A major determinant of the brain levels of methionine enkephalin is peptide transport system-1 (PTS-1). This is an efflux (brain-to-blood) saturable transport system located at the BBB, which has methionine enkephalin as one of its major ligands.[6] Studies across strains and among individuals within a strain suggest that PTS-1 accounts for one-third to half of the variation in brain levels of methionine enkephalin. PTS-1 activity is greatly reduced in rodents made physically dependent on alcohol. Because these animals have reduced levels of methionine enkephalin, the decrease in PTS-1 activity can be seen as adaptive as it would conserve the brain levels of methionine enkephalin. In physically dependent animals, mRNA and protein levels of preproenkephalin no longer correlate with the brain levels of methionine enkephalin. Thus, posttranslational mechanisms become the sole determinants of brain levels of methionine enkephalin.

Mice made physically dependent to alcohol have a reduction in their brain levels of methionine enkephalin; paradoxically, these mice have a further reduction in brain methionine enkephalin levels when they stop drinking. This further reduction is thought to underlie the withdrawal seizures these animals undergo. PTS-1 is a probable cause for this paradoxical decrease in brain methionine enkephalin levels. Although brain levels of methionine enkephalin remain under posttranslational control, PTS-1 recovers its activity within hours of cessation of alcohol drinking. Thus, although the mechanisms for increasing the synthesis of methionine enkephalin (increases in transcription and translation) have not recovered, the mechanism for reducing brain levels (saturable efflux) has. In theory, blockade of this early recovery of PTS-1 could prevent alcohol withdrawal seizures.

GLUT-1 DEFICIENCY SYNDROME

De Vivo et al have described a familial syndrome in a number of patients caused by mutations in the GLUT-1 transporter.[13] Glucose levels in CSF are usually <2.5 mmol/l (~50% below normal), and most cases are caused by a mutation in the SLC2A1 gene, with a number of missense, nonsense, insertion, and deletion mutations described. These patients are characterized by infantile seizures, developmental delays, acquired microencephalopathy, spastic ataxia, and low levels of glucose in the CSF. Because the red blood cell also has GLUT-1, a test measuring the uptake of methyl-D-glucose by red blood cells is useful in the diagnosis of this syndrome. The *V*max for the red cell GLUT-1 is about 50% of normal with no change in K_m.

INSULIN RESISTANCE IN SEPSIS

Insulin and insulin receptors are found throughout the CNS. Originally, the source of CNS insulin was debated, but subsequent work has suggested that little or no mRNA for insulin is found in the CNS.[2] Thus, under normal circumstances most, if not all, of CNS insulin originates from the pancreas. Seminal work by Margolis and Altszuler in the 1960s and by Woods, Porte, colleagues, and others showed correlations between blood and CSF levels of insulin and established that insulin in the CNS has important effects on feeding and metabolism.[24] Work from several laboratories showed that many of the effects of CNS insulin are opposite to those of peripheral insulin. For example, CNS insulin decreases the levels of insulin in blood, increases glucose levels in blood, and inhibits feeding. Thus, insulin can act as its own counter-regulatory hormone. Short-term, CNS insulin would then be believed to produce a kind of insulin resistance. Paradoxically, the long-term effect of CNS insulin seems to be to prevent insulin resistance.[11] This latter conclusion is based on the work in which transgenic animals with a selective knockout of CNS insulin receptors are prone to diet-induced obesity, increased serum insulin levels, resistance to the hypoglycemic effects of insulin, and increased body fat. The paradox that both short- and long-term insulin have opposite effects on insulin resistance is easily reconciled if the most important effect of short-term insulin in the CNS is suppression of appetite. By acting to prevent obesity, CNS insulin would safeguard against this major cause of insulin resistance.

CNS insulin probably plays important roles in several pathophysiological conditions, including insulin resistance and body weight control in inflammatory conditions. CNS insulin can improve cognitive function in Alzheimer's disease.[21] These conditions are associated with both insulin resistance and body weight loss. Treatment of mice with lipopolysaccharide (LPS) enhances insulin transport across the BBB.[25] LPS is derived from the cell walls of gram-negative bacteria and induces the release of proinflammatory cytokines. These cytokines probably are responsible for the effects of LPS on the BBB transport of insulin. The enhanced transport of insulin across the BBB would counter peripheral insulin's effects and so provides a mechanism for insulin resistance in sepsis.

SUMMARY

The BBB is pivotal in an endocrine-like communication between the CNS and peripheral tissues. The BBB does this by regulating the exchange of information molecules such as peptides and proteins between the CNS and peripheral tissues. When the BBB does not perform this function correctly, diseases can occur. Here, five examples of BBB dysfunction and associated diseases were discussed. In most of these cases, the exact magnitude of the contribution of BBB dysfunction to the overall disease process is not established. However, these examples serve to illustrate the concept that the BBB is intimately involved in the onset and promotion of disease processes.

Chapter 228

Hypothalamic Neuropeptides

David J. Begley

ABSTRACT

Until the mid-1980s, it was generally believed that peptides did not cross the blood–brain barrier (BBB), as it was held that their relatively polar nature and high molecular weight would simply lead to their physical exclusion from the central nervous system by the combination of the endothelium and their paracellular tight junctions. In the intervening years, this notion has been quite clearly shown to be mistaken, with many peptides now shown to exert central actions by virtue of either passive or carrier-mediated movement across the BBB. This realization that peptides are part of the complex regulation of physiology via feedback phenomena between blood and brain, and vice versa, is in full accordance with the modern concept of the BBB as a dynamic, reactive, and adaptive interface between the brain and the peripheral tissues. In this chapter, the interaction of many peptides with the BBB, better known for their endocrine function via the pituitary gland, is reviewed.

INTRODUCTION

A large spectrum of biologically active peptides are synthesized by and released by the hypothalamus. These peptides are neuropeptides synthesized by neurons with neurotransmitter/neurohormonal roles, which either regulate the function of the anterior pituitary or in the case of vasopressin and oxytocin are released by the posterior pituitary into the systemic circulation. Additionally, within both the CNS generally and also within the hypothalamus, many of these peptides also have more traditional neurotransmitter roles acting at synapses between neurons.[32]

All the neuropeptides synthesized by the neurons of the hypothalamus as regulatory hypophysiotropic hormones of the anterior pituitary or as systemic hormones are released, at synaptic endings terminating outside of the blood–brain barrier (BBB) within anatomical sites where tight junctions between endothelial cells do not form and minimal BBB function exists. For the hypothalamic neuropeptides, the release structures are the median eminence and the neurohypophysis (posterior pituitary). These release areas, including the pineal gland, transfer neurohormones to blood, and are often referred to as neurohemal organs, which form part of the larger complex of circumventricular organs (CVOs) that are specialized sites in the brain where no BBB exists.[29]

The circumventricular organs	Function
Median eminence	Neurohemal
Neurohypophysis	Neurohemal
Pineal gland	Neurohemal
Choroid plexus	Neurohemal/sensory/ secretory (CSF)
Area postrema	Sensory
Subcommisural organ	Sensory
Subfornical organ	Sensory
Organum vasculosum lamina terminalis	Sensory

The function of the CVOs is to act as windows in the BBB and, thus by virtue of their lack of BBB, permit localization and equilibration of a small volume of parenchymal interstitial fluid to occur with plasma for a wide range of solutes. Within the CVOs, either sensitive dendrites or nerve endings can respond to changes in extracellular solute content, or neurosecretory neuronal terminals can specifically secrete their product into systemic blood. The interstitial fluid within the CVOs is effectively isolated from the bulk of the extracellular fluid in the brain by a layer of ependymal cell with tight junctions between them.[29] Without CVOs, the brain would be sealed off by the BBB from direct influence by blood-borne solutes and additionally could not secrete neurohormones into the systemic circulation. The combination of BBB and the CVOs allows the brain to maintain its own specialized independent internal environment and still to communicate freely and specifically with the soma via blood-borne signals.

