubiscolins-6 and -5, respectively. Their opioid activities were very weak in the GPI and μ receptor binding assays. Results from the receptor binding assay also suggested that rubiscolins are δ-selective opioid peptides.

We examined the conditions for the enzymatic release of rubiscolins from spinach Rubisco by using a model peptide and partially purified protein. Rubiscolins-6 and -5 were released by the action of pepsin, pancreatic elastase, and leucine aminopeptidase. The yield of rubiscolin-5 was higher than that of rubiscolin-6.

In certain algae species, the residue corresponding to Leu^3 of rubiscolin-6 is replaced by Ile. Tyr-Pro-Ile-Asp-Leu-Phe is about 4 times more active than Tyr-Pro-Leu-Asp-Leu-Phe in the MVD assay.[28] The Asp residue in Rubiscolin is essential for δ-opioid activity; it could not be replaced with Glu. Replacement of Leu^3 or Ile^3 with Phe or Trp also results in a reduction of δ-opioid activity. The rubiscolin sequence has been present in Rubisco far longer than the appearance of δ-receptors in animals. The sequence might be essential for enzymatic activity. It may be attractive to speculate that the δ-receptor in animals has evolved to fit the rubiscolin sequence in Rubisco. However, this possibility might be remote. We think that the rubiscolin sequence might have affinity for the δ-receptor in animals just by chance. This might be the case for most plant-derived peptide sequences acting on animal receptors. In this sense, these bioactive peptides could be regarded as those obtained from a sort of random library.

Rubiscolin-6 showed antinociceptive activity in mice after oral administration at a dose of 300 mg/kg. Rubiscolin-6 stimulated acquisition of memory after oral administration at doses of 100/mgkg in a passive avoidance experiment.[27] In the elevated-plus maze test in mice, rubisolin-6 showed anxiolytic activity after oral administration at a dose of 30 mg/kg. Thus, rubiscolin-6 is about 3 times more potent than gluten exorphin-A5 *in vivo*.

Both μ and δ opioids have been reported to inhibit memory consolidation, while κ opioid stimulated it. It is an interesting observation that food-derived δ opioid such as gluten exorphin and rubiscolin stimulate memory consolidation after oral administration.

Rubiscolin-6 stimulated food intake on a normal diet after oral administration in mice at a dose of 0.3 mg/kg in a δ-receptor-dependent manner, followed by activation of prostaglandin D_2 and neuropeptide Y systems (see Kanako et al., 2012, *Mol Nutr Food Res*). However, it suppressed food intake on a high fat diet via a different mechanism. Recently, rubiscolin-6 was reported to suppress the escape reaction of the American cockroach, which might suggest the protective role of the peptide for plants against insects.[9]

Soymorphin

A μ-selective opioid peptide soymorphin-5 (YPFVV), which has a homology to human β-casomorphin, is released from soybean β-conglycinin β subunit by the action of pancreatic elastase and leucine aminopeptidase.[18] It exhibits anxiolytic-like activity after oral administration in mice. Soymorphin-7 (YPFVVN) suppresses food intake and intestinal transit after oral administration in mice at a dose of 10 mg/kg.[15] Soymorphin-5 decreases glucose and triglyceride levels through activating adiponectin and PPARα systems in diabetic KK-Ay mice (see Yamada et al., 2012, *Am J Physiol Endocrinol Metab*). It has been reported that impairment of glucose and lipid metabolism associated with diabetes is improved by ingestion of soy protein. Soymorphin might be one of the active components responsible for such effects.

OPIOID PEPTIDES DERIVED FROM ANIMAL PROTEINS (SEE THE HEMORPHINS/CASOMORPHINS CHAPTER IN THIS SECTION OF THE BOOK)

β-Casomorphin, Cytochrophin, and Hemorphin

β-Casomorphin-7 Tyr-Pro-Phe-Pro-Gly-Pro-Ile, which is derived from amino acid residues 60–66 of bovine β-casein, was isolated by Brantl et al. from commercial casein peptone as the first example of exogenous opioid peptide.[24] β-Casomorphin-5 showed higher activity than β-Casomorphin-7. β-Casomorphin-4 amide Tyr-Pro-Phe-Pro-N_{H2}, which was synthesized first and then isolated from *in vivo* digests, was the most potent among the derivatives. It was the first peptide ligand selective for μ receptor and named morphiceptin. Elongated forms such as β-casomorphins-9, -11, -13, and -21 have been isolated from *in vitro* or *in vivo* digests of β-casein.[12] Opioid activities of these elongated forms were all weaker than

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

β-Casomorphin-7. It should be noted that β-casomorphin-7 is released from β-casein A1, B, and C, minor genetic variants in which Pro^{67} is replaced with His, by the action of pepsin, pancreatic elastase, and leucine aminopeptidase.[12] In human β-casein, β-casomorphin with modified sequence Tyr-Pro-Phe-Val-Glu-Pro-Ile and weaker activity is conserved.[24,34] However, similar opioid peptides will not be released from murine β-casein because Tyr residue essential for opioid activity is not conserved.

From enzymatic digest of bovine blood, two opioid peptides Tyr-Pro-Phe-Thr, and Tyr-Pro-Trp-Thr were isolated by Brantl et al.[24] They were derived from cytochrome b and hemoglobin β and named cytochrophin and hemorphin, respectively. These peptides might work as endogenous opioid peptides under certain conditions. Hemorphin-5, Tyr-Pro-Trp-Thr-Gln, is released by the action of pancreatic elastase from hemoglobin. It should be noted that pancreatic elastase is engaged in the release of β-casomorphin, hemorphin, gluten exorphin, rubiscolin, and soymorphin[3,12,13,18].

Thus, β-casomorphin, cytochrophin, and hemorphin have a Tyr-Pro-aromatic sequence in common, which is also found in endomorphins 1 and 2 (Tyr-Pro-Trp-Phe-NH_2 and Tyr-Pro-Phe-Phe-NH_2)

α-Casein Exorphin

Loukas et al. isolated two opioid peptides RYLGYLE, and RYLGYL from pepsin digest of α-casein.[17] These are derived from the amino acid residues 90–96 and 90–95 of the protein. These peptides are selective for the δ-receptor, and their IC_{50} values in the MVD assay are 30 and 70 μM, respectively.

αs1-Casomorphin

Kampa et al. found that synthetic human αs1-casein(158–162), Tyr-Val-Pro-Phe-Pro, had affinity for $\kappa_1$and κ_2 receptors and named it αs1-casomorphin.[14] αs1-Casomorphin inhibited growth of T47D breast cancer cells.[10] The αs1-casomorphin sequence is found in the structure of casoxin D, Tyr-Val-Pro-Phe-Pro-Pro-Phe, which has been isolated from the pepsin–trypsin–chymotrypsin digest of human casein as an antiopioid and ileum-contracting peptide. As will be described later, Casoxin D has affinity for bradykinin B_1 receptor[29,32] (see the chapter on antiopioid peptides in this section of the book).

Neocasomorphin and Other Casein-Derived Peptides

We isolated an opioid peptide Tyr-Pro-Val-Glu-Pro-Phe, which corresponds to β-casein(194–119), from a pepsin–pancreatin digest of bovine β-casein and named it neocasomorphin.[12] The peptide showed weak opioid activity in the GPI assay (IC_{50}=59 μM). This peptide is classified as an opioid containing the Tyr-Pro-aliphatic residue.

We synthesized Tyr-Pro-Ser-Phe-NH_2 and Tyr-Gly-Phe-Leu-Pro, which are found in the primary structure of human β-casein, residue 59–63, and 41–44, respectively. Their IC_{50} values in the GPI assay were 30 and 270 μM, respectively. They were almost inactive in the MVD assay. We named the latter β-casorphin.[33]

Other Opioid Peptides Derived from Other Animal Proteins

To look for possible opioid peptide sequences in whey proteins, we synthesized Tyr-Gly-Leu-Phe-NH_2 and Tye-Leu-Leu-Phe-NH_2, which correspond to bovine α-lactalbumin(50–53) and β-lactoglobulin(102-105), respectively, and tested them in the GPI assay system. Both peptides inhibited electrically induced twitches of the ileum preparation with IC_{50} values 50 μM and 160 μM, respectively.[33] We named them α-lactorphin and β-lactorphin, respectively. Although inhibition of the twiches by α-lactorphin was blocked by naloxone, those by β-lactorphin was unaffected. Nonamidated α-lactorphin is released by the action of pepsin.

We isolated an opioid peptide Tyr-Gly-Phe-Gln-Asn-Ala from a pepsin digest of bovine serum albumin and named it serorphin.[23] This peptide is derived from amino acid residues 399–404 of the protein. Serorphin is selective for δ-receptor because its IC_{50} values in the MVD and GPI assays were 8.5 and 230 μM, respectively.

As for similar opioid peptide containing Tyr-Gly-Phe sequence, Tyr-Gly-Phe-Gly-Gly and Tyr-Gly-Phe-Ile-Leu have been synthesized by Khachenko et al. These are found in the primary structure of histone H4 and carboxypeptidases A and B, and named historphin and valentorphin, respectively. Historphin showed opioid activity in mouse vas deferens assay (IC_{50}=2.5 μM). They also synthesized similar peptide Tyr-Ser-Phe-Gly-Gly found in the primary structure of immunoglobulin κ–chain and named it kapporphin.[23]

INTRAPROTEIN OPIOID SEQUENCE

Most endogenous and opioid peptides have a Tyr residue at the amino terminus, and a few of them such as gluten exorphin-A have Tyr residue in the second position from the terminus. This is because a positive charge near the phonol group of Tyr is essential for the opioid activity. Lipkowski et al. found that Tyr residue in the midst of peptides could bind to μ-receptor if it is followed by basic residues.[16] They found that this is the case in the GAG protein of HIV virus and speculated that HIV might infect immuno- and neurocells via μ-receptor expressed on them.

CLASSIFICATION OF EXORPHINS ACCORDING TO THEIR STRUCTURE

In Table 1, a typical opioid peptides derived from proteins are classified into 2 groups, those containing Tyr-Pro sequence and others. Then, the Tyr-Pro group is further classified into two groups, those containing Tyr-Pro-aromatic amino acid residues, and Tyr-Pro-non-aromatic amino acid residues. The non-Tyr-Pro group is also subdivided into two groups according to the distance between Tyr and the aromatic amino acid residues. In *in vitro* assay systems, potency of exorphins are usually 1/100–1/100 that of endogenous opioid peptides. However, some exogenous opioid peptides are active after oral administration in which none of the endogenous opioid peptides are active. One of the reason for this may be that Tyr-Pro-X sequence is more resistant to peptidases than enkaphalin sequence.

TABLE 1 Opioid Peptides Derived from Natural Proteins

Structute	Peptides
Tyr-Pro type	
Tyr-Pro-Aromatic type	
H-Tyr-Pro-Phe-Pro-Gly-Pro-Ile-OH	β-Casomorphin

Tyr-X-Aromatic type	
H-Tyr-Gly-Phe-Gln-Asn-Ala-OH	Serorphin
H-Tyr-Gly-Phe-Leu-Pro-OH	*h*β-Casein(41-44)
H-Tyr-Gly-Phe-Gly-Gly-OH	Historphin
H-Tyr-Gly-Phe-Ile-Leu-OH	Valentorphin
H-Tyr-Ser-Phe-Gly-Gly-OH	Kapporphin
Intraprotein opioid sequence	
Ac-Asp-Ile-Tyr-Arg-Arg-Trp-Ile-Ile-Leu-NH_2	HIV GAG protein 24 fragment

Prefix ***h*** means human origin.

OPIOID ANTAGONIST AND ANTIOPIOID PEPTIDE DERIVED FROM PROTEINS

During the screening of opioid peptides in enzymatic digests of proteins, we found that some peptides showed antiopioid activity in the GPI and antinociceptive assays. These are classified into antagonists acting on opioid receptor, and antiopioid peptides acting at the postreceptor level (Table 2).

TABLE 2 Opioid Antagonist and Antiopioid Peptides Derived from Natural Proteins

Structure	Peptides
Opioid antagonists	
H-Tyr-Pro-Ser-Tyr-Gly-Leu-Asn-OH	Casoxin A
H-Pro-Ty-Pro-Tyr-Tyr-OH	Casoxin B

Opioid Antagonist Peptides

The first example of an endogenous opioid antagonist was described in 1979 for MIF-1 (see the Antiopioid chapter in this section of the book). The first exogenous antiopioid peptide is Ser-Arg-Tyr-Pro-Ser-Tyr-OCH_3, a peptide carrying Tyr-methyl ester at the carboxyl terminus. This peptide was obtained as an artificial product from a pepsin digest of bovine κ-casein, and named casoxin-6.[30,31] The esterification of Tyr occurred during the extraction of the lyophilized digest with anhydrous chloroform-methanol. The peptide showed weak affinity for μ and κ-receptors (IC_{50} = 5.5 and 10.1 μM, respectively), and antagonized opioid activities of DAMGO and dynorphin A at 20 μM in the guinea-pig ileum assay. Interestingly, a truncated peptide Tyr-Pro-Ser-Tyr-OCH_3 (casoxin-4) had no affinity for κ-receptor. From the observation that basic residues at the amino terminus region direct the antagonist for te κ–receptor, we speculated that casoxin-6 binds κ-receptor reversewise to κ agonist peptides such as dynorphin, in which basic residues in the carboxyl terminus region are essential for κ selectivity. Affinities of nonesterified peptides for opioid receptors are <1/10 those of the esterified from.

As for natural peptides showing opioid antagonist activitiy, we obtained Tyr-Pro-Ser-Tyr-Gly-Leu-Asn-Tyr from pepsin–trypsin digest of bovine κ-casein.[1] This peptide was named casoxin A, and antagonized opioid activity of DAMGO at 50 μM in the GPI assay. From the synthetic approach, we found that Pro-Tyr-Pro-Tyr-Tyr, and Ser-Tyr-Pro-Tyr-Tyr derived from bovine and human κ-casein, respectively, showed opioid antagonist activity under the same conditions. We named them bovine and human casoxin B, respectively.

As for opioid antagonists having Tyr-methyl ester, we obtained three peptides, Tyr-Leu-Gly-Ser-Gly-Tyr-OCH_3, Arg-Tyr-Tyr-Gly-Tyr-OCH_3, and Lys-Tyr-Leu-Gly-Pro-Gln-Tyr-OCH_3, from pepsin digest of human lactoferrin, and named them lactoferroxins A, B, and C.[22] Because of basic amino acid residues situated at their amino termini, lactoforroxins-B and C showed affinity for κ receptor in addition to μ receptor. Physiological significance of these peptides might be small because opioid antagonist activities of nonesterified forms are very weak.

Antiopioid Peptides

Using the guinea-pig ileum assay, we isolated an antiopioid peptide Tyr-Ile-Pro-Gln-Tyr-Val-Leu-Ser-Arg from a trypsin digest of bovine κ-casein.[1] This peptide was derived from the amino acid residue 25–34 of the protein, and named casoxin C. Casoxin-C showed weak affinity for μ receptor (Ki = 200 μM). Its antiopioid activity in the GPI was more potent than expected from receptor affinity. Further, casoxin-C was different from a typical opioid antagonists such as naloxone and casoxin-A in that inducing contraction of the ileum preparation in the absence of electrical stimuli. Casoxin-C proved to have affinity for receptor for complement C3a.[21] Complement C3a is made of 75 amino acid residues and released from complement C3 on activation of complement system to stimulate immune systems. It induces ileum contraction and inflammation and is called anaphylatoxin. The peptapeptide sequence at the carboxyl terminus of C3a, Leu-Gly-Leu-Ala-Arg, is the minimally essential structure required for C3a activity. This structural requirement could be generalized to hydrophobic residue-X_1-Leu-X_2-Arg. Casoxin C has affinity for complement C3a receptor (IC_{50} = 40 μM) because it meets this requirement. In the GPI, casoxin C and complement C3a antagonized opioid activities of DAMGO and dynorphin A at 10 μM.[21] However, they did not antagonize DPDEP in the MVD. In GPI, casoxin C and C3a induce biphasic contraction, rapid and slow ones. The rapid contraction is mediated by histamine release while the slow contraction is mediated by prostaglandin E_2 and acetylcholine. The antiopioid activities of casoxin C and C3a might be mediated by prostaglandin E_2 and acetylcholine because they are related to the slow contraction. After icv administration, casoxin C antagonized antinociceptive activity of morphin and dynorphin A, but DPDPE. Further, it reversed amnesia induced by scopolamine or cerebral ischemia in mice. Based on this observation, we also found for the first time that complement C3a itself also had antianalgesic and antiamnesic activites.[11] This suggests that C3a may work as an antiopioid peptide *in vivo*.

We obtained a peptide Gly-Tyr-Pro-Met-Tyr-Pro-Leu-Pro-Arg, which showed similar antiopioid activity in the GPI, from a trypsin digest of rice albumin and designated it oryzatensin.[20] Besides affinity for μ-opioid receptor (IC_{50} = 39 μM), oryzatensin has affinity for C3a receptors (IC_{50} = 44 μM) because it satisfies the structural requirements as described above.

A tripeptide Arg-Ile-Tyr isolated from a subtilisin digest of rapeseed protein based on inhibitory activity for Angiotensin I-converting enzyme (ACE) exhibited antihypertensive activity after oral administration in spontaneously hypertensive rats (SHR). The peptide was named rapakinin because it showed vasorelaxing activity in mesenteric artery isolated from SHR, which is mediated by the IP receptor for prostaglandin I_2 and CCK_A receptor downstream of the unidentified receptor of the peptide. The antihypertensive activity of rapakinin is mainly mediated by its vasorelaxation rather than ACE inhibition. Rapakinin antagonized the antinociceptive activity of morphine though it showed no affinity for opioid receptors.[25] This antiopioid activity is also by mediated IP receptor and CCK_B receptor.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Another peptide Tyr-Val-Pro-Phe-Pro-Pro-Phe, which shows antiopioid activity in GPI and MVD assays, was obtained from a chymotrypsin digest of human casein.[32] This peptide is derived from human αs1-casein and named casoxin D. EC_{50} values for antiopioid activity in the GPI and MVD assays were 10^{-6}–10^{-5} M, respectively. However, affinities of casoxin D for μ and δ receptors were very weak (IC_{50} = 250 and 150 μM, respectively). Casoxin D has weak ileum-contracting activity (EC_{50} = 80 μM).[28] Casoxin D also exhibits relaxing activity in canine mesenteric artery (EC_{50} = 3 μM), which was blocked by des-Arg[9]-[Leu[8]]-bradykinin, an antagonist for bradykinin B_1 receptor, and indomethacin. In fact, casoxin D showed affinity for B_1 receptor. However, its antiopioid and ileum-contracting activities are not blocked by the B_1 antagonist. Thus, receptors mediating antiopioid and ileum-contracting activities of casoxin D are still unknown.

CONCLUDING REMARKS

Thus, exorphins and antiopioid peptides are released from various proteins. Stimulated by the concept of exorphin, many kinds of bioactive peptides acting through various types of receptors other than opioid have been also isolated from the enzymatic digest of animal and plant proteins. Those derived from animal proteins may have teleological functions. However, those of plant origin could be regarded as those derived from a sort of random library. Studies on physiological and pathological significance of those bioactive peptides will contribute to the design of foods and drugs to prevent diseases and promote our health.

Chapter 215

Nociceptin/Orphanin FQ

Girolamo Calò, David G. Lambert and Remo Guerrini

ABSTRACT

Nociceptin/orphanin FQ (N/OFQ; FGGFTGARKSARKLANQ) was identified as the endogenous ligand of a previously orphan GPCR now referred to as N/OFQ peptide (NOP) receptor. The peptide and its receptor are widely distributed in the nervous system where via inhibitory mechanisms they modulate several different biological functions including pain, stress and anxiety, locomotor activity, emotional responses, feeding, learning and memory, reward, and addiction. N/OFQ is also able to modulate peripheral functions of the cardiovascular, respiratory, intestinal, genitourinary, and immune systems. The pleiotropic actions of N/OFQ suggest NOP-selective ligands as potential therapeutics for a variety of different pathological conditions. In particular, based on preclinical evidence the following indications seem to be promising: depression and Parkinson's disease for NOP antagonists and anxiety and pain (after spinal administration) for NOP agonists. Finally clinical studies show that intravesical instillation of N/OFQ elicits beneficial effects in patients suffering from urinary incontinence resulting from an overactive bladder.

THE DISCOVERY OF NOCICEPTIN/ ORPHANIN FQ

In 1994, soon after the cloning of classical opioid receptors, several research groups identified a G protein–coupled receptor showing high homology with opioid receptors but not able to bind opioid ligands. On this basis, the protein was named opioid receptor–like-1 (ORL-1). This protein was used to fish for a natural ligand from brain extracts.[11] This process, called reverse pharmacology, was successful since one year after the cloning of ORL-1 receptor two groups reported the identification of the heptadecapeptide FGGFTGARKSARKLANQ, which was named nociceptin[17] for its ability to elicit hyperalgesia after supraspinal administration in mice and orphanin FQ[25] for its ability to recognize a previously orphan receptor and for its first and last amino acid residues (F and Q). Nociceptin/orphanin FQ (N/OFQ) displays a primary sequence very similar to that of opioid peptides. However, the presence of Phe in position 1 instead of Tyr makes this peptide highly selective for its receptor over classical opioid receptors. After the identification of N/OFQ as the naturally occurring ligand of ORL-1, the receptor was renamed, according to IUPHAR recommendations, N/OFQ peptide receptor and abbreviated as NOP. In this chapter, we review the biology of the peptide and its receptor, NOP-selective ligands, genetic tools such as NOP receptor (NOP(−/−)) and ppN/OFQ (ppN/OFQ(−/−)) knockout animals, and the biological functions controlled by the N/OFQ–NOP receptor system. Finally, we discuss the possible therapeutic indications of NOP-selective ligands.

THE N/OFQ PEPTIDE

N/OFQ derives from the peptide precursor preproN/OFQ (ppN/OFQ).[18] The ppN/OFQ gene comprises at least four exons separated by three introns. Exon I contains exclusively 5′ noncoding sequence, exons II and III share the open reading frame of the gene, and exon IV contains most of the 3′ noncoding region of the message. The sequence of murine and human ppN/OFQ genes displays organizational and structural features that are very similar to those of the genes encoding the precursors of the endogenous opioid peptides, namely, prepro-enkephalin, -dynorphin, and -opiomelanocortin, suggesting that the N/OFQ and opioid peptide genes have evolved from a common ancestor. The ppN/OFQ amino acid sequence is highly conserved across animal species, especially at the C-terminus where the sequence of the mature peptide is located between canonical Lys-Arg excision motifs. However, in addition to those framing N/OFQ, the ppN/OFQ sequence contains other cleavage sites, suggesting that ppNOP may generate other biologically active peptides. The peptide nocistatin has been shown to be biologically active[22]; in most cases, nocistatin does not produce any effect by itself but is able to counteract the actions of N/OFQ. Importantly, nocistatin does not bind to the NOP receptor. Despite considerable efforts put in by several groups, the receptor mediating the pharmacological actions of nocistatin is yet to be identified. Another peptide encoded by ppN/OFQ is known as N/OFQ II: this peptide stimulates locomotor activity in mice.

ppN/OFQ mRNA and the N/OFQ peptide are broadly distributed in the central nervous system of the rat.[20] In most brain areas, peptide immunostaining and mRNA expression are very similar, suggesting that the peptide is mainly produced by interneurons. mRNA and peptide are particularly abundant in cortical and limbic structures (hippocampus, dentate gyrus, septal areas, and amygdala), a number of hypothalamic and brain stem nuclei, the dorsal and ventral horns of the spinal cord, and in cell bodies of the dorsal root ganglion. In several pain-related areas, including the superficial dorsal horn of spinal cord, sensory trigeminal complex, and periaqueductal gray, antisera to N/OFQ and opioid peptides label different fibers, consistent with the differential actions of N/OFQ and opioids on nociception.

This N/OFQ distribution in the central nervous system suggests that the peptide is potentially involved in the regulation of a variety of brain functions, including emotional processing, learning and memory, locomotion, reward, pain transmission, and autonomic regulation of peripheral organs and systems.

Little is known about the biosynthesis of N/OFQ, apart from the involvement of prohormone convertase 2 as shown by studies performed in mice knockout for this enzyme (see Peptide Biosynthesis/Processing section of the book). As far as N/OFQ metabolism is concerned, different studies show the involvement of aminopeptidase that generates [desPhe^1] N/OFQ a peptide lacking affinity for the NOP receptor. However, different endopeptidases are also involved in N/OFQ metabolism. Peptidase inhibitors are able to increase N/OFQ potency and, in some cases, maximal effects both *in vitro* and *in vivo*, thus showing an important role of peptidases in N/OFQ signaling. Indeed the inhibitory effect of the peptide in the human vas deferens can be detected in the presence of a cocktail of peptide inhibitors but not in their absence.

THE NOP RECEPTOR

The NOP receptor belongs to the superfamily of G protein–coupled receptors, characterized by seven transmembrane helices interconnected by alternate intracellular and extracellular loops. It displays high homology with opioid receptors, but it has no affinity for opioid ligands. The primary structure of the NOP receptor is highly conserved across mammalian species with mouse and human sequences being >95% identical. The NOP receptor gene is located in the distal region of mouse chromosome 2, and in the q13.2-13.3 region of human chromosome 20. Its coding sequence is organized into introns and exons in a manner similar to that of the opioid MOP, DOP, and KOP receptor genes, suggesting that the four genes have all evolved from a common ancestor, that is, they belong to the same family. Like other members of the opioid receptor family, the NOP receptor gene undergoes alternative splicing. The biological significance of these splice variants is unknown because pharmacological studies have not clearly established the existence of functionally distinct NOP receptor subtypes.

The NOP receptor mRNA is particularly abundant in the central nervous system, notably in the cortical and limbic areas, hypothalamus, brain stem, the dorsal and ventral horns of the spinal cord, and in the cell bodies of the dorsal root ganglion.[19] Extensive autoradiographic mapping of the NOP receptor protein shows similar distribution patterns to those of the mRNA, indicating that the receptor is expressed predominantly in local-circuit neurones. However, detailed studies on the expression of NOP protein by the different cell types have been limited to date by the lack of a specific and selective antibody.

The NOP receptor is coupled to Gi proteins that inhibit adenylate cyclase and calcium currents, and activate potassium channels. These cellular actions reduce synaptic efficacy, either by reducing transmitter release when the receptor is located presynaptically, or by reducing neuronal firing or excitability when the receptor is located postsynaptically. Indeed, many *in vitro* and *in vivo* studies have shown that NOP activation inhibits basal and/or stimulated release of various neurotransmitters, including acetylcholine, dopamine, serotonin, norepinephrine, GABA, glutamate, and substance P, in central as well as peripheral nerve tissues.[29] Similarly, when tested electrophysiologically on individual neurons, NOP activation produces an inhibition of basal and/or stimulated electrical activity.[7] These cellular effects produce inhibitory effects and can also be associated with circuit dependent disinhibitory actions, allowing an explanation of most, if not all of the biological actions elicited by N/OFQ.

There is evidence in the literature that NOP receptors can form heterodimers with classical opioid receptors particularly with MOP. This may have profound implication in terms of receptor signaling and trafficking. For instance NOP/MOP heterodimers were shown to associate with N-type calcium channels, with the activation of MOP receptors triggering N-type channel internalization, but only in the presence of NOP. Further, the formation of OP/NOP receptor heterodimers attenuated the NOP inhibition of N-type channels.[5] This kind of mechanism may be operative in primary sensory neurons and in brain areas relevant for nociceptive transmission and thus may have potentially profound effects on nociceptive processing.

PHARMACOLOGICAL AND GENETIC TOOLS

The first generation of NOP-selective ligands has been identified in the frame of structure activity studies on the N/OFQ peptide sequence.[2] N/OFQ(1-13)-NH_2 (but not N/OFQ(1-13)-OH) is the smallest fragment maintaining the same potency and efficacy of the natural peptide. C-terminal amidation is also useful in the peptide full sequence for increasing potency and reducing susceptibility to carboxypeptidases. A series of structure activity studies performed

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

using N/OFQ(1-13)-NH_2 as chemical template allowed the identification of several interesting NOP-selective ligands such as (i) [Phe^{1}Ψ(CH_2-NH)Gly^2]N/OFQ(1-13)-NH_2, a partial agonist; (ii) [(pF)Phe^4]N/OFQ(1-13)-NH_2, a potent full agonist, (iii) [Nphe^1]N/OFQ(1-13)-NH_2 a low potency pure antagonist. Other chemical modifications such as the Aib substitution in positions 7 and 11 and the replacement of Leu-Ala with an extra couple of Arg-Lys residues in positions 14–15 were applied to the full peptide sequence and found to be useful for generating potent agonists. The above-mentioned chemical modifications applied to the N/OFQ sequence are shown in Fig. 1. In subsequent studies, these chemical modifications were combined into single molecules to identify the second generation of NOP-selective peptide ligands encompassing partial ([Phe^{1}Ψ(CH_2-NH) Gly^2(pF)Phe^{4}Aib^{7}Arg^{14}Lys^{15}]N/OFQ-NH_2, UFP-113) and full ([(pF)Phe^{4}Aib^{7}Arg^{14}Lys^{15}]N/OFQ-NH_2, UFP-112) agonist and pure antagonist ([Nphe^{1}Arg^{14}Lys^{15}]N/OFQ-NH_2, UFP-101) activities. These peptide ligands associated high potency with very high NOP selectivity and were instrumental in advancing our knowledge related to the N/OFQ–NOP receptor system.[1,3,11] Other NOP peptide ligands have been identified by screening of synthetic peptide combinatorial libraries. With this approach, the highly potent and NOP-selective partial agonists Ac-RYYRWK-NH_2 and Ac-RYYRIK-NH_2 were identified.[4] These peptide sequences were used in subsequent studies for generating other interesting NOP ligands including the peptide ZP120 that has been investigated and developed for its aquaretic activity. Another example of NOP ligand identified with combinatorial peptide chemistry approach is the nonselective NOP antagonist peptide III BTD.

The different biological functions controlled by the N/OFQ–NOP receptor system and the therapeutic potential of agents able to selectively activate or block the NOP receptor stimulated industrial interest in this field of research and several companies activated medicinal chemistry programs aimed at the identification of drug-like nonpeptide NOP ligands.[12] This led to the identification and characterization of interesting and useful molecules such as J-113397, a potent and selective antagonist identified by Banyu researchers and Ro 64-6198, a potent and selective agonist discovered at Roche.[30] These molecules are widely used for investigating the role played by the N/OFQ–NOP receptor system in physiological and pathological conditions and together with the peptides UFP-101[1] and UFP-112[3] still represent standard ligands for the NOP receptor. More recently, other nonpeptide NOP ligands were published including the highly potent and pure antagonists SB-612111 and Comp 24 and different series of full agonists identified by Pfizer and Schering-Plough researchers and characterized *in vivo* as innovative anxiolytics (see the chemical structure of nonpeptide NOP ligands in Fig. 2).

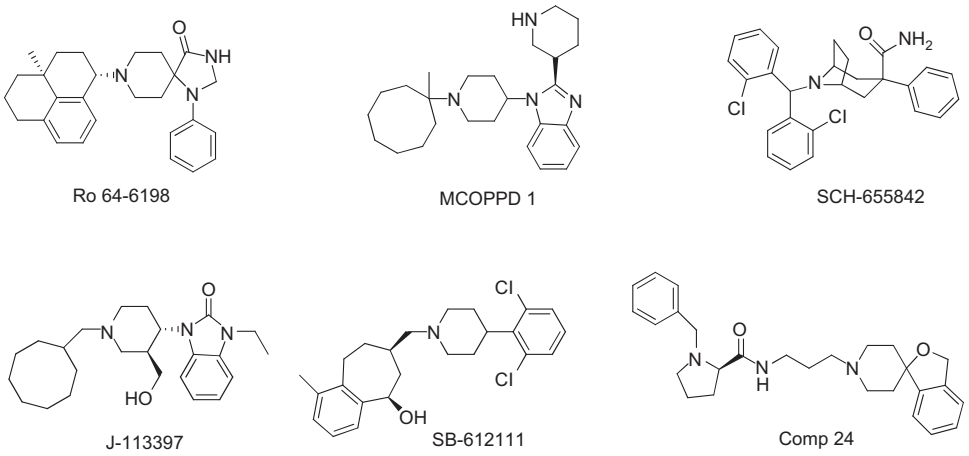

FIGURE 2 Chemical formulas of nonpeptide NOP receptor agonists (top) and antagonists (bottom).

Coupled with selective ligands transgenic animals, particularly knockouts, represent useful research tools in modern pharmacology. For instance, receptor knockout animals facilitate performing simple and meaningful experiments to investigate the *in vivo* selectivity of action of standard and novel ligands and the involvement of the receptor in the control of a given biological function. In most cases, the phenotype of knockout animals is similar to what was observed in normal animals after the administration of a selective receptor antagonist.

NOP(–/–) mice were first generated in 1997.[21] Autoradiography studies showed the complete loss of N/OFQ binding in the brain of these animals. Subsequent *in vitro* functional studies showed that in tissues taken from NOP(–/–) mice, N/OFQ no longer elicits any effect. This includes data from bioassay studies (contractile action in the colon, inhibitory effect in the electrically stimulated vas deferens, inhibition of capsaicin induced bronchoconstriction), to neurochemical investigations (inhibition of serotonin release from cerebral cortex synaptosomes), and to electrophysiological studies (inhibition of excitatory transmission in the spinal cord). In addition, *in vivo* studies on NOP(–/–) mice showed that the N/OFQ actions examined to date are solely mediated by the NOP receptor. Receptor knockout studies are available in the literature regarding the following biological actions of N/OFQ: supraspinal pronociceptive and spinal antinociceptive effects, induction of bradycardia, hypotension and diuresis, stimulation of food intake and inhibition of locomotor activity. NOP(–/–) mice were also used for investigating their phenotype. These animal show (i) normal response to acute pain while they display a pronociceptive phenotype in response to prolonged nociceptive stimulation (i.e. the formalin test), (ii) an antidepressant phenotype in the forced swimming and tail suspension test, (iii) increased anxiety-related behavior in the elevated plus-maze and light-dark box, whereas in other anxiety-related assays, no differences were found compared with that in normal animals, (iv) a better locomotor performance in the rotarod test. Recently, knockout rats for the NOP receptor gene were also generated.[8] In the brain of these animals, N/OFQ binding is not detectable, and the inhibitory effect elicited by the peptide in the electrically stimulated vas deferens is no longer present. *In vivo* studies performed in NOP(–/–) rats showed that these animals display phenotype differences superimposable to those described in mice in the formalin, rotarod, forced swimming, and elevated plus-maze assays[26]; this shows that the control exerted by the N/OFQ–NOP receptor system on these biological functions is very robust across animal species.

Knockout mice for the ppN/OFQ gene have been also generated.[10] However, these ppN/OFQ(–/–) animals were only used in a few studies. The limited information available suggests that these animals behave in a similar manner as NOP(–/–) mice in terms of pain transmission while they display differences from receptor knockout animals in terms of response to stress. However parallel experiments with NOP(–/–) and ppN/OFQ(–/–) mice should be performed before drawing firm conclusions on behavioral differences between the two mutant genotypes. Moreover, as mentioned before, the ppN/OFQ gene contains in addition to N/OFQ itself, other biologically active peptides. Because ppN/OFQ null mice do not express N/OFQ as well as the other peptides encoded by the same gene, caution should be exercised in interpreting behavioral differences between ppN/OFQ(–/–) and ppN/OFQ(+/+) mice as solely due to the lack of N/OFQ.

BIOLOGICAL ACTIONS

Pain

The abundant literature addressing the role of the N/OFQ–NOP receptor system in the control of pain transmission is highly contentious. N/OFQ has been variously reported

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

to cause hyperalgesia, allodynia, analgesia, and even nocifensive behaviors.[11,32] One reason, among others, is that N/OFQ effects on nociception are dependent on the dose and route of administration. Therefore, the information available in this field is next summarized by the analysis of N/OFQ actions at supraspinal, spinal, and peripheral levels.

Supraspinal Effects

N/OFQ was initially reported to cause thermal hyperalgesia when injected supraspinally in mice. However, this effect was soon shown to reflect reversal of stress-induced analgesia, rather than a decrease of nociceptive threshold. Indeed, icv N/OFQ attenuates the analgesic action of opioid and nonopioid drugs. One mechanism whereby N/OFQ attenuates opioid-induced analgesia is by directly inhibiting a descending antinociceptive pathway, which itself is indirectly activated (disinhibited) by opioids. This mechanism might be activated during chronic opioid administration because NOP receptor knockout and antagonist studies show that blocking N/OFQ–NOP receptor signaling counteracts the development of morphine tolerance.

Spinal Effects

When administered intrathecally (i.t.) in rodents, very low doses (femtomole to picomole range) of N/OFQ are reported to cause pronociceptive effects, whereas higher doses (nanomole range) produce antinociceptive effects. Many studies have shown that intrathecal administration of nanomoles of N/OFQ produces robust antinociceptive effects, and this holds true in a wide variety of animal models of phasic (mechanical or thermal) and of tonic (inflammatory or neuropathic) pain. The spinal antinociceptive action of N/OFQ is consistent with the well-documented ability of the peptide to block both normal and sensitized excitatory (glutamate) transmission in the dorsal horn of the spinal cord.[32] Interestingly, spinal N/OFQ, in contrast to classical opioids, seems to be more efficacious in alleviating chronic neuropathic/inflammatory than acute pain states. Evidence first obtained with NOP(−/−) and ppN/OFQ(−/−) mice and then confirmed with receptor antagonists and rat NOP(−/−) studies shows that endogenous N/OFQ–NOP receptor signaling in the spinal cord is activated by prolonged (e.g. formalin, zymosan A, writhing tests, SBL response to i.t. substance P), but not acute (tail flick/immersion test) nociceptive stimulation and the consequence of its activation is the appearance of antinociceptive effects. Finally, in an elegant series of studies, the group of MC Ko showed that in nonhuman primates, spinal administration of N/OFQ or synthetic NOP ligands (i) does not elicit any effect at low doses, (ii) in the nanomolar range of doses, it induces a robust antinociceptive action that is sensitive to NOP antagonists but not naloxone, (iii) in contrast to morphine, it does not induce pruritus, and (iv) it elicits a synergistic antinociceptive effect when given in association with morphine. Thus, evidence coming from nonhuman primates strongly suggests NOP receptor agonists as innovative spinal analgesics. Interestingly, this same research group showed that the NOP-selective nonpeptide agonist Ro 64-6198 given systemically is able to induce dose-dependent antinociceptive effects in nonhuman primates while being inactive in rodents. In monkeys, antinociceptive doses of alfentanil (and in generally of opioids) are associated with respiratory depression, itch/scratching responses, and reinforcing effects under self-administration procedures, whereas in parallel experiments, antinociceptive doses of Ro 64-6198 do not produce these side effects. Further studies are however needed to draw firm conclusions on the therapeutic potential of systemic NOP agonists as analgesics.

Peripheral Effects

Similar to what has been seen at the spinal level in the periphery both pronociceptive and antinociceptive effects were reported for N/OFQ. For instance, intradermal administration of very low doses of N/OFQ stimulates the flexor reflex in mice. This effect involves the stimulation of the release of substance P from peripheral nerve endings. However, at higher doses, N/OFQ prevents the facilitatory effect of substance P. In addition, several groups reported the ability of N/OFQ to inhibit neuropeptide release from peripheral sensory neuron terminals in different organs including the airways, heart, and renal pelvis. Finally, in nonhuman primates, the coadministration of N/OFQ with capsaicin into the tail dose dependently inhibits thermal nociception suggesting that activation of peripheral NOP receptors produces antinociceptive effects.

Reward and Addiction

The rewarding properties of N/OFQ have been examined using the conditioned place preference test that pairs administration of the drug with a particular set of environmental cues. In rats, supraspinal injection of N/OFQ does not induce place preference or aversion, an indication that the peptide lacks intrinsic motivational properties. Most significantly, however, N/OFQ was shown to block morphine-induced place preference, an effect that was later extended to other drugs of abuse, all known to acutely stimulate the dopaminergic mesocorticolimbic pathway, such as alcohol, amphetamine, and cocaine.[31] One mechanism whereby N/OFQ attenuates reward elicited by drugs of abuse is by directly inhibiting dopaminergic mesocorticolimbic neurons, which express the NOP receptor. Of particular relevance to addiction are the observations that N/OFQ blocks reinstatement of alcohol-seeking behavior

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

in alcohol-preferring rats and that the nonpeptide NOP receptor agonist Ro 64-6198 blocks reinstatement of morphine place preference in mice. The endogenous N/OFQ–NOP receptor system seems to control rewarding functions because pharmacological blockade or genetic knockout of the NOP receptor potentiates the rewarding effect of morphine in rats.[27]

Stress, Anxiety, and Depression

One of the most highly investigated actions of N/OFQ is its ability to counteract stress related behaviors and promote anxiolytic-like effects. The pivotal study in this field showed that N/OFQ acts as anxiolytic in several benzodiazepine-sensitive behavioral tests.[9] Similar results were reported in response to the systemic administration of Ro 64-6198, and these findings were confirmed in different assays, species, and laboratories.[30] Interestingly, the anxiolytic-like action of Ro 64-6198 does not show tolerance liability after daily administration for two weeks. In addition, anxiolytic-like effects were reported for several nonpeptide NOP agonists developed by Roche, Shering-Plough, and Pfizer laboratories. Knockout studies corroborate these findings. Indeed, in comparison with wildtype animals, ppN/OFQ(−/−) mice have a greater tendency toward anxiety-like behavior when exposed to a novel and threatening environment and have increased basal and stress-induced levels of plasma corticosterone. In addition NOP(−/−) mice display a mild anxiogenic phenotype in same anxiety-related assays. Superimposable results were obtained investigating the phenotype of receptor knockout rats. The mechanisms by which N/OFQ exerts its anxiolytic effects are not fully understood, but there is evidence that $GABA_A$ receptor signaling, CRF, and serotonin might be involved.[6]

As far as depression is concerned, the seminal study by Redrobe et al.[24] showed that NOP antagonists elicit antidepressant-like effects in the forced swimming test in mice. This initial finding was later confirmed and extended in subsequent studies (summarized in Ref. 6) showing that (i) antidepressant-like effects are measured in response to chemically different NOP antagonists including the peptides [$Nphe^1$]N/OFQ(1-13)-NH_2 and UFP-101 and the nonpeptides J-113397 and SB-612111, (ii) the antidepressant-like effect of NOP antagonists can be reversed by the supraspinal injection of N/OFQ, (iii) NOP(−/−) mice and rats display an antidepressant-like phenotype. Blockade of endogenous N/OFQ–NOP receptor signaling is associated with a facilitatory effect on exercise driven locomotor activity (see below), and this may possibly represent an important bias for the interpretation of findings obtained in the forced swimming test. However, evidence strongly supports the genuine nature of the antidepressant-like effects of NOP antagonists: (i) in rats subjected to chronic mild stress, three-week treatment with UFP-101 dose and time dependently reinstates sucrose consumption; this particular behavioral parameter is not influenced by locomotion, (ii) UFP-101 injected into the dorsal hippocampus produces antidepressant-like effects in the mouse forced swim and tail suspension tests without modifying locomotion, and (iii) there is no correlation between motor performance and phenotype in the forced swimming test in NOP(−/−) rats. Little is known about the possible mechanism(s) involved in the antidepressant effects of NOP antagonists. However, it has been reported that N/OFQ is able to inhibit noradrenaline and serotonin release from cerebral cortex as well as neuronal firing in the dorsal raphe and locus coeruleus. Therefore, assuming that chronic stress/despair conditions stimulate the release of N/OFQ, the peptide may reduce aminergic signaling acting at both presynaptic and postsynaptic sites. By preventing such effects of N/OFQ, NOP antagonists may restore normal levels of norepinephrine and serotonin at their respective synaptic clefts. Thus, NOP receptor antagonists, by acting at different levels and with different mechanisms, may achieve a similar endpoint to that of classical antidepressants, that is, an increase in cortical synaptic concentrations of monoamines.