Many active neuropeptides found in the hypothalamus are known to interact with the BBB at large and are able to either penetrate it directly by passive diffusion or are transported across the endothelial cells by specific saturable mechanisms. These BBB transport processes may also form part of a mechanism whereby feedback mechanisms for systemically secreted CNS peptides can operate and also

provide a means by which peripherally released peptides from other endocrine sites can alter and influence CNS function. The ability of some hypothalamic peptides to cross the BBB also opens a door for the clinical use of these peptides or their analogs as therapeutic agents.[10]

A large variety of peptides are recognized as endogenous to the hypothalamus although this brain structure is not the exclusive site of their synthesis and release. The remainder of this handbook entry contains brief reviews of the interactions of selected hypothalamic peptides with the BBB. Some other peptides, which could be considered to be hypothalamic neuropeptides and whose interactions with the BBB are covered elsewhere in this section will not be included. The concept of hypophysiotropic hormones has also been somewhat modified in recent years with the realization that a single regulatory peptide may influence the release more than one anterior pituitary hormone. For example, growth hormone (GH) can be released by GHRH (GH-releasing hormone), ghrelin, TRH (thyrotropin-releasing hormone), and PACAP (pituitary adenylcyclase-activating polypeptide) and its release is inhibited by somatostatin, while in mammals, TRH will also release prolactin in addition to thyrotropin (TSH) and GnRH (gonadotropin-releasing hormone) releases FSH (follicle stimulating hormone) as well as LH (luteinizing hormone). Clearly, the influences are complex and much depends on the microanatomically specific release of neuropeptide delivered to a specific target either within the CNS or to a specific group of secondary endocrine response cells. In addition, neuropeptide influence on the CNS via the systemic route will differ, whether it is by direct influence through non-BBB areas or via transport across the BBB.

TRH

TRH is a tripeptide synthesized in the paraventricular nucleus releasing predominantly TSH from the anterior pituitary. Intact TRH seems to cross the BBB passively with a permeability thrice that of mannitol.[35] TRH is also subject to hydrolysis, apparently on contact with the BBB as in the experimental system there is no plasma protein present containing circulating peptidases. Its extraction, when radioactively labeled at the proline residue, can be reduced by approximately 50% if the peptidase inhibitor bacitracin (2 mM) is added to the experimental pefusate. The BBB permeability to TRH cannot be reduced further by the addition of 1 mM TRH in addition to the enzyme inhibitor indicating a lack of a saturable component to the transport.[35] A further series of experiments with the perfused sheep choroid plexus also shows a similar passive movement of TRH with peptide hydrolysis on contact with the tissue.[34]

TRH has central actions after iv administration and has antidepressive properties and improves cognition. However its short plasma half-life greatly limits its potency. The addition of methyl groups to the molecule to give a 3-methyprolinamide (RX74355), or a 3,3-dimethylprolinamide (RX77368), extends the plasma half-life, increases lipid solubility, and as a direct result enhances the CNS penetration and activity.[11]

GnRH

GnRH (also called LHRH) is a decapepetide synthesized by neurons with cell bodies located in the ventral hypothalamus and in the mammal releases both FSH and LH from the anterior pituitary.[31,32] Intravenous administration of GnRH potentiates sexual behavior in both male and female rodents and enhances the central actions of dopamine and serotonin. These effects are evident in castrated and hypophysectomized animal and are highly suggestive of transport across the BBB.[8]

GnRH is accumulated by many regions of the rat brain after intravenous injection.[18] GnRH has saturable bidirectional transport from blood to brain. Inclusion of excess10 nM/mL of GnRH into the vascular perfusate significantly inhibits brain uptake of the peptide by the BBB. AVP and Tyr-MIF 1 are without influence on blood-to-brain GnRH transport. Transport out of cerebrospinal fluid (CSF) occurs to an extent greater than would be expected from CSF turnover after intraventricular injection of the peptide. The introduction of excess GnRH, D-Tryp^6-GnRH, and GnRH 7–10 inhibits efflux from CSF. GnRH 1–3 and tyrosine do not inhibit efflux from CSF. It is not clear whether transport in both directions is the result of a single transporter or if two separate transporters are involved.[8]

CORTICOTROPIN-RELEASING HORMONE (CRH)

CRH (41aa) is a classic hypophysiotropic hormone releasing ACTH from the pituitary. It is synthesized and released by the parvicellular neurons of the paraventricular nucleus.[12] CRH is a member of a peptide family that includes urocortin (40aa), urocortin II (38aa), and urocortin III (38aa). The peptides have a high degree of homology. CRH and urocortin I bind to the same receptor CRH-R1, whereas urocortins I, II, and III, bind to CRH-R2.[24] All members of the family are found in the brain and modulate endocrine, autonomic, and behavioral responses to stress.[24] The peptides all inhibit feeding behavior but to different extents.[22]

Their interactions with the BBB are also very different. Urocortin I only enters the brain after a specific saturable carrier for the peptide is activated by circulating leptin. Urocortin II enters the brain passively as a result of its inherent lipophilicity by a nonsaturable mechanism, whereas urocortin III is degraded by BBB enzymes and does not seem to enter the brain intact. CRH itself enters the CNS by a separate saturable transport system, which is not sensitive

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

to urocortins I, II, III, or leptin.[22] CRH is the only member of this family of peptides to have a saturable efflux system out of the brain with a half time of 15 min compared with that of 50 min for albumin.[25] Transport is inhibited by verapamil, ouabain, colchicine, TNFα, and β-endorphin, which might suggest the involvement of an ABC transporter. It is also interestingly enhanced by corticosterone but seems to be cyclosporin insensitive.[25]

VASOPRESSIN (ANTIDIURETIC HORMONE)

Vasopressin is a nonapeptide synthesized in the magnocellular cells of the supraoptic and parventricular nuclei of the hypothamus. After posttranslational processing of the proprotein, the hormone is transported to the posterior pituitary in the axons forming the hypothalamic–hypophysial tract where it is released into systemic circulation after appropriate osmotic and baroreceptor stimulation of the CNS. Its major target is usually considered as the posterior convoluted tubule and the collecting duct of the kidney via V_2 receptors where it stimulates aquaporin insertion into the tubular cell membranes and thus enhances water resorption. The name vasopressin however arises from the peptide's effect of promoting arteriolar smooth muscle contraction in response to significant hemorrhage by acting on the smooth muscle V_1 receptors.

In addition, vasopressin is also recognized as having significant CNS activity associated with an elevated plasma concentration and V_1 receptors are found in the brain. Vasopressin has long been associated with the reinforcement of memory and attention and avoidance behavior[14,27] and an increase in circulating vasopressin has been shown to reduce the blood-to-brain transport of certain large neutral amino acids.[13,30] This effect seems to result from a direct change in the activity of the large neutral amino acid transporter mediated by vasopressin at the BBB. After intracarotid injection vasopressin accumulates in all regions of the brain with a BBB to an extent greater than the reference marker inulin. This accumulation is more marked in pineal gland, the choroid plexus, the neural lobe, and the anterior pituitary, all lacking an endothelial BBB and the extraction ratio of vasopressin to inulin remains similar suggesting no preferential extraction of vasopressin.[17]

The CNS effects of circulating vasopressin centering around the consolidation and reinforcement of memory processes, however, suggest a central mode of action, and many studies have shown a carrier-mediated transport of vasopressin from blood to brain and CSF.[2,27] The blood-to-brain transport of vasopressin is significantly greater than mannitol, is saturable, and is inhibited with a V_1 receptor antagonist. Capillary depletion shows that vasopressin is transported intact across the BBB.

Vasopressin injected into the brain ventricles of the rat and guinea pig shows a rate of clearance from CSF with a terminal half-life of 26 min.[21,27] This is in excess of the rate of turnover of CSF in these species produced by the secretion and turnover of fluid and suggests a specific clearance mechanism for this peptide.

OXYTOCIN

Oxytocin is also a nonapeptide structurally closely related to vasopressin. It is also synthesized in the same hypothalamic nuclei as vasopressin but in separate neurons and is secreted into the systemic circulation by the posterior pituitary. Oxytocin acts on smooth muscle bearing appropriate oxytocin receptors and promotes contraction. In this context, its actions on the uterus during parturition and the smooth muscle of the lactating mammary gland are well described. It is however stored in the posterior pituitary in significant quantities in the nonpregnant and nonlactating state and in the posterior pituitaries of both sexes. It is released into the circulation of both sexes during orgasm.

Oxytocin has similar reinforcing effects on memory processes as vasopressin,[14,27] will reduce food intake and also reduces opioid self-administration in tolerant rats.[16] It also has effects on BBB permeability to orotic acid[23] and possibly other solutes. It is also accumulated in brain after intarcarotid injection with a similar regional distribution to vasopressin,[18] oxytocin also seems to penetrate the BBB and appears in CSF after intravenous injection, but a specific influx transporter is yet to be identified.[27] Oxytocin is also cleared from CSF[21] with a half-life of 19 minutes[16,27] by a carrier-mediated mechanism.[16] The clearance mechanisms for vasopressin and oxytocin seem to be distinct,[2] PTS1 seems to transport vasopressin and PTS2 oxytocin.[6]

SOMATOSTATIN

Somatostatin is a 14aa peptide cyclized by virtue of a disulfide bridge between residues 3 and 14. As its name implies, it inhibits anterior pituitary release of growth hormone. It seems to penetrate the BBB to a moderate extent, apparently by a nonsaturable passive process.[1] The volume of distribution is greater than that of radioactively iodinated serum albumin. The BBB transport of several octapeptide analogs of somatostatin has also been investigated in view of their ability to bind to somatostatin receptors expressed on brain tumors. Of the three analogs RC 161, 160, and 121, RC 161 seems to enter the brain most readily.[3] Interestingly, the brain entry of RC 160 increases >200% when administered in a serum free solution suggesting that protein binding may be a significant factor limiting the brain uptake of some of these analogs. The BBB uptake of octreotide (SMS 201-995) after iv injection has a similar brain uptake to RC 160 and RC 121.[9] For these three analogs of somatostatin, entry to the brain is passive. An *in vitro* study of octreotide movement across

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

a monolayer of bovine cerebral endothelial cells also suggests passive movement with a significant contribution from the paracellular pathway, which is presumably not available in the intact BBB.[20] Interestingly, when injected icv, the clearance of RC 160 and RC 121 is significantly faster than could be explained by turnover of CSF. The efflux of RC160ias saturable and thus carrier-mediated.[5] A confocal study with isolated porcine cerebral microvessels has suggested that octreotide efflux is verapmil, cyclosporin A, and PSC 833 sensitive and is probably mediated`by the ABC transporters P-glycoprotein and multidrug resistance-associated protein 2.[19]

PACAP

PACAP is a member of a family of peptides that includes vasoactive intestinal peptide (28aa) (VIP), secretin (22aa), glucagon (29aa), glucagon-like peptides 1 (36aa) and 2 (33aa) (GLP1–2), gastric inhibiting peptide (42aa) (GIP), and growth hormone releasing hormone (45aa) (GHRH). These various peptides, described in detail in other chapters of this book, show different transport characteristics at the BBB.

PACAP has two principal forms PACAP 27 and PACAP 38. PACAP 27 shows passive diffusive entry into the CNS, while the larger PACAP 38 enters 30% faster and has a self-saturable component to entry.[4,15] PACAP entry to the brain is not inhibited by an analog peptide-T which antagonizes binding to vascular receptors.[4] Once within the brain, PACAP 38 seems to be more resistant to degradation than PACAP 27, but in spite of its passive entry, a greater percentage of the injected dose enters the brain of PACAP 27, as the AUC and pharmokinetics favor its entry.[4] PACAP 38 is transported into the CNS by peptide transport system 6.[7]

PACAP 38 is a potent neurotrophic and neuroprotective hormone, and its rate of BBB entry is significantly faster in the hypothalamus and hippocampus, (4- to 8-fold) than in other brain regions, the pons-medulla showing no measurable PACAP 38 penetration. This suggests that it may have clinical applications in neurodegenerative diseases such as Alzheimers involving the hippocampus,[28] and memory loss and may underpin its protective effect on CA1 neurons after experimental ischemia.[33]

VIP, secretin, and GLP1 all appear to enter the CNS by passive diffusion.[15] Both glucagon and GHRH seem to cross the BBB but the mechanism has not been examined.[1]

Chapter 229

Ingestive Peptides

William A. Banks

ABSTRACT

The passage across the BBB of substances such as leptin, ghrelin, and insulin has emerged in the last decade as a major mechanism by which the central nervous system and gastrointestinal tract communicate. Besides regulation of feeding, many of these substances have effects on cognition and neurogenesis, raising the possibility of their use in the treatment of neurodegenerative diseases as well as obesity and anorexia syndromes. Saturable transport systems in the brain or blood directions exist for many of these substances and others cross by nonsaturable transmembrane diffusion. The transporters are themselves regulated, and their dysregulation results in disease. For example, inflammatory inhibition of insulin transport could explain the insulin resistance of sepsis and impaired transport of leptin is an early cause of the leptin resistance seen in obesity. In summary, many of the central nervous system effects of gastrointestinal substances depend on their transport across the blood–brain barrier.

INTRODUCTION

The discovery in the late 1970s that the central nervous system (CNS) and gastrointestinal (GI) tract contain many of the same peptides and regulatory proteins renewed speculations about how these regions communicate.[9] The blood–brain barrier (BBB) plays a major role in communication between the GI tract and the CNS.[12,14] Clear examples of this communication are provided by peptides and regulatory proteins that arise from the GI tract and reach their targets in the CNS by being transported by saturable systems across the BBB. It was assumed for many years that even small peptides would be too large to cross the BBB. However, when experiments were carefully conducted, it was discovered that many of the principles governing the passage of other substances also applied to peptides and even the larger regulatory proteins.[3,7] Specifically, accumulation of substances by the brain from the blood is a balance between influx and efflux rates. Influx rates and CNS accumulation are primarily determined by the presence or absence of saturable transporters, the physicochemical properties of the substance that determine its rate of nonsaturable transmembrane diffusion, pharmacokinetic parameters (clearance from blood and volume of distribution), capillary sequestration, and binding in plasma. Efflux rates and CNS retention are determined by many factors that include the presence or absence of saturable efflux transporters, cerebrospinal fluid (CSF) reabsorption, degradation within the CNS, and uptake and sequestration by CNS tissues.

The saturable transport systems are themselves regulated by physiological parameters and can be affected in disease states. Taken together, this means that the BBB is a pivotal point in a humorally based communication between the CNS and the GI tract. Understanding this role of the BBB is necessary to understand how the GI tract and CNS interact under physiological conditions and is needed to explain some aspects of disease. Below, we discuss selected examples of peptides and regulatory proteins and some of the major factors regulating their interactions with the BBB.

INSULIN

The question of whether insulin crosses the BBB was investigated in as early as 1954. Insulin has powerful effects on feeding and energy regulation mediated through its receptors in peripheral tissues.[21] However, insulin also has receptors in the brain. Within the CNS, the largest concentration of insulin, insulin receptors, and insulin-degrading enzymes is in the olfactory bulb. Insulin through its CNS receptors has effects on body weight, feeding, glucose, and energy regulation that are often opposite to those mediated through its peripheral receptors.[23] Insulin within the CNS thus may act as its own counterregulatory hormone. CNS insulin has other effects on brain function, including effects on cognition and baroreceptor activity.

Margolis and Altszuler in 1967 proposed that insulin crossed the BBB because levels of insulin in the CSF increased after peripheral administration of insulin. Because the relation between CSF and blood levels of insulin was not linear, they proposed that insulin crossed the BBB by a saturable transport system. However, several other laboratories could not find insulin in the CSF or found insulin in the CNS of streptozotocin-treated rodents. These studies appeared well into the 1980s and were interpreted as

showing that insulin did not cross the BBB and that it was produced within the CNS. In a series of classic studies beginning in 1977, Woods, Porte, and collaborators clearly showed the presence of insulin in the CSF and its nonlinear relation with serum. As it became increasingly clear that little or no insulin is produced in the CSF, it also became clear that these studies showed that there was a saturable transporter for insulin. Studies from the laboratory of Pardridge reinforced this idea of insulin transport. His laboratory demonstrated binding sites on the endothelial cells that comprise the BBB. At least some of these binding sites would represent insulin receptors coupled to intracellular machinery, thus providing a mechanism to explain why insulin has effects on brain endothelial cell function. But some of these binding sites could also represent a transporter mechanism.

Further work by several laboratories, including our own, characterized many aspects of insulin transport across the BBB.[5] The use of radioactive insulin and of species-specific insulin radioimmunoassays not only definitively showed that insulin crosses the BBB but also measured its influx rate and demonstrated the saturable nature of its passage.