Locomotor Activity

In the article reporting its identification as endogenous ligand of the NOP receptor, N/OFQ has been shown to inhibit spontaneous locomotor activity.[25] This effect has been confirmed in mice and rats by different laboratories and the involvement of the NOP receptor has been demonstrated by receptor antagonist and knockout studies. However, the endogenous N/OFQ–NOP receptor system does not tonically control spontaneous locomotion because NOP antagonists do not modify this behavior and knockout animals do not show any phenotype. However the seminal article by Marti et al.[15] shows that systemic administration of J-113397 or supraspinal injection of UFP-101 facilitates, in a dose-dependent manner, rat performance in the drag and rotarod tests. Moreover, NOP(−/−) outperform NOP(+/+) mice in the same assays (a finding later confirmed in NOP receptor knockout rats). These results suggest that endogenous N/OFQ may indeed exert an inhibitory influence over motor activity that becomes relevant during exercise rather than at rest. Consistent with these observations, systemic administration of J-113397 and its analogs Trap-101 and GF-4 increase motor performance in normal rats and in NOP(+/+) mice but are ineffective in NOP(−/−) mice. In addition, preliminary evidence suggests that J-113397 facilitates motor performance in nonhuman primates. Collectively, these findings reinforce the view that NOP receptor blockade may represent a new strategy for the control of hypokinetic disorders. Indeed, a series of elegant studies showed that NOP receptor antagonists attenuate motor deficits in rodent and nonhuman primate models (6-hydroxydopamine, haloperidol, reserpine, 1-methyl-4-phenyl-1,2,5,6-tetrahydropyridine)

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

of parkinsonism. The finding that N/OFQ levels are 3.5-fold elevated in the cerebrospinal fluid of parkinsonian patients compared with controls further strengthens the rational for developing NOP receptor antagonists as drugs to treat Parkinson's disease.

Food Intake

icv N/OFQ dose dependently stimulates food intake in rodents. After the first report,[23] this effect of the peptide has been confirmed in several laboratories, and it has been shown that N/OFQ stimulation of food intake is mimicked by NOP-selective agonists, prevented by NOP antagonists, and no longer evident in NOP(−/−) mice. However, food intake induced by food deprivation is not reduced by NOP antagonists and is similar in NOP(+/+) and NOP(−/−) mice, thus suggesting that the endogenous peptide/receptor system is not activated under fasting conditions. Different neurotransmitter systems seem to be involved in the stimulant action of N/OFQ on food intake. N/OFQ acts as a functional antagonist against anorexia elicited by CRH, the primary mediator of stress, especially in the bed nucleus of stria terminalis. N/OFQ may also increase food intake by decreasing the release of the anorectic peptide CART (cocaine and amphetamine regulated transcript) and/or increasing the release of the orexigenic peptide agouti-related protein. In addition, there is evidence that corticosterone and central glucocorticoid receptors are involved in the orexigenic action of N/OFQ.

Learning and Memory

It was initially shown that microinjection of N/OFQ into the CA3 region of the dorsal hippocampus causes profound impairment of spatial learning in rats trained in the Morris water task.[28] Later, N/OFQ was reported to inhibit long-term potentiation in rat hippocampal slices. These observations received strong support from the observation that NOP(−/−) mice not only display greater learning ability and have better memory than NOP(+/+) animals but also show increased LTP in the hippocampal CA1 region. Improvement of cognitive abilities in mice lacking the NOP receptor gene has been linked to the hyperfunctioning of the NMDA receptor. However, systematic studies on the possible cognitive enhancing properties of selective NOP antagonists have not yet been performed.

N/OFQ Actions on Peripheral Organs

By acting both on the central and peripheral nervous systems, N/OFQ modulates the functioning of several organs and systems including the heart and vessels, airways, kidney, urinary bladder, and the gastrointestinal and immune systems. N/OFQ induces bradycardia and hypotension, possesses vasorelaxant properties, stimulates diuresis and in particular aquaresis, controls several gastrointestinal functions under physiological and pathological conditions, modulates immune function, produces proinflammatory effects, and inhibits some reflexes mediated by sensory fibers such as cough and micturition. Most of these N/OFQ actions have been reviewed in a special issue of the journal *Peptides*,[16] and recent reviews on some of these topics are available in the literature.

All the above-mentioned information regarding N/OFQ effects have been obtained in preclinical studies. Clinical results are only available for the inhibitory effect exerted by the peptide on the micturition reflex, and this makes this topic worthy of further description. In an elegant series of rodent studies,[14] Menarini researchers showed that intravenous administration of N/OFQ inhibits the micturition reflex, and this effect is no longer evident in capsaicin-pretreated rats indicating the involvement of capsaicin-sensitive nerve fibers innervating the urinary bladder. In support of this interpretation, N/OFQ also inhibits the reflex, but not the local bladder contraction, induced by topical capsaicin. Intrathecal N/OFQ produces urodynamic modifications similar to those induced by systemic administration. Intracerebroventricular administration of the peptide also inhibits the micturition reflex in a naloxone-resistant manner suggesting a direct effect on supraspinal sites controlling micturition. Beyond the inhibitory effects exerted by N/OFQ on the micturition reflex, there is a peripheral excitatory effect mediated by capsaicin-sensitive fibers. Application of the peptide onto the bladder serosa when the intravesical volume is subthreshold for triggering of the micturition reflex, activates the reflex, and this is associated with a local tonic-type contraction that is abolished by the coadministration of tachykinin NK_1 and NK_2 receptor antagonists. Collectively, these results indicate that in the rat, NOP receptors are present at several sites for the integration of the micturition reflex and that their activation mainly produces inhibitory effects. Based on these results, Lazzeri et al. performed the first clinical investigation with N/OFQ by testing the urodynamic effects of intravescical application of the peptide in normal subjects and in patients suffering from an overactive bladder.[13] In normal subjects, N/OFQ does not modify urodynamic parameters, whereas in patients, the peptide produces a statistically significant increase in mean bladder capacity and volume threshold for the appearance of detrusor hyperreflexia without affecting maximum bladder pressure. These results were confirmed in a randomized, placebo controlled, double-blind study in which [desPhe^1]N/OFQ (a N/OFQ metabolite that lacks affinity for the NOP receptor) was used as placebo, showing that N/OFQ, but not the placebo, elicits a robust acute inhibitory effect on the micturition reflex in patients with a neurogenic bladder. These promising results obtained after acute administration of N/OFQ allowed the investigation of the feasibility, safety and efficacy of daily intravesical instillation of 1 mg of N/OFQ for 10 days in patients who

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

perform clean intermittent self-catheterization for neurogenic detrusor overactivity incontinence. Urodynamic parameters recorded during the study confirm previous findings. Moreover, during N/OFQ treatment, daily urine leakage episodes are approximately halved and bladder capacity increased by 172%. No significant problems related to feasibility of the procedure and significant side effects were reported by patients. This study shows the clinical efficacy of N/OFQ during 10 days of treatment supporting the use of NOP receptor agonists in the control of detrusor overactivity incontinence.

THERAPEUTIC POTENTIAL OF NOP RECEPTOR LIGANDS

The broad pharmacological spectrum of NOP actions points to a number of potential therapeutic applications of selective NOP receptor ligands. Thus, based on available evidence, NOP receptor agonists are claimed to be potentially useful for treating stress and anxiety, drug addiction, anorexia, and cough. One advantage of NOP receptor agonists over currently used drugs such as benzodiazepines or opioids would be a lack of abuse potential. However, given their broad spectrum of actions, NOP receptor agonists may also be anticipated to have many unwanted effects. This however might not be true for selected indications for which systemic administration is not needed such as urinary incontinence (intravescical route) and intractable pain (spinal route). On the other hand, NOP receptor antagonists could be useful for treating Pakinson's disease and depression, for enhancing cognitive function, and perhaps as novel antinflammatory agents or as adjuncts for preventing tolerance to morphine analgesia. Antagonists are expected to have fewer side effects than agonists, as suggested by the observation that NOP(−/−) mice and rats appear to be outwardly normal.

Finally, although the actions of N/OFQ on nociception have been most extensively studied, it is still highly contentious whether NOP receptor agonists or antagonists have a future as analgesics. The reported opposite pro- and antinociceptive actions of N/OFQ depending on dose and site of administration, raise the question as to the final effect of a ligand able to target simultaneously all NOP receptor sites. In addition, species specific responses to NOP ligands (e.g. systemic Ro 64-6198 elicits antinociceptive effects in non-human primates but not in rodents) further complicate the picture and make more difficult developments in this field.

Drug companies have been rather successful in developing NOP ligands, either agonists and antagonists,[12] but these need be modified in terms of NOP opioid receptor selectivity and oral bioavailability. Only the availability of highly potent, selective, and possibly orally active NOP receptor ligands will allow effective validation of the NOP receptor as a therapeutic target.

Chapter 216

Opioid-Substance P Chimeric Peptides

Andrzej W. Lipkowski, Daniel B. Carr, Iwona Bonney and Piotr Kosson

ABSTRACT

Chimerization of tachykinin and opioid pharmacophores offers a new avenue for analgesic development. The complexities of such design are illustrated by the analgesic efficacy (via different mechanisms) of chimeras that combine pharmacophores with opioid activity and substance P activity, as well as those that combine opioid agonist and substance P antagonist moieties. Although the interaction between substance P and opioid neural systems is more complex than a simple one-way inhibition, the relative balance of activities between tachykinin and opioid pharmacophores will generally determine the net effect of the chimeric molecule as pronociceptive, antinociceptive, or neutral. Intriguingly, endomorphins— (μ-opioid receptor agonists with high intrinsic activity may owe some of this high activity to weak but significant antagonist properties at tachykinin NK2 receptors, implying that these native peptides are endogenous chimeric opioid agonist–tachykinin antagonist compounds.

INTRODUCTION

The discoveries of tachykinins and endogenous opioids were major milestones in the clarification of the role of neuropeptides in nociceptive signal formation, transmission, and perception. The undecapeptide substance P was the first recognized mammalian tachykinin; its amino acid sequence was successfully elucidated[6] in 1971. Subsequently, other members of the tachykinin family and superfamily, and their receptors and variants, were well characterized. Tachykinin peptides are widely distributed in neuronal central nervous system (CNS) and peripheral tissues. Tachykinins interact with specific membranę receptors belonging to the family of G-protein-coupled receptors. Currently, three distinct tachykinin receptors, NK1, NK2, and NK3, have been cloned in different species, including the human.[27] The three tachykinin receptors are recognized with moderate selectivity by endogenous tachykinins. Substance P, neurokinin A, and neurokinin B act as full agonists on the three tachykinin receptors, although they exhibit preferential binding to the NK1, NK2, and NK3 receptors, respectively. Within neuronal tissues, tachykinins act as excitatory neurotransmitters [see the tachykinin chapter in the Brain Peptides and other sections of this book]. However, substance P and other tachykinins are also widely distributed in nonneural tissues, where they mediate multiple homeostatic functions. The role of tachykinins in host defense systems has been extensively studied. Immune cells (T and B cells, endothelial cells, and macrophages) not only express NK1 receptors but also (in macrophages, eosinophils, and endothelial cells) synthesize substance P. The concentration of substance P increases in inflamed tissues,[26] suggesting its importance in the mammalian host defense system. Indeed, available results suggest a multifunctional role for substance P, in which it activates immunological responses, generates a pain signal alarm, and also may itself have direct antibacterial and antifungal properties.[15]

Numerous endogenous pathways are involved in neurological and other disease pathology. Modern therapies therefore commonly rely on multidrug therapies that supplant selective drug use. However, using combinations of drugs has disadvantages, including differences in pharmacodynamic and pharmacokinetic profiles of each component drug. Therefore, the combination of multiple active pharmacophores in one molecule is a promising approach. A good example of such a molecule, based on the sequence of substance P, is the anticancer peptide Arg-D-Trp-Phe(N-Me)-D-Trp-Leu-MetNH_2, which simultaneously blocks receptors for substance P, bombesin/gastrin-releasing peptide, vasopressin, cholecystokinin, and neurotensin.[12] Multitarget therapies have become popular in pain treatment as well (multimodal analgesia).[32] However, available analgesics in clinical practice are naturally, or have been crafted to be, maximally selective for one type of receptor. This chapter describes a new avenue for the development of new analgesics, the chimerization of tachykinin and opioid pharmacophores.

CROSSINTERACTION OF TACHYKININ AND OPIOID SYSTEMS

A large body of experimental evidence indicates that regulatory neuropeptides play modulatory roles in the afferent transfer and postsynaptic processing of nociceptive information within the dorsal horn of the spinal cord.[5,22] The superficial dorsal horn of the spinal cord is an area that receives primary synaptic input from sensory fibers originating from dorsal root ganglion (DRG) neurons. This area is a potentially important site for functional regulation (by modulatory opioid peptides) of nociceptive input mediated by substance P[24] and excitatory amino acids released from primary afferent terminals. Anatomical studies indicate a similar distribution of substance P- and opioid-containing neural elements within this area.[1,29] Ligands of the μ receptor are highly effective in blocking or reducing nociceptive transmission at the spinal level, and this antinociception is believed to be caused at least partially by the inhibition of substance P release.[11] Substance P and opioid neuropeptides share a common metabolic system. The changes in proteolytic specificities and activities in pathological conditions may influence pain signal transmission. In addition, substance P and its metabolites express complicated multitargeted activities. C-terminal hepta- and hexapeptide amides are the fragments that express nociception properties comparable with intact undecapeptide substance P. However, N-terminal heptapeptide interacts with specific receptors, the activation of which results in antinociception and attenuation of opioid tolerance.[35] Endomorphins and, to some extent, enkephalins express affinities to these receptors as well.[4] Interestingly, the antinociceptive and analgesic fragments of substance P and endomorphins partially overlap, which means that changes of substance P metabolic system specificity on the spinal level may result in either nociceptive or antinociceptive effects. Therefore, substance P with a mosaic of receptors and metabolic enzymes forms a "yin-yang" system (Fig. 1) sensitive to pathological changes.[10]

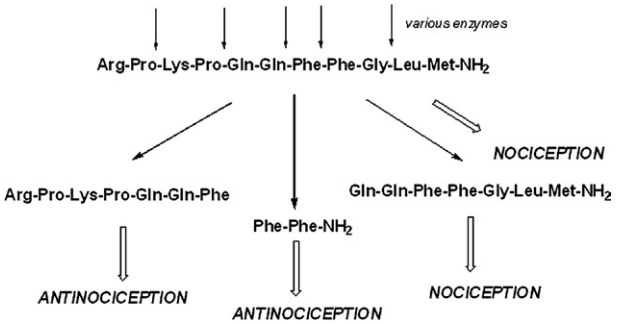

FIGURE 1 Substance P and its metabolites form a "yin-yang" nociception attenuating system (for simplicity, only three possible peptide metabolites are presented).

TACHYKININ ANTAGONIST–OPIOID AGONIST CHIMERIC COMPOUNDS

The majority of neurophysiological and pharmacological studies have indicated that substance P and opioid systems are functionally antagonistic in the mediation of nociception and antinociception *in vivo*.[22] Thus, the simultaneous blockade of substance P receptors and activation of opioid receptors seems to be quite a reasonable approach to the construction of chimeric peptides. Indeed, coinjection of a weak peptide substance P antagonist together with an opioid peptide strongly enhances opioid analgesia.[25] The conclusion obtained from this study indicates that incomplete blockade of substance P receptors enhances opioid analgesia.

Studies of the effects of mixtures of peptides prompted the design of compounds that in one molecule combine substance P antagonist and opioid agonist pharmacophores. The first of this series was AWL60, a peptide in which an endomorphin-like moiety is hybridized (head-to-tail) with a substance P antagonist (Table 1).[19] The resultant compound expresses properties of both hybridized components in an *in vitro* guinea pig ileum preparation. Although AWL60 expresses moderate affinity to mu-opioid receptors (median inhibitory concentration, IC_{50}, 1 μM), the *in vivo* intrathecal application of AWL produces intense, prolonged antinociception (Fig. 2).

Preinjection of naloxone strongly reduces this antinociceptive effect, but it does not abolish it completely. Further structure–activity relationship studies of chimeric morphiceptin–endomorphin molecules led to the conclusion that extension of the tetrapeptide with hydrophobic amino acids

significantly diminishes its affinity for opioid mu receptors. Therefore, a second, different molecule of this type of chimera was constructed. Biphalin, which hybridizes two opioid tetrapeptides head-to-head, is one of the most potent opioid analgesics. Structure–activity studies of biphalin concluded that one opioid pharmacophore could be replaced by one of the hydrophobic amino acids or their derivatives or mimetics.[20] An independent search for substance P antagonists resulted in the development of small aromatic tryptophan derivatives.[20] The consolidation of information from these series of structure–activity studies allowed the development of a new compound, AA501, in which an opioid agonist–a substance P antagonist chimera was synthesized by head-to-head hybridization of a tetrapeptide with *N*-benzyloxycarbonyl-tryptophan.[23] In this chimeric compound, the opioid agonist and tachykinin antagonist pharmacophores partially overlap (Table 1). AA501 has high affinity for opioid receptors and moderate affinity for tachykinin receptors. *In vivo*, intrathecal injection of AA501 provides intense antinociception in acute as well as inflammatory and neuropathic pain models. Prolonged application of AA501 results in a slower rate of tolerance development than produced by the administration of a pure opioid. Introduction of a ditrifluoromethyl-benzyl group to substance P antagonist peptidomimetics greatly enhances antagonist properties at NK1 receptors. Therefore, recent development of analgesics with opioid agonist and substance P antagonist properties included this modification (Table 1) in peptidic[2,33,34] and nonpeptidic series of compounds.

The later discovered endomorphins possess unique analgesic potency and selectivity for a single opioid receptor type μ. Further studies reveal that these peptides also express weak but significant antagonist properties at tachykinin NK2 receptors, [14] implying that these peptides should be considered as endogenous chimeric opioid agonist–tachykinin antagonist compounds. The importance of the tachykinin antagonist component in their unique biological profile should be addressed in further studies.

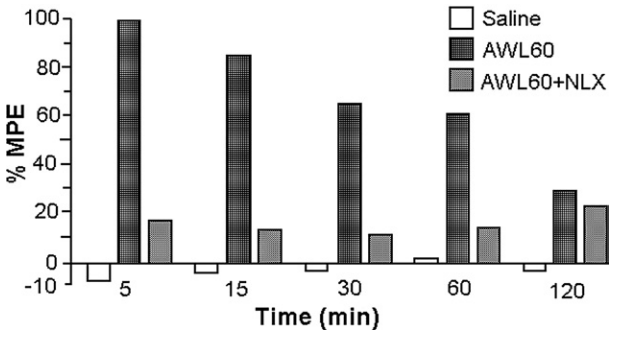

FIGURE 2 Antinociception in rats after intrathecal application of AWL60 (2.5 nmol).[19]

TACHYKININ AGONIST–OPIOID AGONIST CHIMERIC COMPOUNDS

The interaction between substance P and opioid neural systems is more complex than a simple one-way inhibition. In the spinal cord, these two systems are engaged in reciprocal regulation. Although the application of substance P in high doses is algesic, this molecule and its metabolites possess pain-alleviating effects when given in lower doses.[28,30] To some extent, the analgesic effects described for low doses of substance P seem to reflect an opioid-like action because naloxone neutralizes substance P analgesia.[9] The antinociceptive effects of substance P may also be explained by its activation of several self-regulatory mechanisms, including an influence on peptidase activities,[3] modulation of the binding of opioids to their receptors,[16] and influences on serotonin[13] or NMDA[31] pathways.

Selective pharmacological activation of the opioid system may perturb the complex interactions between tachykinin and opioid systems. Simultaneous activation of the opioid system along with partial compensatory supplementation of the tachykinin system is the rationale for the development of chimeras that combine an opioid agonist and a tachykinin agonist. Because the principal effects of substance P and opioids are opposite, the relative balance of activities between tachykinin and opioid pharmacophores will determine the net effect of the chimeric molecule as pronociceptive, antinociceptive, or neutral. In the first compound of this series, SPF[18,21] (Table 2), substance P activity predominates, and intrathecal injection of the compound induces nociceptive symptoms characteristic of substance P (Fig. 3). In that compound, the presence of an opioid component provides only partial antinociception, and coinjection of the opioid antagonist naltrexone further augments the nociceptive properties of the compound. In the second compound synthesized (ESP7), in which the endomorphin-2 and substance P C-terminal fragments were

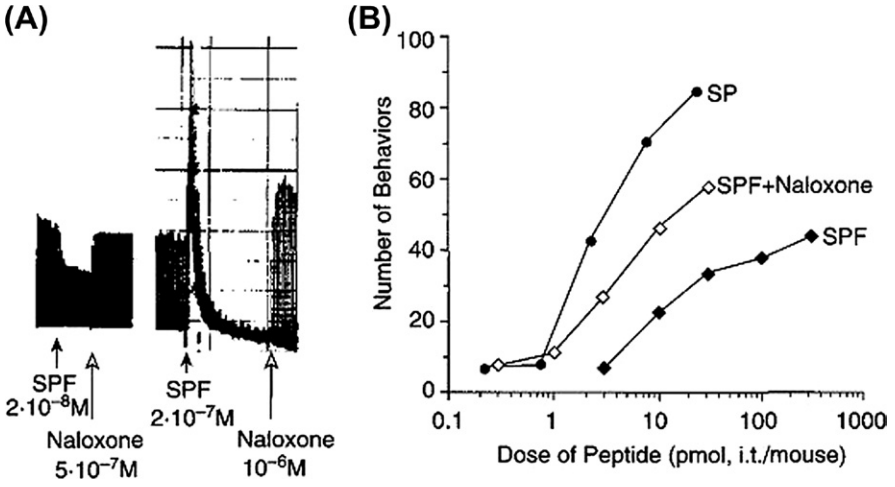

FIGURE 3 Examples of biological activities of SPF. (A) *In vitro* electrically stimulated mouse vas deference: Spontaneus contraction characteristic to substance P and inhibition of electrical stimulation characteristic to opioids, reversed with naloxone.[21] (B) Nociceptive behavior in mice after intrathecal application. Week nociception of SPF was potentiated by naloxone.[18]

hybridized, opioid activity predominates.[8] Although, ESP7 expresses moderate affinity for opioid ($K_i(\mu)$ 218 nM) and NK1 (K_i 289 nM) receptors, after intrathecal application in rats antinociception occurs at a very low dose (0.05 μg). Interestingly, because the molecule comprises two agonists at functionally opposite receptors, in rats, a ceiling effect was observed at 40% of the maximal possible effect (MPE). The application of ESP7 for several days does not produce any evident tolerance. In fact, the application of ESP7 produces analgesia in morphine-tolerant animals.

The C-terminal fragment of substance P is shared by all three endogenous tachykinins. Previous structure–activity studies of tachykinins resulted in the conclusion that substitution of glycine[12] with proline increases selectivity for NK1 receptors. Therefore, in subsequent analogs, the glycine of ESP7 was replaced with proline. The resultant peptide, ESP6, expresses higher affinity for opioid ($K_i(\mu)$ 92 nM) and similar affinity for NK1 (K_i 305 nM) receptors compared with ESP7.[7]

Intrathecal coadministration of morphine and ESP6 clearly slows down the development of tolerance to morphine. Although, ESP6 itself has low antinociceptive potency when it is administered during concurrent NK-1 receptor blockade, a decrease in analgesic potency results, similar to that seen with tolerance to morphine alone. It was thus concluded that ESP6 represents a novel tolerance-eliminating adjuvant for the maintenance of opioid analgesia over time.

Both ESP6 and ESP7 compounds were designed as chimeric compounds with minimal size. Because substance P and endomorphin pharmacophores overlap in these molecules, the size of chimeras was reduced to that of a hexapeptide. Nevertheless, the extension of the original tetrapeptide sequence of endomorphin with additional hydrophobic peptides results in significant decreases of affinity to opioid receptors. Therefore, in the next generation of analogs, two pharmacophores were hybridized in such a way that each pharmacophore was structurally independent and yet also connected by the spacer (Table 2). The resultant peptide, AWL3106, expresses high affinity for opioid ($K_i(\mu)$ 2.5 nM) and NK1 (K_i 7.5 nM) receptors and in addition is very potent when given intrathecally, with an analgesic ceiling at nearly 100% of MPE (Fig. 4). Chronic application of these peptides results in the very slow development of tolerance compared with that of morphine. Interestingly, this peptide is also very potent after intravenous application. It is highly probable that the hydrophobic tachykinin domain of the peptide plays an additional role as a vector that helps it to cross the blood–brain barrier. This latter observation allows the creation of still more templates for the further design of chimeric drugs.

CONCLUSIONS

The construction of opioid–tachykinin chimeric peptides seems to be a very promising avenue for the design of new analgesics. Hybridization of an opioid agonist with a substance P antagonist results in compounds with a synergistic antinociceptive interaction of both hybridized components. The modification of such compounds to provide a lesser degree of activation of the opioid system gives rise to the desirable property that the development of opioid tolerance during repeated administration is significantly slowed. The hybridization of opioid agonists with substance P agonists may also result in effective analgesics without apparent opioid tolerance during chronic application. The possible application of such compounds for the treatment of opioid

tolerance and/or dependence is obvious, but further studies to evaluate their utility are needed.

Chapter 217

POMC-Derived Opioid Peptides

Patricia J. McLaughlin and Ian S. Zagon

ABSTRACT

Proopiomelanocortin (POMC) prohormone is processed to yield many fragments including adrenocorticotropin hormone (ACTH) and β-lipotropin hormone (β-LPH). These proteins are actively cleaved to yield multiple bioactive peptides, one of which is β-endorphin. Concentrated in the anterior pituitary and *pars intermedia*, β-endorphin is distributed widely throughout the body and has been detected in nervous tissue as well as adrenals, heart, liver, and placenta. Concomitant with its broad distribution, the physiological activity of β-endorphin directly or indirectly includes neurotransmitter functions, suppressive effects on respiration, analgesia, maintenance of cardiovascular homeostasis, and even regulation of T- and B-cell function in the immune system. β-endorphin's activity is mediated through classical μ and δ opioid receptors and perhaps a more selective epsilon receptor. Continued research is necessary to further define the signaling pathways associated with β-endorphin's roles in the pathophysiology of pain management, obesity, and even immunological responsiveness.

HISTORY

Endorphins were the first identified endogenous opioid peptides. The term 'endorphins' remains broader than the specific molecules that are truly endorphin derivatives. Endogenous neuropeptides were first identified and named by two independent laboratories in the mid-1970s. In Scotland, the laboratory of John Hughes and Hans Kosterlitz isolated a small peptide sequence from brain tissue isolated from pig and termed it "enkephalin."[6,7] During the same period, investigators in the United States isolated an active molecule that they considered to have morphine-like activity and termed it "endorphin."[14,17] As the field of neuropeptides blossomed, the term "endorphins" was used loosely in reference to all endogenous peptides with opioid-like activity, particularly morphine-like properties. Thus, the term "endorphins" has been assigned to numerous peptides with multiple functions ranging from pain cessation and analgesia to euphoria and neurotransmission.[15]

In common language, an "endorphin-high" is attributed to any euphoric feeling elicited from either physical or emotional challenge, pain, or stress. Frequently, the runner's high experienced near the end of a long, challenging race is attributed to endorphin release and a composite surge of pain-relief peptides that block sensory receptors. Whether this function is actually facilitated solely by β-endorphin molecules remains in debate.

STRUCTURE OF β-ENDORPHIN

Scientifically, the family of endorphins is derived from a single prohormone termed proopiomelanocortin, POMC. The POMC gene has 7665 bp consisting of three exons and two introns. Studies using the cell line AtT-20 from mouse anterior pituitary revealed that POMC processing yields distinct products that were not merely degradation entities.[11] The products included the N-terminal fragment, adrenocorticotropin hormone (ACTH, 16 kD) and β-lipotropin hormone (β-LPH). Neither of these larger proteins (i.e., ACTH, β-LPH) has inherent activity and requires additional processing. Further translation yields the corticotropin-like intermediate protein (CLIP), various forms of melanocyte stimulating hormone (α-MSH, β-MSH, and γ-MSH), and β-endorphin.

Sequences of the POMC gene from many species suggest that there is a single copy of the gene that has been substantially conserved throughout evolution. Data from the National Center for Biotechnology Information document that the POMC gene is located on chromosome 2p23.3 in humans, chromosome 6p14 in rats, and chromosome 12 in mice. The primary products are derived from exons 2 and 3, with all of the bioactive peptides, including β-endorphin being flanked by standard dibasic amino acid cleavage residues. The amino acid structure for β-endorphin is Tyr-Gly-Gly-Phe-Met, Thr-Ser-Glu-Lys-Ser-Gln-Thr-Pro-Leu-Val-Thr-Leu-Phe-Lys-Asn-Ala-Ile-Ile-Lys-Asn-Ala-Tyr-Lys-Lys-Gly-Glu. Interestingly, the first 5 amino acids code for [Met^5]-enkephalin, one of the original opioid

peptides discovered based on binding assays. However, POMC is not considered a primary source for enkephalins. Endorphin substances were originally isolated from camel pituitary and later characterized in rodents.[10] There are at least 20 different endorphins, many of which have activity as neurotransmitters, pain modulators, and anxiety suppressors. Further processing of the 3′-end segment of β-LPH gives rise to γ-LPH and β-endorphin subfragments. These in turn are further processed into β-endorphin 1–31, acetylated β-endorphin, and β-endorphin 1–27. The latter two polypeptides have little or no activity.[11] The primary products include α-endorphin containing 16 amino acids, β-endorphin with 31 amino acids, and γ-endorphin-containing 17 amino acids. Cleavage of the prohormone, as well as the active subunits ACTH and β-LPH, occurs in an orderly manner with proteases PC2 and to a smaller extent PC1, responsible for processing.

LOCATION AND MECHANISM OF ACTION

POMC is primarily expressed in the anterior and intermediate lobes of the pituitary, with each lobe being responsible for different peptide products. Corticotroph cells in the anterior pituitary secrete POMC peptides that control adrenal function, while melanotrophs of the *pars intermedia* secrete POMC-associated peptides (e.g., α-MSH) that influence hair and skin pigmentation and have behavioral and EEG effects on the brain. Although the major source of POMC is the pituitary, radioimmunoassay, western blotting, and ELISAs have found recordable levels in the hypothalamus, arcuate nucleus, medial basal hypothalamus, and median eminence.[4] Lesser amounts of endorphin have been detected in the amygdaloid nucleus, periaqueductal gray, locus coeruleus, and substantia nigra.

Several nonneural tissues have also been shown to express and/or process POMC including the adrenal, small intestines, reproductive tract, spleen, lung, liver, heart, and placenta. With this diffuse presence throughout the body, POMC has many diverse functions.[15] The presence of POMC-related peptides in these tissues, and possibly roles for β-endorphin, are discussed below.

Opioid activity associated with β-endorphin is dependent on its C-terminal residues, and loss of these amino acids substantially decreases the analgesic property of the peptide. Numerous studies have shown that β-endorphin shares many of the physiological actions of exogenous opiates such as morphine and has been documented in animal studies to have effects on analgesia, respiratory depression, vasopressin release, and cardiovascular homeostasis.[8] β-Endorphin can be easily measured in plasma and increases during pregnancy, with elevated levels reported particularly during labor and delivery. Moreover, β-endorphin has heightened presence throughout surgery, and in some pituitary-related diseases such as Cushing's disease and Addison's disease; conversely, pituitary resection results in diminished levels. Cerebrospinal fluid also contains detectable levels of endorphins, with elevated levels after surgically induced analgesia.

Once released into the blood stream, β-endorphin binds to an opioid receptor to elicit its activity. Studies over the last few decades have suggested that endorphins can bind to any or all of the classical opioid receptors (mu, delta, and kappa), and some studies have suggested that there is a specific or selective receptor for endorphin termed the epsilon (ε) receptor. This latter receptor is very much understudied, and its true existence and function are uncertain. The consensus of studies suggests that the highest affinity may be for mu (μ) opioid receptors (MOR1), moderate affinity for MOR2, and delta (δ) opioid receptor (DOR), and little or no affinity for the third subclass of classical opioid receptors known as kappa opioid receptors. Most reports infer that the euphoria associated with the 'runner's high' results from binding at both the traditional pain mediated mu receptors and the kappa opioid receptors.

Genetic POMC deficiencies are compatible with life depending on the extent of mutational rearrangement and/or deletion, and whether the ACTH deficiency can be medically handled by hydrocortisone treatment. In general, the adrenal insufficiency related to genetic POMC deletions is not much different from other clinically based (e.g., tumors) pituitary conditions.

FUNCTION

As with all of the opioid peptides, the function of β-endorphin changes depending on the receptor to which it is binding and the region of brain or location in the whole body. Although the literature supports the fact that β-endorphin binds to μ, δ, and κ classical opioid receptors, as well as to possibly that it has its own receptor termed epsilon (ε), the majority of actions of endorphin can be localized to μ and δ opioid receptors. As with other neuropeptides, such as methionine enkephalin, the ubiquity and generalization of function of endorphin are widespread. Endorphins function in analgesia and pain cessation, satiation and food metabolism, cardiovascular regulation, T- and B- cell proliferation and function in the immune system, as well as the euphoric responses attributed to higher order emotional and neurological systems.

β-ENDORPHIN AND MU RECEPTOR FUNCTIONS

β-Endorphin serves as an agonist for mu opioid receptors and *in vitro* and *in vivo* studies have supported its function at these receptors to be neuroendocrine or neuroimmune in nature. Some studies suggest that β-endorphin has few central nervous system mediated effects when administered systemically

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

because of the inherent difficulty for β-endorphin to cross the blood–brain barrier. Consequently, the classic effects of mu receptors including confirmation of analgesia and respiratory depression are not attributed to the endogenous peptide β-endorphin.[18] *In vivo* studies of the function of β-endorphin at mu opioid receptors suggest that prolactin release after systemic injections mediate many of the neuroendocrine responses.[1] Nonhuman primate studies in which β-endorphin is injected intravenously reported that this peptide most probably acts at mu receptors on the hypothalamus. However, the *in vivo* studies are not completely confirmatory as it is well known that β-endorphin is rapidly metabolized in the plasma and that other bioactive peptides may yield high affinity to opioid receptors and confer the function.

β-ENDORPHIN AND OBESITY

The relationship of POMC and obesity has been well established because POMC is the precursor for ACTH which must be homeostatically secreted to maintain normal adrenal function.[12] Failure to secrete ACTH, related to pituitary dysfunction, results in weight loss. Conversely, POMC deficiency seems to result in both rodent models and humans with increased appetite and weight gain. Targeted genetic manipulation of POMC results in obese mice. These studies suggested that POMC neurons in the hypothalamus and their possible melanocortin-related receptors may have control over the pituitary function of weight control. Polymorphic variations among persons with weight issues fail to support a singular gene association between POMC and obesity.

Some interesting functions of β-endorphin were discovered with the development of a POMC-null mouse.[20] This mouse was hyperpigmented, overweight, and had defective adrenal development. As additional studies were conducted using the mouse model, as well as other transgenic mice, knowledge about the role of leptin activation mediated by POMC neurons and regulation of obesity was uncovered[3] These investigators recorded from POMC neurons and showed that leptin reduced neuropeptide Y/GABA circuitry and further that melanocortin peptides also inhibited this signaling pathway. However, leptin receptors alone are not the sole regulator of body weight homeostasis. Further studies on excitation of POMC neurons in the arcuate nucleus, another center for control of feeding, resolved that more than leptin receptors are involved in weight and eating regulation.

β-ENDORPHIN AS A NEUROMODULATOR OF THE CARDIOVASCULAR SYSTEM

Because cardiac muscle possesses a high density of opioid receptors, the involvement of endogenous opioids, particularly endorphin, in cardiac function has led to many reports implicating a role for endorphins in the management of hypertension, as well as a contraindication of morphine or as a mimic of the exogenous agonists.

In a similar manner to exogenous opioids such as morphine, intravenous administration of β-endorphin causes an immediate drop in blood pressure in rodents, cats, and dogs. Dose-dependent vasodepressor effects along with bradycardia are antagonized by naloxone, suggesting that the effects are opioid receptor mediated.[5] However, the effects of endorphins on the cardiovascular system are dependent on the route of administration and dose. The sympathetic nervous system seems to mediate the drop in pressure and vagal nerve tracts seem to be responsible for bradycardia.[8] Other cardiovascular responses to endorphin may involve a variety of other hormones and effector compounds including serotonin, catecholamines, vasopressin, angiotensin, and aldosterone. Serotonin has been linked with hypotension seen in animals injected with endorphins, as well as in reuptake transmitter models implicating an endogenous release of the compound on stimulation. Endorphins and exogenous opioids such as morphine act on presynaptic receptors in sympathetic nerves to inhibit the release of norepinephrine; however, epinephrine also causes the release of β-endorphin, while β-endorphin seems to invoke a general increase in plasma levels of several neurotransmitters including dopamine, norepinephrine, and epinephrine.[19]

β-ENDORPHIN AND THE IMMUNE SYSTEM

In addition to its role as a regulator of homeostatic functions including respiration, cardiovascular control, and its role as a neurotransmitter, endorphins have shown functional relevance in the immune system. Most of the lymphocyte subclasses (i.e., T and B cells) express one or more of the classical opioid receptors,[2,16] as well as the opioid growth factor receptor.[21,22] Endorphins have been reported to suppress phagocytosis activity of macrophages and to modulate cytokine production and proliferation of T- and B-lymphocytes through binding to δ-opioid receptors or the opioid growth factor receptor.[16,21,22] Some reports suggest that the class of endorphin molecules, and in particular enkephalins, inhibit CD4+ and CD8+ T-cell proliferation in populations of lymphocytes isolated from murine spleen. The responses of endorphins are mediated by delta opioid receptors although the evidence for this singular receptor is circumstantial. Specific data such as that which could be resolved by knockout delta opioid receptor mouse studies are lacking. Several studies examining the role of opioid receptor binding activity using radioactively labeled antagonists (e.g., naloxone), synthetic agonists (e.g., deltorphin), or partial amino acid sequences representative of proopiomelanocortin show the presence of selective and saturable binding for both kappa and delta opioid receptors on lymphoid cells, particularly T-lymphocytes. These results support some level of functional activity by endorphins in the immune system.

MISCELLANEOUS ROLES OF β-ENDORPHIN

Sequence homology between the heavy chain of IgG and ACTH and endorphin has provided an incentive for a few researchers to ask what is the role of β-endorphin at nonopioid receptors. Studies have shown that a β-endorphin-like decapeptide, with sequence homology to human IgG, exhibits some biological activity in the immune system. The peptide activated human and rodent immunocompetent cells both *in vitro* and *in vivo* and to enhance proliferation of leukemia cell lines (Jurkat), blastomeres, and preimplantational mouse embryos.[9,13] This peptide termed immunorphine binds to naloxone-insensitive receptors located on T-lymphocytes, mouse macrophages, and selected rat brain homogenates. Radioactively labeled binding assays confirm nonopioid β-endorphin receptors in nonneural tissues including rodent heart and spleen, as well as brain and adrenal glands. A significant level of research is required to substantiate this role for β-endorphin.

SUMMARY

As with other endogenous neuropeptides, β-endorphin is widely distributed in the central nervous system, as well as other neural-related and nonneural tissues. Consequently, the physiological functions of β-endorphin are diverse and distributed throughout all the major organ systems. With additional research, new, nonfunctional roles for endorphins are continuing to be discovered, and new pathways and mechanisms are being validated. As the specificity of receptors increases and the classes of mu and delta opioid receptors expands, the relationship between receptors and endorphins becomes clearer and more refined. Nonetheless, endorphins remain a large body of peptide/hormones that impact most of the major biological systems in the human body. Research should be encouraged into defining the specific roles played by endorphins in disease states as well as maintaining homeostasis in the developing and adult organism.

Chapter 218

Prodynorphin-Derived Peptides

Santi Spampinato, Andrea Bedini and Monica Baiula

ABSTRACT

The dynorphin family consists of multiple peptides generated by posttranslational processing of prodynorphin. They are widely distributed in the central nervous system and occur in peripheral tissues, such as the heart, the gastrointestinal tract, and the adrenal gland. Dynorphin A(l–17) has been widely investigated because it can represent an endogenous ligand for the K-opioid receptor. It displays several biological functions, including the regulation of pain transmission, feeding, and pituitary hormone release, and it may influence myocardial function. C-terminal fragments of dynorphin A(l–17), lacking the N-terminal tyrosine, do not bind to opioid receptors and are excitotoxic by interacting with glutamate receptors. Increased prodynorphin expression, observed in several pathophysiological conditions such as neuropathic pain and heart ischemia, may tilt the balance toward neurotoxic dynorphin derivatives that may contribute to tissue damage. In recent years, implications of dynorphins in drug addiction, neurodegenerative disease, stress, and depression have been shown.

DISCOVERY

Dynorphins include multiple bioactive peptides generated by posttranslational processing of the large precursor prodynorphin;[8] they include α-neoendorphin (α-NE), big dynorphin (Dyn A 1–32), leumorphin (Dyn B 1–29), dynorphin A (Dyn A 1–17), dynorphin B (Dyn B 1–13), leucine–enkephalin–arginine (Leu–enkephalin–Arg), and potentially leucine–enkephalin (Leu–enkephalin) (Fig. 1).

In 1979, Avram Goldstein et al. reported the characterization and partial sequence of a highly potent opioid peptide obtained from pituitary extracts. This tridecapeptide contained the amino acid sequence for Leu–enkephalin at its N-terminus,[11] and in the guinea pig ileum longitudinal muscle preparation, it was approximately 700 times more potent than Leu–enkephalin. For this reason, it was named dynorphin (1–13), from the greek prefix *dyn* "strength or power." Later, the same laboratory reported the complete sequence of the endogenous heptadecapeptide named Dyn A(l–17). Soon thereafter, other laboratories described the sequence and distribution of the other dynorphins.[10]

STRUCTURE OF THE PRECURSOR mRNA/GENE

The cloning of the prodynorphin cDNA from a porcine hypothalamic library[16] confirmed that all dynorphins are contained and produced within the same protein-inactive precursor and are generated by cleavage at basic residues. The sequence of the prodynorphin gene has been reported for several species, including human. The coding gene contains four exons separated by three introns (Fig. 1). As reported in other opioid peptide genes, exons 1 and 4, which contain nontranslated sequences, are very large (1.4 and 2.2 kb, respectively). Exons 3 and 4 contain the translated regions; prodynorphin mRNA possesses a very long nontranslated 3′-terminal end of approximately 1550 nucleotides. A variety of mechanisms have been shown to lead to species-, tissue-, and treatment-specific differences in the structure of prodynorphin mRNA transcripts, and some of these different structural forms affect function. For example, in rat testis, alternative splicing of the prodynorphin mRNA yields a mature mRNA that lacks exon 2. This exon codes for part of the 5′ untranslated region; the lack of this exon has no apparent effect on translational efficiency.[21] At the peptide level, Dyn A(l–17) is completely conserved across all mammalian species in which its sequence has been determined; however, at the level of the mRNA primary structure, an assortment of mechanisms, including alternative splicing, differential transcription initiation, and site-specific cleavage, lead to the generation of species-, tissue-, and treatment-specific mRNAs for this peptide precursor.[21] The study of mRNA transcripts from the prodynorphin gene continues to provide examples of general and specific mechanisms of regulation of mRNA structure and also, in some instances, mRNA function. The functional significance of the longer form of the prodynorphin mRNA is as yet unknown, but may possibly alter translational efficiency or mRNA stability. Several transcription factor binding sites were identified in the promoter region of the prodynorphin gene and found to be responsible for the enhanced prodynorphin mRNA expression in response to AMP or protein kinase A in the rat.[8]

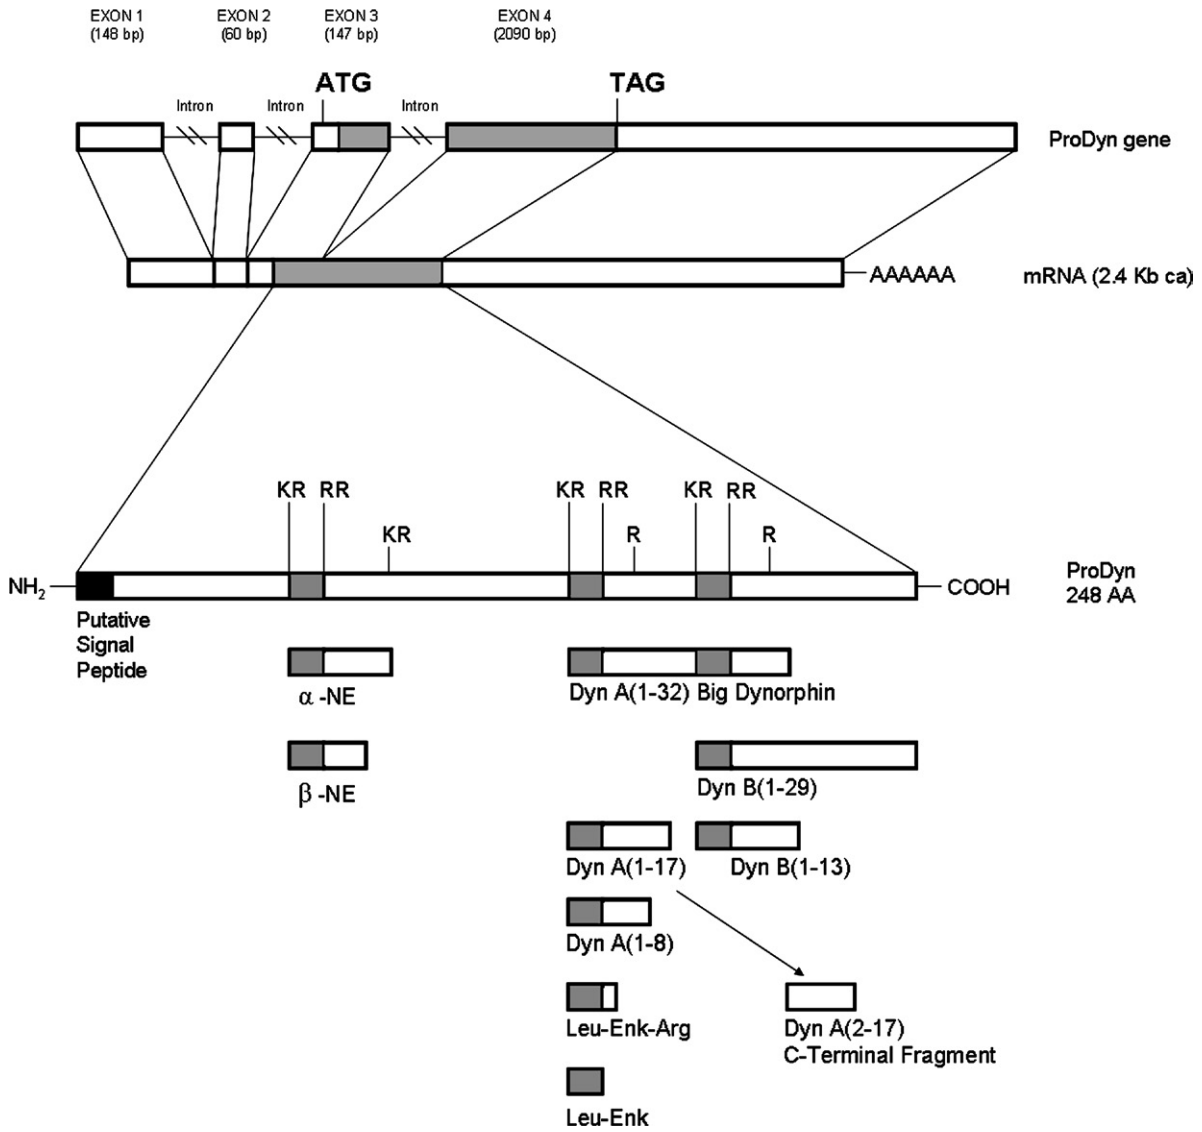

FIGURE 1 Prodynorphin (ProDyn) gene, messenger RNA, protein precursor structure, and processing pathways. Basic amino acid cleavage sites in the precursor are denoted by their single letter codes. K, lysine; R, arginine. Solid box corresponds to the sequence of Leu–enkephalin.