The insulin transporter is not static, but it is regulated in various conditions. For example, the correlation between CSF and serum insulin is lost during hibernation, suggesting that the transporter is turned off. Because the hibernating animal is using but not acquiring energy, this finding would suggest that CNS insulin is more important in the regulation of aspects of energy intake than in states of energy use. Insulin transport is also impaired in obesity, as is leptin transport. Unlike leptin, this obesity-related inhibition is not mediated by triglycerides. Insulin transport is also increased in streptozotocin-induced diabetes. This is not just an apparent increase caused simply by less endogenous insulin being available to compete for transport with the radioactive insulin used to measure influx rate. The increased transport of insulin is seen in diabetic mice even when assessed by the brain perfusion method in buffer rather than blood, which obviates the effects of serum insulin.

Recent *in vitro* work has shown that glucose itself is a regulator of insulin transport at the BBB.[15] Hyperglycemia induces a faster rate of transport across brain endothelial cells cocultured with pericytes and astrocytes. This induction, however, does not seem to be mediated directly at the level of the endothelial cell but is dependent on the crosstalk among the endothelial cells, astrocytes, and pericytes.

Insulin transport is also modulated in mice treated with lipopolysaccharide (LPS), a derivative of the cell wall from Gram negative bacteria.[24] LPS induces an immune reaction mediated by cytokine release. LPS has multiple effects on BBB function, including disruption of the BBB in extreme cases and effects through various mechanisms on some saturable transporters. LPS induces an increase in the saturable transport of insulin that is mediated through nitric oxide. Inhibition of nitric oxide synthase potentiates the effects of LPS on insulin transport, although inhibition of nitric oxide synthase in non-LPS treated mice has no effect on insulin transport. This suggests that LPS induces two pathways affecting insulin transport across the BBB; one enhances insulin transport and the other, mediated through nitric oxide, inhibits it. Because CNS insulin counters the effects of peripheral insulin, enhanced transport of insulin into the CNS by LPS could be a mechanism by which sepsis induces insulin resistance. A possible role for the BBB in mediating the insulin resistance of sepsis is discussed in the chapter "Diseases Mediated by the BBB: Alzheimer's, Obesity, and Beyond."

LEPTIN

Leptin is a 16-kDa protein secreted from fat cells, which acts at the arcuate nucleus in the hypothalamus to inhibit feeding and to promote thermogenesis.[11] An alternate route proposed for leptin uptake that does not exist in the adult is leakage out of the adjacent median eminence. The median eminence contains capillaries that do not form a BBB, and so leptin can leak into this tissue. However, the median eminence is isolated from the ventricular CSF and adjacent hypothalamic tissue by epithelial and tanycytic arms of the BBB.[18,20] These barriers are so robust that even a small molecule like glutamate cannot penetrate them. The tanycytic barrier develops in rodents after birth. It is for this reason that monosodium glutamate can destroy the hypothalamic feeding centers when given to the neonate but not when given to the adults.[18]

Resistance to the anorectic and thermogenic effects of leptin is a hallmark of human obesity and of diet-induced obesity in many strains of rodents.[11] This resistance can occur at three levels: impaired transport at the BBB, receptor/postreceptor impairments, and impairments in the anorectic downstream neuronal circuitries stimulated by leptin. Studies with diet-induced obesity show that resistance first occurs at the level of the BBB.[4] At this stage, rodents can still respond to leptin given directly into the brain but no longer respond to leptin given peripherally. Analysis of the CSF and serum levels obtained from humans with moderate obesity also showed that the major level of resistance is at the BBB. The BBB is a major level of resistance in sheep as well.[1] As discussed in the chapter "Diseases Mediated by the BBB: Alzheimer's, Obesity, and Beyond," this resistance at the BBB may be a major cause of leptin-related obesity.

The leptin transporter is also not static but modulated by various substances and by various conditions. Obesity, starvation, and loss of ovarian function decrease transport of leptin across the BBB.[13] Glucose, insulin, and $alpha_1$

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

adrenergics increase leptin transport, whereas triglycerides inhibit it. There is also a diurnal rhythm to leptin's transport rate.

These aspects of leptin's interaction with the BBB can be used to develop potential therapeutics for the treatments of anorexia and obesity. An analog of leptin designed so as to block the leptin receptor and transporter can act as a potent antagonist to endogenous leptin activity.[19] Such an action recapitulates a leptin-resistance type picture with mice immediately gaining weight. An analog of leptin that can cross the BBB independently of the leptin transporter but still activate the leptin receptor would be active in the face of peripheral leptin resistance.[10] Such a drug would be an anorectic even in obese mice.

GHRELIN

Ghrelin is a 28 amino acid residue peptide hormone characterized by a novel posttranslational acylation that is required for its bioactivity.[22] Ghrelin is secreted by the fundus of the stomach into the circulation before the onset of meals. Current thinking suggests that ghrelin is a major orexigenic peptide stimulating the sensation of hunger from sites within the CNS. As such, it would be logical to assume that ghrelin crosses the BBB. Human octanoyl ghrelin is transported across the mouse BBB bidirectionally; that is, there is a saturable component to both its influx and its efflux.[8] Paradoxically, however, mouse ghrelin is treated differently than human ghrelin. Mouse octanoyl ghrelin, the biologically active form of ghrelin, and mouse des-octanoyl ghrelin are not transported by the influx system. Because human and mouse ghrelin differ by only two amino acids, this shows that these two amino acids are crucial for recognition by the influx transporter. Mouse octanoyl ghrelin, but not the des-octanoyl form, was transported by the efflux system.

Ghrelin transport across the BBB has a complicated interaction with events related to feeding and fasting. As with leptin, ghrelin transport is decreased in obese mice. Unlike leptin, epinephrine has no effect on ghrelin transport and triglycerides or fasting increases transport.[6]

These results show that, as expected, ghrelin crosses the BBB. However, the paradoxical interactions of mouse octanoyl ghrelin with the BBB show that there are aspects of transport yet to be clarified.

OTHER INGESTIVE PEPTIDES AND PROTEINS: SPECIAL INTERACTIONS WITH THE BBB

A number of other ingestive peptides and proteins have been examined for their ability to cross the BBB. Several of these have saturable transport systems and others, although able to penetrate the BBB, could not be shown to be inhibited by unlabeled peptide. These are categorized in Table 1 as having crossed the BBB by the nonsaturable mechanism of transmembrane diffusion. However, it is always possible that saturation may have been shown if a higher dose of unlabeled material had been used.

Many of these peptides and proteins have special aspects affecting their brain uptake and BBB penetration. For example, whereas orexin A crosses the BBB by a nonsaturable mechanism, orexin B is so rapidly degraded in blood that it is difficult to study. Although the nonsaturable transport of orexin A provides a mechanism explaining how it can stimulate appetite after peripheral administration, the rapid degradation of orexin B makes it unlikely that it reaches the brain. Similarly, glucagon-like peptide is very unstable in blood, but it can be shown to cross the BBB when studied by brain perfusion. A more stable analog, [Ser8]GLP, crosses by a nonsaturable system. Amylin is co-secreted with insulin from the pancreas and, like insulin, crosses the BBB. Insulin and amylin have distinct distribution patterns in the brain and, whereas insulin clearly is transported across the BBB by a saturable transporter, amylin transport has not been shown to be self-inhibitable. However, amylin transport is inhibited in mice pretreated with aluminum, a maneuver known to inhibit some saturable transporters. It may be that an amylin transporter exists but with a very high capacity.

Binding in serum, either by serum proteins or by some factor in serum promoting aggregation, influences the BBB permeation of some ingestive peptides and proteins. IGF-1, galanin-like peptide, and adrenomedullin cross the BBB, but a saturable component to that passage is not demonstrable after their intravenous injection. However, the saturable transporter can be demonstrated when studied by the brain perfusion method. This method precludes the influence of circulating substances and allows the study of interactions directly between the BBB and the substance of interest. In the cases of IGF-1, galanin-like peptide, and adrenomedullin, it is likely that binding to serum proteins competes with the BBB transporters in such a way as to make it difficult to show the saturable nature of blood-to-brain uptake. Such a mechanism has been shown to be operable for free fatty acids. Binding in serum also interferes with the uptake of Phe^{13},Tyr^{19}-melanin-concentrating hormone (MCH). No uptake can be observed when studied after iv injection, but a low, nonsaturable entry can be seen when studied by brain perfusion.