PROCESSING

The most common processing signal sequences of the prodynorphin precursor, which is highly basic, are the lysine–arginine (KR), the lysine–lysine (KK), and the arginine–argine (RR) residues; these are cleaved on the carboxyl side of the basic amino acids and followed by removal of the C-terminal basic residue. An endopeptidase-designated dynorphin-converting enzyme (DCE) cleaves neuropeptides such as dynorphins at monobasic sites. After endopeptidase activity, carboxypeptidases remove the basic amino acids from the C-terminus of peptides. Aminopeptidases capable of removing N-terminal Arg or Lys residues from the processed peptides have also been reported.[7] The relative levels of endopeptidase can have a large effect on the bioactivity of neuropeptides because differential proteolysis of a single precursor can result in the generation of several neuropeptides that activate a diverse set of receptors. (See the Peptide Biosynthesis/Processing section of the book for more details.) Thus, processing enzymes play a key role in the modulation of neuropeptide gene expression. Additional bioactive derivatives of prodynorphin probably exist in addition to those previously indicated. Many of the C-terminal fragments of dynorphin A [most likely Dyn A(2–17)], which are intrinsically neurotoxic, have been isolated from neural tissue *in vivo* or *in vitro*.[13] Moreover, neuropeptide processing may occur after secretion.

Initial studies carried out to isolate dynorphins focused on the characterization of small fragments corresponding to the end products of prodynorphin precursor processing.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

However, with antibodies directed against Dyn A or Dyn B, radioimmunoassay analysis of gel-fractioned tissue extracts revealed in certain tissues large-molecular-weight intermediates that were subsequently characterized.[6] The anterior pituitary gland contains several prodynorphin-processing intermediates: a 4-kDa peptide containing Dyn A and Dyn B [Dyn A (1–32)], a 6-kDa fragment comprising Dyn A(l–32) and a C-terminal fragment, an 8-kDa peptide having α-neoendorphin at the N-terminal position of the 6-kDa fragment; and, finally, a 16-kDa fragment comprising the N-terminal portion of the precursor plus α-neoendorphin and a 10-kDa fragment containing α-neoendorphin and Dyn A(l–32). Other intermediates, occurring in a small amount (~10–20%) have not been well characterized. In other brain areas containing dynorphins, these intermediates are present only in trace amounts, and the major components are the small dynorphins such as Dyn A(l–17), Dyn B, and α-neoendorphin.[6] Thus, this suggests that a tissue-specific processing requires the expression of particular processing enzymes.

RECEPTORS

Radioreceptor-binding assays in brain membrane fragments and bioassays in isolated intact tissues have ascertained that Dyn A(l–17) and the other dynorphins bind to κ-opioid receptors (KOR) with a somewhat higher affinity than μ- or δ-opioid receptors (MOR and DOR, respectively), and Dyn A(l–l7) is considered to be an endogenous ligand for the KOR.[10] Dyn A(l–8) and α-neoendorphin have lower affinities for the KOR, with significant affinity for the MOR and DOR sites. In agreement with the preferential binding to KOR, Dyn A(l–l7)-elicited effects on isolated tissue preparations can be blocked by selective KOR antagonists such as nor-binaltorphine.[5]

CONFORMATIONAL ANALYSIS OF DYN A(1–17)

Structural studies of dynorphin in the solid state and the membrane environment show that the N-terminus forms an a-helical structure and is inserted into the membrane with the helical axis almost perpendicular to the membrane surface. It has been suggested that the helical region of the extracellular loop II of the KOR may interact with the helical region of dynorphin with a high affinity in the membrane environment.[22]

DYNORPHIN EXPRESSION IN THE CENTRAL NERVOUS SYSTEM AND POSSIBLE BIOLOGICAL ACTIONS

Initial immunocytochemical studies of dynorphins were carried out in the rat hypothalamus, where Dyn (1–13) was found to be colocalized with vasopressin in magnocellular neurons of the supraoptic and paraventricular nuclei.[17] The immunocytochemical distribution of peptides derived from the prodynorphin precursor in the brain of the rhesus monkey (*Macaca mulatta*) indicates a widespread neuronal localization of immunoreactivity from the cerebral cortex to the caudal medulla. Immunoreactive perikarya are located in numerous brain loci, including the cingulate cortex, caudate nucleus, amygdala, hypothalamus, thalamus, substantia grisea centralis, parabrachial nucleus, nucleus tractus solitarius, and spinal cord dorsal gray laminae. In addition, fiber and terminal immunoreactivity are seen in varying densities in the striatum and pallidum, substantia innominata, hypothalamus, substantia nigra pars reticulata, parabrachial nucleus, spinal trigeminal nucleus, and other areas. The distribution of prodynorphin peptides in the brain of the monkey is similar to that described for the rat brain; however, significant differences also exist. *In situ* hybridization histochemistry has been adopted as a technique to investigate the localization of prodynorphin mRNA in the central nervous system; this approach has confirmed that prodynorphin-containing cells are relatively widespread throughout brain regions that contain dynorphin peptides.[17]

Dynorphins play a role in a wide variety of physiological parameters, including motor activity, cardiovascular regulation, respiration, temperature regulation, feeding behavior, and hormone release.[25] Although they do not elevate pain threshold when injected in the brain, they antagonize opioid analgesia in naive animals and potentiate it in tolerant animals. Dynorphins have beneficial effects on stroke that are like those of opioid antagonists rather than like those of agonists.[29]

Prodynorphin-positive neurons are widely distributed in brain and spinal cord areas involved in the transmission of nociceptive stimuli.[17] Dynorphins may be involved in a local circuit within the spinal cord, and in supraspinal functions. Interestingly, dynorphins were also detectable in cutaneous nerves with a distribution similar to that of calcitonin-gene-related peptide, a specific marker for sensory neurons. A moderate density of KOR binding sites has been seen in the central and peripheral neuronal nociceptive system and in various immune cells.[14] A lack of an antinociceptive action of dynorphin after its administration into the lateral brain ventricle[24] and some slight antinociceptive activity after intrathecal injection[24,29] have been reported. Other KOR agonists also possess some antinociceptive activity after their intrathecal administration. However, the effect is much weaker on a molar basis than that evoked by MOR or DOR agonists. On the other hand, in electrophysiological experiments in spinalized rats, KOR agonists reduce reflexes stimulated by thermal and mechanical nociceptive stimuli to the same extent and in a dose-dependent manner.[20,24] Dynorphin-mediated analgesia has been ascribed to its inhibitory action on neurons at KOR. Electrophysiological evidence

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

supports a KOR-mediated inhibitory effect of dynorphins on synaptic transmission of nociceptive neurons in the spinal dorsal horn.[24] Dynorphins, and other neurotransmitters, can be released and can induce the hyperpolarization of neurons, potentially through a KOR-coupled enhancement of potassium conductance. In addition, dynorphin-mediated activation of KOR suppresses calcium currents and calcium-dependent secretion.[4] Further, dynorphin has been shown to inhibit substance P release in the spinal cord in a KOR-mediated manner.[20] The endogenous dynorphin–KOR system has been suggested to elicit antinociception during inflammation, pregnancy,[24] and acupuncture.[12] These studies support an antinociceptive function of dynorphin by negatively modulating transmission of nociceptive information.

PATHOPHYSIOLOGICAL IMPLICATIONS

Observation of the antinociceptive actions of dynorphin in the spinal cord is hindered by its neurotoxic effects. These can result from a nonopioidergic mechanism of action of the peptide.[13,20] The involvement of spinal dynorphins in animal models of inflammatory pain has been studied in great detail. Profound alterations in the spinal prodynorphin system has been observed when there is peripheral inflammation or chronic arthritis.[27,33] The levels of immunoreactive dynorphin are dramatically increased in the lumbar part of the spinal cord of rats with local inflammation of a hind limb. Further, an increase in prodynorphin mRNA levels induced by acute and chronic inflammation has also been observed in the spinal cord. Thus, many forms of peripheral inflammation induce a dramatic upregulation of prodynorphin biosynthesis in nociceptive neurons of the spinal dorsal horn, which parallels the behavioral hyperalgesia associated with the inflammation. There is much evidence that nerve injury is associated with elevated levels of spinal dynorphins. Spinal injury, which may cause neuropathic pain, also increases the dynorphin level in the spinal cord. Both prodynorphin mRNA and dynorphin levels were significantly increased, whereas those of proenkephalin mRNA and Met-enkephalin remained unchanged 3 days after injury. The increase in the spinal levels of prodynorphin mRNA was the highest in the areas dose to the side of transaction.[20] Thus, endogenous dynorphin levels increase under various conditions associated with neuropathic pain after damage to the spinal cord and injury of peripheral nerves.

The site and time of increase of the dynorphin content in the spinal cord after peripheral nerve injury seem to correlate with the appearance of neuropathic pain. Further, a single intrathecal injection of Dyn A(l–17) to mice induced mechanical allodynia and cold allodynia (acetone applied to the dorsal hind paw) lasting several days.[24] Interestingly, Dyn A(2–17), a nonopioid peptide, induced cold and tactile allodynia analogous to that induced by Dyn A(l–17), indicating the involvement of nonopioid receptors. Further, Dyn A(l–17) has nonopioid activity and may damage the spinal cord when given in high doses and may produce hind-limb paralysis when administered intrathecally to rats. This effect is mediated at least partly via nonopioid receptors because the des-Tyr fragment of dynorphin can induce a similar effect.[24] Dyn A(l–32), intrathecally administered in mice, is a more potent nociceptive peptide than Dyn A(l–17), and its effect was not mediated by opioid receptors; rather, it involved NMDA receptors.[13]

Considerable evidence reveals that dynorphin is actually pronociceptive in chronic pain states. The idea that dynorphins may contribute to the maintenance of neuropathic pain states has been tested in prodynorphin knockout mice.[26] They develop neuropathic pain after nerve injury but fail to sustain it for extended periods of time, and, by 10 days after injury, they are no more sensitive than they were before injury. By contrast, wildtype animals continue to display neuropathic pain. Thus, spinal dynorphins are critical for the maintenance of neuropathic pain, and their upregulation may represent a mechanism for the maintenance of the neuropathic pain state. Several investigators have shown that neurological damage observed after intrathecal dynorphin administration can be prevented by antagonists and modulators of the NMDA receptor, which is known to be an important mediator of neuropathic pain states. Moreover, the long-lasting hyperresponsiveness to both innocuous and noxious stimuli that is elicited by intrathecal dynorphin is not blocked by the opioid receptor antagonist naloxone, but it is prevented by pretreatment with the NMDA receptor antagonist MK-801.[20] This finding suggests that the NMDA receptor is probably a mediator of the nonopioid actions of dynorphin.

The interaction of endogenous dynorphins and NMDA receptors in promoting neuropathic pain may be a consequence of binding of dynorphins to NMDA or they may act as a positive allosteric modulator. Interestingly, Dyn A(2–17) binds to NMDA receptor R1/R2A subunits showing high-affinity binding. Substantial evidence suggests that dynorphin facilitates excitatory amino acid release, and because the binding of dynorphin to NMDA receptors is attenuated by NMDA agonists, dynorphin may not interact appreciably with NMDA receptors under neuronal hyper excitable conditions. It has been proposed that physiological concentrations of dynorphins are antinociceptive and neuroprotective through opiate receptor activation, whereas extremely elevated levels are pronociceptive and even excitotoxic in an NMDA receptor-dependent fashion.[13] Dynorphins can exert protective or proapoptotic effects depending on whether they activate opioid receptors or nonopioid mechanisms (i.e., glutamate receptors or protein–protein interactions) and that they seem to contribute to nervous system pathology through complex interactions involving multiple receptors and pathways.[13]

Contribution of prodynorphin mutations to spinocerebellar ataxia type 23, an inherited neurodegenerative disorder, could open new vistas on the role of this endogenous opioid system[2] and any dysregulation of dynorphins in Alzheimer disease.[34]

In recent years, new insights, provided by investigations on prodynorphin- and opioid receptor-deficient mice, have proved any involvement of dynorphins in neurological and psychiatric diseases. There is increasing evidence for a potential involvement of dynorphin/KOR in schizophrenia,[25] in stress and depression.[18] Bruchas et al.[3] have reported that the anxiogenic properties of stress are encoded by endogenous dynorphins acting in the basolateral amygdala. Further, the anticonvulsant and antiepileptic effects of dynorphin in animal models have been investigated.[25]

DRUG ABUSE AND DYNORPHINS

Rewarding effects and compulsive drug-seeking behavior, characterizing drug addiction, are induced by various drugs of abuse and may require an increase of dopamine neurotransmission in the nucleus accumbens and in the striatum and a glutamate-dependent neuroplasticity. Dynorphins, locally released, may modulate dopamine neurotransmission and interfere with psychostimulants and other drugs that increase it.[19] The dynorphin/KOR system serves as an essential function in opposing alterations in behavior and in opposing alterations in behavior and brain neurochemistry that occur as a consequence of repeated drug use and that aberrant activity of this system may not only contribute to the dysregulation of behavior that characterizes addiction but to individual differences in vulnerability to the pharmacological actions of cocaine and alcohol.[28] Interestingly, in rats exposed to the anabolic androgenic steroid nandrolone, elevated dynorphin levels were observed in brain regions regulating emotions, dependence, and defensive reactions.[15] The authors have proposed that brain dynorphins may participate in behavioral modifications induced by anabolic steroids. Therefore, it has been suggested that the increase of endogenous dynorphins, caused by drugs of abuse, may counteract the effects elicited by these compounds on dopamine neurotransmission.[13] However, it cannot be excluded that considerable higher levels of dynorphins may also interfere with glutamate receptors and may promote, instead of counteract, neuroplastic changes that promote drug-seeking behavior. Exposure to high doses of psychostimulants may cause a neurotoxic loss of neurons and apoptotic cell death.[13] Therefore, as previously described for the spinal effects of dynorphins, it remains to be established whether these peptides may have a dichotomy of actions: at lower levels, they counteract drug addiction, whereas at supraphysiological levels, they may contribute to drug abuse toxicity. In this regard, it should be mentioned that dynorphin dysregulation might be associated with various neurological disorders such as Parkinson's and Huntington's disease; moreover, dynorphin alternations have been associated with the pathogenesis of refractory seizures.[13]

DYNORPHIN EXPRESSION IN PERIPHERAL TISSUES

In the periphery, numerous tissues express prodynorphin-derived peptides. Initially, Spampinato and Goldstein[31] reported the presence of immunoreactive dynorphin in the following rat tissues: stomach, intestine, adrenal gland, ovary, testis, skeletal muscle, and heart. Gel-permeation chromatography revealed a larger apparent molecule than that of Dyn A(l–17). Moreover, dynorphins have been detected in rat and human plasma.[31,32] However, the processing and the physiological role played by dynorphins in peripheral tissues are still largely unknown. The heart has drawn particular attention for its capacity to biosynthesize dynorphins in the rat atrial and ventricular tissue; dynorphins also occur in the human heart.[30] In single cardiac myocytes, Dyn A(1–17) elicited an increase of cytosolic calcium via KOR. These peptides could play an early but crucial role in ischemic tolerance; in the rabbit model, this was explained by the unique role kappa opioids provide in adrenergic regulation. Only KORs are found on presynaptic nerve terminals, and nerve terminal secretory vesicles contain dynorphin peptides. Both dynorphins and norepinephrine are released from nerve terminals during ischemia, but dynorphin activation of KOR then results in negative feedback on norepinephrine release.[23] As a governor of catecholamine stimulation during ischemia, dynorphins may reduce postischemic injury caused by deleterious, adrenergically enhanced cellular metabolism and contractile function. Nonselective blockade of opioid receptors increases the canine cardiac response to adrenergic stimulation, supporting the regulatory role of endogenous opioids. The influence of KOR agonists may thus be confined to early events in ischemic injury to temper sympathetic stimulation. However, in the isolated heart Dyn A(l–17) may exacerbate infarct size and increase hydroxyl radical production.[1] Thus, this peptide may exert opposing effects on the ischemic heart depending on concentration, exposure time, and experimental model. Finally, circulating dynorphins may contribute to pressor effects observed in hypertensive patients during episodes of stress-induced blood pressure increase.[9]

PERSPECTIVE

Dynorphins are multifunctional peptides acting through different receptors in either a protective or toxic way. These interactions depend on the manner in which dynorphins are

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

processed and degraded. Dynorphins display multiple effects in the central nervous system and in peripheral tissues. Prodynorphin mutations could contribute to neurodegenerative diseases. In recent years, novel approaches based on the use of prodynorphin knockout mice and animal models of diseases have provided new vistas on the role played by these peptides as modulators of injury and disease outcome in the central nervous system and in the heart.

Chapter 219

Proenkephalin-Derived Peptides

Patricia J. McLaughlin

ABSTRACT

Proenkephalin-derived opioid peptides include the active pentapeptides [Met^5]-enkephalin and [Leu^5]-enkephalin. These peptides are processed from the preproenkephalin A gene and are distributed widely throughout the central nervous system and other nonneural systems of the body. Although these opioid peptides were initially reported to bind to classical μ and δ opioid receptors, and to function as neuromodulators, new receptors and new roles have been discovered that markedly expand their importance in maintaining mammalian homeostasis. One opioid peptide, [Met^5]-enkephalin, also termed opioid growth factor (OGF), is a potent regulator of cell proliferation, acting through a tonically active inhibitory axis, and is dependent on opioid growth factor receptor (OGFr), a novel nuclear-associated receptor. OGF uses the p16 and/or p21 cyclin-dependent inhibitory kinase pathway, and requires clathrin-mediated endocytosis for its inhibitory activity. Recently, enkephalins have been implicated in the pathogenesis of diseases including complications of diabetes, autoimmune diseases (e.g., multiple sclerosis, Crohn's), and cancer.

DISCOVERY OF THE ENKEPHALINS

The discovery of endogenous opioid peptides in 1975 by Hughes et al.[9] followed the identification of native opioid receptors in the brain and gastrointestinal tract that occurred in 1973 in three different laboratories.[19,22,25] With the new approach of using radioactive ligand binding, brain extracts containing opioid-like activity were isolated and two enkephalins, [Met^5]-enkephalin and [Leu^5]-enkephalin, were identified that mimicked morphine in a manner that was blocked by the opioid antagonist naloxone.[24] [Met^5]-enkephalin has the amino acid structure of Tyr-Gly-Gly-Phe-Met (i.e., YGGFM), whereas [Leu^5]-enkephalin differs in the fifth amino acid position by having a leucine molecule in place of methionine (i.e., YGGFL).

In addition to the pentapeptides, there are many larger peptide fragments that include all or some of the enkephalin sequence. Some of these larger peptides (e.g., octapeptide) have functions similar to that of the pentapeptides, whereas others do not resemble the neurotransmitter functions of methionine or leucine enkephalin. Numerous derivatives have been synthesized that deleted an amino acid, added a chemical modification, and/or reoriented the amino acids to alter their function.[24] However, to date, the pentapeptides remain the most active byproducts of preproenkephalin. The tyrosine and glycine residues have potential to function in many other nonenkephalinergic functions suggesting that the original enkephalins are members of, and play a role in, powerful dopaminergic, glycinergic, and enkephalinergic pathways.

STRUCTURE OF THE PRECURSOR GENE

The gene for the enkephalin pentapeptides is preproenkephalin A (PPE)[18] from which both [Met^5]-enkephalin and [Leu^5]-enkephalin are derived. Under normal biosynthesis, six copies of [Met^5]-enkephalin are produced and one copy of [Leu^5]-enkephalin. The opioid products from all three genes associated with endogenous opioids (proopiomelanocortin, prodynorphin, and proenkephalin) share an N-terminal core sequence but have different C-terminal amino acids and bind to different opioid receptors.[7] Comparison of the genes for proenkephalin, proopiomelanocortin (POMC), and prodynorphin indicates a highly conserved open reading frame with nearly 90% of the open reading frame in each gene being coded on a single, terminal exonr.[7]

DISTRIBUTION OF ENKEPHALIN mRNA AND PEPTIDE

Autoradiographic studies revealing the distribution of enkephalins were integral in the process of isolating and characterizing them. Initially, their virtual coexistence with opioid receptors was a key factor in their identification. The use of autoradiographic studies to determine the location of receptors provided a good estimate of enkephalin distribution.[22] Once the peptides were isolated and purified, antibodies were produced that facilitated the visualization of enkephalins.[24] Early immunohistochemical studies detected

enkephalins in axon terminals and cell bodies, and these observations strongly supported the role of the enkephalins as neurotransmitters,[8] as did the presence of enkephalins in small interneurons of the spinal cord. Not until the advent of highly specific antisera for each peptide could a distinct location of [Met^5]-enkephalin be discerned from that for [Leu^5]-enkephalin, and the wide distribution of these peptides be fully appreciated.

Although each pentapeptide has distinct locations wherein there are enriched pools of peptide such as the [Met^5]-enkephalin-enriched hippocampus and thalamus, many neuronal populations share both peptides and support the concept of "redundant" expression, whereby either peptide can function if one or the other is defective. [Met^5]-enkephalin is located in the CNS structures including globus pallidus, hypothalamus, periaquaductal gray area, amygdala, and spinal cord. Because the two pentapeptides differ by only one amino acid that is coded by only one different base pair, it can be conjectured how the two peptides might be colocalized. PPE gene expression has been identified predominately in the posterior pituitary unlike POMC gene expression which is found in the anterior pituitary, and in the spinal cord, and sympathetic nervous system. However, gene expression of preproenkephalin has been detected by Northern blot analysis and/or *in situ* hybridization studies in many other noncentral nervous system structures such as the adrenal medulla, ocular tissue, and gastrointestinal system including pancreas and intestine, cardiovascular system, and the placenta.[15,35] In many cases, the gene expression of PPE may coincide with the presence of the smaller peptides in a variety of nonneural tissues, including neoplasia.

PROCESSING

The PPE gene undergoes transcription, RNA processing, and translation to the preprohormone and prohormone of the same name—preproenkephalin A and proenkephalin, respectively. This prohormone undergoes further proteolysis and peptide cleavage to give rise to a variety of active proteins including [Leu^5]-enkephalin, [Met^5]-enkephalin, Met-enkephalin-Arg-Phe (active heptapeptide), and an octapeptide termed proenkephalin. PPE codes for six copies of [Met^5]-enkephalin and one copy of [Leu^5]-enkephalin, and the two pentapeptides have received the most attention for their widespread distribution and multifunctionality. The primary site for processing of these peptides is within secretory granules of the Golgi apparatus, and typically the cleavage occurs between pairs of basic amino acids such as Arg–Arg, Arg–Lys, and Lys–Lys.

Despite differences in phosphorylation and/or post-translational processing, the enkephalins share the same four initial amino acids—tyrosine, glycine, glycine, and phenyalanine (YGGF)—with the N-terminus signifying distinctions in the resulting peptides. Processing of the prohormones is an ongoing event in order to sustain levels of rapid degradable peptides, which have been shown to biodegrade within minutes. In the case of enkephalins, hydrolysis and cleavage of the tyrosine–glycine bond is an initial catabolic step. Further degradation occurs when amino peptidase or nonspecific enkephalinases carve up the pentapeptides into 2, 3, or 4 amino acids, each of which retain some biological activity and serve as signaling entities or as precursors to inhibitory neurotransmitters.[14] Two aminopeptidases termed NAP and NAP-2 are responsible for the tissue degradation of these peptides. Additionally, aminopeptidases CD10 and CD13 are specific membrane peptidases reportedly in abundance in plasma and responsible for the very short half-lives of enkephalins ranging from 2 to 5 min in circulating blood.[29]

A discussion on the processing of opioid genes would be remiss if gene duplication from an evolutionary viewpoint was not mentioned.[7] The striking similarity in the genes for POMC, prodynorphin, and proenkephalin, and their products suggests that gene duplication leads to the formation of gene families in which there was some divergence in function, as well as duplication of functional end products, throughout phylogenetic development. There are many examples showing that peptides from one or more of the opioid genes (i.e., prodynorphin and proenkephalin genes) serve the same function (e.g., as analgesic molecules) in the same or different region of the central nervous system.

RECEPTORS

Classical Opioid Receptors

Opioid receptors were identified by three independent teams of investigators who, at about the same time, observed specific and saturable binding of radioactively labeled opiates to membrane receptors in the nervous tissue.[19,22,25] Further biochemical studies of the receptors identified the specific opioid binding sites as members of the rhodopsin-like 7 transmembrane G-coupled-signaling molecule.[15,24] Molecular cloning of the three classical receptors revealed homology among all receptors at both the gene and protein level, with 60% amino acid sequence identity.[11] Distinctions in the receptors seem to be a result of small changes in the N-terminal domains. Subsequent studies were able to readily generate knockout animals lacking in a specific mu, delta, or kappa opioid receptor,[11] and this enabled determination of selective, or at least somewhat specific, agonists for each receptor. Enkephalins seem to be more ubiquitous in their binding capability and thus are effective agonists with different affinities for several receptors, each having different functions. Methionine enkephalin binds predominantly to δ (delta) or μ (mu) opioid receptors, of which there are several subsets

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

with various terminology including DOR1, DOR2 or δ_1, δ_2 and MOR1, MOR2 or μ_1, μ_2. The coupling of enkephalins to mu and delta opioid receptors confers the physiological cellular response and in this case results in hyperpolarization and subsequent inhibition of neurons, whereas agonist-activated kappa opioid receptors seem to possess both inhibitory and activated signaling pathways. The interaction between endogenous opioid agonists and their receptors activates transduction pathways that result in intracellular events such as calcium concentration changes, increased calcium influx into cells, increases in cGMP levels, and inhibition of phosphotidylinositol production.[24] This cascade of events is similar regardless of the peptide and receptor pairing. Classical opioid receptors for enkephalins are located throughout the body but are found in concentrated regions primarily in the olfactory system, neocortex, dorsal horn of the CNS, primary afferent terminals, and the limbic nuclei. Mu opioid receptors are historically associated with pain mediation and are distributed throughout the central and peripheral nervous system. Delta opioid receptors have also been identified in cardiovascular tissues, cancerous cells, gastrointestinal tract, and a variety of other nonneural related cells and tissues,[24] and thus their activation by enkephalins broadens the role of these peptides and their receptors in other physiological and pathological functions.

Along with the natural endogenous ligands, there are several well-known exogenous agonist ligands including DPDPE ([D-Pen^2, D-Pen^2]enkephalin), DADLE (D-ala^2, D-Leu^5]enkephalin), DSLET ([D-Ser^2, Leu^5]enkephalin), and DTLET ([D-threonine^2, Leu^5]enkephalin), deltorphin I (Tyr-D-Ala-Phe-Asp-Val-Val-Gly-NH_2), and deltorphin II (Tyr-D-Ala-Phe-Glu-Val-Val-Gly-NH_2). Antagonists for δ and μ receptors, and thus for blocking the action of enkephalins, include nonspecific antagonists such as naloxone, naltrexone, and BNTX (7-benzylidenealtrexone maleate), and more specific antagonists such as naltrindole, ICI-174,864, norbinaltrophimine (GNTI), and the synthetic peptides CTAP and CTOP. The range of antagonists and agonists that activate opioid receptors continues to grow, supporting their breadth of presence and function in mammalian homeostasis.

Nonclassical Opioid Receptor—Opioid Growth Factor Receptor (OGFr)

In addition to the classical δ and μ receptors serving as binding sites for enkephalins, the opioid growth factor receptor (OGFr), originally termed the zeta (ζ) opioid receptor, has been identified, isolated, characterized, cloned, and sequenced in mouse, rat, and human.[34] OGFr was initially discovered by pharmacological studies with radioactively labeled OGF in binding assays of developing rat brain;[34] specific and saturable binding, with a one-site model of kinetics was identified in the nuclear enriched fraction of postnatal rat brain and cerebellar homogenates. Subcellular fractionation studies showed that the OGFr is an integral membrane protein associated with the nucleus.[34] Antibodies generated to a binding fragment of OGFr facilitated the cloning and sequencing of this receptor in human and rodent.[33,34] Chromosomal identification of OGFr in humans links it to chromosome 20q13.3.[33]

Classical opioid receptors, predominately μ and δ, and the OGFr differ from each other in a variety of structural and molecular characteristics.[33,34] The commonality between them is their hallmark opioid pharmacology. That is, their ability to bind the same endogenous opioid peptide in a specific and saturable manner, and to do so, in a naloxone-reversible manner. Binding to OGFr is dependent on protein concentration, time, temperature, and pH, was sensitive to 100 nM Na^+, Ca^{2+}, and Mg^{2+}, but is not markedly reduced by the addition of guanyl nucleotides such as GppNHp. Optimal binding to the OGFr requires protease inhibitors and pretreatment of the cell homogenates; trypsin markedly reduces [^{3}H]-[Met^5]-enkephalin binding, suggesting that the binding site is proteinaceous in character. Displacement experiments indicate that [Met^5]-enkephalin, but not [Leu^5]-enkephalin, is the most potent displacer of [^{3}H]-[Met^5]-enkephalin, although [Met^5, Arg^6, Gly^7, Leu^8]-enkephalin and [D-Ala^5, D-Leu^6]-enkephalin also have K_is within approximately 3-fold that of [Met^5]-enkephalin in whole-cell homogenate preparations. Drug displacement studies reveal a requirement of an N-terminus tyrosine group. Moreover, binding of radiolabeled [Met^5]-enkephalin displayed stereospecificity, with (−)-naloxone being 18-fold more potent than (+)-naloxone. The genetic profile for OGFr and the subcellular location for this receptor provide distinctions between classical opioid receptors and OGFr. The molecular and protein structures of OGFr have little resemblance to that of any classical opioid receptor and have no significant homologies to known domains or functional motifs with the exception of a bipartite nuclear localization signal. Immunoelectron microscopy and immunocytochemistry investigations, including colocalization studies, have detected OGFr on the outer nuclear envelope where it interfaces with OGF.[32] It is currently postulated that the peptide–receptor complex associates with karyopherin, translocates through the nuclear pore and can be observed in concert with the inner nuclear matrix or at the periphery of nuclear heterochromatin. By immunoelectron microscopy and postembedding technique, double labeling experiments have revealed that complexes of OGF–OGFr colocalize on the outer nuclear envelope, in the paranuclear cytoplasm, perpendicular to the nuclear envelope in a putative nuclear pore complex, and in the nucleus adjacent to heterochromatin.[32] These results support the existence of an additional receptor for the endogenous peptide [Met^5]-enkephalin (i.e., OGF), and also indicate that

signal transduction for cell proliferation (discussed below) seems to involve an OGF–OGFr complex that interfaces with chromatin in the nucleus.

OGFr Location and Function

Complexes of OGF–OGFr are colocalized on the outer nuclear envelope, in the paranuclear cytoplasm, and have been visualized perpendicular to the nuclear envelope in a putative nuclear pore complex.[32] OGFr is frequently identified associated with karyopherin β. These immunoultrastructural studies suggest that OGFr resides on the outer nuclear envelop where OGF interacts with the receptor rather than on the cytoplasmic membrane as documented for classical opioid receptors. The OGF-OGFr complex translocates between cytoplasm and nucleus through the nuclear localization pore,[32] using one of three nuclear localization signals found in OGFr to facilitate this process. Molecular biology studies taking advantage of siRNA technology to systematically inactivate each nuclear localization signal, and monitor OGFr using OGFr–eGFP transfected cell lines, confirmed this requirement for activity at the OGFr site.

The specific transport factors required for movement of OGF complexed with OGFr from cytoplasm to the nucleus have been identified by siRNA knockdown studies of karyopherin α1, α2, α3, α4, α6, karyopherin β2, and Ran. Regulation of cell proliferation by the OGF–OGFr axis seems to be dependent on nucleocytoplasmic transport by karyopherin β1 as well as the RanGTP/RanGDP gradient across the nuclear envelope. Other adaptor molecules related to karyopherin do not seem to be essential for the passage and function of this enkephalin-based axis.[6]

Molecular Regulation of OGFr

The bioactive OGF–OGFr axis tonically regulates the growth of neoplasia and normal proliferating cells. The repercussions of amplifying OGFr were investigated in several human cancers including ovarian, pancreatic adenocarcinoma and squamous cell carcinoma of the head and neck.[16] pcDNA3.1+ plasmids engineered with OGFr were transfected into cell lines and studied both *in vitro* and *in vivo*. Saturable binding of OGFr was increased 2- to 8-fold in head and neck cancer cell lines overexpressing OGFr relative to wildtype cancer cells. Proliferation rates were reduced up to 68% in these OGFr clonal lines relative to wildtype, with doubling times being nearly two-thirds longer. The addition of exogenous OGF further reduced replication in these neoplasias suggesting that the OGFr receptor is integral to cell division and that genetic modifications of receptor and/or regulation of endogenous opioids, specifically OGF (i.e., methionine enkephalin) may be effective as biotherapies.

BIOLOGICAL ACTIVITY OF ENKEPHALINS

Enkephalins as Neurotransmitters

The role of enkephalins has been widely studied and continues to develop as more specific antagonists and agonists are discovered. In general, enkephalins play a role in neurotransmission and pain modulation.[1] Their role as neurotransmitters was initially determined from localization studies in which immunohistochemical mapping revealed that enkephalins were in close proximity to autoradiographic mapping of opiate receptors.[21,24] The cellular localization of enkephalin suggested that its role was to act on opiate receptors positioned on terminals of sensory pain fibers and inhibit the release of neurotransmitters such as substance P,[17] vasopressin, or dopamine. Along with the inhibitory role of enkephalins to prevent release of transmitters is the modulatory role of enkephalins to alter calcium influx.[17] The direct hyperpolarization of neurons by enkephalins also supports their inclusion in the long list of neurotransmitters. Nonetheless, enkephalins have been implicated in a variety of functions in addition to "classic" neurotransmission.

Enkephalins as Neuromodulators

Total body mapping of enkephalin-processing neurons and their specific locations have been aided by immunohistochemistry.[24] Enkephalin-enriched neuronal regions process inhibitory sensory information; however, enkephalins are also modulators of synaptic activity outside of being neurotransmitters. In regions of the spinal cord (e.g., substantia gelatinosa), pain perception is integrated by enkephalin-enriched fiber tracts. The periaqueductal gray region is rich in enkephalins that resolve analgesia and inhibit the release of excitatory neurotransmitters.[24] High concentrations of enkephalins in the hypothalamus suggest a role for endocrine modulation. Other major enkephalin pathways are associated with motor activity, intestinal tract motility, and peristalsis, limbic system regulation of emotional behavioral, and the hypothalamic neuroendocrine axis.

Studies on enkephalins and endorphins as modulators of pain and addiction are currently an active area of research.[3] Although many of the reward pathways associated with addiction and dependence involve mu or kappa opioid receptors, the distinctions in addictive properties between exogenous agonists such as morphine and endogenous agonists such as enkephalins are still unclear. Nicotine addiction may involve endogenous enkephalins and endorphins acting on mu opioid receptors to inhibit nicotine-rewarding effects, and play a role in the development of physical dependence,[3] whereas prodynorphin peptides participate in nicotine aversive events. Animal studies using mu and kappa knockout mice have reported attenuated self-administration of alcohol in animals without these opioid receptors.[11]

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

The functional role of enkephalins has expanded into the physiology of respiration. Krajnik[13] has mapped proenkephalin, and methionine enkephalin, as well as processing enzymes to alveolar macrophages, submucosal glands, and pulmonary neuroendocrine cells of bronchial epithelium. The precise functional roles of the opioid peptides are still under investigation.

Enkephalins as Growth Factors

During the early 1980s, the hypothesis was put forth that endogenous opioid peptides, particularly [Met^5]-enkephalin are involved in growth regulation of normal and abnormal cells and tissues. [Met^5]-enkephalin was renamed OGF to distinguish the function of the peptide as a neuromodulator[1] from that of an inhibitory growth factor.[28,34,35] In support of this hypothesis, many reports have put forth evidence to support the role of OGF in governing the growth of developing, neoplastic, renewing, and healing tissues, with documentation of growth regulation extending from prokaryotes through higher orders of eukaryotes.[2,16,26,29,34,35] OGF is a potent, reversible, species unspecific, tissue nonspecific negative growth regulator with action that is opioid receptor mediated.[34] The peptide is autocrine and paracrine produced, secreted, and effective at concentrations consistent with physiological behavior. OGF is rapid in biologic action and obedient to intrinsic rhythms of the cell (e.g., circadian rhythm).

Our knowledge and understanding of OGF as a growth factor emanates from investigations conducted in the 1980s on normal neural tissue, namely, the developing rat cerebellum and/or brain, and abnormal neural tissues, namely, neuroblastoma cells grown *in vitro* or transplanted into nude mice to produce tumors.[28–31] Nearly all of the characteristics of OGF as an inhibitory growth factor have been reproduced in all three models (i.e., normal brain, cancer cells *in vitro*, and tumors). To briefly summarize, OGF inhibits DNA synthesis in a receptor-mediated (i.e., OGFr) manner. Continuous blockade of the OGF–OGFr interaction results in accelerated proliferation. OGF has been detected immunologically in tissues where the growth effects have been documented, and the specificity of OGF has been studied extensively. In murine neuroblastoma cells (both *in vitro* and tumor transplantation),[34] and in subsequent studies with the developing rat cerebellum,[28,29] [Met^5]-enkephalin (OGF) was discovered to be the most potent opioid peptide associated with growth. In the case of tumor cells, peptide concentrations as low as 10^{-10} M inhibit the growth of log-phase S20Y neuroblastoma cells exposed to drug for 48 hr. Other PPE peptide derivatives such as the heptapeptide ([Met^5, Arg^6, Phe7]-enkephalin), octapeptide/proenkephalin ([Met^5, Arg^6, Gly^7, Leu^8]-enkephalin), and [Leu^5]-enkephalin also exhibited inhibitory properties but to a much lesser extent. The chemical structure of [Met^5]-enkephalin is also selective and specific. For example, no changes in cell growth occur when the amino acids Tyr^1 or Met^5 are deleted or when smaller fragments of the [Met^5]-enkephalin molecule such as Tyr–Gly or Tyr-Gly-Gly are used. Alterations in the basic structure of [Met^5]-enkephalin by N-terminal modifications (e.g., [Met^5]-enkephalinamide, [Met^5]-enkephalin sulfoxide) yield compounds that are ineffective in growth regulation. Other opioid peptides and analogs related to the prodynorphin and POMC genes (e.g., β-endorphin, α-neo-endorphin, dynorphin B/rimorphin), compounds selective for μ, δ, or κ opioid receptors (e.g., β-FNA, DADLE, EKC), have no significant influence on cultured cells even at concentrations as great as 10^{-6} M. In a wide variety of cells and tissues examined (e.g., colon cancer, heart, squamous cell carcinoma of the head and neck, pancreatic cancer, developing nervous system) in humans and animals, both *in vitro* and *in vivo*, [Met^5]-enkephalin has been identified as the primary opioid peptide involved with growth.

Opioid modulation of cell proliferation in zebra finches[12] confirms earlier studies that opioid antagonist treatment of cultured ventricular zone neurons enriched for enkephalin resulted in increased cell proliferation as measured by 5-bromo-2-deoxyuridine incorporation. *In vivo* studies with administration of methionine enkephalin to the finches directly resulted in decreased neurogenesis and gliogenesis in the ventricular brain regions.

Peptide Location

The subcellular distribution of methionine enkephalin in epithelium reveals that this neuropeptide, and its receptor OGFr, colocalize on the paranuclear cytoplasm and in the nuclei of keratinocytes in the *stratum basale*. Immunoelectron microscopic studies with 5- and 10-nm gold particles show that OGF is not always bound to the OGFr,[32] which in turn is associated with the outer nuclear envelope (see above for more discussion of OGFr transport).

Because of the ubiquitous nature of the presence of OGF in normal and neoplastic cells, human and vertebrate, as well as the quickness of effect observed after addition of OGF, the passage of OGF into cells was studied with OGF labeled with 5,6-tetramethylrhodamine (RhoOGF). In a cell line that is devoid of classical opioid receptors, COS-7 (African green monkey kidney cells), OGF internalization is temperature dependent. Within 15 min of adding RhoOGF to culture, it is detected in the cytoplasm of cells incubated at 37 °C, and within the nucleus after 30 min. No movement is detected at 4 °C. OGF enters cells by active transport with internalization being dependent on clathrin-mediated endocytosis.[5]

Mechanisms of Action

OGF is a tonic, stereospecific, reversible, noncytotoxic peptide. Studies analyzing the effect of OGF on migration, chemotaxis, invasion, or adhesion of multiple types of cancer cells reveal that at concentrations ranging from 10^{-4} to 10^{-6} M, OGF has no effect on migration or invasion. Moreover, OGF does not change adhesion properties to collage I, collage IV, fibronectin, laminin, or vitronection. Other endogenous opioids and at least one other proenkephalin-derived peptide—leucine enkephalin—evaluated under the same conditions have no effect on migration, invasion, or adhesion.[31]

OGF is not cytotoxic and does not induce apoptosis as studied by Annexin V and TUNEL assays in a variety of neoplasias, nor does it seem to play a major role in differentiation.[30] Neither process outgrowth nor distributions of βIII-tubulin, involucrin, or actin were altered by OGF treatment of neural and nonneural human cancer cell lines.[30]

One target for the mechanism of OGF activity seems to be cell replication. In-depth cell cycle analysis shows that the G_0/S phases of the cell cycle are targeted by the inhibitory effects of OGF.[4] Specifically, OGF down regulation of the retinoblastoma protein by upregulation of the cyclin-dependent inhibitory kinases p16 or p21 leads to the inhibitory activity of the opioid peptide. Different cancers use separate CKI pathways. Squamous cell carcinoma of the head and neck uses the p16 CKI pathway, whereas pancreatic adenocarcinoma uses the p21 pathway. Normal cell lines including human umbilical vein endothelial cells, human epidermal keratinocytes, human dermal fibroblasts, and mesenchymal stem cells are depressed in replication by OGF modulation of the $p16^{INK4a}$ and $p21^{WAF1/CIP1}$ pathways; OGF did not affect p15, p18, p19, or p27 protein expression in either cell type. Exploration of the involved pathways show that OGF decreases the phosphorylation of retinoblastoma protein without decreasing total Rb protein, and reduces Cdk4 or Cdk2, kinase activity, but not total Cdk4 or Cdk2.[4] Upstream of these kinases, OGF increases the cyclin-dependent kinase inhibitors p16 or p21 depending on the presence of CKI in cell lines.[4] Inhibition of p16 (INK4a) activation by p16-specific siRNAs blocks the repression action of OGF in head and neck cancer cell lines, whereas this pathway is mutated/deleted in pancreatic adenocarcinoma. The p21 CKI pathway functions to activate OGF repression in pancreatic cancer cells.

PATHOPHYSIOLOGICAL IMPLICATIONS

The basic science and clinical implications of the enkephalins are wide ranging and have enormous potential. The native pentapeptides are not only produced by multiple genes, but they also have divergent functions and different sites of activity (i.e., receptors). Known to be conserved phylogenetically enkephalins play a role in two very necessary processes of animal survival—growth and neurotransmission. As such, enkephalins have a broad reaching impact on maintaining mammalian homeostasis and play a role in reversing disease states as well. OGFr mRNA has been detected to a certain level in all organs of adult rodents. It may be that homeostatic functions in these organs are minimal but that the genetic machinery is retained for cell restoration in the case of injury. The OGF–OGFr axis has been shown to be involved in regulation of neoplasia, wound healing, normal homeostatic functions, embryonic development, angiogenesis, with other areas of activity possibly not yet discovered. Mediation of enkephalin activity and harnessing the inhibitory action of enkephalins for therapeutic treatment and/or diagnostics has great clinical potential.

Role in Immunobiology and Autoimmune Diseases

OGF represses the incidence and magnitude of a mouse model of multiple sclerosis, myelin oligodendrocytic glycoprotein (MOG)-induced autoimmune encephalomyelitis (EAE). Daily injections of OGF (10 mg/kg, i.p.) initiated at the time of disease induction delay appearance of EAE behavior and attenuated behavioral signs for 60 days.[20] Neuropathology related to EAE including activated astrocytes, neuronal damage, and demyelination is significantly reduced in OGF treated mice at 10, 30, and 60 days after the induction of disease.[20]

Based on these findings, the role of methionine enkephalin on T and B lymphocyte proliferation was evaluated in culture. Lymphocytes were isolated from the spleens of normal adult male mice, dissociated and seeded into culture. Cells were stimulated with lipopolysaccharide to activate B cells or with phytohemagglutin to activate T cells. Both OGF peptide and receptor were detected on T and B lymphocytes by immunohistochemistry, and OGF treatment (10^{-6} M) markedly depressed the number of stimulated T and B cells.[27] The inhibitory action of OGF is mediated by the OGFr axis as siRNA knockdown of the mu, delta, and kappa opioid receptors does not alter the repressive effects of OGF on T and B cell number. The function of OGF on T and B cell activities *in vivo* in cells isolated from normal mice, as well as mice with autoimmune diseases such as multiple sclerosis and Crohn's disease, is currently being studied. Whether the role of OGF in autoimmunity is strictly related to proliferation, or also involves other modulatory activity as described more than two decades ago,[1] is unclear.

CLINICAL STUDIES WITH OGF

With the widespread, off-label use of low dosages of naltrexone (i.e., LDN), shown to upregulate enkephalins and

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

opioid receptors, the importance of enkephalins for therapeutic treatment of both autoimmune diseases, as well as cancer, has taken a more prominent place in biology. In particular, exogenously administered OGF has been shown to lack toxicity when given intravenously to pancreatic patients. In this Phase I trial, the end-stage patients had failed all standard therapy, yet some remarkable observations were made regarding improved life style and survival time supporting further study with OGF. Phase II clinical trials with 250 μg/kg of OGF intravenously showed clinical benefit to 53% of the patients in comparison with patients receiving gemcitabine or 5-fluorouracil.[23] OGF-treated patients survived three times longer than untreated patients, and no adverse effects were noted. Clinical trials with OGF alone or in combination with other chemotherapy are in various stages for treatment of hepatocellular carcinoma and squamous cell carcinoma of the head and neck.

Clinical trials with low dosages of naltrexone that upregulate the production of enkephalins and receptors have also shown promise in the treatment of autoimmune diseases such as Crohn's, lupus, and multiple sclerosis. It is evident at these early stages of clinical research that both direct therapy with enkephalins (i.e., OGF), and indirect treatment using LDN, have shown positive outcomes for these low-cost opioid peptide-based biotherapeutics.

Chapter 220

Activity-Dependent Neuroprotective Protein (ADNP) and Davunetide (NAP)

I. Gozes and P.W. Baas

ABSTRACT

Activity-dependent neuroprotective protein (ADNP) is essential for mouse brain formation and embryogenesis. At the neuronal level, ADNP is important for neurite outgrowth. ADNP haploinsuffiency in mice results in a neurodegenerative phenotype associated with age-dependent cognitive and social deficits, neurofibrillary tangle formation, and neuronal death. ADNP is a member of a protein family including ADNP2, which is important for cellular survival. The ratio of expression of ADNP and ADNP2 is dysregulated in schizophrenia. ADNP-binding partners include heterochromatin protein alpha1 and members of the chromatin remodeling complex, SWI/SNF—a complex that is important for neurodifferentiation. NAP, a peptide derived from ADNP, partially protects against ADNP deficiency. NAP (subsequently named davunetide) exhibits potent neurotrophic/neuroprotective action in multiple models of neurodegenerative disorders, protecting the microtubule cytoskeleton against breakdown. Davunetide is currently in phase II/III clinical studies in Progressive Supranuclear Palsy, a neurodegenerative disease that is characterized by neurofibrillary tangle formation.

DISCOVERY AND STRUCTURE OF ADNP AND DAVUNETIDE (NAP)

Activity-dependent neuroprotective protein (ADNP) was discovered in the laboratory of Illana Gozes (one of the authors of the current Book Chapter), as part of an ongoing collaboration with the laboratory of Douglas Brenneman.[1] The team originally isolated neuroprotective proteins from conditioned medium of astrocytes exposed to the major neuropeptide vasoactive intestinal peptide (VIP). The working hypothesis was that neuronal VIP activates the brain support cells (in this case astrocytes) to provide neuronal upkeep, enhancing the crosstalk between neurons and glia in the brain.[3] Thus, activity-dependent neurotrophic factor (ADNF) was discovered. In dissecting the ADNF structure, a small peptide, ADNF-9 (SAL) was identified, which provided the smallest epitope within ADNF that exhibits potent neuroprotective characteristics. ADNF antibodies recognizing ADNF-9 were further used to identify similar epitopes in other proteins, allowing the identification and isolation of ADNP by expression cloning from mouse P19 teratocarcinoma cells induced to differentiate into neurons and glial cells.[1] The ADNF-9-like epitope (S**A**LLR**SIP**A) on ADNP was identified as NAP (and later given the generic name, davunetide)—N**A**PV**SIP**Q. The shared amino acids between ADNF-9 and NAP are shown in bold type.

The cloning of the human ADNP (hADNP) gene[33] from a fetal brain cDNA library was followed by bioinformatic analysis and showed 90% identity with the mouse sequence at the mRNA level, including several single nucleotide polymorphic sites. The deduced protein structure contained nine zinc fingers, a proline-rich region, a nuclear bipartite localization signal, and a homeobox domain profile, suggesting a transcription factor function. Further comparative analysis identified an ADNP paralog (33% identity and 46% similarity), indicating that these genes belong to a novel protein family with a nine-zinc finger motif followed by a homeobox domain. However, the ADNP2 protein does not contain the NAP motif. Importantly, within its homeobox profile, ADNP contains a nuclear export signal and an import signal, signifying possible extracellular functions. Further, a potential interaction with cytoplasmic microtubules has been observed,[10] and this interaction provides part of the basis for our proposed mode of action of NAP to positively impact neurons and glial cells of diseased or injured animals and humans.

THE ADNP GENE

The hADNP gene structure spans approximately 40 kb and includes five exons and four introns with alternative splicing of an untranslated second exon. The hADNP gene was mapped to chromosome 20q12–13.2, a region associated with aggressive tumor growth, frequently amplified in many neoplasias, including breast, bladder, ovarian, pancreatic, and colon cancers.[33] In depth analysis of the ADNP gene chromosome locus shows that it is flanked by type-II-diabetes-linked genes (http://ensembl.rzpd.de/Homo_sapiens/contigview?c_20:48584983;w_50000.5). For example, the ADNP gene is separated by 3438 bp from DPM1 (D20S196; http://www.ncbi.nlm.nih.gov/genome/sts/sts.cgi?uid_57739) that has been linked to type-II diabetes (p _ 0.00010). In this respect, type-II diabetes has been associated with poor cognitive performance and dementia, particularly in elderly patients.[15,32]

Structural comparison of the hADNP gene versus human ADNP2 gene (chromosome 18q23) (NCBI, UCSC, and Gozes published data[33]) revealed five exons for the ADNP gene (with exon 2 that can be alternatively spliced) and four exons for ADNP2. EMBOSS Pairwise Alignment Algorithms in the EMBL-EBI was used showing that exons 1 and 2 in ADNP correlate with exon 1 in ADNP2, exon 3 of ADNP with exon 2 of ADNP2, exon 4 of ADNP with exon 3 of ADNP2, and exon 5 of ADNP with exon 4 of ADNP2. In both cases, the major protein coding domain is on the last exon.[16]

ADNP EXPRESSION

Mouse ADNP RNA is expressed at the time of neural tube closure, detected at E7.5 and increased on E9.5. Expression is augmented in the brain (E12.5), sustained throughout embryogenesis, and regulated by VIP.[25] ADNP2 expression mimicked in part the expression pattern of ADNP. In non-differentiated P19 cells, there is a very close linear correlation between ADNP and ADNP2 mRNA levels ($r = 0.999$, $p = 0.001$). In the neurodifferentiated state, the expression level of both ADNP and ADNP2,[19,16] is increased and a significant correlation is maintained ($r = 0.98$, $p = 0.001$).[8] ADNP RNA expression is enriched in the adult mouse hippocampus and cerebellum[1] in comparison with other tested tissues. In the adult human, enrichment is also seen in the cerebellum, the cortex, skeletal muscle, kidney, and placenta.[33]

Alcohol exposure during embryonic development results in ADNP dysregulation as follows.[26] When timed, pregnant C57Bl6/J mice were treated with alcohol on day 8 of pregnancy, embryonic ADNP mRNA was significantly increased in the ethanol-exposed embryos compared with control embryos, 1 and 10 days after ethanol exposure. The authors explained this increase as a potential compensatory mechanism, given the neuroprotective activity of ADNP. In a study of chronic rather than acute ethanol exposure,[24] female rats received liquid diet (ethanol or control) for a minimum of 40 days before mating with male rats. After mating, the dams were placed in separate cages and kept on ethanol or control liquid diet during the gestation. Primary cortical astrocytes prepared from gestation day 21 fetuses showed a reduction in ADNP mRNA, which was associated with decreased neurotrophic/neuroprotective activity.[24]

Another study suggested that the anesthetic gas xenon that provides tissue protection also regulates ADNP expression in neonatal rat brain. It was further suggested that the differential expression of ADNP in the rat neonatal brain may account for the preconditioning and neuroprotective effects exerted by xenon.[35]

Closed head injury is associated with delayed increases in ADNP mRNA levels one month after the injury. Similarly, closed head injury is associated with a delayed increase in the expression of the immune cell surface glycoprotein Mac-1 (CD11B antigen). By immunocytochemistry, the increase in ADNP was localized to microglia and astrocyte-like cells.[14] The increase in ADNP in injured brains is suggested to be a part of an endogenous compensatory mechanism.

By using kainic acid (KA)-induced epileptic seizures, the regulation of ADNP expression in the hippocampus was suggested to be associated with the nitric oxide (NO)-cGMP pathway. Specifically, inhibitors of NO synthase (NOS) or soluble guanylyl cyclase (sGC) activity reduce ADNP expression in the absence of seizures when measured 30 h after dosing. KA-induced seizures increase neuronal NOS in neurons and inducible NOS in glia cells and suppress ADNP-immunoreactivity in the hippocampus. Under those conditions, repeated treatments with the NOS inhibitor N(G)-nitro-L: -arginine methyl ester (L: -NAME) before KA cause increases in ADNP mRNA expression in granule cells as measured 3 h after the KA treatment.[5] Interestingly, ADNP expression was suggested to exert autocrine regulation.[18]

As brain protection may be dysregulated in schizophrenia, the Gozes laboratory evaluated a possible involvement of ADNP and ADNP2 in the pathophysiology of schizophrenia in humans, measuring relative brain mRNA transcripts of both proteins compared with control subjects. Quantitative real-time polymerase chain reaction in postmortem hippocampal specimens from normal control subjects exhibits a significant ADNP to ADNP2 transcript level correlation ($r = 0.931$, $p < 0.001$). By contrast, in the hippocampus of matched schizophrenia patients, this correlation ($r = 0.637$, $p = 0.014$) is significantly decreased ($p = 0.03$), mirroring disease-associated increased ADNP2 transcripts. Thus, imbalance in ADNP/ADNP2 expression in the brain may influence disease progression in schizophrenia.[8]

ADNP INTERACTING PROTEINS

Bioinformatics search identified a conserved potential heterochromatin protein1α (HP1 α) binding motif PxVxL on human, rat and mouse ADNP.[18] Nuclear proteins extracted from P19 cells using Pierce NE-PER nuclear extraction buffer (Pierce, Rockford, IL) supplemented with protease inhibitors cocktail (Sigma St. Louis, MO) were therefore used for ADNP/HP1 α immunoprecipitation using anti-ADNP (Bethyl, Montgomery, TX), HP1 α (Upstate, Lake Placid, NY) or nonspecific rabbit IgG antibodies. Using coimmunoprecipitation on differentiated and nondifferentiated P19 nuclear protein extracts, the Gozes laboratory showed that a low amount of HP1 α-like immunoreactivity is recovered after immunoprecipitation with ADNP antibodies and similarly ADNP-like immunoreactivity is recovered after immunoprecipitation with HP1 α antibodies, suggesting that HP1 α may be a binding partner of ADNP.[18] These original findings were corroborated and extended to show that HP1 recruits ADNP to H3 lysine 9 trimethylation (H3K9me3) marked pericentromeric heterochromatin for silencing of major satellite repeats.[23] In short, H3K9me3 is a histone posttranslational modification (PTM), a hallmark of pericentromeric heterochromatin. Mammalian cells contain three HP1 proteins, HP1 α, HP1 β, and HP1 γ all binding to H3K9me3 and mediating this histone PTM. The interaction of ADNP with H3K9me3 is mediated by all three HP1 isoforms *in vitro*, whereas, in cells, ADNP localization to areas of pericentromeric heterochromatin is only dependent on HP1 α and HP1 β. ADNP silencing is associated with major satellite repeats, thus regulating transcription.[23]

To further discover ADNP interacting proteins, the HEK293 human embryonic kidney cell line that allows efficient transfection with recombinant DNA was used. By using coimmunoprecipitation assays, the essential SWI/SNF (mating type switching/sucrose nonfermenting) chromatin remodeling complex is associated with ADNP. In short, in-gel protein digests and mass spectrometry identified BRG1, BAF250a, and BAF170 of the SWI/SNF chromatin remodeling complex, as proteins that coimmunoprecipitate with ADNP. This complex has been shown before to interact with HP1 α, connecting the HP1 results with the SWI/SNF interaction.[17]

ADNP BIOLOGICAL ACTIONS

The SWI/SNF complex was previously shown to be associated with neurodifferentiation. Using ADNP short hairpin RNA downregulation, the Gozes laboratory has shown microtubule reorganization and changes in cell morphology including reduction in cell process formation and cell number, using the pluripotent teratocarcinoma cell line P19 as a neuroglia differentiating model. An approximately 80% decrease in ADNP led to a substantial reduction in embryoid body formation and a reduction (~50%) in neurite numbers. These results directly associate ADNP with neuronal cell differentiation and maturation.[19] As indicated above, these morphological changes are closely associated with the SWI/SNF complex multifunctionality. Taking ADNP from the cellular scenario to the whole animal, complete knockout of ADNP results in embryonic lethality at the time of neural tube formation. Detailed analysis reveals cranial neural tube closure failure and death on E8.5–9.0 of the ADNP-knockout embryos. Oct4 expression, associated with germ-line maintenance, is markedly increased in the knockout embryos, whereas Pax6, crucial for cerebral cortex formation, is not detected in the brain primordial tissue of the ADNP-knockout embryos.[25] To further elucidate ADNP associated pathways, Affymetrix 22,690-oligonucleotide-based microarrays were used on ADNP-knockout and control mouse embryos (E9) separated completely from extra embryonic tissue.[18] More than 400 genes show significant differences in expression profiles between ADNP-deficient embryos and ADNP-expressing embryos. In detail: a group of dramatically upregulated gene transcripts in the ADNP-deficient embryos are clustered into a family encoding for proteins enriched in the visceral endoderm such as apolipoproteins, cathepsins and methallotioninins. A down-regulated gene cluster, associated with ADNP deficiency in the developing embryo, consisted of organogenesis markers including neurogenesis (Ngfr, neurogenin1, neurod1) and development of the heart (Myl2). Together, the results demonstrate the pivotal developmental role of ADNP.

Original studies have also associated ADNP with cancer growth and inhibition of ADNP expression in the cancer cells is related to reduction in cancer growth.[33]

In mouse astrocytes, partial loss in ADNP expression (ADNP haploinsufficiency) is associated with reduced capacity of the astrocytes to provide the required neuronal support.[32] Similar results were obtained with astrocytes from prenatal ethanol-exposed fetuses.[24] In the haplo insuffient mouse (ADNP+/−), the animals show cognitive deficits and age-dependent increase in tau pathology, hyperphosphorylation, and tangle-like formation emanating from astrocytes. This is coupled to age-related increase in brain cell death.[32] These findings of tau pathology are usually associated with decreased microtubule function, which are believed to be the basis of the ADNP-derived peptide—NAP (davunetide) protective activity, which protects partly against ADNP deficiencies (see below).

THE ADNP-DERIVED NEUROPROTECTIVE PEPTIDE NAP: BIOLOGICAL ACTIONS AND MICROTUBULE CONNECTION

As indicated above, NAP was discovered as a collaborative work of the laboratories of Illana Gozes and Douglas Brenneman.[1] Originally, NAP was shown to provide a

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

broad range of neuroprotection.[1] It was then shown to interact with microtubules,[7] with increased interaction with the neuron-specific beta III tubulin isotype.[6] NAP activity at substoichiometric levels suggested that it could not conceivably substitute for any known microtubule-related protein or act in a fashion similar to any known microtubule-active drug.[1,6,7] NAP also shows neurotrophic activities enhancing neurite outgrowth *in vitro*[12] and protecting synaptic structures *in vivo*.[15] It further provides protection to astrocytes both *in vitro*[7] and *in vivo*.[15]

Here, we speculate a novel mode of action, wherein NAP subtly alters the microtubule's lattice so that it interacts with microtubule-related proteins differently than it otherwise would. For example, when tau is depleted from neurons, microtubules become abnormally sensitive to the microtubule-severing protein katanin, but this abnormal sensitivity to katanin is ameliorated by treatment with NAP.[31] Theoretically, this could extend to an array of other proteins relevant to the integrity of the microtubule such as proteins that promote depolymerization (such as stathmin), stabilization (such as tau or MAP6), and degradation (such as proteases). In addition, such changes in the microtubule lattice could alter the manner by which the microtubule interacts with molecular motor proteins relevant to axonal transport.

As NAP is associated with highly potent *in vitro* activity, it is plausible that NAP modulates kinase activities leading to a cascade of events that modulate the microtubule lattice. Evidence for such a potential cascade comes from the following observations. NAP potentiates axonal outgrowth in cerebellar granule neurons by activating the sequential tyrosine phosphorylation of Fyn kinase and the scaffold protein Crk-associated substrate (Cas). Pharmacological inhibition of Fyn kinase or expression of a Fyn kinase siRNA abolishes NAP-mediated axonal outgrowth. Concentrations of ethanol that are considered to be readily attained after social drinking (25 mM ethanol) block NAP-mediated axonal outgrowth by inhibiting NAP activation of Fyn kinase and Cas.[4] Interestingly, other studies have shown interactions of Fyn kinase with tau (information freely available on the web: jcs.biologists.org/content/111/21/3167/full.pdf). These findings tie in with other *in vitro* studies associating NAP activity with the Akt and ERK (externally regulated kinase) pathways as Fyn kinase is associated with these pathways, protecting against oxidative stress. Thus, cortical neurons co-cultured with astrocytes obtained from prenatal ethanol exposed fetuses[24] have reduced dendrite number and shorter dendritic branching than neuron-control glia co-cultures. In this system, NAP significantly increases dendritic and axonal growth or branching as well as the density of the synaptic structures as stained by SNAP-25 and synaptophysin. NAP treatment also stimulates the activity of ERK and Akt in a time-dependent manner. Further, NAP increases cAMP response element-binding protein (CREB) phosphorylation, which is known to be a downstream target of the MAPK/ERK and PI-3K/Akt pathways stimulated by growth factors in neurons. CREB is an important transcription factor, and accumulating results suggest that patterns of transcription regulation represent the molecular signatures of long-term synaptic changes and memory formation, implicating NAP activity in transcriptional regulation processes associated with memory.[24]

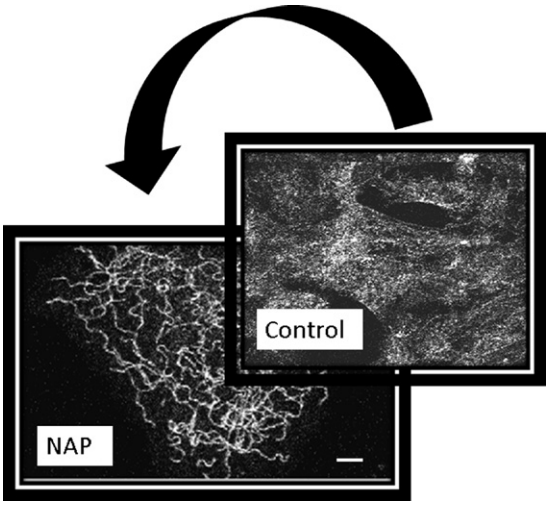

FIGURE 1 NAP and microtubule reorganization.[7] Confocal microscopy. NAP (10^{-15} M) was added to two-week-old rat cortical astrocyte cultures and incubated for 4 h. Control peptide (C2 = VLGGGSALL, 10^{-15} M) was incubated for the same time periods. Tubulin was detected with mouse monoclonal antibodies (as cited above) and secondary rhodamin-labeled goat antimouse IgG (Bars represent 20 μm), an extreme difference is shown.

Fig. 1, based on the original findings from the Gozes laboratory,[7] shows changes in the microtubule lattice in rat astrocytes after 4 h of 10^{-10} M NAP treatment. Interacting proteins, outcomes, and protection against toxicity are the subjects of future research.

CYTOSKELETON PROTECTION, *IN VITRO*

As indicated above, studies at the Gozes laboratory evaluating the mechanism of action of NAP suggested an interaction with tubulin.[7] Several follow-up studies at the same laboratory explored the ability of NAP (davunetide) to protect against microtubule disruption using a variety of microtubule poisons. These experiments in cell cultures (neuronal and glial) treated with NAP (davunetide) are as follows: [i] NAP (davunetide) treatment protected against zinc-induced toxic aggregation of tubulin.[6,7] [ii] After microtubule depolymerization in the presence of nocodazole, NAP (davunetide) treatment enhances rapid microtubule reassembly and stimulates neurite outgrowth.[11] [iii] NAP (davunetide) provides protection against microtubule

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

breakdown associated with oxygen–glucose deprivation.[35] [iv] NAP (davunetide) protects against amyloid-beta-related increases in tau hyperphosphorylation.[29] Studies from the Baas laboratory show that neurons contain sufficient levels of the microtubule-severing protein katanin to completely breakdown the axonal microtubule array if not attenuated by microtubule-associated proteins, chief of which is tau. In neurons depleted of tau, NAP (davunetide) diminishes microtubule loss resulting from katanin activity.[31]

Importantly, in various systems, NAP (davunetide) provides neurotrophic functions promoting neurite outgrowth as originally discovered *in vitro* as a collaboration with Smith-Swintosky, Gozes, Brenneman, D'Andrea, and Plata-Salaman later confirmed and reviewed.[12] Further, these authors suggested that NAP increases synapse formation by increasing synaptophysin expression, as confirmed *in vitro*,[24] leading to *in vivo* studies.

CYTOSKELETON PROTECTION, *IN VIVO*

Several collaborative studies between the Gozes laboratory and the Grigoriadis, the Rosenmann as well as the Aisen-Matusuoka laboratories extend the NAP (davunetide) protection against tau hyperphosphorylation *in vitro*[29] into animal cognitive protection in three *in vivo* transgenic lines including: [i] a model of ADNP haploinsufficiency;[32] [ii] a model of tauopathy (expressing the human double mutant tau protein [P301S;K257T] fused to the tau promotor);[28] and [iii] a triple transgenic Alzheimer's disease model that recapitulates both tau and amyloid-beta pathology.[20] [i] NAP (davunetide) protects against tau hyperphosphorylation and increases performance in the Morris water maze in the model of ADNP haploinsufficiency.[32] [ii] NAP (davunetide) protects against tau hyperphosphorylation and tangle-like formation coupled to increased performance in the water maze, in the mouse model of tauopathy.[28] [iii] NAP protects against tau hyperphosphorylation and increased performance in two cognitive tasks, habituation–dishabituation and the water maze, in the triple transgenic Alzheimer's disease model.[20]

Collaborative studies between the Gozes and the Andrieux laboratories extended NAP (davunetide) to models of deficiencies of microtubule-associated proteins other than tau. Knockout mice for MAP6 (also called STOP—stable tubule only protein) are a model for schizophrenia. Mice exhibiting STOP haploinsufficiency show schizophrenia-like symptoms (hyperactivity) that are ameliorated by chronic treatment with the antipsychotic drug, clozapine. NAP (davunetide) treatment significantly decreases hyperactivity in these STOP-deficient mice and protects visual memory in the object recognition test.[21] Further, microtubule protection is translated to a broad range of neuroprotective activities *in vivo*.

BROAD NEUROPROTECTIVE SCOPE

Together, the above-mentioned reports suggest a broad neuroprotective scope for NAP (davunetide). More recent (2009–2011) publications further extend the scope of NAP (davunetide) neuroprotection as follows: [i] In a rat model of kainic acid toxicity mimicking epilepsy, the Gozes laboratory in collaboration with the Sapolsky laboratory at Stanford showed that NAP (davunetide) treatment protects against kainic-acid-induced hippocampal (CA3) neuronal death.[34] These results extend the neuroprotective scope of NAP (davunetide) and showed parallel regulation of key genes associated with proconvulsant properties and with long-lasting changes that underlie the epileptic state. [ii] In mice overexpressing alpha-synuclein—a model for idiopathic Parkinson disease—intranasal NAP (davunetide) improves motor function and reduced alpha-synuclein inclusions; these *in vivo* studies were performed in collaboration with MF Chesselet, UCLA, and Allon Therapeutics.[9] [iii] In a mouse model of brain lesion mimicking cerebral palsy, NAP (davunetide) potently protects against ibotenate-induced excitotoxic damage in the cortical plate and the white matter of P5 mice as well as against brain lesions of P0 mice.[30] Here, the mechanism of protection involves the PI-3K/Akt pathway in the cortical plate or both PI-3K/Akt and MAPK/MEK1 kinases in the white matter (a collaboration of Pierre Gressen's laboratory and the Gozes laboratory). [iv] NAP (davunetide) neuroprotective effects also occurs in laser-induced retinal lesions in rats. Intravitreal treatment has an early short-term effect, whereas the effect of systemic administration is delayed and prolonged.[2] [v] NAP (davunetide) protects against cognitive decline in a diabetes rat model, coupled with structural protection of the brain, protecting glial cells against apoptosis and against synaptic loss (synaptophysin expression).[15] [vi] Lastly, corroborating work in the literature shows that intranasal NAP (davunetide) administration in conditions of hypobaric hypoxia results in increased expression of Nrf2, the master regulator of antioxidant defense system coupled to improved performance in memory in rats.[27]

GENERAL CONSIDERATION FOR MICROTUBULE PROTECTION

Microtubules are critically important cytoskeletal elements in neurons that act as both architectural struts and railways for organelle transport. A growing body of evidence suggests that microtubules may be vulnerable to loss or distortion in a number of different disease and injury scenarios as also described in our respective publications.[20,28,29,31] This may be the primary reason for axonal degeneration. Traditional microtubule-stabilizing drugs such as taxol provide fortification of the microtubules and in theory could

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

be helpful for staving off axonal degeneration resulting from loss of microtubules. Indeed, such drugs show promising indications of enabling functional recovery in animal models of diseased and injured neurons as discussed in our previous publications.[20,21] Although this is good proof-of-principle, prolonged use of taxol is notorious for causing neuropathy, as a portion of the microtubule array must remain dynamic for neurons to remain healthy.[20] The ideal drug would fortify microtubules against loss and also correct microtubule distortions that may have already occurred, while still allowing the microtubules to participate in their normal dynamics. Although such a drug has been elusive, previous studies indicate that NAP (davunetide) may hold promise in this regard.

CLINICAL PROGRESS

Based on these preclinical results, NAP (davunetide) has progressed through a drug development program.[13] Preclinical and clinical assessments indicated that davunetide is safe and well tolerated with brain bioavailability after intranasal or intravenous systemic administration.[22] The protection against microtubule disruption and tauopathy suggests a broad range of potential clinical applications as exemplified in the animal models described above.

NAP (davunetide) is currently in Phase II/III clinical-trials for Progressive Supernuclear Palsy (patients exhibiting microtubule dysfunction in the form of tau pathology or tauopathy), (Allon Therapeutics Inc.; ClinicalTrials.gov Identifier: NCT01110720). NAP (davunetide) has shown positive indications of increasing cognitive scores in patients with mild cognitive impairment (another tauopathy): Schmechel D, Gerard G, Vatakis NG, Harper L, Ross JS, Bari M, et al. A phase 2, double-blind, placebo-controlled study to evaluate the safety, tolerability, and effect on cognitive function of AL-108 after 12 weeks of intranasal administration in subjects with mild cognitive impairment Alzheimer's and Dementia. 2008;4:T483. Activity of davunetide in these trials is supportive of the hypothesis linking microtubule protection to reduced neurodegeneration.

WORKING HYPOTHESIS AND FUTURE PERSPECTIVES

ADNP

At the level of ADNP, an open question is its regulation in tauopathies and the mechanism by which ADNP deficiencies lead to tauopathy. Examination of the genes that ADNP regulates during development, apolipoprotein E is upregulated at least 15-folds on ADNP knockdown.[18] Further, ADNP specifically interacts with the apolipoprotein E gene promoter in neuroglia-differentiated P19 cells.[18] Apolipoprotein E4 gene is a major risk factor gene for Alzheimer's disease with suggested mechanisms of action that influence tauopathy as described also by Daniel Michaelson group, working with apolipoprotein E-deficient mice (original works reviewed in Ref. 1). Thus, findings reviewed here encourage further interest in the evaluation of the involvement of ADNP expression and function in Alzheimer's disease and other tauopathies.

NAP (davunetide)

It is entirely possible that NAP (davunetide) functions in a variety of different ways, some of which fortify microtubules and some of which provide other neuroprotective benefits. However, there seems to be a growing body of evidence supporting the hypothesis that the primary mode of action of NAP is to interact with microtubules and through this interaction, stave off and even reverse neuronal degeneration. Whether this primarily results from a direct interaction between NAP and the microtubule remains to be seen, as the possibility exists that NAP may impact various pathways that impact microtubules. Understanding of the mechanism of action of NAP is not only important for its optimal use in the clinic, but also for devising future strategies that could potentially be even more powerful than NAP at fortifying the microtubule array against loss and/or distortion. Our underlying hypothesis is that NAP interacts with microtubules, resulting in a change in its lattice structure. This could, in turn, cascade into a variety of changes throughout the neuron, given how essential microtubules are to various signaling pathways. Additional influences and cascades of events may include activation of kinase-associated pathways. Future studies elucidating the mechanism of its action will provide for better understanding of how davunetide can be used to treat a variety of diseases and injuries of the nervous system, and also provide insights into how potentially even more potent drugs can be developed to preserve microtubules against loss as well as correct distortions of microtubules caused by such pathologies.

CONFLICT OF INTEREST

Professor Gozes serves as the Scientific Cofounder and a Director at Allon Therapeutics Inc., the company that develops davunetide (NAP) (www.allontherapeutics.com).

Chapter 221

Erythropoietin

Y. Haim Ohana, T. Liron, S. Prutchi-Sagiv, M. Mittelman, M.C. Souroujon and D. Neumann

ABSTRACT

Erythropoietin (Epo), the major hormone that regulates erythropoiesis, is produced mainly in the kidney of adults in response to hypoxia. Recombinant human Epo (rHuEpo) is considered a major treatment for various types of anemias. The past decade has revealed extrahematopoietic sites of Epo production along with abundance of Epo receptors (Epo-Rs) in various tissues and cell lines, suggesting that this hormone may have pleiotropic activities. The unexpected discovery that Epo and its receptor are expressed also in cells of the central nervous system (CNS) has opened new avenues for research regarding the biological effects of Epo in the brain. This chapter reviews the classical well-known features of Epo and the more novel findings with emphasis on its effects in the CNS, and their possible underlying mechanisms.

DISCOVERY AND STRUCTURE OF EPO

The first milestones in the discovery of Epo were the pioneering experiments by Carnot and Deflandre in 1906. They demonstrated that plasma from a donor rabbit that is anemic resulting from hemorrhage, elicited reticulocytosis in the recipient rabbit. The phenomenon was attributed to a "hemopoietin" factor. Its production in the kidney was revealed from the observation that bilaterally nephroctomized rabbits or rats did not respond to hemorrhage with the expected increase in erythropoietic activity. The paucity of Epo necessitated several thousands of liters of human urine to get a pure Epo preparation that was obtained in the late 1970s.[9] Partial amino acid sequences of Epo were thus deduced.

In the mid-1980s, the human Epo gene was cloned, and recombinant DNA technology allowed for the large-scale production of erythropoiesis-stimulating agents (ESAs) that mimic the cytokine's physiological function. The first commercially available rHuEpo, also known as epoetin, was a full-length unmodified Epo polypeptide that has an identical amino acid sequence to that of endogenous Epo and is widely used to correct low hemoglobin levels in anemia.[5]

The crystal structure of human Epo complexed to its receptor was identified in 1998 [Protein Data Bank (PDB) ID code 1EER].[30] Epo consists of a single polypeptide chain backbone that contains four alfa helices (helices A–D) connected by loops. Helices A (residues 8–26) and D (residues 138–161), are held together by a disulfide bridge between Cys 7 and Cys 161. Helices B (residues 55–83) and C (residues 90–112) are linked by a short loop. A second disulfide bond, cysteine 29 to cysteine 33, links the end of the A helix with part of the loop between helices A and B.[30] These disulfide bonds stabilize and preserve the molecular structure of Epo.[15]

THE EPO GENE

The human Epo gene is located on the long arm of chromosome 7 and occupies a 5.4-kb region of genomic DNA. It encodes a 193-amino-acid polypeptide chain. The mature circulating protein consists of 165 amino acids resulting from cleavage of the 27 N terminal amino acid leader sequence and loss of the C terminal arginine during post-translational modification.[15]

The protein sequence of Epo from various mammals displays 80–90% identity to the human Epo.[32] Although the Epo protein in remote species, such as fish, displays only 32% identity to human Epo, the overall structure of the gene, and the hydrophilicity plots of the molecule, display striking similarities to those of human Epo.[6]

Hypoxia and anemia are the main inducers of Epo gene expression. The Epo gene is subjected to induction by hypoxia through a 50-bp hypoxia-inducible enhancer. The hypoxia responsive elements (HRE) are differentially located in the Epo genes in the kidney and the liver. Tissue-specific transcription factors bind to regulatory sequences and control gene transcription.[5]

DISTRIBUTION OF EPO AND EPO mRNA

In the fetus and in neonatal life, the Epo gene is expressed mainly in the liver, whereas after birth, it is expressed in the kidney which then becomes the predominant site of Epo

production. This differential site of expression between prenatal and postnatal life is regulated at the gene transcription level. In the fetal liver, hepatocytes surrounding central veins contain Epo mRNA. Hepatic Ito cells also seem to be Epo producers. Until recently, Epo-producing kidney cells were not clearly identified. However, the peritubular interstitial cells of the kidney are believed to be the main producers of Epo in postnatal life.[5,15]

Aside from the kidney and the liver, Epo mRNA was detected in nonerythroid compartments, suggesting that this hormone is by far more pleiotropic than initially anticipated. Epo and Epo-R are expressed in the brain and in the cardiovascular, digestive, endocrine, female and male reproductive, and respiratory systems. In the CNS, neurons express Epo-R, and astrocytes produce Epo. Thus, the CNS can be regarded as a paracrine Epo/Epo-R system. In peripheral nerves, Epo-R is expressed only in myelin sheaths (Schwann cells). In the cardiovascular system, Epo and Epo-R are expressed in endothelial cells and in smooth muscle cells. Epo-R is also expressed in cardiac myocytes. With respect to the digestive tract, cells in the gastric mucosa and enterocytes in the fetal and neonatal small intestine of the rat express Epo-R. In the female reproductive tract of humans, Epo is expressed in the cervix, endometrium, ovary, and oviduct. Although Epo production in the kidney, liver, and brain is hypoxia inducible, in the oviduct and endometrium, it is modulated by estrogen and the supply of oxygen. With respect to the male reproductive system, the testes produce both Epo and Epo-R. Sertoli and peritubular myoid cells in particular express Epo mRNA, whereas Leydig cells express only Epo-R. Epo production has also been demonstrated in the epididymis.[15]

Generally, serum concentrations of Epo range between 4 and 27 mU/mL[5] and the terminal half-life ($t_{1/2}$) of Epo is 5 hours.[8] High concentrations of Epo are present also in human milk and milk from other species, such as the rat, suggesting that it plays a role in the erythropoiesis, neurodevelopment, and maturation of the gut of neonates.[15] In most of these organs, the Epo-R is expressed in cells that are in close proximity to the cells expressing the Epo protein, thus pointing to a local paracrine feedback system.[17]

PROCESSING OF EPO

Mature Epo is a glycoprotein of molecular mass 30.4 kDa. It consists of a 165 amino acid (aa) polypeptide core, which is generated by the cleavage of a 27 aa signal peptide and the loss of the C terminal arginine during posttranslational modification from the 193 aa precursor.[10]

The polypeptide moiety of Epo is sufficient for binding to its receptor. The carbohydrate portion, which consists of three N-linked and one O-linked acidic oligosaccharide side chains, comprises about 40% of the Epo molecule. The carbohydrate moiety of Epo is required for secretion and *in vivo* stability of the mature hormone and can protect the molecule from damage caused by oxygen radicals. Minor quantitative differences in the composition of the N and O glycans exist between urinary and serum Epo. The functional significance of these differences is not clear.[10]

A variety of erythropoiesis-stimulating agents (ESAs) including epoetin alfa, epoetin beta, epoetin delta, epoetin omega, and darbepoetin alfa (DPO) are used in the clinic. Epoetin alfa, beta, delta, and omega are four isoforms of rHuEpo. DPO is produced by glycoengineering, containing two additional N-linked carbohydrate chains to improve the stability and pharmacokinetic properties.[4] Although the affinity of DPO for the Epo-R is lower than that of the natural ligand, it has an advantage over other commercially available rHuEpo preparations, because of its threefold higher plasma half-life, and its increased biological potency *in vivo*.[10] These recombinant products are identical to the natural human Epo with respect to their primary and secondary structures; however, they differ slightly in their carbohydrate structure, which facilitates the detection of rHuEpo doping in athletes.[10]

THE EPO RECEPTOR

Epo-R is a type I transmembrane protein with a mass ranging between 59 and 70 kDa, which belongs to the cytokine receptor superfamily. In the bone marrow, Epo-R is expressed in erythroid progenitors and in megakaryocytes, myeloid cells, and endothelial progenitors. Recently, Epo-R was identified in nonerythroid cells in the heart, lung, brain, and the immune system as well as in several cancer types. Although the activity of the Epo-R on the tumor cells is still controversial,[1] its presence in malignant cells raises the concern that activation of Epo-R by treating cancer patients with Epo may lead to their undesirable proliferation.[19]

One of the hallmarks of the Epo-R is its low cell surface expression and its high levels in the endoplasmic reticulum (ER).[34] The numbers of receptor molecules per cell range from 34 to about 3,000.[15] The Epo-R consists of an approximately 230 aa extracellular ligand-binding domain, a single transmembrane segment, and an approximately 230 aa cytosolic domain. Its extracellular domain includes four conserved cysteines that form two disulfide bonds and the WSXWS motif near the membrane-spanning segment. The proximal region of the cytosolic domain contains three conserved segments: box 1, box 2, and the region between boxes 1 and 2.[26]

A single Epo molecule binds to 2 adjacent Epo-Rs on the target cell membrane and begins an intracellular signaling

cascade. Like other cytokine receptors, including those of growth hormone, prolactin, thrombopoietin, oncostatin M, and several interleukins, Epo-R has no endogenous tyrosine kinase activity. Dimerization of Epo-R activates the receptor-associated tyrosine kinase (Janus Kinase 2, Jak2) by transphosphorylation.[15] The box regions of the cytosolic domain of the receptor are implicated in the association of Epo-R with Jak2.[26] Jak2 then phosphorylates tyrosine residues on the receptor's cytoplasmic domain.[15] This process creates docking sites for SH-2 containing adaptor molecules, which subsequently recruit the transcription factor signal transducer and activator of transcription (STAT), mitogen-activated protein kinase (MAPK), phospholipase-Cγ, phosphatidylinositol 3-kinase (PI3-K), and the protein tyrosine phosphatases SHP1 and SHP2. Numerous other adaptors and intermediates are involved in Epo-R signaling, generating multiple interactions that produce a complex interplay of signaling cascades[26] (Fig. 1).

Beta common receptor (βcR), a shared receptor subunit of interleukin-3 (IL-3), IL-5, and granulocyte-macrophage colony stimulation factor (GM-CSF) receptors, mediate several nonhematopoietic effects of Epo in various types of cells. It is involved in Epo-induced nitric oxide (NO) production and phosphorylation of AKT, Src, and Jak2[29] (Fig. 1).