Urocortin does not cross the BBB under normal conditions. However, a saturable transporter for it can be induced either by treatment with leptin or with glucose. Galanin-like peptide transport is increased with glucose and inhibited by food deprivation. Secretin was the first hormone to be discovered. Bayliss and Starling first described its actions on pancreatic exocrine secretions in 1902. About 80 years later, secretin was discovered in the brain. Very low doses of secretin

TABLE 1 Transport Systems for Ingestive Peptides and Proteins

Substance	Influx	Efflux	Action with CNS
Leptin	Sat	Nonsat	Anorectic
Insulin	Sat	Ret	Anorectic
Ghrelin*	Nonsat	Sat	Orexigenic
Des Ghrelin*	Nonsat	Nonsat	Inactive
Orexin A	Nonsat	Nonsat	Orexigenic
Orexin B	None	NS	Orexigenic
GLP	None	NS	–
Exendin	Sat	Nonsat	Anorectic
PP	Sat	Nonsat	Anorectic
Ser^8-GLP	Nonsat	NS	–
$ARP_{83–132}$	Nonsat	Nonsat	Orexigenic
Amylin	Nonsat?	NS	–
IGF-1	Sat	NS	–
Adrenomedullin	Sat	Nonsat	Anorectic
$Mahogany_{1377–1428}$	Nonsat	–	Anorectic
$PYY_{3–36}$	Nonsat	Nonsat	Anorectic
MSH	Nonsat	NS	Anorectic
MCH	None	Nonsat	Orexigenic
Galanin-like peptide	Sat	Nonsat	Anorectic
CART	Nonsat	Nonsat	Anorectic
NPY	Nonsat	Nonsat	Orexigenic
Urocortin	None/inducible sat	Nonsat	Anorectic
Secretin	Sat (CSF)	NS	–
–	Nonsat (Vascular)	–	–
Nesfatin	Nonsat	Nonsat	Anorectic
Adiponectin	None/Nonsat	–	–

Sat = saturable transport; Nonsat = passage by nonsaturable mechanisms (transmembrane diffusion for influx and bulk flow for efflux); Ret = retained by brain (little or no efflux) after intracerebroventricular injection; None = no blood-to-brain uptake after intravenous injection; NS = not studied.
GLP = glucagon-like peptide; PP = pancreatic polypeptide; ARP = agouti-related peptide; IGF-1 = insulin-like growth factor; MSH = alpha melanocyte-stimulating hormone; MCH = Phe^{13},Tyr^{19}-melanin-concentrating hormone; CART = cocaine- and amphetamine-related transcript; neuropeptide Y.
Special notes: murine ghrelin as studied in the mouse.

administered into the brain also induce pancreatic secretions. Secretin crosses the vascular BBB at a low rate by a nonsaturable mechanism but crosses the blood–CSF barrier at a much higher rate and by a saturable system. Adiponectin accumulates in the CNS less well than albumin and in some studies its penetration into the CNS cannot be demonstrated at all. However, it binds to brain endothelial cells, the cells that comprise the vascular BBB, to alter their secretion of interleukin-6; this cytokine, in turn, can have effects on feeding.

Many other peptides and regulatory proteins which are not considered as ingestive substances nevertheless have profound effects on appetite and metabolism. These include opiate peptides, corticotrophin-releasing hormone (CRH), and cytokines.[17] These are not considered here except to contrast their BBB interactions with the substances discussed above. For example, most cytokines found to have significant entry into the brain are transported across the BBB by a saturable system. CRH and endogenous opiate peptides are substrates for various efflux systems, most notably P-glycoprotein and peptide transport system-1. No saturable influx system has yet been described for an opiate peptide and only one saturable efflux system for a cytokine (IL-2) has been described.

ACTIONS OTHER THAN FEEDING

The gastrointestinal hormones are emerging as pleuripotent substances with actions on the CNS beyond those immediately related to feeding or appetite. These include effects on cognition, neurogenesis, reproduction, respiration/breathing, thermoregulation, and baroreceptor function. Conditions from Alzheimer's disease to preeclampsia have been postulated to arise in part from an impaired transport of insulin across the BBB.[2,16] Future studies will likely find other conditions that result from altered transport of hormones across the BBB.

SUMMARY

The BBB is a major regulatory interface coordinating a humoral-based communication between the GI tract and the CNS. Leptin, insulin, and ghrelin are important examples of substances involved in this communication. Their interactions with the BBB illustrate several principles, including the importance of saturable and nonsaturable mechanisms of passage, the regulation of BBB transporters, and the occurrence of disease with dysregulation of passage across the BBB.

Chapter 230

Neurotrophic Peptides

Weihong Pan and Abba J. Kastin

ABSTRACT

Neurotrophic peptides are not only essential for normal CNS function but they also reduce neurodegeneration after trauma, ischemia, and neuroinflammation. Many neurotrophic peptides permeate the blood–brain barrier (BBB) by specific transport systems and/or they can modulate BBB function. In conditions with partial disruption of the BBB, there are regulatory changes of specific transport systems for selective neurotrophic peptides. Naturally occurring neurotrophic peptides for which interactions with the BBB have been studied include epidermal growth factor (EGF), transforming growth factors (TGFs) α and β, insulin-like growth factors (IGF) I and II, acidic and basic fibroblast growth factor (FGF), colony-stimulating factors, pituitary adenylate cyclase activating polypeptide (PACAP), and several basic peptides. Here, we review their pharmacokinetics, cellular endocytosis and trafficking, and specific effects in CNS disease models. We also summarize the current understanding of peptide-based drug delivery systems.

INTRODUCTION

The functions of neurotrophic peptides are discussed elsewhere in this book. Three points should be stressed: (1) They can be produced both within the CNS and elsewhere, yet their induced expression after an insult to the CNS may not be sufficient to rescue neurodegeneration. (2) Like typical cytokines, they are multipotent and may not always be beneficial or neuroprotective. (3) Endogenous neurotrophic peptides can function as autocrine or paracrine signals and serve as neuromodulators, whereas exogenous neurotrophic peptides introduced by targeted delivery across the blood–brain barrier (BBB), or by implanted cells and tissue, could have a greater influence on CNS function.

Here, we discuss interactions of these peptides with the BBB. The reason that this is an important and critical topic is because the BBB serves as a diffusion barrier and regulatory interface at the same time, and is an essential target when addressing peptide delivery to treat CNS disorders. As a neurovascular interface, the BBB also provides a bidirectional route of communication. An efflux transport system explains part of the peripheral effects of brain-derived neuropeptides, determines whether a peptide is retained in the CNS after influx, and is also important for the clearance of some peptides that are potentially cytotoxic, such as β-amyloid. Deposition and specific interactions of peptides with the cerebral and spinal vasculature precede the influx transfer of selective peptides. Because of their importance in vascular pathology and therapeutic potential in CNS diseases, the blood-to-brain (and spinal cord) influx of neurotrophic peptides is a main focus of this chapter.

Rather than direct permeation across the BBB, some peptides alter endothelial signaling and induce subsequent functional changes. Exocytotic release of secondary signals from the basolateral side of the BBB endothelia can thus modulate cerebral function. Vasoactive peptides are specific examples, as there may be robust changes of cerebral blood flow and metabolism even in the absence of direct permeation of the peptides across the BBB.

Regional specificity of enzymes and specific receptors dictates the pharmacokinetics of peptides in different brain and spinal cord areas. The actions of peptides, of course, are coupled with the phenotypes of neurons and glia in the particular regions. This can make a peptide neurotrophic in one situation, but can stimulate other actions such as feeding suppression or antidepression in another. All these factors need to be taken into consideration when discussing their interactions with the heterogeneous BBB.

The studies of interactions of neurotrophic peptides with the BBB originated from our initial observation that peripheral peptides can exert unconfounded CNS effects — a well-known fact that was controversial four decades ago. The ability of a peptide to cross the BBB in intact form, like its longer biological actions than the half-life in blood, are among the concepts that we presented in the early stage of peptide-BBB research.[13] The BBB is undoubtedly a huge neurovascular unit for information exchange between the CNS and the periphery. As Abbott points out, "For the typical human brain, capillary length is around 650 km (distance from Paris to Dublin). This provides an enormous 12–20 m^2 of surface area for molecular exchange across the capillary wall. The mean distance between capillaries is approximately 40 μm, so that no neuron is more than about 8 μm from a capillary." Here, we summarize the interac-

tions between neurotrophic peptides and the BBB in regard to permeability and endothelial cell signaling, mainly discussing normal physiology but also commenting on studies related to neurological diseases where exogenous neurotrophic support would be beneficial.