EPO BIOLOGICAL ACTIONS

Erythropoiesis

The key biological role of Epo in erythropoiesis has been well known for the past 40 years. However, the under-

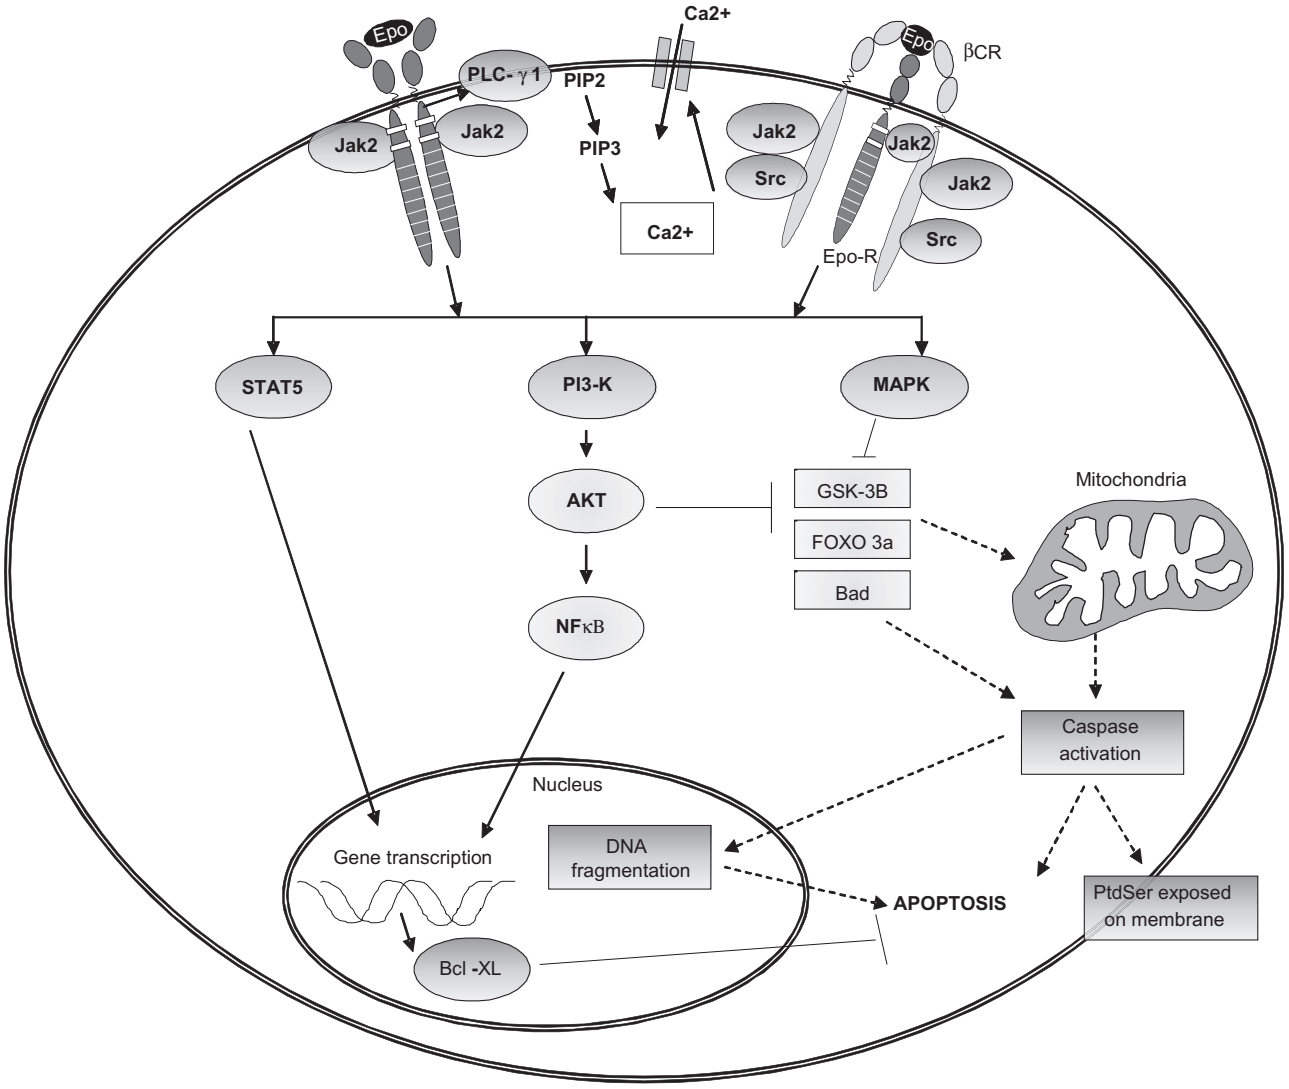

FIGURE 1 Epo-mediated intracellular signal transduction pathways. It is proposed that signaling pathways in the CNS are activated via Epo binding to its cognate Epo-R or to an Epo-R-βcR complex.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

lying mechanisms have been elucidated only in the last decade. Elaborate reviews have been published regarding the role of Epo in erythropoiesis, the signal transduction pathways controlling the process and the interaction with additional cytokines that lead to normal red cell production.[5]

Under hypoxia conditions, Epo production is induced in adult kidney through the activation of HIF and the downregulation of GATA transcription factors.[5] Epo then circulates to the bone marrow, where it binds to Epo-Rs on the surface of erythroid progenitor cells. Its primary target cells in the bone marrow are colony-forming unit erythroid (CFU-E) cells.[15]

Ligand binding to the Epo-R initiates a series of second-messenger complex cascades that ultimately transmit signals to the nucleus. These signals orchestrate the complex regulation of erythroid-specific gene expression to prevent erythroid apoptosis and to support terminal proliferation and differentiation.[15,26] Molecules that are involved in these processes include Jak2, STAT, MAPK, phospholipase-Cγ, PI3-K, AKT1, Ras, and Ca^{2+}.

Epo is the critical growth factor that acts on bone marrow erythroid progenitor cells to prevent them from undergoing apoptosis.[15] Two main signaling pathways activated by Epo-R are responsible for preventing apoptosis: (**1**) the Jak2/STAT5 signal transduction pathway, which activates numerous target genes, including the apoptosis-inhibitor Bcl-XL; a member of the Bcl-2 proteins and required for the survival of erythroid cells at differentiation and maturation stages and (**2**) the PI3-K pathway which activates the protein kinase B (PKB)/AKT1 and subsequently a member of the Forkhead family (FH) of transcription factors FKHRL1, which apparently regulates the generation of Epo-dependent anti-apoptotic signals.[26]

Beyond Erythropoiesis: Epo and Epo-R in the CNS

The finding of additional Epo-producing organs such as the liver, uterus, heart, immune system cells, and brain, has led to the discovery of additional biological functions of Epo, broadly beyond erythropoiesis, as summarized in Table 1.

The unexpected discovery that Epo and its receptor are expressed in the brain has elicited great interest in the scientific and medical communities, because of its potential activity as a neuroprotective agent and its possible clinical relevance in various brain pathologies. In the brain, as in the kidney and liver, hypoxia is a major stimulus of Epo transcription mediated by the HIF-1 pathway. Other factors such as insulin,[16] reactive oxygen species (ROS), injury, metabolic stress,[25] and certain cytokines such as insulin-like growth factor-1 (IGF-1), tumor necrosis factor α (TNFα), IL-1β, and IL-6, may also regulate Epo and Epo-R expression in the brain.[16]

Neurons and astrocytes are the main sites of Epo production in the CNS.[23] Epo and Epo-R mRNA have been identified in various cell types such as mesenchephalic (midbrain), hippocampal and cortical neurons, astrocytes, oligodendrocytes, and brain capillary endothelial cells. Their expression is increased after exposure to hypoxia, leading to increased sensitivity to Epo that may play a role in the activation of the endogenous neuroprotective pathways.[1] Moreover, Epo-R is expressed on the myelin sheath of peripheral nerves.[15] Brain-derived Epo and Epo-R molecules are smaller than their peripheral counterparts, resulting from the differences in sialic acid content.[3] The observation that Epo is produced by astrocytes and subsequently binds to the Epo-R on neighboring neurons,[15] suggests that Epo mediates paracrine and autocrine effects in neurons.

Neurotrophic and neuroprotective effects of Epo were shown *in vivo* in response to neuronal injury caused by hypoxia, ischemia, or brain hemorrhage, as well as by a variety of stressors such as glutamate, NO[23] and glucose deprivation.[1] These occurred when Epo was administered directly into sections of the brain, or systemically by crossing the blood–brain barrier.[23] *In vitro* studies in neural cell lines and primary cultures have shown that Epo stimulates neuronal function and viability by activating calcium channels and release of choline acetyltransferase and of neurotransmitters such as dopamine and acetylcholine.[18] In a mouse model of parkinsonism induced by drug treatment, exogenous Epo injected above the substantia nigra improved locomotor activity and survival of dopaminergic neurons. Adenoviral vector encoding Epo injected into rabbit brain augmented endothelium-dependent relaxation to acetylcholine.[23] The mechanisms by which Epo acts as a neuroprotectant can be summarized as follows:

(1) Decrease in glutamate toxicity

Glutamate toxicity is regarded as the main cause of ischemia-induced neuron death. This effect is accomplished by inducing a rapid, transient increase in intracellular Ca^{2+} concentration in neuronal cells, by raising the Ca^{2+} influx from outside of the cells. Epo blocks this calcium-induced exocytotic glutamate release and could interfere *in vitro* at any step within the well-described cascade of neuronal cell death, induced by exposure to glutamate or glutamate-receptor agonists.[18]

(2) Effects on apopotosis

Epo acts by upregulation of antiapoptotic genes or by the suppression of caspases. This is similar to the case in

erythroid precursor cells where, as mentioned above, Epo activates the expression of antiapoptotic genes such as Bcl-2 and Bcl-XL.[18] In addition, Epo increases the expression of the apoptosis-inhibitor genes *XIAP* and *c-IAP2* in cerebrocortical cells.[1]

(3) Effects on inflammation

Epo acts by reducing inflammatory processes that play a key role in many forms of brain injury. Studies on mice showed that Epo causes reduction of astrocyte activation and the recruitment of leukocytes and microglia into an infarction produced by middle cerebral artery occlusion. In this model, neuronal injury-related inflammation is attenuated by an indirect mechanism involving Epo-mediated reduction of neuronal apoptosis and increased resistance to secondary inflammatory injury.[17] In a mouse model of autoimmune encephalomyelitis, Epo treatment at the onset of paresis significantly improves neurological functional recovery associated with a significant reduction in inflammatory infiltrates and demyelination.[1] Noteworthy, ischemia-induced production of the proinflammatory cytokines TNFα, IL-6, and monocyte chemoattractant protein 1 concentration are reduced after rHuEpo administration.[17,18] In addition, Epo prevents phagocytosis of cells that are tagged by membrane phosphatidylserine exposure induced by anoxia and NO, and can thus precipitate a latent cellular inflammation. These processes are involved in various neurodegenerative diseases such as Alzheimer's disease and other dementias.[16]

(4) Effects on NO production

Epo effects on nitric oxide synthase and NO production may depend on cell type or conditions. In endothelial cell cultures, although short-term exposure to Epo decreases or leaves unchanged endothelial nitric oxide synthase (eNOS) and endothelin-1 expression, the combination of Epo and hypoxia increases Epo-R and eNOS expression as well as NO and cGMP production, showing a direct effect of Epo on eNOS and NO production. The participation of Epo in the regulation of NO production and blood flow may contribute to its neuroprotective role in brain ischemia. However, Epo inhibits the expression of inducible nitric oxide synthase (iNOS) in the hippocampus after bilateral carotid occlusion and in primary oligodendrocyte cultures exposed to inflammatory stimuli.[23]

(5) Effects on angiogenesis

Epo leads to increased angiogenesis, thus enabling additional transport of erythrocytes and thereby increasing the amount of oxygen delivered to the hypoxic brain.[18] Nevertheless, in an *in vitro* model of the bovine blood–brain barrier, Epo protected the blood–brain barrier against vascular endothelial growth factor (VEGF)-induced permeability. In addition to its direct protective effect on neurons, protection of the blood–brain barrier may contribute indirectly to Epo neuroprotection.[23]

The signal transduction pathways by which Epo protects neuronal cells from apoptosis have not yet been fully elucidated; however, it has been shown that the signal transduction pathways leading to CNS cell protection involve Jak2, MAPK, and PI3-K. Phosphorylation of AKT1 through the PI3-K pathways is central to the ability of Epo to prevent several pathways of cell death. It includes those pathways that involve glycogen synthase kinase 3β and forkhead transcription factor FOXO3a.[3] In addition, Bcl-2-associated death promoter (Bad), an AKT downstream substrate, is phosphorylated by activated AKT and thus becomes inactivated. Through AKT activation, Epo also maintains mitochondrial membrane potential preventing the release of cytochrome c and caspase 1, 3, and 8 -like activities. Inhibition of AKT partially reduces Epo neuroprotection, suggesting the participation of additional signaling pathways in Epo neuroprotection. Epo activation of Jak2 also results in the phosphorylation of the inhibitor of NF-κB (IκB), subsequent nuclear translocation of the transcription factor NF-κB, and NF-κB-dependent transcription of neuroprotective genes.[23]

A few years ago, an alternative Epo-R signaling pathway has been postulated. This was based on the generation of Epo derivatives (e.g. carbamylated Epo; CEpo) that bind to the Epo-R and display a tissue-protective effect, but not an erythropoietic one.[3] The premise is that CEpo-mediated tissue protection in the CNS and in myocardial tissue is carried out through a heteroreceptor complex that comprises an Epo-R monomer and a dimer of the common β receptor (βcR) subunit (CD131), which is the signal-transducing element, common to the granulocyte-macrophage colony stimulating factor (GM-CSF), IL-3, and IL-5 receptors. βcR provides increased ligand-binding affinity to the receptor complex.[3]

Epo also plays a role in neural progenitor cell survival and neuronal cell generation in the developing brain. The lack of Epo-R signaling affects murine brain development as early as E10.5, resulting in a reduction of neural progenitor cells and increased apoptosis, and in a marked reduction in the survival of neuronal cell cultures exposed to hypoxia.[1]

Figure 1 illustrates the possible signals mediated by Epo.

PATHOPHYSIOLOGICAL IMPLICATIONS

Abnormal Serum Levels of Epo

Low serum levels of Epo are typical in patients with end-stage renal failure, which is corrected by rHuEpo injections.[5] This treatment results in increased hemoglobin (Hb), hematocrit (Hct) and red blood cell counts, as well as

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

reduction in the blood transfusion requirements (BTR), and on the whole an improved quality of life.

Other clinical situations requiring treatment by Epo include anemia associated with chronic disease, as well as perisurgical use in an attempt to reduce BTR in elective surgery.[31] Cancer-related anemia (CRA) has become a major indication for rHuEpo administration.[19] In these patients, the level of serum Epo—albeit higher than normal, is still inadequate, or rather low—relatively to the value predicted because of their anemia.[21] These patients, suffering from symptomatic anemia with relatively low serum Epo levels (in contrast to the true Epo deficiency found in end-stage renal disease) also respond to treatment with rHuEpo.[19]

High serum levels of Epo are commonly detected in patients with chronic hypoxia often associated with chronic lung diseases or other hypoxic situations (heart disease). High serum levels of Epo have also been documented in cases such as renal cell cancer, hepatocellular carcinoma, polycystic kidney disease, and uterine leiomyoma.[20] The high serum Epo levels are associated with polycythemia (erythrocytosis), resulting in the related clinical implications. In the classical hypoxic states such as chronic lung disease, high serum Epo levels are associated with secondary polycythemia (erythrocytosis), resulting in the related clinical implications including blood viscosity leading to thromboembloic complications. Recently, similar complications have been reported with CRA treatment when Hb level was allowed to increase too high.[27]

Exogenous use of rHuEpo injections (doping) has become popular among athletes, especially bike riders,[10] resulting in higher Hb and Hct levels that improve their physical performance. Unfortunately, young athletes are not always aware of the iatrogenic risks of such a treatment.

Epo and Epo-R Variants in Clinical States

Once the Epo and Epo-R genes and proteins have been cloned and characterized, attempts were made to identify related abnormalities that could explain certain clinical disorders. One possibility to be considered is an abnormal protein structure of Epo, but this so far has not been reported. A more complex picture emerges regarding the involvement of Epo-R in disease states. Primary familial and congenital polycythemia (PFCP) is a rare cause of inherited erythrocytosis resulting from mutations in the Epo-R genes. PFCP was first described in a family of Finnish descent, in which erythrocytosis was inherited in an autosomal dominant fashion. Subsequent testing of these kindred showed a heterozygous mutation in Epo-R. To date, 16 additional mutations in Epo-R have been described in PFCP. Some of these mutations result in the truncation of the cytoplasmic domain of the receptor impairing downregulation of signaling via the Epo-R and increasing the sensitivity of erythroid progenitors to Epo.[24] In experimental states, it has been shown that mutations in the exoplasmic domain of the Epo-R lead to constitutive activation of the receptor and tumorigenicity.[35] These were not described as yet, in clinical states in human.

Clinical Uses of rHuEpo—Perspectives

Cloning of the Epo gene has led to the introduction of ESAs into clinical practice in various anemias, including cases that are associated with kidney disease and cancer.[4] Treatment with rHuEpo has increased Hb and Hct, reduced blood transfusion requirements and improved the quality of life in anemic, cancer, and hemodialysis patients. Apart from alleviating anemia, Epo might have additional effects such as antineoplastic,[22] neuroprotective,[23] and immunomodulatory.[14]

Despite that, clinical trials since 2003 have linked rHuEpo therapy to increased risk of tumor progression, thrombovascular events, and mortality and thus prompted implementation of restrictions to their use to minimize potential for harm.[19] The increased risk of tumor progression in cancer patients treated by rHuEpo for their primary or treatment-associated anemia has been attributed to the presence of Epo-R on malignant cells. It should however be noted that several meta-analyses regarding the effect of rHuEpo therapy on cancer cells have not been conclusive.[2,33] A recent report summarizing a long-term surveillance of >7 years, in children with lymphoma and solid tumors treated with rHuEpo, confirmed the role of this hormone treatment in improving their anemia and failed to detect a significant shorter survival.[7]

Further research is needed to devise methods that will enable to identify the cases in which adverse effects of Epo might be predicted, and distinguish them from those where rHuEpo treatment would be beneficial. Until this important issue is clarified, one should adhere to clinical guidelines for the use of Epo, such as the recently published joint ASCO/ASH guidelines.[27]

Chapter 222

Insulin-Like Growth Factor-1

Itay Bentov and Haim Werner

ABSTRACT

The insulin-like growth factor-1 (IGF-1) is a pleiotropic growth factor with multiple roles in various aspects of normal and pathological growth and differentiation. The biological actions of IGF-1 are mediated by the IGF-1 receptor (IGF1R), a cell-surface heterotetramer structurally and functionally related to the insulin receptor. The effects of IGF-1 are modulated by a family of binding proteins (IGFBPs) that carry the ligand in the circulation and extracellular fluids. IGF-1 is widely expressed in the central nervous system (CNS) where it promotes proliferation, survival, and differentiation of neuronal and nonneuronal cells. Further, IGF-1 is a potent neurotrophic factor, rescuing neurons from apoptosis and enhancing neuronal growth and myelination. In addition, the IGF-1-signaling pathway has a key role in cancer development and attempts to target this pathway for therapeutic purposes are currently in progress. Understanding the role and regulation of the IGF-1 system will be of significant basic and clinical relevance.

DISCOVERY

The discovery of insulin-like growth factor-1 (IGF-1) is dated to the late 1950s, when the anabolic effects of growth hormone (GH, or somatotropin) in hypophysectomized rats were studied. The model measured incorporation of radioactive sulfate (in the form of chondroitin sulfate and keratin sulfate) into the hyaluronan macromolecule, the protein core of cartilage. Serum from these animals (with low GH levels) failed to stimulate incorporation of sulfate into cartilage. Moreover, the addition of GH to the incubation medium had no effect on sulfate incorporation. By contrast, serum of GH-treated hypophysectomized rats significantly enhanced sulfate uptake. Therefore, it was concluded that incorporation of sulfate was not a direct effect of GH, but rather that GH stimulated the action or production of a secondary, serum-borne factor, which was termed "Sulfation Factor."[27] The list of effects of the sulfation factor on cartilage development expanded in the following decade to include stimulation of thymidine incorporation into DNA, proline into collagen, and uridine into RNA. Furthermore, the global nature of the sulfation factor was established by studies showing that its growth-promoting activities were not limited to cartilage. Subsequently, the term "somatomedin" was introduced, reflecting the fact that the serum factor mediated the effects of somatotropin at somatic target tissues.

During the 1970s, the list of actions of somatomedin further expanded to incorporate many activities that were not restricted to growth, including an insulin-like activity in the diaphragm and the stimulation of glucose uptake in adipose tissue. Further, two closely related peptides with growth-promoting activities were discovered in the serum fraction. Although these peptides displayed a striking homology between their N-terminal domains and the insulin B chain, their insulin-like activities were not suppressed by insulin antibodies.[24] Thus, the factors that were originally termed "sulfation factor," "somatomedins," and "NSILA" (nonsuppressible insulin-like activity) were finally named insulin-like growth factor-1 and insulin-like growth factor-2 (IGF-1 and IGF-2). Although bearing a strong structural and functional resemblance, both peptides represent distinct entities that are the products of two different genes, the IGF-1 gene located on chromosome 12 and the IGF-2 gene on chromosome 11. This chapter will focus on IGF-1.

STRUCTURE OF PRECURSOR mRNA/GENE

The IGF-1 gene, located on chromosome band 12q22-q24, is about 100-kb long and contains six exons. Because of alternative transcription initiation, alternative splicing, and different polyadenylation sequences, numerous IGF-1 mRNAs are produced. These transcripts slightly differ in their coding sequences but mostly diverge in their 5′ and 3′ untranslated regions (UTRs). Exons 1 and 2 are alternative first exons, encoding each one a different 5′-UTR and an alternative N-terminal sequence of the IGF-1 precursor. Extrahepatic production of IGF-1 mRNA is almost exclusively from exon 1, whereas hepatic production, although predominantly from exon 1, can occur also from exon 2.

The differences between transcripts stem not only from the use of either exon 1 or 2. Both exons contain a cluster of start sites (four start sites in exon 1 and two sites in exon 2), which indicates the existence of a complex control mechanism. Further, the usage of different transcription start sites in the IGF-1 gene is modulated by the nutritional status of the animal as well as by GH levels. Exon 3 encodes part of the signal peptide whereas exon 4 encodes a common N-terminal domain that is similar in humans, rats, and mice. Exons 5 and 6 encode each a different C-terminal product, containing each of them a stop codon. Alternative splicing results in two isoforms of the E peptide moiety of the prohormone—Ea and Eb. In humans, exon 4 is spliced directly either to exon 5 to encode the Eb isoform, or to exon 6 to produce the Ea isoform. The effect of genetic polymorphism within the IGF-1 gene on circulating IGF-1 levels and cancer risk is variable. Genetic variation in the 3′ region of the IGF-1 gene influence circulating levels of IGF-1. Specific IGF-1 single nucleotide polymorphisms (SNPs) account for up to 5% change in circulating IGF-1 levels, but no associations were observed between this polymorphism and breast cancer risk.[22] Common haplotypes in the block covering the 3′ region of the IGF-1 gene (using haplotype tagging assessment of SNPs) showed global association with prostate cancer risk.[16] Interestingly, in a study that examined prostate cancer risk, a single SNP was found to be associated with increased risk without changing IGF-1 circulating levels.[28]

In rodents, IGF-1 mRNA contains either exons 4, 5, and 6, or exon 4 spliced directly to exon 6. Exon 6 contains multiple polyadenylation sites, resulting in molecules containing alternative 3′-UTR domains of several hundred nucleotides in length. IGF-1 mRNA in humans and rats exists in three sizes: 0.8–1.2, 2.2, and 7.5 kb. The large isoform contains a long (~6.5 kb) AU-rich sequence, which results from the use of a downstream polyadenylation site and which renders the 7.5-kb IGF-1 mRNA molecule remarkably unstable.

DISTRIBUTION OF THE mRNA

In rodents, very low IGF-1 levels and high IGF-2 levels are observed during the prenatal period, while postnatal stages are characterized by an increase in circulating IGF-1 values and disappearance of IGF-2. These early observations might have led to an erroneous broad interpretation of the roles of IGF-2 and IGF-1 as fetal and pubertal growth factors, respectively. In humans, however, this expression pattern does not exist, and both ligands are produced from prenatal to postnatal periods. In fact, circulating IGF-2 levels in adults are higher than IGF-1 levels.

Circulating (endocrine) IGF-1 levels are mostly dependent on liver production, which is tightly controlled by GH. In addition to its hepatic production, many extrahepatic tissues also produce IGF-1, which usually exhibits paracrine and autocrine modes of action in these organs. Numerous factors have been shown to control circulating IGF-1 levels. These factors include both direct effectors (e.g., GH, protein calorie intake, thyroxine, catabolic stressors) and indirect factors (e.g., age, body fat, exercise, various hormones). The relative importance of liver-produced (endocrine) IGF-1 *versus* locally produced (paracrine/autocrine) IGF-1, was studied in several mouse models. When the liver IGF-1 gene is knocked-out using the cre–lox recombinase system, circulating IGF-1 levels are reduced by approximately 75%, and GH levels are elevated compared with normal littermates. However, there is almost no phenotypic difference, nor is there a disparity in tissue IGF-1 mRNA production that might have acted as a local compensatory mechanism.[29,35] However, in another mouse model, IGF-1 cDNA was inserted by knock-in into a mutated, inactive IGF-1 locus and was conditionally expressed from cognate promoters exclusively in the liver. In this model, liver-produced IGF-1 contributes about 30% of the adult body size and sustains postnatal development, including reproductive functions.[30] It is generally agreed that liver-derived and locally produced IGF-1 have overlapping growth-promoting effects in the maintenance of normal longitudinal bone growth. However, the paracrine/autocrine IGF-1 cannot replace liver-derived IGF-1 for the regulation of a large number of other parameters including GH secretion, cortical bone mass, progression of some tumors, and other functions.

PROCESSING

The IGFs are approximately 7-kDa peptides, which share a remarkable structural homology with proinsulin. The amino acid sequence of IGF-1 has been elucidated for >10 mammalian species and about the same number of non-mammalian vertebrate species. In most species, including humans, IGF-1 is a 70-amino acid, linear, basic peptide. It consists of B and A domains that are homologous to the B and A domains of insulin. The N-terminal B domain contains 29 residues while the A domain contains 21 residues. By a few substitutions in the A and B domains, it is possible to create an IGF-1 analog that binds to the insulin receptor with an affinity that is similar to that of insulin.[10] In addition, between the A and B domains lies a 12-residue C domain. Unlike insulin, the C domain is not cleaved out, and this may explain the immunologic difference between IGFs and insulin that led to the historical finding of the nonsuppressible insulin-like activity of IGF-1. The IGF's 8-residue D domain, located in the C-terminal end, is not found in insulin. The E domain, located in the C-terminus, is cleaved during secretion in the Golgi apparatus. The sizes of the E domain differ; thus, the IGF-1A protein contains a 35-residue E domain, whereas IGF-1B contains a 77-residue E domain. Because part of the E domain is

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

encoded by exon 4 in both proteins, the initial 16 residues are identical.

Although the mammalian IGF-1 is highly conserved, a more significant variability is observed among IGF-1 molecules derived from nonmammalian vertebrates. Conserved amino acids include six cysteines that form three disulfide bonds (two between the A and B domains and one inside the A domain), suggesting that the overall spatial 3-D topography of the molecule is conserved. In addition, three tyrosine residues are conserved (analogous to positions B24, C31, and A60 in the human IGF-1 protein), and it was suggested that these residues are critical in high-affinity binding to the receptor.

RECEPTORS

IGF-1 and IGF-2 activate a common, ubiquitously expressed receptor, the IGF-1 receptor (IGF1R) or Type 1 IGF receptor, which signals mitogenic, antiapoptotic, and transforming activities. The IGF-2/mannose 6-phosphate receptor (IGF-2/M6PR) does not participate in IGF signaling, and its main role is to target IGF-2 for lysosomal degradation. The IGF1R gene is located on the long arm of chromosome 15 (15q25-q26) and it encodes a 1367-amino acid precursor protein that is proteolytically processed to yield mature α and β subunits. The functional cell-surface receptor is composed of two extracellular α-subunits, involved in ligand binding, and two transmembrane β-subunits containing a cytoplasmic tyrosine kinase domain. The IGF1R is coupled to several intracellular second messenger pathways, including the *ras-raf*-MAPK and PI3′K signaling cascades.[18]

IGF1R action is vital for cell survival, as illustrated by the lethal phenotype of mice in which the IGF1R gene was disrupted by homologous recombination. During normal ontogenesis, the IGF1R is expressed at every developmental period, including the oocyte stage. Late embryonic and adult stages, in which the percentage of dividing cells declines, are associated with an overall reduction in IGF1R mRNA levels. The seminal role of the IGF1R in normal and pathological growth has been demonstrated in animal models and in patients with chromosomal abnormalities that disrupt the IGF1R locus and in patients with specific IGF1R gene mutations. In mice, disruption of the IGF1R gene by homologous recombination results in animals weighing 45% of control littermates at the time of birth.[2] These animals exhibit generalized developmental abnormalities, including hypoplasia, abnormal skin formation, delayed bone development, and abnormal central nervous system (CNS) morphology, and they die in the immediate postnatal period from respiratory failure.

Chromosomal aberrations involving the 15q26 locus (e.g., ring chromosome 15) were shown to be associated with hemizygosity for the IGF1R locus and severe growth failure.[23] However, a patient with three copies of the gene resulting from partial duplication of the long arm of chromosome 15, presented with height and weight above the 97th percentile and showed accelerated cellular growth.[21] Combined, these studies underscore the link between IGF1R number and cellular proliferation. Two children with mutations in the IGF1R gene were described in two pediatric cohorts; the first cohort consisted of children with unexplained intrauterine growth retardation and subsequent short stature, and the second group included children with short stature and high circulating IGF-1 levels.[1] A girl from the first group was identified as a compound heterozygote for point mutations in exon 2 of the IGF1R gene. Fibroblasts cultured from the patient had decreased IGF1R binding and phosphorylation. In the second cohort, a boy was identified with a nonsense mutation, leading to reduced IGF1R expression. Additional mutations within the IGF1R gene that are associated with growth retardation and short stature were recently described. Reports included mutations that result in a kinase-deficient IGF1R, nucleotide duplication, which introduces a premature termination codon, and even a mutation causing retention of the nascent IGF1R in the endoplasmic reticulum.

Finally, examination of various tumors (including breast, ovary, prostate, colon, hematopoietic, rhabdomyosarcoma, and kidney) showed an abundant expression of IGF1R mRNA and protein, suggesting that the upregulation of the IGF1R gene constitutes a common paradigm in different types of cancer.

ACTIVE AND/OR SOLUTION CONFORMATION

Most of the IGF-1 peptide in the circulation is found in a ternary complex that includes, in addition to the IGF-1 molecule, a liver-derived glycoprotein (the acid-labile subunit, ALS) and an high-affinity-binding protein, the IGF-binding protein 3 (IGFBP3). The portion of free (active) IGF-1 is usually very low. Six IGFBPs (IGFBP1–6) and many IGFBP-related proteins have been characterized to date. IGFBP3, the predominant IGFBP in serum, is the largest and, therefore, the only one that cannot traverse the capillary membrane. The ternary complex between IGF-1, IGFBP3, and ALS modulates IGF-1 action by protecting the growth factor from proteolysis and prolonging its half live in the circulation. In addition, some IGFBPs exert their biological effects in an IGF-independent manner. In general, the IGFBPs inhibit the metabolic and proliferative actions of IGF, although some IGFBPs display IGF-potentiating effects as well. IGFBP3 in particular is recognized as an inhibitor of proliferation, driving the cell to apoptosis. Several potential mechanisms of action were postulated to explain IGFBP3 inhibition of IGF action, including sequestration of IGF-1 from the receptor and binding competition with the IGF1R.

BIOLOGICAL ACTIONS

The structural and functional similarities between insulin and IGF-1 suggest that both molecules are derived from a common ancestral precursor that probably participated in food intake and regulation of cellular growth.[25] A divergence of functions most likely occurred before the appearance of the first vertebrates, with insulin mostly active in the regulation of metabolism and IGF-1 in growth processes. In view of their common evolutionary origins and semiconserved architecture, however, there is a certain degree of crosstalk between insulin, IGF-1, and their receptors. Accordingly, insulin exhibits many IGF-1-like activities, including growth stimulation, and IGF-1, on the other hand, exerts certain metabolic effects. In addition, the fact that IGF-1, but not insulin, is carried in the circulation and extracellular fluid by IGFBPs, may further contribute to the divergent actions of both ligands.

At the cellular level, IGF-1 stimulates a mitogenic response and inhibits cell death in a wide variety of cell types, including primary cultures and cancer cell lines. Quiescent cells in G_0 can be induced to enter G_1 by competence factors (e.g., PDGF, bFGF). Once the cell enters into G_1, subphysiological doses of IGF-1 will allow it to evade arrest in G_1 and to progress through the cell cycle. Thus, IGF-1 functions as a progression factor. IGF-1 can also induce differentiation and this activity can be blocked by specific antisense oligonucleotides. IGF-1 exhibits a variety of cellular functions, including regulation of hormone synthesis and secretion, chemoattractant migration, immune cell recognition, and neuromodulation. Metabolic effects of IGF-1 include elevation of glucose uptake and hypoglycemia, without lowering free fatty acid levels. In addition, IGF-1 was suggested to improve renal function by increasing renal blood flow and glomerular filtration rate.

The essential role played by the IGF system in growth and development was demonstrated by the severe growth deficits observed in mice in which various components of the IGF system were disrupted by homologous recombination. Thus, heterozygous mice for a disrupted IGF-1 allele had a body weight at the time of birth that was about 10–20% less than of wild-type animals, whereas null homozygotes weighed about 40% less than did wild type. Further, null homozygotes had very high perinatal mortality rates and many phenotypic aberrations. Interestingly, screening of IGF levels in species with distinct phenotypic features revealed that in different breeds of dogs circulating IGF-1 levels are matched with breed size. As a general rule, smaller breeds have lower IGF-1 levels than larger breeds. Further, many epidemiological observations in human populations highlight the pivotal role of the IGF axis in normal growth. For example, circulating IGF-1 levels in African pygmies are markedly lower than in the general population. Moreover, GH and IGF-2 levels are normal in pygmies, whereas IGF-1 levels in adolescent males and females are significantly lower. As a result of this reduction, the growth spurt associated with puberty is absent.

PATHOPHYSIOLOGICAL IMPLICATIONS

Growth Disorders

The importance of IGF-1 in normal growth is classically illustrated by the Laron Syndrome (LS).[26] LS patients are characterized by mutations in the GH receptor, leading to resistance or insensitivity to GH action and diminished IGF-1 production (despite normal or even high GH levels). LS patients' height is four to ten standard deviations below median normal height, and acceleration of linear growth was demonstrated by continuous, long-term treatment of affected patients with recombinant IGF-1. More recently, a homozygous partial deletion of the IGF-1 gene has been reported in a 15-year-old boy with severe prenatal and postnatal growth deficiency, sensorineural deafness, and mental retardation.[34] An additional component of the IGF system whose mutation was shown to have an impact on growth processes is the ALS subunit of the ternary complex. Mutation of the ALS gene in a 17-year-old boy resulted in undetectable levels of circulating IGF-1 (due to instability of the ternary complex), delayed onset of puberty, and slow pubertal progress.[8] This mutation, however, had only a minimal effect on linear growth. Finally, the effects of mutations in the IGF1R gene were described above.

Cancer

The proliferative and antiapoptotic effects of IGF-1 led to several observational studies that were intended to elucidate the possible connection between circulating IGF-1 levels and an increased risk of neoplasia. Large epidemiological studies have suggested that high circulating IGF-1 levels are associated with an increased risk for breast, prostate, lung, and colorectal cancer. Specifically, in a prospective nested control study (the Nurse's Health Study) the relative risk (RR) of breast cancer in premenopausal women was 4.6 in the upper tertile of IGF-1 values, in comparison to women in the lower tertile.[13] The RR increased to 7.3 when the concentrations of IGFBP3 were included in the analysis. Likewise, the RR of prostate cancer in men (evaluated in the Physician's Health Study) in the upper quartile of IGF-1 values was 2.4 (4.3 when normalized for IGFBP3).[4,5] In addition to hormone-dependent prostate and breast carcinomas, the importance of IGF-1 as a risk factor was evaluated in various nonhormone-dependent types of cancers. Analyses of colon cancer risk in the Nurse's Health Study and the Physician's Health Study showed an increased risk in individuals with the highest IGF-1 values (although a lower RR was observed).[11,12]

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Several mechanisms have been postulated to explain the possible role of the IGF system in the initiation and/or progression of neoplasia.[14] Although IGF-1 was shown to increase chromosomal fragility under experimental conditions, it is usually considered to be nongenotoxic. The proliferative actions of IGF-1, however, have been well characterized. Once a malignant transformation has occurred, cell survival of transformed cells depends on IGF-1 action.[3] The disruption of internal checks and control mechanisms associated with the neoplastic phenotype is further emphasized by the finding that IGF-1 action can override the cellular signals of apoptosis. Several monoclonal antibodies and small-molecule inhibitors that target the IGF1R and its autophosphorylation have been tested in preclinical studies and early-phase clinical studies. Early clinical trials indicate that these drugs are reasonably safe, and there is pharmacodynamic evidence that IGF1R inhibition is possible in patients.[19]

Longevity

Inhibition of the IGF-1 system results in stress resistant, long-lived worms,[17] flies,[32] and mice.[15] Interestingly, in a cohort of Jewish Ashkenazi centenarians, their offspring, and offspring-matched controls, the biochemical, phenotypic, and genetic variations demonstrated a gender-specific increase in serum IGF-1. This change was associated with a smaller stature in female offspring of centenarians. Sequence analysis of the IGF1R gene of female centenarians showed overrepresentation of heterozygous mutations that were associated with high serum IGF-1 levels and reduced activity of the IGF1R as measured in transformed lymphocytes. Thus, altered IGF signaling pathways are suggested to play a role in modulation of human lifespan.[31]

Neuroprotection

IGF-1 is widely expressed in the CNS where it promotes proliferation, survival, and differentiation of neuronal and nonneuronal cells. IGF-1 is a potent trophic factor for motor and sensory neurons as well as for glial cells. Further, circulating IGF-1 is an important determinant of brain function and its effects range from classical neurotrophic actions, such as housekeeping and antiapoptotic/prosurvival effects, to modulation of blood–brain barrier permeability, neuronal excitability, myelination, and new neuron formation.[9] Stimulation of sensory neurons by capsaicin increases tissue levels of IGF-1 and IGF-1 mRNA in various organs.[20] Upregulation of IGF-1 in the CNS was observed 1–7 days after various insults such as hypoxic-ischemic brain injury, brain contusion, and penetrating brain trauma, suggesting a role for IGF-1 in repair processes.[33] In a model of cerebral infarct, IGF-1 treatment reduced ischemia and improved neurological function. Interestingly, administration of IGF-1 in combination with erythropoietin (a neuroprotective agent in itself) resulted in a synergistic neuroprotective effect, whereas blockade of IGF-1 entry into the brain prevented the exercise-induced increase in neurogenesis.[7] The effect of IGF-1 is not limited to brain injury. Central administration of IGF-1 has been shown to result in an antidepressant effect. IGF-regulated mechanism that protects from amyloid beta toxicity (the main constituent of amyloid plaques found in the brains of patients with Alzheimer's disease) is conserved from worms to mammals and suggests that modulation of this signaling pathway can aid in the development of Alzheimer's disease therapy.[6] In conclusion, the potential therapeutic applications of IGF-1 in the treatment of common debilitating neurological conditions is showing great promise and is currently under extensive investigation.

CONCLUSIONS AND FUTURE DIRECTIONS

The IGF-1 axis has an important role in multiple growth and developmental processes. Derangement in IGF-1 action is linked to several pathologies, ranging from growth impairment, malignancies, and CNS anomalies, including Alzheimer's disease. In addition, the IGF-1 axis plays a role in the modulation of lifespan. Of importance, the IGF-1 axis emerged as a promising molecular target for therapeutic purposes. A better understanding of the biochemical and molecular mechanisms responsible for the regulation of the IGF-1 system will have important basic and translational implications, including the possibility of delivering more efficient and rationale therapies in pathologies in which the IGF-1 axis is involved.

Chapter 223

Neuregulins

Kim B. Seroogy, Jonathan W. Dickerson, Sarah N. Cassella
and Lixin Zhang-Auberson

ABSTRACT

Neuregulins are pleiotrophic growth factors that influence cell survival, proliferation, differentiation, and organogenesis throughout the body. Their effects are mediated via interactions with the ErbB family of transmembrane receptor protein tyrosine kinases and subsequent activation of downstream intracellular signaling events. This chapter focuses on the expression and emerging neurotrophic, neuroprotective, and neuromodulatory actions of neuregulins in the central nervous system. Potential pathogenic and/or reparative roles for neuregulin/ErbB signaling in several neurological disorders are also discussed.

DISCOVERY AND STRUCTURE

Neuregulins (NRGs) are a family of structurally related signaling proteins that bind to receptor tyrosine kinases of the ErbB family and mediate a myriad of cellular functions including survival, proliferation, and differentiation in both neuronal and non-neural systems. Discovered independently over a decade ago by several different groups, these peptide growth factors were originally described as neu differentiation factor (NDF), heregulins, glial growth factors (GGFs), acetylcholine receptor-inducing activity (ARIA), and sensory and motor neuron-derived factor (SMDF) (see Refs. 12, 13 for reviews). It is now known that all these NRG proteins are encoded by the same gene, named NRG-1. Four genes (termed NRG-1, NRG-2, NRG-3, NRG-4) have been identified that encode NRGs in vertebrates, and the best characterized of these is the NRG-1 gene. The entire human NRG-1 gene has been sequenced.[23]

More than 30 isoforms are generated by multiple promotor usage and alternative splicing of the NRG-1 gene, including the above-mentioned NDFs, heregulins, GGFs, ARIA, and SMDF (see Refs. 3, 12, 13, 18 and original references therein). Multiple splice variants are also produced from each of the NRG-2, NRG-3, and NRG-4 genes. The most important portion of the NRG molecule is the EGF-like domain shared by all the isoforms because this alone is sufficient for receptor binding and the stimulation of intracellular signaling pathways; hence, the EGF domain is both necessary and sufficient for biological activity. This extracellular domain contains about 50 amino acids and is characterized by three pairs of cysteines that are important for its tertiary structure and biological function, and the alternate splice variant at this domain gives rise to α and β isoforms. Six types of NRG-1 (types I, II, III, IV, V, VI) are also divided based on the differences in their extracellular amino-terminal domains: types I, II, IV, and V have an immunoglobulin-like (IgG-like) domain followed, for example, by a glycosylation-rich region (type I) or a GGF-specific (kringle) domain (type II). Type-III contains the typical extracellular EGF domain, but is unique in containing a cysteine-rich domain (CRD) that loops back intracellularly along with its N-terminal sequence. In addition, it seems that all the types of NRG-1 have both transmembrane forms and secreted forms (except Type III NRG-1) depending on whether the isoform is initially synthesized as a transmembrane or nonmembrane protein.[3,13,18]

DISTRIBUTION AND PROCESSING

Neuregulin-1 transcripts are broadly but discretely expressed throughout the nervous system during development as well as in adulthood (see Refs. 2, 3, 12, 13, 18, 19 and original references therein), with the highest levels of expression in brainstem motor and sensory nuclei, spinal cord motor neurons, and sensory ganglia. Neuregulin-1 mRNAs are also found in the cerebral cortex, diencephalon, hippocampus, basal forebrain, substantia nigra, and cerebellum, as well as in the proliferative forebrain subventricular zone. Neuregulin-2 and -3 mRNAs are also expressed in the brain, but exhibit distinct expression patterns from NRG-1, with NRG-2 primarily restricted to the olfactory bulb, cerebellum, and hippocampal dentate gyrus in the adult, whereas NRG-3 expression seems widespread. Within the rodent central nervous system (CNS), intriguing differences between NRG-1 and NRG-2 have been identified.[17] For example, with respect to mRNA expression, the pattern of NRG-2 is essentially distinct from and sometimes complementary to sites mapped for NRG-1 expression. Thus, the products of these two different genes could have

distinct functions in different brain circuits. The temporal patterns of expression in the brain also differ between the two genes. NRG-1 mRNA expression is relatively high perinatally, followed by downregulation during maturation into adulthood. By contrast, NRG-2 mRNA expression in the brain is the opposite, low prenatally and high in adulthood.[17] It has thus been hypothesized that NRG-1 might function preferentially in early prenatal and perinatal developmental events, whereas NRG-2 may be the preferred NRG ligand in the mature brain.[24] Finally, the subcellular distribution of the two NRGs differ in that NRG-2 is targeted to dendrites whereas NRG-1 is mainly localized to axonal and somatic compartments,[17] suggesting different functional roles for the ligands in the establishment, maintenance, and plasticity of synaptic connections. Taken together, the specific and distinct molecular and biochemical interactions of the two NRG ligands with their receptors, as well as their differential spatial, temporal and subcellular expression patterns in the brain, raise the possibility of differing functions of NRG-1 vs NRG-2 in the CNS. Neuregulin-4 transcripts have not been detected in the CNS. For the most part, immunohistochemical demonstrations of NRG-1 and NRG-2 proteins correspond fairly well with their mRNA localization in both rodent and human brain.

The proteolytic processing of NRG proproteins has been reviewed.[13,18] Briefly, most (but not all) NRGs in the nervous system are initially synthesized as single transmembrane proproteins with an extracellular N-terminal ectodomain (containing the biologically active EGF domain), a juxtamembrane stalk region, the transmembrane domain, and the intracellular cytoplasmic tail. A bioactive ectodomain fragment is generated and released via metalloprotease-mediated cleavage of the proprotein in the stalk region. Other NRGs are produced directly as soluble, secreted proteins (e.g. GGF2). The type-III NRG proproteins have two transmemembrane domains including an N-terminal region that loops back through the membrane resulting in an intracellular N-terminus, in addition to the intracellular C-terminus. Proteolytic cleavage at the stalk region results in an anchored N-terminal fragment (with the bioactive EGF-like region); further juxtamembrane proteolytic processing may release the fragment.[13] Another mode of NRG processing is back-signaling in which, upon NRG typeIII/ErbB binding, the intracellular C-terminal domain is proteolytically released into the cytoplasm where it subsequently travels to the nucleus and modulates gene expression.[18] The ultimate result of these various avenues of NRG isoform processing is that NRGs garner the capacity to signal via autocrine, paracrine, juxtacrine, and possibly intracrine mechanisms.

RECEPTORS

Neuregulins interact directly or indirectly with members of a subfamily of receptor tyrosine kinase proteins called ErbB receptors. The four members of the ErbB family include the epidermal growth factor (EGF) receptor (also known as ErbB1; the human homolog is termed HER1, human EGF receptor 1), ErbB2/Neu/HER2, ErbB3/HER3, and ErbB4/HER4. All family members have in common an extracellular ligand-binding N-terminal domain, a single transmembrane portion, a cytoplasmic tyrosine kinase domain, and a cytoplasmic C-terminal domain containing autophophorylation sites. Upon ligand binding, the receptors form homo- or heterodimers, which consequently stimulate the intrinsic tyrosine kinase activity of the receptors and triggers autophosphorylation of specific tyrosine residues within the cytoplasmic domain.[6,8,18] These phosphorylated residues serve as docking sites for signaling molecules involved in the regulation of intracellular signaling cascades, mainly through stimulation of the Ras/Raf/ERK mitogen-activated protein kinase (MAPK) pathway, the phosphatidylinositol-3 kinase (PI3 K) pathway, the PLCγ/PKC pathway, and the JAK/STAT pathway.[8] An alternative signaling mechanism for ErbB4 upon ligand binding includes presenilin-dependent intramembrane proteolysis by gamma-secretase to release an intracellular ErbB4 C-terminal fragment that translocates to the nucleus to regulate gene expression.[6,18] The ErbB receptors form a complex hierarchical network based on their relative affinity for the ligands, intrinsic tyrosine kinase activities, ability to recruit specific signaling molecules, and cellular distribution.[26] This network is critical to the ErbB signaling pathway because ErbB2, which exhibits the highest degree of kinase activity, has no known direct ligands and ErbB3 is kinase-defective; therefore, neither of them can function by homodimerization. However, by heterodimerizing with other ErbB receptors, they can form potent signaling assemblies (i.e. ErbB2/ErbB3, ErbB3/ErbB4, etc.) and ErbB2 is the most potent partner to any ErbB family member. ErbB4 itself contains moderate kinase activity; therefore, its presence alone is sufficient for biological activity, and it can function via both homodimerization and heterodimerization.

Neuregulins can directly bind to only the ErbB3 and ErbB4 receptors, which can then heterodimerize with ErbB2 (an orphan receptor) and ErbB1 to activate and/or potentiate subsequent signaling activity. All four NRG gene products can bind ErbB4, whereas only NRG-1 and NRG-2 proteins can bind ErbB3.[6,8] ErbB4 is also noteworthy for the fact that multiple isoforms of the receptor may exist based on sequence alterations in the extracellular juxtamembrane (JM) region and in the cytoplasmic (CYT) C-terminal domain. These ErbB4 splice variants differentially activate downstream signaling cascades, resulting in unique functions for each isoform.[18,28] Interestingly, some members of the EGF ligand family, including betacellulin, epiregulin, and heparin-binding EGF-like growth factor (HB-EGF), can bind and activate the ErbB4

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

receptor.[6] Thus, not only are there complex interactions among each of the ErbB receptor family members after NRG binding, but the possibility of receptor crossactivation with select EGF family ligands must be taken into consideration.

ErbB receptor mRNAs are differentially expressed throughout the nervous system during development, both spatially and temporally, and are continuously expressed throughout adulthood. ErbB2, ErbB3, and ErbB4 transcripts and protein are broadly expressed throughout all areas of adult rat brain and spinal cord, including cortex, amygdala, hippocampus, medial habenula, reticular thalamic nucleus, substantia nigra pars compacta, ventral tegmental area (VTA), cerebellum, pons, and medulla (see Refs. 2, 3, 6, 12, 18, 19 and original references therein). These three receptors are differentially expressed in neurons and glia. In general, ErbB4 is more prevalent in neurons and ErbB3 in glia in white matter tracts, whereas ErbB2 is present in both neural cell types at lower density. Notably, ErbB4 expression defines a large subset of GABAergic interneurons in forebrain regions[2,19] (see Fig. 1) and dopaminergic neurons in the ventral midbrain,[33–35] suggesting some specific neurotransmitter-related functions for NRG/ErbB4 signaling in the brain. Moreover, the widespread expression of ErbB receptors in the adult brain points to numerous roles for NRG in the mature nervous system.

BIOLOGICAL ACTIONS

First recognized as glial cell mitogens, the NRGs are now believed to play essential roles in cell survival, migration, and differentiation in both neural and non-neural cells. Outside the nervous system, NRGs and their receptors are essential, for example, for proper development and/or function of the heart, mammary gland, skin, lungs, stomach, pancreas, skeletal muscle, and gonads. In terms of dysfunction, NRG/ErbB signaling is associated with many different cancers including those of the breast, lung, stomach, pancreas, kidney, bladder, ovary, prostate, colon, and brain.[6,8,13,22] Targeting of ErbB/HER receptors in human cancers (e.g. anti-HER monoclonal antibodies) has proven to be a useful therapy in some cases.[22] With regard to cardiac disease, initial results from a recent clinical trial indicate that treatment with recombinant human NRG-1 was safe and tolerable and improved cardiac function in patients with chronic heart failure.[15] The remainder of this review will focus on the broad array of effects of NRGs and their receptors in the nervous system, and particularly in the CNS.

The most well-characterized functions of NRGs and ErbB receptors associated with the nervous system include roles in glial and neuronal cell proliferation, migration, maturation, differentiation, and survival, as well as neuromuscular acetylcholine receptor induction, (e.g., see

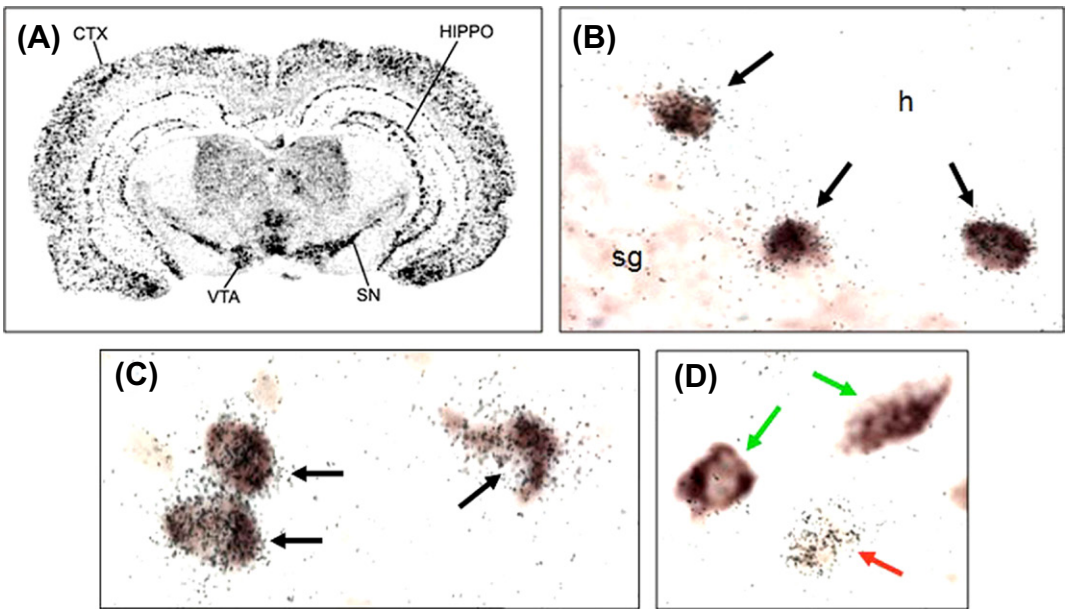

FIGURE 1 (A) Distribution of ErbB4 mRNA-expressing neurons in rat cortex and midbrain as revealed by in situ hybridization. The vast majority of the scattered ErbB4 mRNA-labeled cells in the cerebral cortex (CTX) and hippocampal formation (HIPPO) represent GABAergic interneurons. In the substantia nigra (SN) and ventral tegmental area (VTA) of the midbrain, ErbB4 is expressed by virtually all of the dopaminergic mesotelencephalic neurons. (B,C) Double-labeling in situ hybridization demonstration of the extensive coexistence of ^{35}S-labeled ErbB4 mRNA and digoxygenin-labeled glutamic acid decarboxylase (GAD, the biosynthetic enzyme for GABA) mRNA in neurons of the rat hippocampal dentate gyrus (B) and primary motor cortex (C). Black arrows denote double-labeled cells. (D) Demonstration of the *non-coexistence* of ^{35}S-labeled ErbB4 mRNA (red arrow) and digoxygenin-labeled GAD mRNA (green arrows) in the rat substantia nigra. h, hilus; sg, stratum granulosum. Refs. 3, 13, 18 for reviews). Analysis of mutant knockout mice deficient in either NRG-1, ErbB2, ErbB3, or ErbB4 reveals severe reduction in several neural crest-derived cell populations including Schwann cells, neural crest–derived cranial sensory neurons, and sympathetic neurons and demonstrates critical roles for the receptors and ligand in aspects of hindbrain development.[1] Findings from additional genetic mouse mutation studies are described below when discussing the relationship of NRG/ErbB4 signaling and schizophrenia.

Neuregulins can regulate multiple neurotransmitter receptors in the brain, including GABAergic, glutamatergic, and acetylcholine receptors. Findings in cerebellar and hippocampal slices and cultures show that NRGs increase the expression of an NMDA receptor subunit (NR2C) and modulate expression of $GABA_A$ receptor α and β2 subunits. In hippocampal cultures, NRGs upregulate several subunits of nicotinic acetylcholine receptors.[12] Trophic functions are suggested by findings showing that NRGs enhance neurite outgrowth from cultured cerebellar granule cells, hippocampal neurons, dopaminergic neurons, and PC12 cells.[6,12,34] The potential role of NRGs and their receptors in activity-dependent neuronal mechanisms is underscored by the demonstration that several forms of activity (seizures, forced locomotion, LTP) induce an upregulation of NRG and ErbB4 expression in hippocampal, neocortical, and/or amygdaloid neurons.[11]

Neuregulins also exert a modulatory role in synaptogenesis and adult brain synaptic plasticity. ErbB4 is enriched in brain postsynaptic densities (mainly somatodendritic and axon initial segment compartments) and interacts functionally with PSD-95 in cortical and hippocampal synapses.[12,19,25] Neuregulins stimulate synaptogenesis, enhance existing synapses, and facilitate excitory synaptic transmission in GABAergic interneurons, likely via stabilization of PSD-95.[2,19,25] Most evidence indicates that NRG/ErbB4 signaling inhibits LTP in the hippocampus and reduces glutamatergic neurotransmission in the cortex.[2] Thus, NRGs regulate both inhibitory and excitatory cortical circuitries that ultimately exert a strong influence upon pyramidal cell output. Dysfunction of NRG/ErbB4 signaling and resulting implications for schizophrenia and other neurological disorders are discussed below.

Taken together, the above findings illustrate that NRG/ErbB signaling influences multiple activities of neurons and provide a strong basis to postulate neurotrophic and/or neuromodulatory functions for NRGs and their receptors in brain neuronal systems.

Neuregulins are Neurotrophic for Nigrostriatal Dopaminergic Neurons

Accumulating results suggest that ventral mesencephalic dopaminergic neurons are responsive to the neurotrophic and neuroprotective effects of NRGs. ErbB4 mRNA is expressed within a substantial population of dopaminergic neurons within the substantia nigra and VTA of both rodents and primates, including human.[33–35] Because ErbB2 and ErbB3 are sparsely expressed in the ventral mesencephalon, it is likely that any functional effects of NRGs on midbrain dopaminergic neurons (see below) are mediated via ErbB4 receptor activation. Interestingly, there is a significant reduction of both mRNA and protein for the ErbB4 receptor in the substantia nigra of aged rats.[9] These findings raise the possibility that diminished NRG/ErbB4 signaling could contribute to the increased susceptibility of aged midbrain dopaminergic neurons to degeneration and may have implications for the etiology of Parkinson's disease (PD).

As determined by *in vivo* microdialysis, a single supranigral injection of the NRGs heregulin-β1 or GGF2 induced a substantial increase in dopamine overflow in the ipsilateral striatum.[32] This was among the first *in vivo* demonstrations of NRG actions in the brain and provided initial evidence that NRGs can augment dopaminergic nigrostriatal function. A subsequent microdialysis study showed that NRG-1β stimulated dopamine release in the hippocampus via the activation of dopamine D4 receptors,[2] indicating modulatory actions of NRGs upon dopaminergic mesolimbic systems. In each case, a direct effect of NRGs on dopaminergic release is suggested by the substantial colocalization of ErbB4 and tyrosine hydroxylase in neurons of the substantia nigra and VTA, which give rise to the dopaminergic mesotelencephalic system.

Consistent with these findings, *in vitro* results indicate substantial neurotrophic and neuroprotective roles for GGF2 in primary cell cultures derived from fetal rat mesencephalon.[34] The effects of GGF2 were tested on developing dopaminergic neurons in the midbrain cultures under both serum-free and 6-OHDA-challenged conditions. GGF2 significantly promotes dopaminergic neuron survival, increases dopamine uptake, and enhances dopaminergic fiber outgrowth under both conditions compared with controls.[34] The presence of glial cells is absent or extremely rare in these serum-free midbrain cultures, suggesting that the neurotrophic effects of GGF2 on the dopaminergic cells are direct, and not mediated via glia. Notably, in separate experiments in midbrain cultures, the NRG-2 protein NRG-2β also enhances dopamine neuron survival and process outgrowth, and protects the dopamine cells against 6-OHDA-induced degeneration (D.M. Yurek and K.B. Seroogy, unpublished). Finally, human post-mitotic dopaminergic neurons are protected against 6-OHDA-induced toxicity *in vitro* by the extracellular domain of NRG-1-β1 [NRG-1β1-ECD; Ref. 5], raising

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

the possibility that adult human midbrain dopaminergic neurons could be responsive to NRGs *in vivo*.

Evidence suggests that administration of NRG *in vivo* is neuroprotective and perhaps neurorestorative for dopaminergic neurons in rodent models of PD. In the rat 6-OHDA model, supranigral infusion of GGF2 or NRG-2β via osmotic minipumps is protective and partially restorative in terms of increased survival of nigral dopaminergic neurons and preservation of associated motor behaviors. Similar results were also obtained with GGF2 in an aged rat model of PD, suggesting that treatment with this NRG can overcome the age-related loss of nigral ErbB4 expression [J.W. Dickerson and K.B. Seroogy, unpublished]. In a 6-OHDA mouse model of PD, intraperitoneal injection of NRG-1β1-ECD is also neuroprotective and neurorestorative for injured midbrain dopaminergic cells.[5] The intriguing, but perhaps unexpected, finding that systemic administration of NRG-1 successfully improves survival of damaged dopaminergic neurons inside the brain is partially explained by the ability of NRG-1 to cross the blood–brain barrier.[16,20] This peripheral route of administration may hold promise in terms of potential therapeutic delivery of NRGs for the treatment of PD and other CNS disorders.

Neuregulins and Neurological Disorders

Increasing evidence of roles for NRG/ErbB signaling in the etiology and treatment of several neurological disorders is rapidly accruing. The amount of NRG is decreased in active multiple sclerosis (MS) lesions suggesting that insufficient levels of NRG may account, in part, for the demyelination seen in the disease.[27] In the experimental autoimmune encephalitis (EAE) mouse model of MS, administration of GGF2 results in significant beneficial effects including a reduction in inflammation and demyelination and enhanced remyelination.[4] Supported by the well known trophic effects of NRGs on oligodendrocytes, and the suppression of activated microglial responses by GGF2,[10] these findings raise the possibility of NRGs as a treatment for demyelinating disorders such as MS.

In animal models of stroke, both NRG and ErbB receptors are upregulated in the peri-infarct region in both neurons and macrophages/microglia. Pretreatment and acute post-treatment with NRG-1 in these transient focal ischemic stroke paradigms reduce infarct volume, block secondary neuronal degeneration and pro-inflammatory responses, and improve functional outcome indicating a neuroprotective role for NRGs in ischemic brain injury.[31] In a model of permanent focal ischemic stroke, functional recovery is promoted by GGF2 with treatment starting as long as one week post-occlusion, indicating neurorestorative effects.[14]

The expression of NRG-1 within neuritic plaques and of both NRG-1 and ErbB4 within reactive astrocytes and microglia surrounding the neuritic plaques has been identified in human Alzheimer's disease (AD) brain.[7] Upregulation of ErbB4 immunoreactivity also occurs in neurons of the hippocampus, amygdala, superior frontal gyrus, and basal forebrain of postmortem AD brains and in the hippocampus and cerebral cortex of the amyloid precursor protein/presenilin 1 (APP/PS1) transgenic mouse model of AD.[30] These findings raise the possibility of aberrant NRG/ErbB4 mechanisms in the pathogenesis of this debilitating neurodegenerative disorder.

The identification of the NRG-1 and ErbB4 genes as probable susceptibility genes for schizophrenia[21,23] has spawned a wealth of studies aimed at deciphering the role of NRG/ErbB4 signaling in the psychiatric disorder (see Refs. 2, 18, 19 for recent reviews). In particular, numerous mouse genetic manipulation studies indicate that NRG-1 and ErbB4 mutant mice (e.g. heterozygous knockouts, conditional knockouts) exhibit behavioral, electrophysiological and morphological phenotypes relevant to schizophrenia (see Ref. 19 for an excellent summary table). These consistently include defective long-term potentiation, impaired working memory, impaired prepulse inhibition, locomotion hyperactivity, impaired synapse formation, reduced number of cortical interneurons (GABAergic, parvalbumin-positive) impaired GABAergic transmission, hyperactive cortical pyramidal cells, disrupted dendritic morphology and spine density, and dysfunctional NMDA receptors. Key findings point to cortical developmental deficiencies, disrupted inhibitory circuits, and associated excitatory pyramidal cell dysfunction. Thus, emerging evidence strongly suggests that defects in cortical NRG/ErbB signaling contribute to the molecular, cellular, and physiological basis of schizophrenia. The NRG-3 gene has also been identified as a risk factor for schizophrenia;[29] possible roles of this gene and its cognate proteins in the pathogenesis of schizophrenia remain to be determined.

Chapter 224

Neurotrophins

Ljubica Ivanisevic and H. Uri Saragovi

ABSTRACT

The neurotrophins belong to a family of homodimeric polypeptide growth factors that regulate neuronal development, survival or death, neuritogenesis, synaptic strength, and plasticity, and nervous system function. Moreover, other cell types also respond to neurotrophins. Nerve Growth Factor (NGF) is the prototype Neurotrophin. It is synthesized as a precursor proNGF that is further processed to a mature polypeptide, and each form has distinct activities. On binding to its receptors—the common p75 receptor (TNF-superfamily member) and a selective Trk tyrosine kinase receptor—the neurotrophins activate signaling. Each receptor can signal independently, and when coexpressed, the receptors regulate each other in terms of ligand affinity, net signal effects, and resulting biological endpoints. Neurotrophins and their receptors are implicated in human neurodegenerative diseases, pain, inflammation, and certain types of cancer, making these proteins targets for treatment.

DISCOVERY OF NERVE GROWTH FACTOR

Nerve Growth Factor (NGF) was discovered in the 1950s by Rita Levy Montalcini and Viktor Hamburger while studying the developing nervous system and the peripheral structures it innervates. A nerve growth-promoting factor essential for the survival and maintenance of sensory and sympathetic neurons was identified, on the basis of a functional assay measuring the effects of a secreted soluble factor that enabled specific sensory neuron fiber outgrowth and hypertrophy from dorsal root ganglia, but not motor neurons. *In vitro* experiments performed by Cohen et al. led to the identification of a nerve growth-promoting protein that was later cloned and identified as NGF.

From this work, the Neurotrophic Factor Hypothesis was developed, stating that developing neurons that innervate or are attempting to target a tissue are in competition for limited supplies of trophic factors made by the target tissue, and neurons that make appropriate connections obtain growth factors that help them survive while neurons that do not obtain growth factors die.[3]

After the discovery of NGF and its physiological roles in the central and peripheral nervous system, other neuron survival promoting neurotrophic factors were cloned and identified including brain derived neurotrophic factor (BDNF), neurotrophin-3 (NT-3), and neurotrophin-4/5 (NT-4). Each of these neurotrophic factors affects a different neuronal population, with limited overlap, because different mature neurons express different types of neurotrophin receptors.[17]

STRUCTURE OF THE mRNA/GENE

The human NGF gene is located on the short arm of chromosome 1 (1p22) with the human beta NGF gene being highly homologous to mouse NGF gene. The NGF gene is >43 kbp and contains 4 exons: exons IA and B, exon II, exons IIIA and B, and exon IV. Part of exons IA, II, IIIB, and IV code for NGF precursor. Exon IV codes for all mature NGF (118 amino acids) and additional 125 amino acids in the amino terminus.[28] Exon IIIA is noncoding (Fig. 1).

There are four different NGF transcripts, with transcripts A and B being the most abundant and differing at the alternative splicing at exon II. There is a characteristic expression pattern of these transcripts, with B being more abundant than A in all the tissues except for submaxillary gland and placenta.[29] Therefore, the NGF gene is regulated by transcription initiation and RNA processing. In addition, basic residues in the NGF precursors are cleavage sites that once processed result in the mature NGF proteins.

Although there is little information about the physiological roles of each NGF transcript, much is known about alternative spliced proteins for BDNF. For example, different transcripts can be regulated epigenetically, and they play different roles in some types of memory.[18]

DISTRIBUTION OF THE mRNA

Distribution of NGF mRNA was determined by in situ hybridization and northern blot analysis in different tissues. NGF mRNA is expressed by different cells of the peripheral and central nervous system. In the periphery, NGF mRNA is expressed in the tissues that are targets of sensory and sympathetic ganglion neurons. The highest levels of NGF mRNA are present in the heart and the spleen.[29]

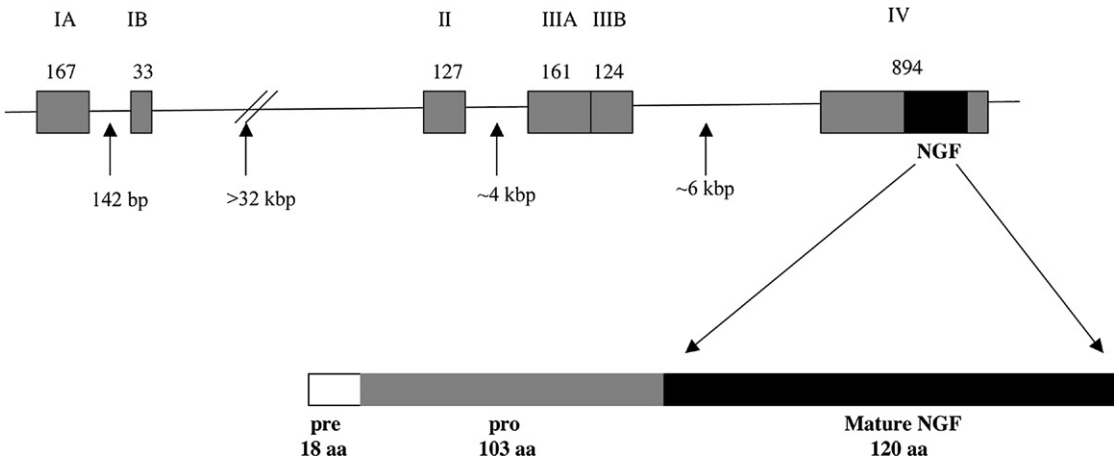

FIGURE 1 Structure of the NGF gene. Introns are shown as a line, and exons as a box. The size of exons and introns in base pairs (bp) is shown. There are 3 ATG start codons in different exons—exon IA, II and IV. The black box represents exon IV coding for mature NGF.The structure of preproNGF precursor is shown underneath. 142 bp >32 kbp ~4 kbp ~6 kbp. Modified from Selby et al., *Mol Cell Biol* 1987;**7**:3057–64.

NGF mRNA is also present in epithelial cells, smooth muscle cells, fibroblasts, and male germ cells. In the brain, the highest levels of NGF mRNA are expressed at postnatal week 3. NGF mRNA expressing cells are found in all areas of the hippocampus, almost exclusively in neurons.

Precursor Protein: Processing and Activity

NGF is synthesized as precursor, 31–35 kDa preproNGF that is processed until it is secreted as mature homodimeric NGF of 28 kDa. The pre-mRNA codes for a signal sequence that directs the synthesis of the protein at endoplasmatic reticulum (ER) ribosomes. Subsequently, the protein is sequestered in the ER, with cleavage of the signal peptide resulting in proNGF, which then forms spontaneous noncovalently linked proNGF homodimers.

Further processing of NGF occurs in the ER with N-linked glycosylation in the prodomain that affords protein stability to NGF. ProNGF homodimers then transit to the Golgi and accumulate in the membrane stacks of the trans-Golgi network.[35]

Sulfation of N-linked oligosaccharides and cleaving of the N-terminal domain of proNGF give rise to mature NGF. ProNGF is cleaved by furin and proconvertases, PACE4 and PC5/6B to yield C-terminal mature neurotrophin dimers. Intracellular cleavage of proNGF to produce mature NGF is at the Arg-Ser-Lys/Arg-Arg sequence.[28]

From the Golgi, NGF can undergo secretion through the constitutive or the secretory pathways, depending on the cell type. Cells have the ability to process and secrete biologically active NGF, and also proNGF can be secreted. Curiously, although mature NGF binds 2 receptors (TrkA and p75) and can afford neuronal survival, proNGF binds in a more restricted manner (p75 only) or to a different subset of receptors and signals toward death in neuronal cells, smooth muscle cells, and oligodendrocytes.

The p75-mediated apoptotic signals are carried through a functional (and physical) association of p75 receptor with sortilin. The prodomain of NGF interacts with the cysteine rich region of the sortilin extracellular domain, whereas the mature NGF domain interacts with p75.[12]

CONFORMATION

The mature NGF is cleaved from the preproNGF precursor (240–260 amino acids). It is a noncovalent homodimer with each monomer having a mass of 13 kDa or 118–129 amino acids. NGF is a member of cysteine knot family because of a double loop formed by two disulfide bonds, which is then penetrated by a third disulfide bond. The crystal structure of NGF reveals the monomer structure consisting of mostly β structure domains, with seven β strands A, A′, A″, A‴, B, C and D, which contribute to three antiparallel pairs of β strands. The core of the NGF monomer is formed by a pair of two-stranded, twisted β sheets with a cysteine knot motif and a reverse turn on one side and three β-hairpin loops on the other side. The large twist between each pair of β strands and the interface between the A′–A″ and B–C double stranded sheets form the hydrophobic core.

The cysteine knot motif and several side-chain to side-chain hydrogen bonds also contribute to hydrophobic core and give rise to the same overall three-dimensional structure of NGF and other members of the neurotrophin family. Two NGF homodimers interact in a parallel manner through hydrophobic interactions, and this explains the high association constant for the two subunits. A comparison of neurotrophin family proteins shows that most of the variable residues are located in the N-terminus, the three β-hairpin

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

loops (residues 29–35, 43–48, and 92–98), and the reverse turn from residues 59–66.[20] The other characteristic feature of the NGF dimer is that it is a basic protein with isoelectric point >9 and clustered positive charged surface close to β-hairpin Asp-30 to Lys 34 that might be involved in binding to the acidic p75 receptor that has an isoelectric point of 4.4.

Variable residues are involved in the selective receptor binding of NGF to its selective TrkA receptor, whereas conserved residues between all the members of neurotrophin family might enable the binding to common neurotrophin receptor p75. The crystal structure of human TrkA-IgC2 domain in complex with human NGF has been elucidated. The ligand–receptor interface consists of two patches, one involving the central beta-sheet at the core of dimeric NGF and the loops at the TrkA-IgC2 domain C-terminal end, and second patch with contacts between N-terminal region of NGF and "ABED" sheet of TrkA-IgC2.[32]

The crystal structure of extracellular domain of p75 in complex with NGF was also determined. p75 Binds along the homodimeric interface of NGF, which disables the second p75 binding site through an allosteric conformational change. Therefore, p75 receptors may bind NGF in a 1:2 stoichiometry.[9] Although it has not been possible to cocrystalize p75-Trk or p75-NGF-Trk heteromeric complexes, there is compelling ligand binding, functional, and biochemical evidence that these complexes may exist.

RECEPTORS—BINDING SITES

NGF elicits its function by binding to two families of transmembrane receptors—the selective and specific TrkA tyrosine kinase receptor and the common p75 neurotrophin receptor. The first NGF binding protein that was cloned was p75, but later, it was discovered that it binds all members of neurotrophin family (BDNF, NT-3, NT-4). TrkA was initially discovered as an oncogenic fusion protein and was an "orphan receptor" until it was discovered that NGF induces its fast tyrosine phosphorylation.

Cells expressing TrkA alone display a small number of high affinity NGF binding sites (K_d 10^{-12} M), but the majority of sites have intermediate binding affinity (K_d 10^{-10} to 10^{-11} M), with a very slow association rate. The p75 receptor binds all mature neurotrophins with low affinity (K_d 10^{-9} M) but with different kinetics. Coexpression of p75 with TrkA receptors leads to the formation of a larger number of NGF high affinity binding sites (K_d 10^{-12}) and a faster association rate. The formation of high affinity NGF binding sites depends on the ratio of the numbers of p75 and TrkA receptors on the cell surface, and the juxtamembrane and transmembane domains of TrkA and p75 are required.

Other members of Trk receptor family include TrkB that binds preferentially BDNF and TrkC that binds preferentially NT-3. The picture is even more complex, because high affinity NT-3 binding to p75 has been reported, and p75 in complex with sortilin also creates highaffinity binding sites for proNGF proBDNF and proNT-3. Indeed, proNGF can activate p75 signaling more efficiently than does mature NGF. However, the biological consequences of proNGF activation of p75 differ from mature NGF: proNGF is generally thought to cause cell death.

TRKA AND P75 RECEPTORS—STRUCTURE

All Trk receptors are type I receptor tyrosine kinases. They have an extracellular ligand-binding domain, a single transmembrane domain and a cytoplasmic part with tyrosine kinase catalytic activity.

The extracellular domain is a ligand-binding domain, and it is glycosilated with 40 kDa of carbohydrate moiety. The extracellular domain has a characteristic subdomain organization. On the N-terminus, there is one cysteine rich domain (also known as D1) that is separated from the second cysteine rich domain (also known as D3) by three consecutive leucine rich motifs (also known as D2). The C-terminal region of the extracellular domain has two immunoglobulin (IgG) like domains, IgC1 and IgC2 (also termed D4 and D5 respectively) (Fig. 2). There is 75% sequence identity in the tyrosine kinase catalytic domains of Trk family members, and around 50% sequence homology in the extracellular domains.

Domain swapping studies between TrkA, TrkB, and TrkC identified their IgC2 domain as the ligand-binding domain and functional activation domain (also termed a "receptor hot spot"); and this was confirmed by crystallography.[30] The IgC1 domain has a role in regulating receptor dimerization and preventing constitutive receptor activation, likely acting as a hinge region. In addition, the D1 domain seems to be an allosteric receptor hot-spot which is unmasked when p75 receptors are coexpressed on the cell.[33]

Biochemical and mutational studies indicate that the Trk transmembrane domain linking the extracellular and intracellular domains plays important roles in ligand activation of the receptor, in the formation of Trk receptor dimers, and in association with p75 receptors.

The p75 receptor is a member of tumor necrosis factor (TNF) superfamily. Structurally, it has a ligand-binding extracellular domain, a single transmembrane domain and an intracellular domain. The extracellular domain has four cysteine repeats (CR1–CR4) that create binding sites for all neurotrophins and proneurotrophins. The cytoplasmic domain has no catalytic activity and has a strong sequence homology to the death domain of the proteins of the TNF superfamily. Thus, p75 has no intrinsic catalytic activity, but it can signal through several adaptor proteins.[4] In addition, the transmembrane domain of p75 has a reduced Cysteine

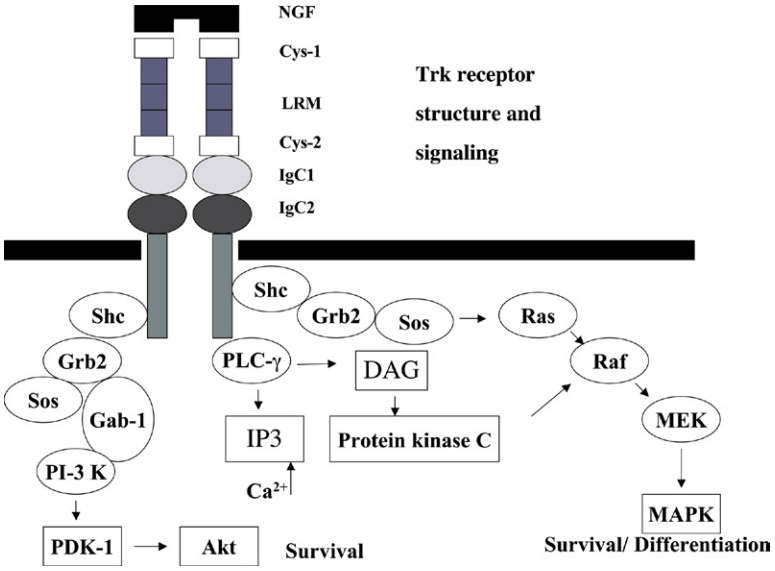

FIGURE 2

that under certain conditions is able to disulfide bond to create stable p75 homodimers that can signal without ligand.[31]

TRK RECEPTOR SIGNALING

The first step in Trk tyrosine kinase receptor activation is a ligand-induced receptor homodimerization followed by transphosphorylation of tyrosine residues in the activation loop. This leads to autophosphorylation of tyrosine residues that serve as recruitment sites for specific signaling proteins and adaptors. Binding of adaptor proteins containing phosphotyrosine binding (PTB) or Src-homology (SH-2) motifs to phosphtyrosines of Trk couples the receptor to intracellular signaling pathways, including Ras-MAPK protein kinase pathway, the phosphatidylinositol-3 kinase (PI-3 kinase)/Akt kinase pathway and phospholipase C-γ (PLC-γ) pathway.[13]

On TrkA activation, phosphorylation of tyrosine 490 leads to recruitment and phosphorylation of Shc that recruits the Grb–SOS complex via SH-2 domain, leading to the activation of MAPK kinase family extracellular signal-related kinases 1 and 2 (Erk1/2) via Ras/Raf/MEK-1 activation. On activation, Erk1/2 translocate to the nucleus where they activate transcription of genes regulated by NGF leading to cell survival.

Direct activation of PI-3 kinase by Ras is a major survival-promoting pathway in most neurons. Phosphatidylinositides generated by PI-3 kinase activate the protein kinase B (Akt) via phosphoinositide dependent kinase-1 (PDK-1). Phosphorylation of Akt by PDK-1 on threonine 308 followed by autophosphorylation on Ser 473 activates Akt and allows it to facilitate survival by phosphorylating different substrates, including transcription factors that modulate cell survival.[10]

Phosphorylation of TrkA at Y785 recruits and activates PLC-γ directly. Activated PLC-γ induces hydrolization of phosphatidyl inositide 4,5 biphosphate to generate inositol-3 phosphate (IP_3) and diacylglycerol (DAG). IP_3 induces Ca^{2+} release resulting in the activation of various protein kinases and phosphatases activated by cytoplasmic Ca^{2+}. DAG activates DAG-regulated protein kinase C isoforms (PKC). PKCs are a family of intracellular serine-threonine kinases that can activate Raf and MAPK cascade regulating cell survival or neuronal differentiation (Fig. 2).

P75 RECEPTOR SIGNALING

p75 Receptors can modulate Trk receptor signaling, but they also signal independently of Trks. Depending on the developmental stage, cell type, whether they are unbound or ligand bound, and the type of ligand, p75 can activate apoptosis or survival, regulate Schwann cell migration, myelination, axonal growth, and regeneration.

During development, p75 signals toward apoptosis to eliminate unnecessary neurons. The signaling pathways of p75 induced apoptosis involve activation of JNK via the recruitment of p75 interacting proteins NRIF (neurotrophin receptor interacting factor), NADE (neurotrophin associated cell death executor), NRAGE (neurotrophin receptor interacting MAGE homolog), and tumor necrosis factor associated factors (TRAFs).

Neurotrophin binding to p75 can activate the MAP kinase pathway leading to cell survival or apoptosis depending on the cell type or ligand type (Fig. 3). Different outcomes of p75 signaling may be caused by differential subcellular

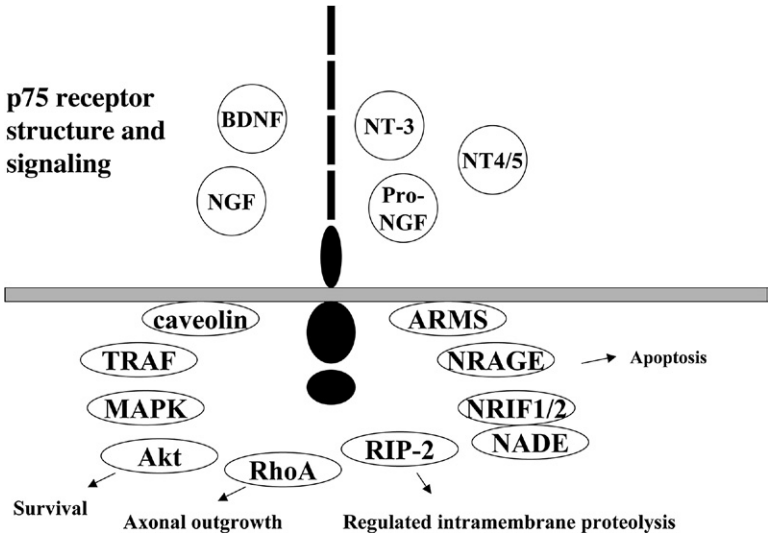

FIGURE 3

localization and transport of p75 complexes. Mature NGF induces very slow internalization of p75, whereas proNGF in the presence of sortilin enables much faster kinetics of internalization of p75-NGF complex.

Another signaling paradigm where p75 participates includes a receptor complex with Nogo receptor and Lingo-1 that mediates growth inhibition in response to myelin-based growth inhibitory proteins (Nogo), myelin-associated glycoprotein, and oligodendrocyte–myelin glycoprotein. p75 plays a role in RhoA activation that is required for growth inhibition. The role of regulated intramembrane proteolysis (RIP) of p75 by α and γ secretases is important in the p75-mediated activation in response to myelin-based growth inhibitory proteins.[6]

The field of p75 signaling is evolving, with new ligands and intracellular interactors being identified, and the identification of p75 homodimers that dissociate on ligand binding, thus the monomers perhaps function differently. However, p75 is a very complex receptor, with varying and sometimes opposite functions, dependent on the cellular context, and therefore, work continues to delineate the molecular pathways that enable p75 to regulate neuronal life, death, motility, and growth inhibition.

NEUROTROPHINS—RETROGRADE TRANSPORT

During development, retrogradely transported NGF promotes survival of appropriately connected neurons. NGF bound to TrkA at the axon terminals is internalized into signaling endosomes and retrogradely transported to the cell bodies. Activated phospho-TrkA in signaling endosomes is linked to downstream signaling pathways that promote neuronal survival and differentiation, whereas surface NGF bound TrkA receptors regulate axonal growth.[14]

After endocytosis, signaling receptors move into early endosomes. From early endosomes, Trk receptors can either return to the plasma membrane for reuse or go along the degradation pathway in a microtubule-dependent fashion, reaching late endosomes and the physical destruction of Trk receptor takes place in lysosomes.

The p75 receptor internalizes and recycles relatively slowly, although ligands do accelerate the rate of internalization. Perhaps one additional regulatory function for p75 is to retain the activated Trk at the cell surface, by reducing the internalization of ligand–Trk complexes, thereby altering the physiological outcomes.[27] These studies show the relevance of receptor location in stimulation, and afford a possible explanation of how different biological outcomes may be achieved by the activation of cell surface versus internalized Trks.

NEUROTROPHINS—PHYSIOLOGICAL ROLE AND ROLES IN PATHOLOGY

Neurotrophins induce cell survival and neurite outgrowth on different neuronal populations. In the PNS, NGF supports DRG neurons during development, the maintenance of mature cholinergic neurons, and regulates arborization and neurotransmitter release. One of the major roles of NGF is to mediate the selective survival of a proportion of developing sympathetic and sensory neurons as they innervate their particular target tissues. In the CNS, NGF also influences synaptic function and plasticity, and phenotypic (and probably also functional) maintenance in the mature cholinergic system.

NGF is trophic to small-diameter sensory fibers and regulates nociception. Being a proinflammatory protein, NGF also plays a role in inflammatory pain. Thus, NGF antagonists could be useful in the treatment of certain forms of pain. The TrkA ectodomain fused to the Fc portion of an immunoglobulin reduces inflammatory pain, presumably by mopping NGF. Anti-NGF antibodies have been used with similar results.[26]

Neurotrophins and their receptors also play a role in the progression of certain types of cancer—neuroblastoma (TrkA, NGF), prostate cancer (TrkA, NGF), and medulloblastoma (TrkC) just to name a few.[25]

There is evidence for neurotrophic factors being effective at delaying neurodegenerative diseases in animal models and humans. NGF has been shown to have an effect in models of diabetic peripheral neuropathy and Alzheimer's disease. Phase II clinical trials using NGF for diabetic neuropathy had initial positive results, but in larger scale phase III trials, there was no beneficial effect.

Because a quantitative decline in TrkA expression in cortex and nucleus basalis correlates well with cognitive decline and stage of disease in Alzheimer's disease, in aged-associated cognitive impairment, and in Down's syndrome,[21] it is conceivable that neurotrophic factors may be useful as therapeutics.

However, problems associated with the use of neurotrophins as drugs are numerous: proteins are not orally bioavailable, they tend not to cross the blood–brain barrier in large amounts, they have a poor pharmacokinetic profile, and they can elicit immune reactions. Also, neurotrophins bind to at least two receptors, and the receptors are present sometimes on the same tissue and sometimes on different tissues, where they can carry out differing signals and biology.

Because neurotrophins have potential for the treatment of neurodegenerative diseases, several approaches have been used to circumvent some of the problems listed above.[24,25] Approaches include gene therapy, cell therapy, and microencapsulated slow-release implants. Gene therapy has entered a nonrandomized, nonplacebo clinical trial with somewhat promising results. However, all these approaches require surgery and are still in the early stages.

A more traditional pharmaceutical approach has been the development of small molecule nonpeptidic neurotrophin mimetics. Such mimetic compounds, defined on the basis of their activity, can have different mechanisms of action: activating receptors directly as ligands, indirectly by upregulating the production of endogenous neurotrophins, affecting receptor signaling pathways, or affecting coreceptors that regulate neurotrophin receptor activity.