RESOLUTION OF MYTHS ABOUT PEPTIDES AND THEIR CNS EFFECTS: *IN VIVO* AND *IN VITRO* METHODOLOGIES

Although the endothelial cells forming the BBB make a thin monolayer, they are joined by tight junctions and lined by a continuous basement membrane. This is further reinforced by pericytes, astroglial endfeet, and extracellular matrix. Besides the anatomical structure, intracellular degradative enzymes and extracellular matrix proteases also reinforce a biochemical barrier. Merely a few decades ago, when we first proposed the CNS affects of peptides, it was considered inconceivable that peptides (and even some larger proteins) in the periphery might effect the CNS. It was a long journey of more than a decade to convince the neuropeptide community that peptides can indeed cross the BBB.

The first stage of showing neurotrophic peptides can cross the BBB in intact form involves pharmacokinetic assays. If the overall structure of the BBB is considered as a semipermeable membrane, the permeation of peptides and proteins is slow, because they are relatively large and lipid insoluble. Permeation is often incomplete, which means that proper mathematical modeling and correction for partial degradation are necessary.

With the exception of several vasoactive peptides, permeation of peptides and proteins across the BBB is not dependent on blood flow. Banks and Kastin established the method of multiple-time regression analysis for *in vivo* studies . The peptide to be studied is radioactively labeled to ensure sensitive and specific detection and delivered by intravenous bolus injection to anesthetized animals. In mouse studies, each time point is represented by individual animals. A period during which most of the peptide remains intact in circulation is reconstructed by the use of multiple mice sacrificed at different time points. The brain/serum ratio over time reflects BBB permeability to the particular peptide. To correct for the disappearance of peptide in the blood over time, and to provide a steady-state value, the theoretical "exposure time" is calculated.[9] Two parameters of permeability can thus be derived from multiple-time regression analysis: the unidirectional influx rate (how fast) and the volume of distribution (how much). The analysis can be extended to different regions of brain and spinal cord and can be applicable to peripheral organs. With this method, permeability of different peptides can be compared, and the effects of potential modulators tested.

There are certain questions beyond the resolution of the two-compartmental model of the BBB that are answered by other techniques. The capillary depletion studies assists in addressing the events in the endothelial cell compartment in addition to cerebral vascular space and brain parenchyma. Analysis of isolated cerebral microvessel endothelial cells *in vitro* further provides another powerful tool to identify the mechanisms of permeation. Internalization of a peptide can be determined after removal of specific surface binding by mild acid wash, trypsin digestion, or other similar procedures.

Cultured primary cerebral microvessel endothelial cells can form relatively tight junctions. This enables measurement of apical-to-basolateral flux (simulating blood-to-brain transfer) and basolateral-to-apical flux (mimicking brain-to-blood permeation) when the cells are grown on a supportive monolayer, such as the side-by-side diffusion chamber or the transwell insert. Because a relatively large quantity of viable cells is needed, many researchers choose bovine or porcine primary cells; however, studies are also performed on cells of rat or mouse origin. A tight monolayer is a prerequisite for *in vitro* permeability studies, so that the nonspecific paracellular diffusion is low. Nonetheless, endocytosis studies can also be performed on freshly isolated microvessels or immortalized endothelial cells. The list of available cell lines suitable for BBB studies are growing. Rat cell lines include RBE4 and TR-BBB cells; mouse cell lines are represented by TM-BBB4, b.End3, and b.End5 cells; whereas the best characterized human cell line is hCMEC/D3 cells.

The second stage to determine transcytosis and regulatory changes of peptides across the BBB involves morphological studies. Fluorescent conjugation and confocal microscopic imaging techniques have shown membrane interactions of peptides and their intracellular trafficking. Theoretically, total internal reflection fluorescence microscope (TIRFM) technology should enable the analysis of exocytic events. Electron microscopy (EM) and EM autoradiography are useful tools to determine the vectorial transport of peptides across the BBB. Studies of molecular trafficking in non-CNS cells have progressed much further than those in BBB cells, and it is yet to be determined whether cerebral endothelia and other cellular constituents process peptides differently during the course of transport. This will be further discussed below.

The third issue is the direct effects of peptides after permeating the BBB vs cellular signaling and secondary mediators generated at the BBB level.[26] Many neurotrophic peptides may provide secondary signals by their effects on BBB endothelia, thus affecting CNS function. The specific examples of vasoactive peptides and cell-penetrating peptides such as human immunodeficiency virus (HIV)-specific protein transactivator of transcription (Tat) are discussed elsewhere.

BINDING PROTEINS THAT AFFECT THE STABILITY AND PERMEATION KINETICS: INTRAVENOUS DELIVERY VS IN SITU BRAIN PERFUSION

A complex of the peptide with its binding protein(s) usually makes the peptide more stable and less susceptible to degradative enzymes in the blood circulation and provides a reservoir for its permeation across the BBB. A specific example is epidermal growth factor (EGF). Binding to proteins and cell-surface heparin sulfate proteoglycans (HSPG) can also accelerate peripheral degradation and reduce BBB permeation, such as occurs with the receptor-associated protein (RAP). Further, aggregation and polymerization of a peptide may deter or even abolish the permeation across the BBB, such as occurs with the chemokine MIP-1[1] and the feeding-related peptide AgRP (83-132).[8]

To accurately assess the permeability of the BBB, the first two issues can be resolved by in situ brain perfusion in blood-free physiological buffer. The radioactively labeled tracers are delivered at a constant rate to the brain at a time when the BBB is still viable and functional (usually within 10 min), and multiple-time regression analysis can be performed. This method also detects rapid influx within the first few minutes that might have been missed by *in vivo* studies. The last issue of aggregation and polymerization can be addressed by chemical methods such as gel chromatography or capillary electrophoresis.

PRESENCE OF RECEPTORS AT THE APICAL OR BASOLATERAL SURFACE OF THE BBB: USEFUL OR NOT FOR PEPTIDE TRANSPORT?

Cell-surface biotinylation and ligand binding methods can determine the relative distribution of receptors on the apical and basolateral surfaces. There are also experimental approaches that differ from whole cell biology, involving preparation of apical or basolateral membranes of the endothelial cells or plasma membrane-derived inside-out vesicles. Thus far, EGF and bFGF are the two neurotrophic peptides for which the distribution of receptors in endothelial cell subdomains is well known. EGFR is a peptide with characteristic 6 half-cystines in the primary structure that is mainly located at the basolateral surface of the epithelial cell. It is known that EGFR mediates the endocytosis of EGF from the basolateral surface. However, most trafficking studies have been performed on nonpolarized cells in which the sorting motifs in the EGFR (located at the apical surface) determine its fate including lysosomal degradation,[15] and sorting nexin 1 also is involved in the trafficking.[16] Intact EGF can be exocytosed from the basolateral to apical side in intact form in MDCK cells of kidney origin, with exocytosis being the rate-limiting step of transport.[33] In animal studies of the BBB, the blood-to-brain transfer of EGF is a saturable process, indicating the presence of a specific transport system.[22] Nonetheless, this influx does not seem to be an EGF receptor-mediated process, because TGFα that binds to the same receptor does not cross the BBB efficiently. Rather, it is retained in the vascular space of the brain.[27] Thus, in this case, the cell surface receptor for EGF and TGFα does not mediate blood-to-brain transport.

Acidic FGF (aFGF, or FGF-1) has limited stability in the blood circulation and therefore cannot be studied by our multiple-time regression analysis. However, basic FGF (bFGF, or FGF-2) has been shown to cross the BBB by adsorptive endocytosis.[5] Perlecan, a heparin sulfate proteoglycan, is involved in its endocytosis from the apical surface of the endothelial cells. Thus, the receptor does not play a significant role in the transport of bFGF across the BBB.

Although a receptor is not always the transporter for a peptide across the BBB, there are many examples of receptor-mediated transport, such as for insulin, IGF-1, tumor necrosis factor (TNF)α, and transferrin. The crossinhibition of insulin and IGF-1 permeability indicates that the transport systems are at least partially shared.

ADSORPTIVE ENDOCYTOSIS AND CHEMICAL MODIFICATIONS THAT ENHANCE DELIVERY ACROSS THE BBB

Several neurotrophic peptides are basic and therefore bear positive charges in solution. For instance, the isoelectric point (pI) of mouse bFGF is 9.59, making it possible to enter cells by adsorptive endocytosis. Binding of bFGF to heparin facilitates HSPG-mediated interaction with endothelial cells.

For peptides crossing the BBB by simple diffusion, physiochemical properties such as lipophilicity, hydrogen bonding, conformation, size, and polymerization are important determinants of permeability. Thus, chemical modifications to enhance stability, lipophilicity, and selective interactions with cerebral endothelial cells will help. Among the posttranslational modifications, glycosylation increases the permeability of some proteins.[29] Pegylation enhances the stability of a peptide in blood but might reduce its permeation across the BBB.[30,31] Some of the modifications, especially immunoliposomes, have been used successfully to increase the bioavailability of a peptide drug to the CNS.

THE INTRACELLULAR TRAFFICKING OF PEPTIDES THAT LEADS TO EXOCYTOSIS

The intracellular trafficking of neurotrophic peptides in the endothelial cells composing the BBB has not been extensively studied. Our unpublished results with urocortin

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

indicates that substantial amounts of fluorescently labeled urocortin are colocalized with endosomes within 2 min and translocate to the Golgi complex and proteasomes at a later time. Urocortin is a 4 kDa peptide that binds to CRH receptors and is primarily involved in feeding behavior and energy expenditure as well as being neurotrophic in certain circumstances. More than 10% of radioactively labeled urocortin can be exocytosed by cultured cerebral microvessel endothelial cells over a time course of 5 min to 1 h in intact form.[35] It is yet to be confirmed whether endocytosis is the rate-limiting step for transport, and much needs to be learned about the trafficking routes and any cytoskeletal motors, ions, or energy processes driving the exocytosis.

Exocytosis of endocytosed peptides and proteins has not received much attention, but valuable information can be learned from studies of those newly synthesized. Although not a complete analogy, the trafficking patterns of a newly synthesized peptide or protein illustrate the diversity of potential pathways encoded by its structure and its interacting partners. The classical secretory route involves the Golgi complex. Sorting may be related to the signal peptide that is cleaved from the mature peptide, associated with sorting nexins, and dependent on chaperon proteins. There are also alternative exocytosis pathways, such as multivesicular bodies and exosome-like vesicles, exovesicles related to membrane blebbing, transporters residing at the plasma membrane, and lysosomal secretion.[32]

SPECIFIC EXAMPLES OF THE PHARMACOKINETICS OF BBB PERMEATION

It seems that cerebral endothelial cells render a different fate to neurotrophic peptides than that shown in other cells such as fibroblasts, lymphocytes, and hepatocytes. Earlier work with radioactively labeled EGF in fibroblasts and other cell types clearly showed its intracellular degradation.[4] Later, polarized sorting was shown to be different when EGF was applied apically vs basolaterally. Kozu et al. provided strong evidence that EGF can be exocytosed in its intact form and that exocytosis is the rate-limiting step of transport.[14] *In vivo* studies in mice also showed that EGF is relatively stable in blood and crosses the BBB by a specific transport system. The amount of EGF in brain parenchyma at 10 min accounts for >50% of the total radioactivity, as contrasted with only 20% in blood vessels.[22] TGFα, although sharing the same receptor as EGF, is retained in the cerebral vasculature without meaningful penetration of the BBB after intravenous injection.[27] TGFβ1 is stable in circulating blood but does not show influx from the blood to the brain.[10]

IGF1 delivered into the blood is mainly protein bound; however, it has a saturable transport system at the BBB. The passage of IGF-1 across the BBB might partially explain the effect of peripheral growth hormone at the CNS, because growth hormone itself has limited permeation of the BBB by simple diffusion.[28] The rate of entry of ^{125}I-IGF1 from blood to CNS shows apparent regional differences, and excess unlabeled IGF1 paradoxically increases the influx of the radioactively labeled tracer in each region tested, probably explained by the displacement of ^{125}I-IGF1 from its binding proteins in the periphery.[23]

Receptor-mediated endocytosis of insulin in cerebral microvessel endothelial cells has been studied both *in vivo* and *in vitro* by several groups. There are regional differences of insulin transport and its regulation in diabetes and various models of obesity. Based on its capability to transport insulin, the insulin receptor has been a target for the design of vehicles (antibody-based cargos) to deliver other neurotrophic peptides and proteins from blood to brain.

Granulocyte macrophage-colony stimulating factor (GM-CSF) enters the brain and spinal cord by a saturable transport system in both mice and rats.[18] Its presence in blood and relative stability in both blood and CNS indicate that GM-CSF plays an important role in modulating the physiological functions of neurons and astrocytes.

As mentioned above, the uptake of bFGF occurs by adsorptive endocytosis and involves HSPG. PACAP is a peptide related to secretin, glucagon, GLP1, and GHRH and it binds to PACAP/VIP receptors as discussed elsewhere in this book. PACAP illustrates how the size of the primary structure does not determine the behavior of its permeation across the BBB. $PACAP_{1–27}$ has a slower influx that is not saturable, whereas the larger $PACAP_{1–38}$ has a faster and saturable influx.[2] The efflux of these two PACAP peptides from brain to blood is impaired in a mouse model of Alzheimer's disease (SAMP8).[3] The structurally related VIP is more vasoactive; it is able to enter the brain from the blood by simple diffusion and is retained in the CNS.[7]

THE SITUATION OF THE PARTIALLY DISRUPTED BBB AND SELECTIVE REGULATION OF THE TRANSPORT SYSTEM IN PATHOPHYSIOLOGY

Neurotrauma, ischemia, and inflammation are associated with increased permeability of the BBB, altered axonal transport, and disrupted neuronal and glial functions. When the BBB is partially disrupted, certain transport systems for cytokines are not abolished but upregulated. This has been specifically shown by TNFα transport after spinal cord injury,[20] head trauma,[25] experimental allergic encephalomyelitis (EAE),[21] and lipopolysaccharide (LPS) administration.[19] The enhanced transport is related to increased mRNA expression of the transporting receptors.[24] Similar regulation of TNFα transport is also present after focal cerebral ischemia.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

BBB permeability of $PACAP_{1-38}$ is decreased at selected times (24 h) in rats after 2 h of middle cerebral artery occlusion followed by reperfusion, and the change seems to be bilateral rather than unilateral.[34] One common feature found for both TNFα and $PACAP_{1-38}$ is that regulation is not only confined to the damaged area but also extends to remote regions, such as the hemisphere contralateral to ischemia. This suggests a general and possibly hormonal factor in the regulation of transport.

However, for neurotrophic proteins that enter the brain and spinal cord by adsorptive endocytosis or other non-receptor-mediated mechanisms, regulation does not always lead to increased uptake. Ebiratide—a synthetic analog of an MSH/ACTH peptide and potent neurotrophic factor—has a high baseline penetration across the BBB, and spinal cord injury does not further facilitate its permeation from blood to brain and spinal cord.[20] EGF uptake by the injured spinal cord also fails to show a significant increase over time in different CNS regions.

ENHANCED DELIVERY OF NEUROTROPHIC PEPTIDES: HOW IT AFFECTS NEUROREGENERATION

Unlike classical hormones and neurotrophins, the neurotrophic peptides have a broader distribution in both synthesis and targets of action. Because insults to the CNS often affect multiple populations of cells and extracellular matrix, the provision of trophic support by these peptides is extremely useful. To deliver neurotrophic peptides as CNS therapeutics, the peripheral route is more advantageous than invasive application directly to the CNS. However, there are only a small proportion of neurotrophic peptides crossing the BBB by specific transport systems; the rest depend on the time- and space-related partial disruption of the BBB. Even for those normally entering the CNS by saturable transport, there does not seem to be substantial enhancement of transport in the diseased state. With the additional concern of peripheral degradation, peptides are often linked to delivery vehicles for adequate transfer. These experimental approaches include immunoliposomes, phage display, viral vectors, stem cells, fusion proteins, and stable, more lipophilic synthetic analogs.