The first rationally derived TrkA agonist is a peptidomimetic compound termed D3. D3 is a proteolytically stable monovalent small molecule, a selective TrkA partial agonist that binds the IgC2 (D5) domain of TrkA. *In vivo* D3 binds to TrkA receptors and affords a significant and long-term rescue of cholinergic neurons in the cortex and in the nucleus basalis that correlates well with an enhanced cholinergic phenotype and a significant improvement of memory/learning in cognitively impaired aged rats.[5]

Small molecule TrkA agonists are neuroprotective and can enhance cognition and short-term memory in a mouse overexpressing amyloid-β as a model of Alzheimer's Disease,[1] can delay neuronal death in a traumatic model of optic nerve injury,[15] and delay the death of retinal neurons in animal models of glaucoma.[2]

CLINICAL PROSPECTS

Neurotrophins belong to a family of polypeptide growth factors that control the apoptotic death or survival, growth, and differentiation of neurons. NTFs also regulate several other cell populations such as lymphoid, epithelial, oligoglia, and mast cells. Altered activity (upregulated or down regulated) of neurotrophins or their receptors plays a well-defined role in certain human pathologies. Consequently, the neurotrophins and their receptors are important therapeutic targets, and pharmacological modulation may have applications ranging from treatment of chronic or acute neurodegeneration and some forms of cancer and chronic pain with agonists, as well as some forms of cancer or acute pain with antagonists.

Several clinical trials have been attempted with neurotrophins, some of them seemingly premature and burdened with serious pharmacokinetic/pharmacodynamic issues, low stability, low efficacy, pleiotrophic effects because of the binding of multiple receptors, and high cost.

Although neurotrophins as therapeutics in the treatment of neurodegenerative diseases have been widely tested experimentally and in some human clinical trials, their use as drugs is limited by their poor pharmacokinetic and the high costs associated with their manufacturing. These obstacles have driven the scientific community toward the identification of small molecule neurotrophin mimetics, with more favorable drug-like properties.[23,25]

Therapeutic rationales targeting Trk receptors include the use of compounds that directly bind to and activate Trk (selective agonists of neuroprotective pathways); compounds that enhance or potentiate release of endogenous neurotrophins (secretagogs); and compounds that regulate signaling pathways (potentiators or biological response modifiers).

Therapeutic rationales targeting p75 receptors include the use of compounds that directly bind to and inactivate p75 (selective receptor antagonists or antagonism of neurodegenerative pathways); compounds that modulate or antagonize proneurotrophins; and compounds that prevent death signaling pathways (biological response modifiers).

Neurotrophin mimetics are small molecules that resemble the structure and function of key domains or hot spots of the proteins. They have been designed as cyclic peptides[16,26] or organic peptidomimetics.[19,34] The term mimetic is also used for compounds that have little relationship to the neurotrophins, such as Gambogic amide, but which seem to directly regulate signal pathways through TrkA.[7,11] Similar strategies have been used to develop antagonists of p75 receptors.

Some Trk-agonists and p75 antagonists have been developed preclinically and have shown efficacy in animal models for the diseases, including glaucoma, motor neuron disease, traumatic nerve injury or stroke, and neuropathic pain.[2,8,22] At this time, one small molecule mimetic agonist of TrkA is under late clinical development for ophthalmic indications as topical eye-drops.

As we learn more about these important ligands and receptors, and as pharmacological tools evolve and are refined, we may still see the successful targeting of neurotrophin receptors or neurotrophin proteins in human disease.

Chapter 225

TGF-β

Veronica Lifshitz and Dan Frenkel

ABSTRACT

Transforming growth factor β (TGF-β), a pleiotropic polypeptide, regulates multiple biological processes, including embryonic development, adult stem cell differentiation, immune regulation, wound healing, and inflammation. TGF-β family members are synthesized as prepropeptide precursors and are then processed and secreted as homodimers or heterodimers. Most ligands of this family signal through transmembrane serine/threonine kinase receptors and Smad proteins to regulate cellular functions. Alterations of specific components of the TGF-β-signaling pathway may contribute to a broad range of pathologies such as cancer, autoimmune diseases, tissue fibrosis, and cardiovascular pathology. This chapter focuses on the diverse properties of TGF-β in physiological and pathological conditions.

DISCOVERY

Todaro and De Larco,[11] in 1978, made the important discovery that murine sarcoma virus-transformed 3T3 cells produced a "factor" that induced nonneoplastic rat kidney fibroblast cells (NRK) to assume a neoplastic phenotype. They called this factor "sarcoma growth factor" (SGF) and assayed its transforming activity by the ability of cells to grow in soft agar.[11] It was suggested that SGF was a mixture of at least two constituents.[11] One fraction, which competed with epidermal growth factor (EGF) for receptor sites and induced formation of only a few small colonies of NRK cells in soft agar, was named "transforming growth factor-a" (TGF-α).[1] The second fraction, which induced the growth of many large colonies of NRK cells in the soft agar assay in the presence of small amounts of EGF, was named "transforming growth factor- β" (TGF-β).[1]

The TGF-β superfamily consists of >35 members in vertebrates, including TGF-β isoforms (TGF-β1, TGF-β2, and TGF-β3), bone morphogenetic proteins (BMPs), growth differentiation factors (GDFs), activins, inhibins, Nodals, and Müllerian inhibitory factor (MIF).[25] Members of the extended superfamily are found in a wide variety of species as diverse as insects, amphibia, birds, and human.[25]

STRUCTURE OF THE RNA/GENE

Currently, five distinct isoforms of TGF-β have been identified, and they share 64–82% identity; three of these (TGF-β1, TGF-β2, and TGF-β3) are expressed in mammalian tissues.[23] Among mammals, the sequence homology within a given isoform can reach as high as 100%. In humans, the three isoforms are located on three different chromosomes, 19q13, 1q41, and 14q24, respectively.[23] All genes have a length of >100 kb and contain seven exons.

PROCESSING OF THE PRECURSOR

The three mammalian TGF-β isoforms, TGF-β1, TGF-β2, and TGF-β3 are synthesized as latent precursor proteins (LTGF-β), 390–412 amino acids in length, with a longer N-terminal propeptide followed by a shorter C-terminal mature polypeptide.[28] The LTGF-βs are cleaved intracellularly by furin into a larger C-terminal proregion, also known as latency-associated peptide (LAP), and a shorter N-terminal active peptide, which forms the mature TGF-β-homodimers (25 kDa)[28] (see the furin chapter in Peptide Biosynthesis/Processing section of the book). LAP remains noncovalently associated with the mature TGF-β 25-kDa dimer forming a small latent complex (SLC; ~100 kDa). LAP serves as a chaperone during exocytosis of the complex and keeps TGF-β in an inactive form. LAP also mediates the deposition of TGF-β in the extracellular matrix (ECM), through its covalent association with large secreted proteins called latent TGF-β-binding proteins (LTBPs) and with ECM proteins. The binding of the SLC to LTBP produces the large latent complex (LLC; 235–260 kDa).[28] Often, the LLC is bound to collagen and other tissue matrix proteins through binding sites on the LTBP. Most cell types secrete TGF-β as part of LLC, although some cells (such as the bone cell line UMR-106) secrete SLC.[28]

The mature TGF-β protein can be released from the inactive complex by either proteolytic cleavage by various proteases (such as plasmin, thrombin, plasma transglutaminase, or endoglycosylases), or by physical interactions of the LAP with proteins, such as thrombospondin-1 and integrins

αvβ6 and αvβ8.[28] After TGF-β is released from its latency-associated peptide, it is able to initiate its diverse cellular responses by binding to specific cell-surface receptors.[28]

RECEPTORS AND SIGNALING CASCADES

TGF-β Receptors

Each member of the TGF-β superfamily can bind to cell-surface serine/threonine kinase TGF-β receptors types I and II (TβRI and TβRII, respectively, see Fig. 1). Five type II and seven type I receptors also named ALKs (activin-like receptor kinases) have been identified in vertebrates.[31] There are additional receptors for TGF-β including the type III (TβRIII) and type V (TβRV). The type IV TGF-β receptor has been identified only in pituitary cells but has not been well characterized. TβRIII, also known as betaglycan, is a proteoglycan containing glycoprotein that functions as a coreceptor by presenting ligand to TβRII 14. TβRV, also known as IGFBP-3R or LRP-1, is a receptor for TGF-β, and IGFBP-3 and is coexpressed with TβRI, TβRII, and TβRIII in most cell types.[17]

Ligand binding to the constitutively active TβRII induces the assembly of type I and type II receptors into complexes, in which TβRII phosphorylates TβRI in the 'GS domain' (domain which is rich in glycine and serine residues).[21] Signaling from activated TβRI to the nucleus occurs predominantly by phosphorylation of cytoplasmic proteins known as Smad proteins (Fig. 1).

Smad Proteins

Smad proteins (Sma and Mad proteins from *Caenorhabditis elegans* and *Drosophila*, respectively) convey signals from TGF-β receptors to the nucleus (Fig. 1). Different members of the Smad family have different roles in signaling. The receptor-associated Smads (R-Smads: Smad1, 2, 3, 5, and 8) are recruited to the activated TβRI by auxiliary proteins such as Smad Anchor for Receptor Activation (SARA).[31] ALK1, ALK2, ALK3, and ALK6 phosphorylate Smad1, Smad5, and Smad8, whereas ALK4, ALK5, and ALK7 phosphorylate Smad2 and Smad3 (Fig. 1). Smad1, Smad5, and Smad8 are specific for signaling of BMPs, whereas Smad2 and Smad3 transduce signals for TGF-βs and activins[21] (Fig. 1). However, in endothelial cells that express both ALK1 and ALK5, TGF-β signaling is mediated by two different pathways, namely, Smad1/5/8 and Smad2/3[28] (Fig. 1). Activated

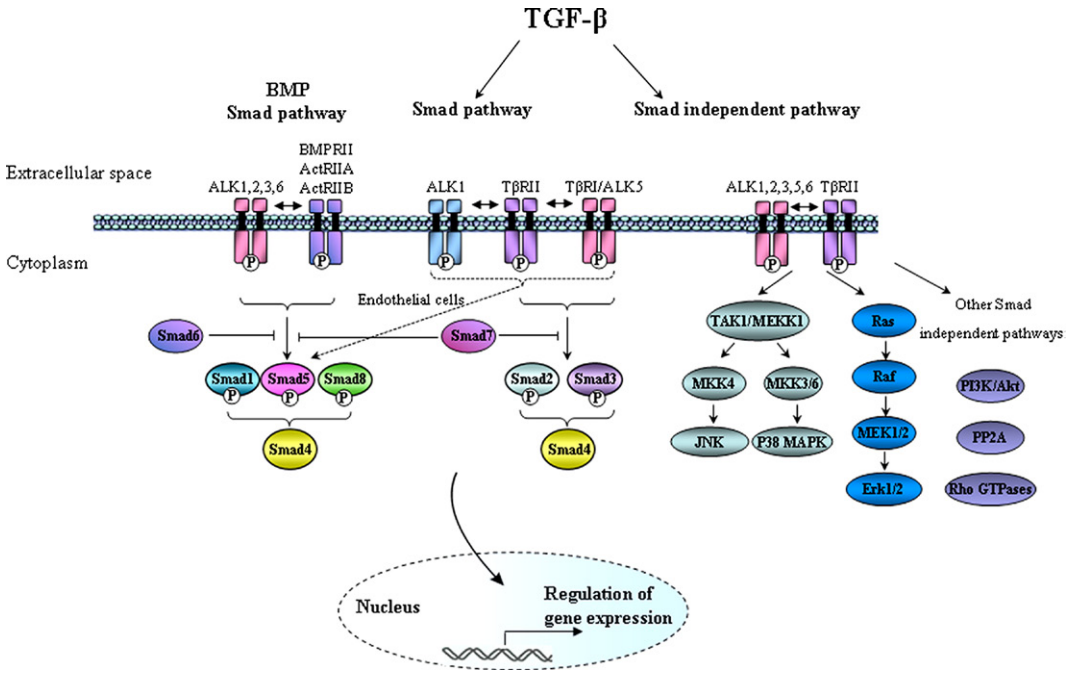

FIGURE 1 TGF-β signaling through Smad-dependent and Smad-independent pathways. TGF-β binds a complex of transmembrane receptor serine/threonine kinases (TβRII and TβRI) and induces phosphorylation and activation TβRI by TβRII. In most cells, TGF-β interacts with TβRII and ALK5, but in endothelial cells, it can also signal via ALK1. BMPs signal via BMPRII, ActRIIA, and ActRIIB, and type I receptors ALK1, 2, 3, and 6. Activated type I receptors induce the phosphorylation of specific receptor regulated Smads (R-Smads: Smad1, 2, 3, 5, and 8). ALK5 induces phosphorylation of Smad2 and Smad3, and ALK1, 2, 3, and 6 mediate phosphorylation of Smad1, Smad5, and Smad8. Activated R-Smads form heteromeric complexes with common mediator Smad4, which accumulate in the nucleus, where they can act as transcription factor complexes and regulate the expression of specific target genes. Inhibitory Smads, such as Smad6 and Smad7, can antagonize TGF-β signaling by inhibiting the activation of R-Smads. TGF-β activated receptor complex (TβRI and TβRII) can activates Smad-independent signaling pathways, such as extracellular-signal regulated kinase (Erk), p38 mitogen-activated protein kinase (p38 MAPK), c-Jun N-terminal kinase (JNK), phosphatidylinositol-3-kinase (PI3 K/Akt), Src, and pathways involving Rho GTPases. See color plate 61.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

R-Smads form heteromeric complexes with the common mediator, Smad4. The resulting Smad complex then moves into the nucleus, leading to the expression of different type of genes (Fig. 1). The inhibitory Smads, Smad6 and Smad7, compete with R-Smads for binding to activated TβRI and thus inhibit the phosphorylation of R-Smads and/or recruit E3-ubiquitin ligases to activated TβRI, resulting in receptor degradation. Additionally, they may recruit protein phosphatase-1 (PP1) to the receptor complex, resulting in the dephosphorylation, thus inactivation, of the receptors via the catalytic subunit of PP1, GADD45.[31]

Smad signaling is essential for most, but not all, TGF-β gene responses. TGF-β can also exert its biological effects through the activation of Smad-independent pathways, including extracellular-signal-regulated kinase (Erk), p38 mitogen-activated protein kinase (p38 MAPK), c-Jun N-terminal kinase (JNK), phosphatidylinositol-3-kinase (PI3 K/Akt), Src, and pathways involving Rho GTPases.[13,14]

DISTRIBUTION OF THE mRNA/PEPTIDE

TGF-β1-3 are widely distributed in both embryonic and adult tissues. Virtually every cell in the body, including epithelial, endothelial, hematopoietic, neuronal, and connective tissue cells, produces TGF-β and expresses receptors for it.[10] TGF-β1 mRNA is expressed in endothelial, hematopoietic, and connective tissue cells. TGF-β2 mRNA is mostly expressed in epithelial and neuronal cell, and TGF-β3 mRNA is primarily expressed in mesenchymal cells.[10] During development, TGF-β1 and TGF-β3 are expressed early in structures undergoing morphogenesis, whereas TGF-β2 is expressed later in mature and differentiating epithelium.[10]

BIOLOGICAL ACTIONS

TGF-β has been implicated as an important regulator of almost all major cell behaviors and activities, including cell growth, apoptosis, differentiation, adhesion, migration, extracellular matrix production, immune functions, hematopoesis, angiogenesis, wound repair, and mammalian embryogenesis and organogenesis.[25] In each cell type and each context, different sets of genes and signaling responses are activated or repressed in response to TGF-β signals, leading to distinct cellular responses in each case.[25]

The importance of TGF-β isoforms in mammalian biology is highlighted by the lack of viability in TGF-β knockout mice. TGF-β1 null mice die within 3 weeks after birth because of widespread inflammatory disease.[27] TGF-β2 null mice die in the perinatal period because of developmental defects in areas including the heart, lung, limbs, spinal column, eye, inner ear, and urogenital system. TGF-β3 null mice die soon after birth because of an impaired lung maturation and defective palatogenesis.[10]

TGF-β Effects on the Extracellular Matrix

TGF-β, through Smad2/3/4 signaling, regulates the synthesis and deposition of extracellular matrix proteins (ECM) such as collagen, fibronectin, osteonectin, and thrombospondin.[24] TGF-β also influences matrix degradation by regulating the expression of proteases such as MMP1, collagenase, transin, and plasminogen activator, while increasing the production of protease inhibitors such as plasminogen activator inhibitor-1 (PAI-1) and tissue inhibitors of metalloproteinases-3 (TIMP-3) as well.[24] Furthermore, TGF-β induces or represses numerous members of the integrin family, which are the key mediators of the cell-ECM interactions. Because of these differential effects, TGF-β has a role in cell attachment, migration, invasion, wound healing, and fibrosis.[24]

TGF-β Effects on Cell Proliferation

TGF-β inhibits the growth of most cell types, including epithelial cells, endothelial cells, and hematopoietic and glial cells, but stimulates the growth of certain mesenchymal cells (e.g. skin fibroblasts) and some other specific cell types.[17] Signaling by TGF-β family members can block a cells transition from the G1 to S phase, a process known as growth arrest, by down regulating the activity of cyclin-dependent kinases (cdks), which regulate progression through the cell cycle.[17] TGF-β signaling influences cdk activity by modulating the transcriptional activity of cdk inhibitors, p15 and p21.[23] In addition to the prominent TβRI/TβRII Smad2/3/4 signaling pathway, it has been suggested that the Ras/ERK signaling pathway, linked to the Smad-independent pathway, is involved in mediating TGF-β–induced growth inhibition in certain epithelial cell systems. The TβRV signaling cascade seems to cooperate with the TβRI/TβRII signaling cascade in mediating TGF-β–induced growth inhibition.[17]

TGF-β Effects on Apoptosis

TGF-β-mediated apoptosis plays an important part during tissue formation and remodeling and during the phase of ontogenetic neuron death.[26] TGF-β serves as a potent inducer of apoptosis in hepatoma cell lines by inducing the transcription of death-associated protein kinase (DAP kinase), Bim in human gastric epithelial cells and programmed cell death 4 (PDCD4) in human hepatocellular carcinoma cells.[26] TGF-β can also repress the expression of antiapoptotic genes, such as B-cell leukemia/lymphoma 2 (Bcl-2) in hematopoietic cells and breast cancer cells.[26] The apoptotic effect of TGF-β is implicated in the elimination of immature lymphocytes and prostatic epithelial cells.[26] However, it is also clear that the death-inducing capacity of TGF-β is context dependent, that is, it is restricted to certain cell types, to a certain state of differentiation, and

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

most notably, to the presence or absence of other growth factors.[26]

TGF-β can also protect against apoptosis through (i) the induction of antiapoptotic gene expression (such as Bcl-2 in rat hippocampal neurons and pre-B cell lines), (ii) repression of proapoptotic gene expression (such as Bad in rat hippocampal cells, CD95 ligand in rat hepatic stellate cells), (iii) cooperation with other survival pathways (by activating Akt and inducing retention of apoptotic transcriptional factor FKHRL1).[26]

TGF-β Effects on Cell Differentiation

During development, TGF-β signaling frequently acts to promote the differentiation of pluripotent cells into specific cell types.[12] TGF-β family members have essential roles in self-renewal, the differentiation potential of embryonic and somatic stem cells, selection of the differentiation lineage and progression along that lineage.[12] TGF-β family proteins actively participate in redirecting the differentiation of ectodermal and epithelial cells toward mesodermal and mesenchymal differentiation (EMT).[12] In osteoblast, skeletal myoblast, and adipocyte cells, TGF-β can inhibit differentiation and stimulates the proliferation of these cells before they reach full maturation.[12]

TGF-β Effects on Angiogenesis

TGF-β signaling is critical for both the formation of the primary vascular plexus (vasculogenesis) and the subsequent extension and remodeling into a complex vascular network (angiogenesis).[4] Gene-targeting studies in mice have shown that inactivation of TGF-β1 causes midgestation lethality resulting from defects in the yolk sac vasculature and hematopoietic system. Moreover, the vessels of the TGF-β1 mutant embryos have decreased wall integrity caused by a defect in endothelial cells differentiation into capillary-like tubules.[4] A similar phenotype is exhibited by mice lacking the TβRII and in mice with null mutations of the genes encoding the TGF-β-signaling components ALK5, ALK1, endoglin, and Smad5.[4]

TGF-β Effects on Nervous System Physiology

Early in mammalian embryology, all three TGF-β isoforms and their TGF-β receptors are expressed in the central nervous system (CNS).[18] In the adult, TGF-β2 and TGF-β3 can be found in all areas of the CNS, whereas TGF-β1 is widely expressed in the choroid plexus and meninges, and in some specific regions of the brain such as the hippocampus and the cortex.[18] TGF-β1 expression is drastically upregulated in the CNS during injury and neurodegeneration, where it is secreted predominantly by activated microglial cells.

TGF-β2 and TGF-β3 are involved in the regulation of precursor cell divisions, migration of neural precursors, neuron and glial cell survival, differentiation, and synaptic plasticity.[6] TGF-β1 has been clearly implicated in several processes of brain development, such as expression of glial fibrillary acidic protein (GFAP) gene expression and astrocyte differentiation, neuronal migration, and cortex lamination, and neuronal survival. TGF-β1 protects neurons against damage induced by excitotoxins, hypoxia/ischemia, and deprivation of trophic factors. TGF-β1 prevents neuronal apoptosis through the inhibition of caspase-3 activation and an increased expression of the antiapoptotic proteins, Bcl-2 and Bcl-xl.[26] TGF-β1 can also activate the ERK pathway in neurons, thus promoting the phosphorylation and subsequent inhibition of the proapoptotic protein, Bad.[8] Furthermore, TGF-β1 enhances the expression of brain derived neurotrophic factor (BDNF)[8] and is required for a full neuroprotective activity of nerve growth factor (NGF), glial-derived neurotrophic factor (GDNF) and BDNF, thus contributing to neuronal survival.[8] There is increasing evidence that hippocampal learning correlates strongly with neurogenesis in the adult brain.[7] Glia secrete the TGF-β ligand myoglianin to instruct developmental neural remodeling in Drosophila.[3] This may suggest that TGF-β plays an important role in remodeling of neuronal network.

TGF-β Effects on the Immune System

TGF-βs have key roles in immune cell activation, inflammation and repair after injury.[30]The gut-associated lymphoid tissue is the largest immune organ in the body and is the primary route by which we are exposed to antigens.[32] Tolerance induction is the default immune pathway in the gut that is important for the maintenance of homeostasis following feeding.[32] TGF-β inhibits the proliferation of T cells and cytokine production via Foxp3-dependent and independent mechanisms. Furthermore, Th3-type T regulatory cells (Foxp3-positive T cells) express LAP on their surface and secrete TGF-β. Th3-type T regulatory cells were suggested to mediate oral tolerance.[32] Smad2 and Smad3 may play essential roles in Foxp3 induction and anti-inflammatory cytokine response, whereas Th17 differentiation and pro-inflammatory response (secretion of IL-17) is promoted via the Smad-independent pathway. Mutual suppression of signaling between TGF-β and inflammatory cytokines is necessary for the balance of immunity and tolerance.[35]

PATHOPHYSIOLOGICAL IMPLICATIONS OF TGF-β

Aberrant TGF-β signaling has been linked to various developmental disorders and diseases, such as cancer,[22] vascular disorders,[5,19] fibrosis,[15] reproductive disorders,[15] autoimmunity,[32] wound healing disorders,[15] and neurodegenerative diseases.[8,29]

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Some of these diseases are hereditary conditions such as HHT (hereditary hemorrhagic telangiectasia), familial primary pulmonary hypertension, and JP (juvenile polyposis).[5]

Developmental Disorders

Appropriate TGF-β superfamily signaling is critical during embryogenesis from the initial stages of blastula formation, during gastrulation, and throughout the multiple stages of organ development.[10] Defects in TGF-β signals may disrupt overall embryonic patterning, leading to premature termination of human embryogenesis. At later developmental stages, they often result in patterning defects and malformation of embryonic organs and have been linked to several human birth defects.[10] Thus, TGF-β2 knockout mice and ALK3 conditional knockout mice have specific defects in the development of valves and septa of the heart.[10] Embryos lacking ALK1, ALK5, TβRII, or endoglin die during midgestation because of impaired vascular development, exhibiting hyperdilated and leaky vessels.[10] A variety of craniofacial malformations have been associated with mutations in TGF-β superfamily members.[10] Mice lacking TGF-β3 have cleft palate and abnormal lung development.[12] Polymorphisms in the gene for TGF-β3 also have been linked to the development of cleft palate in humans.[10]

Mutations in genes encoding TGF-β superfamily proteins, their receptors, and binding proteins result in a variety of skeletal malformations including complete absence of skeletal structures, formation of additional skeletal elements, failure of segmentation of a structure, undergrowth, or abnormal morphology.[10]

Autoimmunity

Deficiency of molecules involved in TGF-β signaling, such as TGF-β1 and TβRII, causes spontaneous lymphocyte activation and differentiation, cell adhesion molecule expression, autoantibody production, multiorgan inflammation and cell apoptosis.[2] Spontaneous initiation of autoimmunity in the TGF-β1 knockout mouse suggests that dysregulation of TGF-β signaling may potentially underlie a number of autoimmune disorders,[32] including multiple sclerosis, experimental autoimmune encephalomyelitis, and inflammatory bowel disease.[2] More detailed examination of the role of TGF-β in inflammation and inflammatory diseases suggests that it has a critical role in the induction of Th17 cells, which play a major role in autoimmune diseases.[32]

Fibrosis in Different Organs

TGF-β is a critical regulator of extracellular matrix production and therefore, increased TGF-β signaling is a critical contributor to the progression of fibrotic diseases. Fibrotic diseases are characterized by excessive scarring resulting from excessive and abnormal deposition of extracellular matrix (ECM), consisting of fibronectin, laminin, vitronectin, and collagen. This occurs by long term activation of myofibroblasts.[15] If the build-up of ECM occurs in organs such as the lungs, liver, kidneys, and skin, it can interfere with organ function, and unabated, results in organ failure.[15] Examples of fibrotic diseases include diabetic nephropathy, liver cirrhosis, rheumatoid arthritis, and arteriosclerosis.[15] TGF-β regulates the expression of proteins involved in executing the fibrotic cascade through (i) regulation of many matrix proteins expression, (ii) regulation of the expression and activity of matrix-degrading proteases and their inhibitors, (iii) TGF-β promotes connective tissue growth factor (CTGF) expression in fibroblasts, which promotes collagen synthesis and myofibroblast differentiation, (iv) TGF-β-induces epithelial to mesenchymal transition (EMT) in renal tubular epithelial cells, which is associated with increased expression of fibroblast-associated proteins, such as alpha smooth muscle actin (SMA), (v) increasing the expression of the vasoconstrictive peptide endothelin-1, which contributes to persistent fibrosis by inducing fibroblasts to produce and secrete ECM.[15]

Cancer

The TGF-β-signaling pathway has complex and contradictory roles in the pathogenesis of human cancers.[15] In normal and premalignant cells, TGF-β enforces homeostasis and suppresses tumor progression directly through cell-autonomous tumor-suppressive effects (cytostasis, differentiation, apoptosis) or indirectly through effects on the stroma (suppression of inflammation and stroma-derived mitogens).[22] However, when cancer cells lose TGF-β tumor-suppressive responses, they can use TGF-β to their advantage to initiate immune evasion, growth factor production, motility, invasion, and metastasis of tumors that have formed.[22]

Malignant cells can circumvent the suppressive effects of TGF-β either through (i) inactivation of core components of the pathway, such as TGF-β receptors, Smad proteins, etc. or (ii) selectively amputate the tumor-suppressive arm of the pathway. In particular, biallelic inactivation of TβRII by mutations that truncate the receptor protein or inactivate its kinase domain occur in colon, gastric, biliary, pulmonary, ovarian, esophageal, and head and neck carcinomas.[22] In addition, frameshift and missense mutations in the TβRI coding region are present in subsets of ovarian, esophageal, and head and neck cancers.[22] Decreased expression of TβRI or TβRII occurs frequently in lung, gastric, prostate, and bladder cancers.[22] Smad2 mutations have been detected at low levels in colon, head and neck, and lung carcinomas. Smad3 mutations have been noted in gastric cancer and T cell lymphoblastic leukemia.[22] Smad4 mutations are present in more than half of pancreatic carcinomas, sporadic colorectal tumors without microsatellite, and in a high proportion of esophageal tumors.[22]

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Cardiovascular Disorders

TGF-β superfamily members critically regulate many different processes within the cardiovascular system (CVS), including cardiac development and angiogenesis.[15] Mutations in endoglin or the ALK1 receptor have been linked to an autosomal-dominant disorder called hereditary hemorrhagic telangiectasia (HHT). The most common clinical manifestations of HHT are nose bleeds and mucocutaneous, small, localized vascular malformations called telangiectasias, and arteriovenous malformations in the brain, lungs, liver, and gastrointestinal tract.[5] Another common genetic defect in TGF-β superfamily entails a mutation in BMP receptor type II gene, which leads to pulmonary arterial hypertension (PAH). PAH is a disease caused by constriction of small pulmonary arteries leading to an increase in blood pressure.[5]

In atherosclerosis, TGF-β regulates lesion phenotype by controlling T-cell responses and stimulating smooth muscle cells to produce collagen. Although TGF-β is believed to protect from atherosclerosis, several lines of evidence support increased TGF-β signaling as a major contributor to restenosis. Restenosis contributes to excessive intimal fibrocellular proliferation and inward remodeling. TGF-β contributes to restenosis by augmenting neointimal cell proliferation and collagen accumulation.[5]

Neurodegenerative Diseases

An impairment of TGF-β1 signaling critically contributes to the pathogenesis of diverse neurodegenerative disorders, including motor neuron diseases, Huntington's disease and Alzheimer's disease (AD).[8,29]

Role of TGF-β1 in Alzheimer's Disease (AD)

Alzheimer's disease is the most common type of dementia occurring in the elderly. The main cause of AD is generally attributed to the increased production and accumulation of amyloid-β (Aβ), as well as neurofibrillary tangle (NFT) consisting of intracellular hyperphosphorylated tau protein, and loss of synapses and neurons.[19]

Many reports have also shown a significant impairment of TGF-β1 signaling in AD brain.[29] Tesseur et al.[29] showed that the expression of TβRII by neurons is reduced very early in the course of AD. Furthermore, neuronal expression of the kinase deficient TβRII in AD transgenic mice promotes Aβ deposition and neurodegeneration, by suppression of neurotrophic factor expression.[29] In addition, genetic studies have revealed that single nucleotide polymorphisms (SNPs) of the TGF-β1 gene at codons +10 (T(C)) and +25 (G/C), which affect the levels of expression of TGF-β1, have been associated with an increased conversion of mild cognitive impairment (MCI) in AD.[8,19] Increased TGF-β1 levels have been found in cerebrospinal fluid and the brain parenchyma of AD patients, whereas a reduction of inactive (50 kDa) forms has been reported in AD plasma.[8] Furthermore, the levels of TGF-β mRNA are 3-fold higher in the frontal cortex of AD brains than control brains.[8] Additionally, in AD, an ectopic localization of phosphorylated Smad2/3 has been detected in the cytoplasm rather than the nucleus of hippocampal neurons[9] in addition to colocalization of phosphorylated Smad2/3 with amyloid plaques and NFT. *In vitro* studies have shown that TGF-β1 prevents Aβ-challenged cortical neurons from entering the S-phase of the cell cycle.[8] Cell-cycle inhibition is one of the mechanisms by which TGF-β1 exerts its neuroprotective effect against Aβ toxicity, another being the prevention of Aβ-induced tau hyperphosphorylation via the inhibition of the tau-phosphorylating enzyme, GSK-3β.[8] Furthermore, TGF-β1 has a constitutive role in the suppression of inflammation and seems to control the degree of microglial activation in the CNS.[8]

Cerebral Amyloid Angiopathy (CAA)

CAA is defined as the deposition of vascular amyloid in the walls of the meningeal and parenchymal arteries, arterioles, capillaries, and, albeit rarely, veins. The vascular amyloid deposits in CAA consist primarily of the β-amyloid peptide (Aβ) and a number of other molecules, such as extracellular matrix proteins, α1-antichymotrypsin, apolipoprotein E, acetylcholinesterase, and cystatin C. The prevalence of CAA, estimated from autopsy series, is approximately 10%–40% in the general elderly population and almost 80% of AD cases. The most widely recognized clinical manifestation of CAA is intracerebral hemorrhage (ICH) and cognitive impairment.[16] Cortical TGF-β1 messenger ribonucleic acid (mRNA) levels correlate positively with the degree of cerebrovascular amyloid deposition in AD cases, and TGF-β1 immunoreactivity in such cases is elevated along the cerebral blood vessels.[34] Heterozygous transgenic mice that overexpress TGF-β1 in astrocytes develop vascular Aβ deposits. Using magnetic resonance imaging (MRI) we found[20] that TGF-β1 mice show a significant cerebrovascular pathology that correlates with CAA. Further, these mice suffer from cognitive impairment that may reflect vascular dementia in patients.

Town et al. (2008) have found that blocking TGF-β/Smad2/3 signaling in peripheral macrophages reduced cerebrovascular Aβ deposits and Aβ abundance in Tg2576 mice, and these events result in promotion of Smad1/5/8 signaling with increased infiltration of Aβ-containing peripheral macrophages around cerebral vessels and β-amyloid plaques.[30]

We have suggested the importance of healthy interactions between endothelial cells (EC) and peripheral immunity to prevent toxic deposition of cerebrovascular amyloid.[20] This crosstalk may be disrupted after pathological expression of TGF-β1 by astrocytes along the cerebrovascular system.[20] We have shown[33] that TGF-β1 affects EC and peripheral immunity crosstalk, leading to a reduction in macrophage

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

activity as measured by protein levels and migration ability. The investigation of TGF-β1 mediated cellular pathways in EC may provide useful therapeutic intervention targets for cerebrovascular amyloidosis diseases such as AD.

SUMMARY

The crucial role of TGF-β in different cycles of the cell ensures it as a major target for modulation. Better understanding of the molecular mechanisms of TGF-β signaling in pathological events may be an important basis for understanding and treating different pathological diseases.

Chapter 226

Augurin and *Ecrg4*-derived Neuropeptides

Conrad Johanson, Ana Gonzalez, Miles Miller, Sonia Podvin, Edward Stopa and Andrew Baird

ABSTRACT

The candidate tumor suppressor gene Ecgr4 encodes a preproneuropeptide ligand-like precursor protein that is proteolytically processed into smaller peptides. The Ecrg4 product augurin (14 kDa) is particularly abundant in the choroid plexus (CP) epithelium and detected in the cerebrospinal fluid (CSF). On secretion by CP, augurin anchors to the CSF-facing membrane, poised for rapid release after CNS injury. After traumatic brain injury (TBI) in rats by cortical stabbing, there is immediate CP release of Ecrg4-encoded peptides in early inflammation (*activation phase*). This may protect the subventricular zone (SVZ) from an immune-activated surge of growth factors and cytokines. Shortly thereafter, Ecrg4 gene expression in CP is transiently downregulated in response to TBI. A lower level of Ecrg4 in CP-CSF coincides with the proliferation phase of neural progenitor cells (NPCs) in the neurogenic niches of the SVZ. The working hypothesis is as follows: CP-derived Ecrg4 normally inhibits NPC mitosis, but when its synthesis/release into CSF post-TBI is diminished, the resultant NPC dysinhibition enhances subependymal neurogenesis.

INTRODUCTION

The discovery of the polypeptide hormone augurin in choroid plexus (CP), the major source of cerebrospinal fluid (CSF), opens up new neuroscience research vistas. A promising area of investigation is neuroendocrine modulation of the brain interior: its development, response to injury, and aging.[10,15,18] Peptides and proteins secreted by CP into the ventricles control subependymal cell growth and homeostasis, preserve brain fluid balance, and regulate neuronal functions. Augurin is one of the protein products of *ecrg4*, a gene that is down regulated in epithelial cancers. It seemed reasonable to explore how the altered expression of Ecrg4 in the CNS might impact the epithelial linings of the ventricular system. These include CP, ependyma and subependymal cells. A knowledge about how Ecrg4 controls these periventricular regions may also provide an insight into the generation of CNS primary tumors. For the purposes here, it also provides information on the dynamics of nascent neuron generation in ontogeny, neuronal replacement in senescence, and the compensatory response to brain trauma.

This chapter describes how the use of Markov modeling[13] identified the novel prohormone-like gene, describes the gene products of *ecrg4*, and specifies the elevated Ecrg4 expression sites around CNS ventricles. It also highlights how some experimental manipulations that alter levels of Ecrg4 gene expression modify the associated degree of mitosis in neurogenic niches (NNs). Because CP-derived ecrg4 gene products evidently modulate stem cell targets in NNs via CSF endocrine distribution mechanisms, another topic treated herein is basic CSF neuropeptide physiology. Documented CSF transport of neuroactive materials[31] helps to bolster a neuroendocrine-like role for Ecrg4-derived peptides in regulating neurogenesis at sites distant from CP. Before describing Ecrg4 biological activities, we first discuss the genomic features, molecular structure, and expression patterns of this newly introduced neurohormone-like peptide precursor.

DISCOVERY OF PREPONDERANT EXPRESSION OF AUGURIN IN CHOROID PLEXUS

The initial step in uncovering Ecrg4 as a CP-CSF expressed peptide was enabled by the prediction of its existence by Hidden Markov Modeling (HMM).[13] On the basis of amino acid sequence information, obtained from the alignment of peptides registered in multiple proteomics databases, the mature peptide product now known as augurin was predicted from HMM. An in-depth search into the human genome, using an HMM bioinformatics approach, revealed that the *Ecrg4* gene contains the features of a neuropeptide precursor within its primary sequence and at least one highly conserved secreted polypeptide. Mirabeau et al. coined the name augurin for one of these anticipated neurohormones[13] encoded by Ecrg4(31–148).

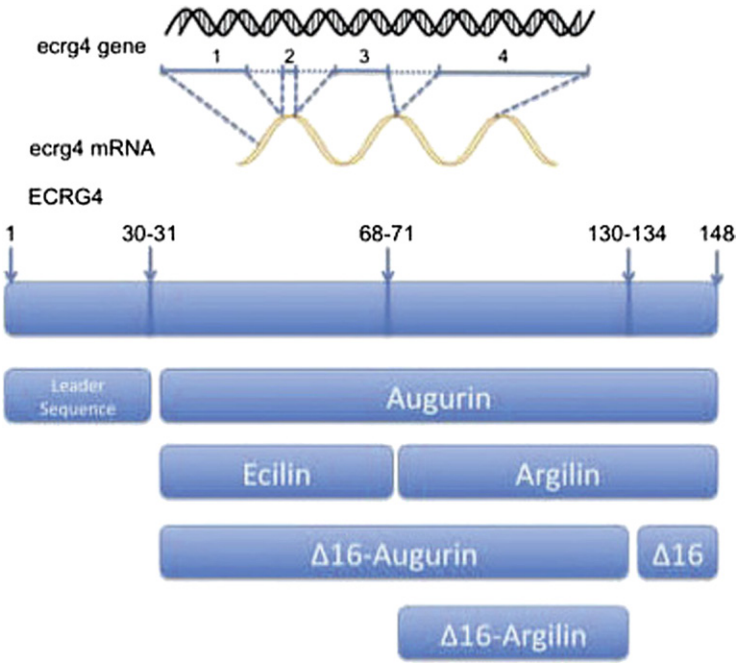

FIGURE 1 Candidate peptides generated from *Ecrg4* gene expression. Algorithms predict that the single augurin gene can produce 8 potential protein/peptide cleavage products. Intact augurin, including the 30-amino-acid leader sequence, consists of 148 amino acids. Ecilin and argilin consist of amino acid fragments 31–70 and 71–148, respectively. Δ16C-terminal cleaved homologs include the Δ16 peptide itself as well as CΔ16-augurin and CΔ16-argilin. Consensus processing sites include those for removing the signal peptide, and for cleavage by furin-like hormones and thrombin.

Accordingly, augurin (also known as Ecrg4(71–148)) is produced by proteolytic processing of the esophageal-cancer-related gene (ecrg4) holoprotein. Including the leader sequence (amino acids 1–30), the augurin precursor molecule consists of 148 amino acids. *Ecrg4* gene products are schematized in Fig. 1. This novel neuropeptide and its cleavage products include an amino terminal "**EC**" domain which we call ecilin (amino acids Ecrg4 (31–70)), a carboxyl terminal "**RG**" domain which we call argilin (Ecrg4(71–148)), and a variety of other potential products depending on whether the 16 C-terminal peptide domain (CΔ16) is also processed from the precursor protein. No gene product had a known biological function at the time of prediction.

Ecrg4 amino acid sequences for a variety of species are aligned in Table 1. Open reading frame (ORF) comparisons reveal a high degree of conservation across diverse species (Table 2). Homology is particularly high (99%) when the chimpanzee *Pan troglodytes* is compared with the ORF for humans. Mice and rats have 84% and 83% homology, consistent with the crossreactivity of the antibody with augurin (recombinant human) in all three species analyzed by us.

The amino acid sequence of augurin within the *Ecrg4* ORF has all the features of a neuropeptide-like precursor. The sequence fits a highly conserved secreted hormone. Therefore, we decided to focus the initial investigations on CP and secretory tissues known for neuroendocrine mediation and homeostasis. Significant expression of Ecrg4 occurs in the pancreas and adrenal gland, but the greatest expression by far occurs in the CP epithelium (Fig. 1A).[5] A distinguishing feature of the CP-CSF function is the secretion/transport of multiple peptides/proteins that influence the state of neurogenesis in periventricular regions.[8] This applies to normal brain development[26] and to periventricular homeostatic responses in adult CNS injury.

In contrast to many neural and nonneural tissues, the mRNA for augurin is strikingly abundant in CP (Fig. 2A). Ecrg4 transcript in CP is several orders of magnitude greater than in the heart, lungs, kidney, and cerebral cortex (Fig. 2B).[5] Immunostaining of rat tissues displays the augurin signal in the CP and adjacent ependymal wall (Fig. 3A). Moreover, immunohistochemistry of human CP reveals the 14 kDa augurin localized to epithelial cells, especially prominent at the CSF-facing apical membrane (Fig. 3B). Immunoblotting of rat CP confirms the presence of a manufactured 14 kDa molecule, that is, augurin (Fig. 3C).

Both human and rat CP release augurin at the epithelial apical surface. Cultured adult human CP epithelium transfected by adenovirus with Ecrg4 cDNA express augurin,[5] but the secreted peptide detected in the conditioned medium by an ELISA[5] is of lower molecular weight suggesting that

posttranslational processing occurs on the cell surface or after shedding. CP also releases Ecrg4-derived peptides *in vivo* into the ventricles as suggested in follow-up experiments that assayed augurin in rat CSF .[17] Taken together, the various methods and species analyses (mouse, rat, and human) constitute strong evidence for augurin prominence in the mammalian CP-CSF-ependymal nexus.

EXPLORING PHYSIOLOGIC ROLES FOR AUGURIN

Early evidence points to multiple homeostatic roles for Ecrg4. These include regulation of cell proliferation, senescence, inflammation, tumor progression. and stress responses involving the hypothalamus–pituitary–adrenal axis. Few systematic studies have been conducted on Ecrg4 to date.[5,17,28] The aforementioned initial observations, however, serve to guide experimentation for establishing its cell biology and physiology.

Another candidate role for augurin and Ecrg4, of particular interest to our research group, is related to the ability of the CSF circulation to carry ventricular neuropeptides to target cells within the brain. Peptides secreted by CP are extensively involved in neuronal homeostatic phenomena.[10] This is because of the brisk CSF bulk flow that rapidly distributes macromolecules to regions near the ventricular wall, for example, the SVZ and hippocampal dentate gyrus (DG). Therefore, CSF hydrodynamics efficiently conveys peptides and proteins from CP secretory sites to receptors in periventricular neuronal networks. Neural progenitor cells (NPCs) are housed in specialized subependymal niches, the SVZ and DG, where mitosis is ongoing. All in all, these observations prompt the working model that augurin participates in the control of subependymal neurogenesis.

CSF AS A CIRCULATORY LINK BETWEEN CP AND BRAIN

Many reports indicate that CSF functionally couples choroidal and cerebral metabolic activities.[9,11] CSF performs diverse endocrine functions.[15] Acting like a ventricular "neuroendocrine organ,"[6] the CP is strategically positioned to provide hormones and trophic factors to the CSF-brain axis.[1] As a distributing medium, the CSF circulation conveys peptides and proteins to multiple target cells in the hippocampus, SVZ, and hypothalamus. Targeted cells include ependyma in the ventricular wall and immature neurons in the hippocampal neurogenic nitches (NNs). Hypothalamic nuclei such as the arcuate nucleus also contain peptide receptor targets.[19] Periventricular target cells are accessible to CSF-borne peptides by way of bulk flow and cytoskeletal transport mechanisms in tanycyte fibers. Being a permeable interface, the ependyma in adult mammals permit great diffusional exchange of large molecules between ventricular CSF and subependymal ISF.[9]

Neuropeptides, by way of CSF signaling mechanisms, mediate diverse homeostatic responses in the CNS. Homeostasis entails the regulation of fluid balance and cell metabolism, as well as the production of new neurons after causing physical harm to the brain. Nascent neurons are needed in increased numbers after ischemic and traumatic injuries that destroy neuronal networks.

CSF circulation is an essential component of all CNS transport models. Accordingly, a major convective system for translocating peptides destined for the NNs is the CP-CSF nexus. The CP at the blood–CSF interface engages in transport (hormones from blood) and secretion (choroid epithelial synthesis) of peptides into the ventricles. In fetal brain, a plethora of growth factors and neurotrophins are

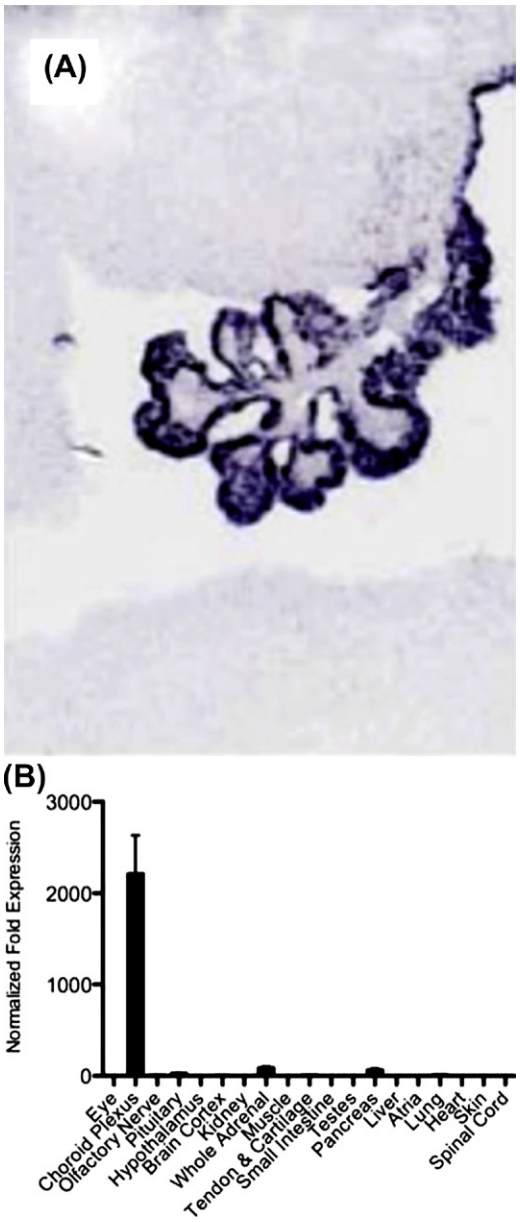

FIGURE 2 Major sites of *Ecrg4* expression in CNS. **(A)** *Ecrg4* gene expression in mouse CP and ependymal lining. *In situ* hybridization signal (mRNA) localizes primarily to the tuft (frond) of choroid plexus epithelial cells (center of figure) and, to a lesser extent, the single layer of ventricular ependymal cells lining the brain interior (top right). **(B)** Quantitative *Ecrg4* gene expression by RT-qPCR. After extraction of tissues from donor adult mice, highest *Ecrg4* expression is found in dissected CP; very low expression is observed in the cerebral cortex. Data, calculated by ΔCt, were normalized to values from testes.[5] A similar expression magnitude occurs in male rats (data not shown). Low gene expression is detectable in all tissues. Error bars are mean ± standard deviation, n = 5.

distributed along the CP–CSF ependyma. These regulatory molecules promote mitosis, differentiation, and migration in the subependymal NNs. Such events occur during ontogeny when the expanding brain is relatively avascular and therefore dependent on micronutrient (vitamin) and hormonal provisions from CSF.[26] In later adult life when the brain suffers harm and requires trophic support for restitution, the CP again takes on a critical role in copiously supplying peptides/hormones to NNs in hippocampus and SVZ. This suggests an emerging role for ecrg4 and augurin production in regulating the proliferation of neural progenitors.

PEPTIDE TRAFFIC THROUGH THE BLOOD–CSF BARRIER VS. BLOOD–BRAIN BARRIER

For solute distribution, the CP–CSF nexus works in parallel with the brain microvessel–neuron interface to furnish substances to the CNS. Thus, another major source of hormonal peptides and micronutrients for NPCs and neuronal networks is the cortical endothelium of the BBB. Accordingly, the cerebral endothelial cells transport and secrete peptides across the capillary abluminal membrane into interstitial fluid (ISF).[34] Concurrent fluid secretions from the CP epithelium via CSF, and the BBB endothelium via ISF, thereby support the NPCs in the SVZ and DG. Unique expression profiles of transporters and translocated peptides at the BCSFB vs. BBB enable variegated effects on NPCs by the respective secretions. Because CP displays the highest expression of Ecrg4 among >15 tissues analyzed (including cortex), it is interesting to speculate that augurin distribution and kinetics at the BCSFB–CSF interface and in adjacent ventricular ependymal regions are involved in CNS homeostasis.

CP translocates a host of polypeptides in the CSF secretory process. Peptides are derived from the circulating blood in the plexus by transport,[2] and from the choroidal epithelium by *de novo* synthesis.[3] Examples of such peptides conveyed from the BCSFB into CSF are insulin-like growth factor (I and II), basic fibroblast growth factor, extradermal growth factor, nerve growth factor, hepatocyte growth factor, as well as brain derived- and glial-derived neurotrophic factors. CSF-convected hormones, received from CP epithelial secretions, include leptin,[29] prolactin,[23] and insulin. Many principles and characteristics of CSF distribution of the aforementioned established hormones probably apply to augurin. By volume transmission or bulk flow, these peptides/proteins are swept down the neuraxis from the lateral ventricles to CSF cisterns at the base of the brain. In transit through the cerebroventricles of the telencephalon, diencephalon, and myencephalon, the CSF-borne growth factors and neurotrophins permeate the ventricular wall and gain access to NNs. NPC cell mitosis, growth, differentiation and migration are stimulated (or inhibited) by these polypeptides that move from ventricular CSF into the brain interior. Hemodynamic perturbation of CP[16] or hydrocephalic distortion of the ventricles[33] thwarts CSF delivery of peptides to neurogenic regions.[14] Interrupted provision of CSF peptides to neural stem cells

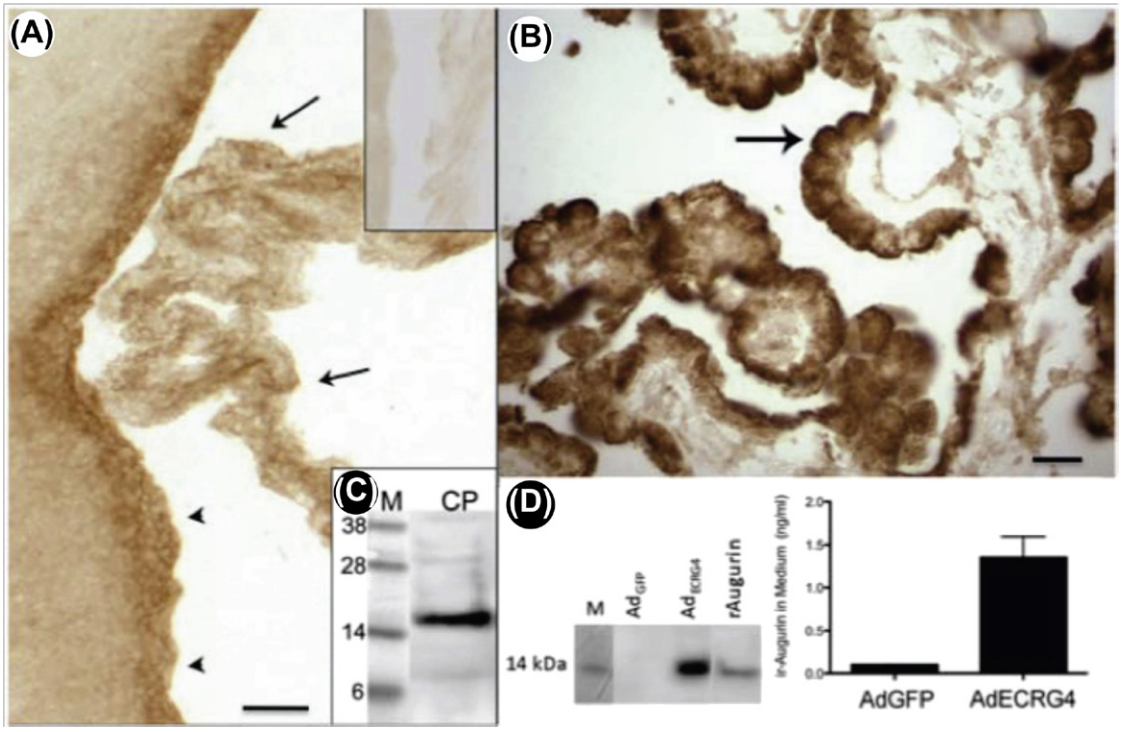

FIGURE 3 Choroid plexus expression of augurin, a 14-kDa processed protein of the *ECRG4* ORF (amino acids 31–148). **(A)** Immunoreactive augurin in adult rat CP (arrow) and ependyma (arrowhead) of third third ventricle, compared with preimmune IgY control (top inset). Scale bar = 20 μm. **(B)** Adult human tissue shows similar augurin staining localized primarily to CPe (black arrow). Bar = 20 μm. **(C)** Rat CP immunoblotting reveals a 14-kDa band, corresponding to the anticipated molecular weight of augurin. **(D)** Augurin secretion *in vitro*: Adult primary human CPe cells, transduced with adenovirus vector (Ad) containing green fluorescent protein gene (Ad_{GFP}), fluoresced (data not shown); and like untreated CP cells in culture, do not express augurin. Cells transduced with Ad containing *Ecrg4* cDNA (Ad_{Ecrg4}) express augurin protein, detectable in RIPA lysates by immunoblotting. Ad_{ECRG4}-transduced CPe secreted augurin into conditioned medium, measurable by ELISA but not by immunoblotting. M = molecular weight marker. rAugurin = recombinant augurin purified from *E coli* and used as standard. Images are from Ref. 5.

can compromise restorative adaptation to diseases and injuries.

CSF-PEPTIDE-MEDIATED HOMEOSTATIC RESPONSES IN CNS PATHOPHYSIOLOGY

Multiple homeostatic mechanisms in CP work to maintain brain fluid composition in a steady state.[10] Marked disturbances of the *status quo* physiology, occurring in stroke and trauma, trigger compensatory actions to restore equilibrium. Diverse insults to the CNS by hyperthermia,[20] TBI, hydrocephalus, hypertension, ischemia, and Alzheimer's disease[27] generate common pathophysiologic sequelae. These include disrupted barriers, ventriculomegaly, cerebral edema, and injured neurons.[21,22,35] Homeostatically upregulated or downregulated peptides have a prominent role in the biochemical and functional adjustments to stress-induced pathophysiology.

Are brain "injury signals" transmitted to the CP to elicit a compensatory response for repairing damaged neural tissue? Supporting evidence comes from the seminal finding of Walter et al.[32] who showed in a rat TBI model that insulin-like growth factor-II (IGF-II), upregulated in CP after a cortical stab wound, is carried by CSF flow to the injury site to promote healing. The CP is sensitive to chemical changes in nearby CSF.[7] Receptors for cytokines and neuropeptides abound at the choroid apical (CSF-facing) membrane.[10] We theorize that "injury signal" peptides (e.g. cytokines), released at the damage site in cortex, diffuse or flow into ventricular CSF. There, cytokine transport and binding to CP epithelial receptors initiate a compensatory response that includes altered peptide synthesis and secretion into the ventricles. CSF thus constitutes the medium for receiving "injury signals" (afferent arm) and then dispersing the CP-derived response peptide (efferent arm) back to the injury site to facilitate healing. Evidence presented herein indicates that CP–CSF augurin, like IGF-II, participates in the efferent arm of an injury response. The augurin injury response, that is, a postulated reduced secretion of augurin into CSF, by CP in which Ecrg4 is downregulated (Fig. 4), may therefore be permissive to stimulate neurogenesis for recovery from TBI.

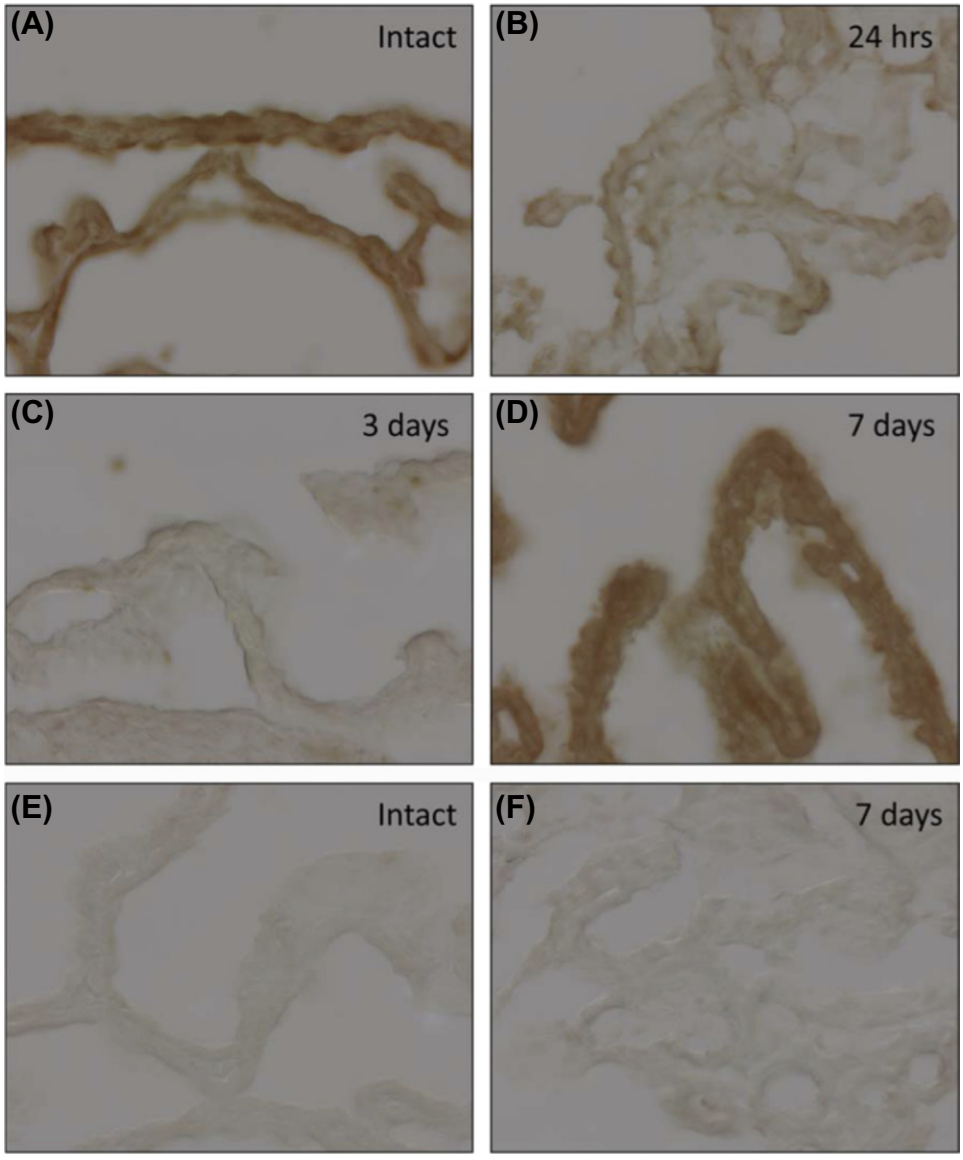

FIGURE 4 Decreased expression levels of *Ecrg4* in CP epithelium after TBI. Brain was stabbed by ophthalmic knife penetration of adult rat dorsal cortex to transect the corpus callosum 3 mm deep and lateral to the right lateral ventricle. Gene expression was evaluated by *in situ* hybridization (binding of an Ecrg4 mRNA antisense probe) in the contralateral CP in intact rat brains **(A)**; and in postinjured specimens at 24 hr **(B)**, 72 hr **(C)**, and 7 d **(D)**. The greatly reduced *Ecrg4* signal (brown reaction product) at 3 d post-TBI is restored to control levels at 7 d. A synthetic, negative control mRNA probe was generated from the pSPT18-Neo plasmid control backbone and used to assess background signal in control (E) and 7 day (F) sections. Images represent 3 rats for each group. Images are from Ref. 17.

ELEMENTS OF AN INJURY RESPONSE FEEDBACK LOOP

Ecrg4 is a candidate neuropeptide gene for responding homeostatically to TBI. Criteria for servomechanistic injury repair, presented below, are offered to encourage future analyses. In modeling CSF–brain homeostasis, the CP is a useful reference point for (i) receiving peptides that function as injury signals, (ii) binding molecular 'signals' released from the trauma site and transported to the blood-CSF interface, (iii) upregulating or downregulating, and secreting, a response peptide (e.g. augurin and/or a growth factor), and then (iv) decreasing or increasing the dispersal of the modulating agent (e.g. augurin or IGF-II) to other CNS regions for beneficial effects that are either a) neurogenic (affecting NPCs) or b) nonneurogenic (promoting wound healing). Criteria i and ii are part of the afferent arm of the response, although iii and iv are related to the efferent arm.

Criterion i awaits elucidation. Candidates include cytokines/peptides released at the injury site. Leukocytes in the inflammation zone, secondary to trauma, may also

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

transfer "signals" to first responder cells, for example, CP. By convection or diffusion from brain to ventricular CSF, such 'injury molecules' or cells reach the CP. The second criterion involves receptors for 'injury signals.' Substantial evidence shows that the CSF-facing membrane of CP is studded with receptors for cytokines, growth factors, hormones, and fluid-regulating peptides. This apical membrane also houses Kolmer cells,[24] the antigen-presenting macrophages that are activated when CSF immune molecule concentration increases. Criterion iii deals with altered expression/secretion of peptides by CP post-TBI. It is backed by evidence for IGF-II[32] and augurin.[5,17] Finally, criterion iv involves a circulatory-distributive mechanism carrying CP-secreted peptides to remediate hippocampal and cortical injury sites. This is accomplished by CSF bulk flow from ventricular CP to SVZ/DG, and to cortex enveloping the brain (proximate to subarachnoid CSF). Moreover, ependymal and pia-glial surface permeability[25] allows CSF-borne peptides to readily penetrate the target regions in the injured neural parenchyma.

LEVEL OF AUGURIN PEPTIDE EXPRESSION AND DEGREE OF NPC MITOSIS IN TBI

TBI and other CNS injuries lead to compensatory enhancement of SVZ mitosis and neurogenesis. Neuropeptide mobilization, or its attenuation, has been implicated in the boosted neurogenic response.[8] Interestingly, NPC proliferation occurs in the SVZ/DG of the brain interior, even though the injury site is in overlying cortex distant from CP, CSF, and periventricular NNs. The rescue or improvement of cognition, after TBI damage, depends on greater conversion of NPCs to nascent neurons.

A wide array of neuropeptides modulates neurogenesis. Ecrg4 overexpression and hence augurin overproduction, can regulate cell division of NPCs. An established role of *Ecrg4* as a tumor suppressor gene intimates the ability of its product, augurin, to curtail mitosis even in noncancerous tissue. Therefore, we suggest that augurin normally supplied by CP-CSF to subependymal NPCs constituitively inhibits proliferation in the SVZ/DG. Relieving the inhibitory tone on mitosis, by decreased Ecrg4 expression and curtailed delivery of augurin to the SVZ after injury, would consequently dysinhibit the cells. Enhanced neurogenesis would be the outcome.

Any model implicating a homeostatic feedback role for the BCSFB in response to CNS disturbances must provide convincing evidence that the CP expression level of peptide is sensitive to pathophysiology at an injury site distant from the choroidal epithelium. Dysinhibition pathology could result from neural disease, stroke, or trauma. We selected TBI in part because of the previous observation that another peptide, IGF-II, undergoes enhanced secretion by CP into CSF after a stab wound.[32] Two days after stabbing the rat cortex, there is downregulated Ecrg4 gene expression and augurin protein in CP epithelium and concurrent increase of neurogenesis in the nearby SVZ.[5,17] This fits the notion that after TBI, a progressively decreasing titer of CP–CSF augurin, a probable suppressor of mitosis, is relieving constitutive inhibitory tone on NPC cell division in the SVZ.

What happens in the SVZ after cortical trauma? Observations in rats document an increase both in BrdU incorporation (reflecting greater mitosis) and in the immunoreactive signal for nestin (a biomarker for NPCs). This fits the proposed augmented neurogenesis in subependymal regions such as SVZ. Consequently, a faster rate of production of nascent neurons, and their subsequent incorporation into injured neuronal circuits, would be expected to counter the cognitive diminution suffered in TBI. The potential for Ecrg4-derived peptides such as augurin along with other neuropeptides to facilitate these putative homeostatic mechanisms, which promote neurogenesis, prompts consideration of additional endogenous peptide factors in restoration of the brain after TBI.[8]

TBI has been widely used for analyzing the response of subependymal NNs to CNS injury.[8] Consistently, SVZ neurogenesis is upregulated after physical brain trauma. Moreover, periventricular mitosis is also stimulated by cerebral ischemia.[4,12,30] Although the specific role of augurin in TBI recovery has been implicated, data from other Ecrg4 manipulation experiments (below) bolster the working model that neurogenesis (or SVZ mitosis) is inversely related to the CSF augurin level.

TITRATING SVZ PROLIFERATION BY ALTERING AUGURIN IN THE CP–CSF–EPENDYMAL NEXUS

We sought more evidence for the Ecrg4-neurogenesis model with experiments that ranged from creating injury pathology (plus augurin transfection) to instilling vector-carrying Ecrg4 into intact ventricular CSF or cultured CP epithelium (Table 3). All together, these transfection experiments furnish evidence that CSF augurin from CP/ependyma is a peptide factor that regulates NPC activity level in subependymal regions of the lateral ventricle (Table 3).

Human CP epithelial cells in culture express Ecrg4 and secrete peptides into the *in vitro* conditioned medium (fluid analogous to CSF). Augurin presence in the cultured epithelium was confirmed by ELISA of whole cell lysates, but the smaller peptide fragments were found in media.[5,17] In an *in vivo* experiment on rats, also involving transfection of CP/ependyma by viral vector (ADEcrg4 icv), to boost the level of augurin synthesized *in vivo*, it was the 14 kDa parent augurin peptide that was detected in endogenous CSF by immunoblotting.[17] These two lines of investigation

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

thus show that mammalian CP epithelium and ependyma produce Ecrg4-derived peptides for release into ventricular CSF (Table 3). Documentation of these steps of synthesis and release is essential to show in our model that Ecrg4/augurin participates in the CP–CSF modulation of subependymal NPC proliferation.

The ability of Ecrg4/augurin-derived peptides to modify neurogenesis was tested by other approaches. If augurin exerts neurogenic effects by receptor-mediated action, then experimentally changing the concentration of augurin in CP, CSF, and subependymal regions, should reset the response level of the SVZ to TBI. Levels of augurin in the CNS can be "titrated" by experimental manipulation like transduction with Ecrg4 (Table 3). Knowing that icv viral vector transduction of *Ecrg4* alone increases augurin in CSF-SVZ, we sought to reverse the effects of TBI (which normally decreases the peptide level) by first instilling AD_{Ecrg4} into a lateral ventricle *and* then stabbing the cortex.[5] Using BrdU and nestin immunostaining intensity to reflect degree of neurogenesis (endpoint), we obtained evidence that stimulated neurogenesis in TBI is countered (abolished) by swamping CSF with excess exogenous augurin (Table 3). This reinforces our working model that the augurin level in CSF-ependyma-SVZ impacts the brain neurogenic adjustment to TBI.

Advantages accrue to the use of diverse species and stages of development to differentiate the effects of *ecrg4* gene expression. Zebrafish *Ecrg4* has substantially less homology to the human gene than do rodents tested in the TBI model (Tables 1 and 2). With an *Ecrg4* homology of 43–45%, the gene structure in zebrafish is more dissimilar to that of humans than that of rodents (83–84% homology). Accordingly, the polypeptide cleavage products (Fig. 1) may differ substantially across species (fish vs. mammal), leading to unique phenotypes (and responses to injury) when genes are upregulated by vectors or knocked down by morpholinos. Limitations exist in comparing data in Table 3, because of variables in the stage of development and methods for altering gene expression. Nonetheless, a pilot study with zebrafish[5] provides additional clues on how augurin expression in CSF brain impacts CNS fluid homeostasis and progenitor division in the NNs.[5] Knockdown of *ecrg4* in embryonic zebrafish (Table 3) results in disturbed fluid balance (hydrocephalus-like edema) and increased proliferation of GFAP-positive cells. Mitotic activity in NNs includes both neurogenesis and gliogenesis. Consequently, Ecrg4/augurin

TABLE 3 Manipulated Augurin Expression in the CP–CSF–ependyma-SVZ: Impact on Neurogenesis

Species	Model	Treatment or manipulation	Result	Significance	Reference
Human (adult)	Primary culture of CP epithelium	*In vitro* transduction by adenovirus with Ecrg4 transgene	Augurin peptide found in cell lysate and in conditioned medium	CP synthesizes and secretes augurin out of choroid epithelial cells	5,17
Rat (adult)	Viral vector delivery of transgene into the ventricle	ADEcrg4 transgene injected into CSF (exposure for 2 days)	Augurin became tethered to the CP apical surface; CSF augurin (14 kDa) found by immunoblot analysis	Augurin synthesized in CP is secreted for autocrine and endocrine-like actions	17
Rat (adult)	Traumatic brain injury (TBI)	Stab injury to parietofrontal cortex	In CP ↓ immunoreactive augurin and ↓ Ecgr4 gene mRNA	↓ Augurin in CP is a response to TBI and leads to ↑ neurogenesis in SVZ	5,17
Rat (adult)	TBI *plus* overexpression of Ecrg4 in ependyma	Stab wound *plus* ADEcrg4 delivery to ventricular CSF and ependyma	↓ BrdU incorp-oration by SVZ progenitors; ↓ immunoreactive nestin (NPCs)	Ecgr4 overexpression can override TBI effect on the neurogenesis	5
Zebrafish (embryo)	Gene knockdown with morpholino	↓ Expression of Ecrg4 in CSF-brain nexus	↑ Proliferation of GFAP+ cells in brain and induced hydrocephalus and edema	Rescue by coinjected antisense (Ecrg4) suggests augurin-specific effect	5

may help to control the formation of both neurons and glia in development. Cross-species variation in gene products (augurin, ecilin, argilin, and other peptide fragments) also gives rise to the possibility that injury responses and homeostatic mechanisms vary considerably with differentials in expression and posttranslational processing. Nevertheless, despite phenotypic differences in mammals vs. nonmammalian systems, there is evidence for common effects across phyla and that Ecrg4 expression/augurin production can modulate NPCs in the NNs (Table 3).

AUGURIN RELEASE: RELATION TO AUTOCRINE VS. ENDOCRINE HOMEOSTATIC MECHANISMS

Homeostatic adjustment to CNS injury spans several phases (Fig. 5). Some peptides act in more than one phase of the injury response to foster repair. This seems to be the case for augurin released from CP in brains subjected to physical trauma. Autocrine (local to the same cell) and paracrine/endocrine (distant from the peptide-releasing cell) release/distribution processes are common in peptide physiology. An autocrine function of augurin may contribute to the relatively low rate of tumor formation in plexus epithelium despite great choroidal vascularity and blood flow.[10] The neuroendocrine-like function of augurin, distributed by CSF bulk flow after release from CP, may relate more to peptide conveyance to targeted regions in hypothalamus and SVZ.[8] Accordingly, Ecrg4 expression and augurin modulation of germinal cells in the SVZ have implications for the prevention of primary tumor formation and for adaptive responses of the brain to injury and disease.

CP and ependymal cells that abut CSF prominently regulate cell division in regions surrounding the ventricles. Peptide release mechanisms at the BCSFB and CSF–brain interface, in response to stressful states, are an integral part of the homeostatic control machinery. Various mechanisms and organelles in epithelial cells mediate the extrusion of proteins and polypeptides. Augurin immunostaining of CP epithelium occurs in cytoplasmic vesicles (punctate distribution) and at the apical surface where staining is uniformly dense.[17] Both

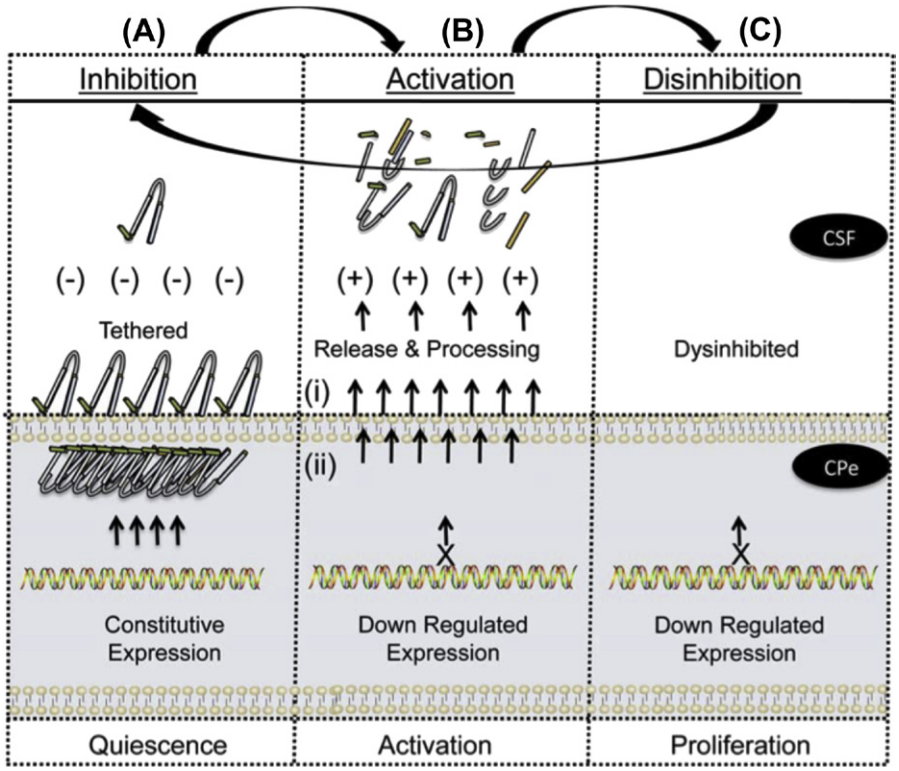

FIGURE 5 Attenuated augurin activity and central neurogenic dysinhibition: a multiphasic model for states of quiescence **(A)**, activation **(B)** And proliferation **(C)**. Choroid epithelial cells (CPe) normally express *Ecrg4*, containing the 14 kDa augurin protein in an inhibitory conformation. Unprocessed peptide is compartmentalized in (i) Cellular vesicles (punctate staining), (ii) the CSF-facing apical membrane (condensed polarized staining), and (iii) the ventricular apex of epithelium to which it tethers. On TBI, there is a sudden release of CP augurin and cleavage apically. Subsequent augurin extrusion (B) from intracellular stores is a "panic signal" to indicate central (brain) injury. The initial proinflammatory response shuts down *Ecrg4* for 1–3 hr post-TBI. Consequently, repair cells proliferate during the early injury stage because the normally constitutive inhibition of neurogenesis by augurin is absent. When *Ecrg4* expression returns to CP and ependyma, periventricular quiescence is restored and CNS homeostasis reestablished. Diagram is from Ref. 17.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

regions are potential release sites for the peptide being translocated from cell to CSF. By separating and analyzing the apical membrane, with the use of subcellular fractionation and confocal microscopy, we identified augurin at the CSF-facing brush border and a smaller fragment that is released from *in vitro* CP cells into the conditioned medium.[17] This 6–8 kDa peptide is a candidate for release into CSF soon after TBI insult and could be distinct from the constituitive release of 14 kDa augurin. Spatially, the proximity of the apical site to CSF favors this region as a rapid responder to any molecular signal brought from injured cortex to induce augurin release from CP. Cytoplasmic vesicle release of augurin, eventually reaching CSF, may represent another mechanism for exerting actions on target cells (NPCs or injured neurons) distant from CP. Peptidergic release mechanisms in CP, hypothetically activated following damage to cortex, need delineation to ascertain the applicability to the initial *immune* response and the later proliferative phase (Fig. 5).

CONCLUSIONS

Neuropeptide modulation of neurogenic niches, especially in regard to generating nascent neurons to maintain sound cognition, has vast translational research potential. Heretofore, several peptides and proteins supplied by the CSF circulation have been strongly implicated in nourishing and protecting stem cells in the NNs bordering the lateral ventricles. Augurin is yet another polypeptide with marked effects on germinal cells, by way of fortifying the interstitial microenviroment in SVZ/DG niches and controlling the mitosis of NPCs. Investigations of the bioactivity profiles of products derived from the Ecrg4-augurin precursor (e.g. ecilin, argilin, and CΔ16), and the cloning of their cognate receptors, will be critically important in advancing basic research and clinical progress with this newly-identified peptide. Although this chapter emphasizes the CP–ependyma–CSF source of augurin, other cells may furnish ecrg4-derived peptides to NNs. If so, they may also eventually prove useful in devising therapeutic regimens to enhance the viability of the NNs and associated cognitive processes.

Chapter 227

Diseases Mediated by the BBB: Alzheimer's, Obesity, and Beyond

William A. Banks

ABSTRACT

The blood–brain barrier (BBB) interfaces between the central nervous system (CNS) and circulation and regulates the exchange of informational molecules, including peptides and regulatory proteins. When this regulation is faulty, diseases can occur. Examples of BBB dysfunctions and their associated diseases are impaired transport of amyloid beta protein out of the brain and Alzheimer's disease, impaired transport of leptin into the brain and obesity, recovery of methionine enkephalin efflux in animals dependent on alcohol and alcohol withdrawal seizures, impaired transport of glucose into the brain and developmental retardation, enhanced insulin transport into brain and the insulin resistance of sepsis.

INTRODUCTION

The blood–brain barrier (BBB) prevents the unrestricted leakage of substances between the blood and the central nervous system (CNS) fluids (the brain's interstitial fluid and the cerebrospinal fluid). The BBB also transports into the brain the glucose, amino acids, vitamins, minerals, and other nutrients required for brain function and transports out of the brain toxins, electrolytes, and xenobiotics. Some peptides and regulatory proteins cross the BBB, in the blood-to-brain direction, the brain-to-blood direction, or bidirectionally. Immune cells are increasingly recognized as being able to cross the BBB under physiological, not under just pathological, conditions. Taken together, this means that the BBB has protective, nutritive, homeostatic, and communication roles to play toward the brain. When the BBB fails to perform these roles properly, diseases can arise.

It is well appreciated that the BBB can, like other tissues of the body, be a target of diseases. But this chapter will emphasize a different category of disease: those in which the BBB plays a central role, even a causal role, in disease.

LEPTIN AND OBESITY

A hallmark of obesity in humans is a resistance to the anorectic actions of leptin. Leptin is a 16- kDa protein secreted from fat cells, which acts at the arcuate nucleus in the hypothalamus to inhibit feeding and to promote thermogenesis.[15] Leptin is one-fourth the size of albumin and is too large to cross the BBB without the aid of a saturable transporter. Such a transporter has been shown *in vivo* and *in vitro* in brain endothelial cells and *in vivo* at the choroid plexus. Leptin is transported across the BBB into all major brain regions, but transport is especially high at the arcuate nucleus.

Resistance to the CNS actions of leptin arises in obese humans and in rodents with diet-induced obesity.[15] In general, this resistance first occurs at the level of the BBB.[3] At this stage, rodents can still respond to leptin given directly into the brain but no longer respond to leptin given peripherally. Analysis of the cerebrospinal fluid (CSF) and serum levels of leptin show that in obese humans the major level of resistance is also at the BBB.[8]

Several laboratories have shown that leptin transport across the BBB is decreased in obese animals. Exogenous leptin is blocked from entering the CNS in part because of competitive inhibition by the high levels of leptin in the serum of obese animals. However, this self-inhibition explains only a minor part of the BBB defect seen in obesity. Other components, including those not immediately ascribable to circulating factors, are major contributors to an impaired transport of leptin across the BBB. These defects in BBB transport are acquired in tandem with increasing obesity and reversible with weight loss. Starvation also impairs leptin transport across the BBB.

The findings of inducible and reversible defects in leptin transport show that the transporter is not static, but responsive to metabolic needs. This, in turn, implies that the leptin transporter is itself regulated. To date, several agents have

been noted to modulate leptin transport: insulin, cholecystokinin, glucose, adrenergic agents, and triglycerides.[1,4,12,17] These agents are themselves major players in energy use in general and involved in other aspects of leptin metabolism.

Leptin transport is enhanced by the administration of alpha$_1$-adrenergics.[1] Transport can be more than tripled with the intravenous or intraperitoneal administration of epinephrine, but central administration is without effect. Enhanced transport of the anorectic leptin into the brain could be one mechanism by which peripheral administration of epinephrine induces weight loss. Leptin enhances sympathetic tone to fat and other tissues and stimulates the release of epinephrine into blood by binding to leptin receptors located on the adrenal gland's epinephrine-secreting cells. Hence, mice that lack leptin have decreased blood epinephrine levels. This increased sympathetic tone, in turn, suppresses leptin secretion from fat cells by binding to β3 adrenergic receptors. This forms a negative feedback loop between leptin and epinephrine and explains the inverse relation between blood levels of epinephrine and leptin. Epinephrine-enhanced transport of leptin would reinforce this inverse relation between serum epinephrine and leptin levels in two ways. First, by elevating the brain levels of leptin, increased serum levels of epinephrine would be increasing the anorectic signal to the brain. This would eventually lead to a decrease in body fat, resulting in lower leptin levels. Second, leptin and epinephrine have opposite effects in the CNS than in the periphery. Specifically, leptin inhibits epinephrine release from neurons and CNS epinephrine stimulates feeding. Thus, peripheral epinephrine reinforces its anorectic effect by indirectly, through leptin, inhibiting its antianorectic CNS levels.

Leptin transport is inhibited by the peripheral administration of triglycerides.[4] Triglycerides are increased in obesity, and so, this is probably a major mechanism by which obesity mediates a decrease in leptin transport. In fact, the rate of leptin transport is inversely related to serum triglyceride levels in diet-induced obesity and in fasted animals. Unlike most other metabolic effects induced by triglycerides, the effects on leptin transport are mediated by the triglycerides themselves and not by the free fatty acids (FFA), which can be hydrolyzed from them. The effects of triglycerides on leptin transport can also be shown by lowering of the triglycerides pharmacologically and by direct administration of triglycerides *in vivo* and *in vitro*.

As with epinephrine, the interaction between the BBB transporter for leptin and triglycerides is important in a negative feedback loop between leptin action and triglycerides. Leptin decreases triglyceride levels by promoting triglyceride hydrolysis and FFA oxidation and inhibiting FFA synthesis. Patients with severe lipodystrophy or lipoatrophy (i.e., little or no fat and so little or no leptin) also have very severe hypertriglyceridemia, which is reversed by treatment with leptin. The ability of triglycerides to induce leptin resistance at the level of the BBB would block the leptin-induced shift toward use of triglycerides as an energy source and so help to conserve fat stores and keep triglyceride levels elevated.

Triglyceride inhibition of leptin transport may also explain the fundamental paradox of leptin resistance in obesity: Why should leptin resistance lead to the development of obesity, when otherwise it would be so effective in maintaining body weight? Triglycerides are also elevated in starvation. During most of evolution, animals have been confronted with the problem of obtaining enough calories in the diet rather than having to deal with too many. Thus, healthy baboons living in the wild in nonfamine conditions have body fat mass and serum leptin levels seen only with anorectic conditions in Western humans.[22] Only when food sources become abnormally abundant do leptin levels approach those seen in Westerners and, with it, evidence of obesity-related diseases. Through evolutionary pressures, hypertriglyceridemia probably has come to represent to the brain a signal of starvation, rather than of obesity. The ability of triglycerides to inhibit the transport of an anorectic signal to the brain would provide great survival value to the starving animal.

AMYLOID β PROTEIN EFFLUX AND ALZHEIMER'S DISEASE

Amyloid β peptide (Abeta) has emerged as playing a major role in the cause of Alzheimer's disease. Abeta is neurotoxic and both transgenic mice and those with spontaneous mutations (the SAMP8 mouse) that overexpress Abeta develop cognitive impairments.[18] Reversals of histological changes and cognitive impairment have been shown in transgenics after active or passive vaccination to Abeta. In the SAMP8, antisense directed against amyloid precursor protein or antibodies directed against Abeta reverse cognitive impairments, reverse oxidative stress, and improve cholinergic tone.

The level of a substance in most tissues is the result of an equilibrium between synthesis and degradation. For substances in the brain, including Abeta, two additional factors are also important: transport into the brain from blood and efflux from the brain into blood.[26] In the case of Abeta, both of these events are mediated by saturable transporters located at the BBB. The receptor for advanced glycation end products, or RAGE, is the main influx transporter and both LDL receptor–related protein-1 and p-glycoprotein to act as efflux transporters.[14]

Evidence from both humans and animal models suggests that efflux of Abeta is impaired in Alzheimer's disease. Levels of LDL receptor–related protein-1 are reduced in the brain vasculature of patients with Alzheimer's disease.[23] Efflux

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

is impaired in both transgenics and SAMP8 mice. Efflux of $Abeta_{1–42}$, the more toxic form of Abeta, is impaired more than is the efflux of $Abeta_{1–40}$ in the aged SAMP8.[9] However, LDL receptor–related protein-1 has a preference for $Abeta_{1–40}$. Whether separate transporters exist for the 1–40 and 1–42 forms is not currently established. The rate of reabsorption of cerebrospinal fluid into the blood, known as bulk flow, is also impaired in normal aging, in Alzheimer's disease, and in the SAMP8 model. Thus, both the saturable and the nonsaturable clearances of Abeta from brain are impaired.

Whether decreased efflux is caused from alterations in Abeta primary structure/conformation vs. alterations in transporter synthesis and function remains unknown. Either is possible, as mutations of Abeta (such as at codon[22]) can result in proteins not transported by the BBB and mutations in LDL receptor–related protein-1 results in accumulation of Abeta by brain. Work with SAMP8 mice suggests another mechanism, that of impairment induced by Abeta itself. Treatment of SAMP8 with antisense directed to Abeta restores both the saturable efflux of Abeta and bulk flow.[7] In addition, inflammatory processes inhibit Abeta efflux at the BBB.[16] Oxidative stress could be a common mechanism by which Abeta and inflammatory processes inhibit Abeta efflux.[19]

Lack of clearance from brain could be a major contributor to accumulation of Abeta levels in brain. This lack of clearance of Abeta from brain, in turn, could explain how potential therapies work. Passage and active immunization against Abeta results in antibodies in the circulation which bind Abeta and so prevent it from crossing from blood-to-brain.[20] This would prevent the influx mechanism from contributing to the brain levels of Abeta. It could also prevent any Abeta that is effluxed from brain into blood from returning to brain. CSF shunting has also been proposed as a mechanism by which unidentified toxins contributing to Alzheimer's disease are rid from the brain. Shunting could restore a type of clearance of Abeta from the brain.

In summary, Abeta is transported by saturable mechanisms both into and out of the CNS. Impairment of the BBB's mechanisms for efflux of Abeta from the brain is postulated to be a major mechanism by which this protein accumulates in the brain of Alzheimer's disease patients. Antisense directed toward Abeta can restore the BBB's efflux mechanisms. Further, treatment with antibodies or with CSF shunting may act by restoring a sort of balance between the influx and efflux rates of Abeta.

METHIONINE ENKEPHALIN AND ALCOHOL WITHDRAWAL

An inverse relation exists between the levels of methionine enkephalin in brain and the amount of alcohol an animal will voluntarily drink.[5,10] This relation has been shown to occur across strains that are alcohol-naive and in animals whose brain levels of methionine enkephalin have been manipulated. Physical dependence to alcohol also lowers the brain levels of methionine enkephalin.