Apart from the delivery of blood-borne neurotrophic peptides such as by intravenous, subcutaneous, and intraperitoneal injections, and by intravenous infusions, an alternative pathway is nasal delivery. Although the detailed mechanism of nasal mucosa and olfactory nerve-mediated transfer is not clear, nasal delivered IGF-1 can reduce the infarct volume and neurological deficit in rats after focal stroke.[17] Transmission within the CSF has enabled the neuropeptides to rescue neuronal cell death after neurodegeneration and cerebral ischemia.

Despite progress in the attempts to use neurotrophic peptides as CNS therapeutics, there have not been many successful long-term effects. Part of the overall picture is that their actions are time and situation dependent, and that other factors, especially inhibitory molecules for neuroregeneration, are also present in the local environment.[12] Nonetheless, the effects of neurotrophic peptides probably extend beyond their roles as cell survival factors to contribute to neuroplasticity both structurally and physiologically.[6]

SUMMARY

Neurotrophic peptides not only affect the functions of endothelial cells and other components of the BBB, but they also may cross the BBB themselves. The permeation of neurotrophic peptides across the BBB is determined by physiochemical properties of the peptides (for those permeating by simple diffusion) or the presence of a carrier system (for those involving receptor-mediated transport, adsorptive endocytosis, or other specific interactions with the cell surface). There are multiple approaches to enhance the permeability of these peptides across the BBB, to conjugate them to targeted delivery systems, or to bypass the BBB. The long-term effect of exogenous neurotrophic peptides on CNS regeneration and neurobehavioral changes are finally receiving more extensive study, about 40 years after the first notion that peripheral peptides have direct CNS effects.[11] It is now established that BBB permeation of neurotrophic peptides can be involved in neuroendocrine changes and neuroplasticity.

Chapter 231

Oligopeptide and Peptide-Like Drug Transport

Richard F. Keep and David E. Smith

ABSTRACT

A knowledge of peptide transport at the blood–brain and blood–CSF barriers is important in understanding both endogenous neuropeptide activity and delivery of oligopeptide or peptide-like drugs to the brain. Although some oligopeptides use specific transport systems to gain entry into brain, the low lipophilicity of many small peptides and the presence of peptidases at the blood–brain barriers limit their entry into the central nervous system. In addition, the presence of several transporters that clear peptides from the brain or the CSF to the blood, such as PEPT2, P-glycoprotein, and PTS-1, has a major impact on brain peptide concentrations.

INTRODUCTION

The ability of some peptides to affect cell function means that their concentrations in the extracellular space are critical. This is particularly true in the brain where many peptides are neurotransmitters or neuromodulators. Perturbations in peptide concentration may come from brain parenchymal cell release, protein/peptide degradation within the brain, and blood-borne peptides. The aim of this chapter is to summarize our knowledge of the mechanisms that may influence the movement of oligopeptides (focusing on peptides with fewer than 10 amino acids) between the blood and brain and, thus, regulate peptide activity within the brain. A knowledge of such mechanisms is important in understanding the effects of endogenous neuropeptides, but it is also important for designing ways of delivering peptide or peptidomimetic therapeutic agents to the brain.

BLOOD–BRAIN BARRIERS: GENERAL PROPERTIES

Passive Permeability

The movement of peptides between the blood and brain is regulated by two barrier systems, the blood–brain barrier (BBB) and the blood–cerebrospinal fluid barrier (BCSFB). The BBB is formed by the cerebral endothelial cells and the tight junctions that link them. The BCSFB is formed by choroid plexus (CP) epithelial cells, situated in the two lateral, third and fourth cerebral ventricles, and the cells of the arachnoid membrane that overlays the surface of the brain. These cells are also linked by tight junctions that limit paracellular permeability of polar compounds (such as many peptides). By contrast, even some large compounds, such as horseradish peroxidase, can permeate between the brain and the CSF across the ependyma. Thus, homeostasis of the brain microenvironment relies on the coordinated action of both the BBB and the BCSFB.

Although tight junctions limit paracellular diffusion at the BBB and the BCSFB, there are major quantitative differences between these two barrier systems. Thus, the transendothelial electrical resistance of the BBB is about 3000–8000 $\Omega\,cm^2$, whereas the transepithelial resistance of the CP is about 150–175 $\Omega\,cm^2$. This is reflected in the passive diffusion of polar compounds across the barriers. The permeability of mannitol (MW 182) and inulin (MW 5000) is about 10- and 100-fold greater at the BCSFB compared with that of the BBB.[28]

CSF Sink Action

In addition to the low permeability of the BBB and BCSFB to polar compounds, the continual replenishment of CSF will also help limit the penetration of polar compounds from the blood to the brain or CSF. The CSF is primarily produced by the CPs and drains back into the blood at the arachnoid villi and other drainage sites. This turnover of CSF will continually clear compounds that have entered the brain from the blood, and this has been termed the CSF sink action. Thus, even during chronic administration, inulin concentrations in CSF only reach 1–3% of levels found in plasma, whereas sucrose (MW 342) may only reach 4–9% of plasma levels.[28]

Transport Properties

Although the blood–brain barriers were first described in terms of their ability to exclude dyes from the CNS, brain

homeostasis requires more than a simple physical barrier. Thus, for example, the brain requires acquisition of nutrients from, and removal of waste products to, blood. Both these functions are potentially hindered by the occlusion of the BBB and BCSFB paracellular pathways by tight junction proteins. There are, therefore, a series of transport proteins at the BBB and BCSFB to fulfill these functions. Thus, Glut1 is present at the BBB to facilitate the entry of glucose from blood to brain, while there is an array of organic anion transporters at the BBB and BCSFB to remove metabolic waste products.[7,15] Although some barrier transporters are facilitative and enhance the rate of transport without imparting directionality (e.g., Glut1), others are coupled directly (e.g., P-glycoprotein) or indirectly (e.g., the peptide transporter, PEPT2) to ATP utilization. Many transporters are polarized in distribution (i.e., present on the blood-facing or brain-facing membrane of the barrier tissue) and involved specifically in blood to brain (CSF) or brain (CSF) to blood transport.[7,15]

For larger molecules, such as polypeptides and proteins, blood to brain uptake can involve either fluid-phase, absorptive, or receptor-mediated endocytosis.[3,5] It should be noted, however, that the level of endocytosis in cerebral endothelial cells is low compared with that in systemic capillaries and that endocytosis does not necessarily indicate transcytosis across the barrier tissue into the brain parenchyma or CSF. Thus, endocytosed compounds may accumulate in the barrier tissue, undergo degradation, or be recycled back to the blood.

Enzymatic Barriers

Apart from the low paracellular permeability of the BBB and BCSFB and the presence of efflux transporters at those barrier tissues that clear compounds from the brain, the entry of organic compounds into the brain from the blood can also be prevented by enzymatic degradation at the level of the BBB or BCSFB. For example, the BBB contains a variety of neurotransmitter-metabolizing enzymes such as monoamine oxidase, cholinesterases, GABA transaminase, aminopeptidases, and endopeptidases that will help prevent the entry of neurotransmitters from the blood to the brain.[3]

Nasal Delivery

There has been considerable interest in delivering peptide therapeutics to brain across the nasal epithelium to circumvent the blood–brain and blood–CSF barriers. Oligopeptides (and larger peptides) can be delivered by this route in animals and humans.[2,8] The delivery of peptides by intranasal delivery is very brain region specific (i.e., high to the olfactory bulb and along the trigeminal nerve[31]).

OLIGOPEPTIDE TRANSPORT AT THE BBB

Blood to Brain Transport at the BBB

Because of potential pharmacological and physiological importance, many studies have examined whether a variety of peptides can cross the BBB.[3,5,19,32,35] The BBB permeabilities of the dipeptides Gly-Phe, Gly-Leu, and carnosine are all very low.[35] It seems that these compounds enter the brain by passive diffusion as their permeabilities are not different from mannitol, a compound of similar molecular weight. Cyclo (His-Pro) has a greater BBB permeability, although it is still low.[1] Its uptake into brain is nonsaturable, and the greater brain uptake results from its greater lipophilicity and its resistance to enzymatic degradation.[1] Although it has a low permeability, cyclo (His-Pro) has central nervous system effects when administered systemically, showing the important point that peptides may have physiological effects within the brain at very low concentrations. The tripeptide, glutathione, has a much greater brain uptake than the dipeptides studied. This reflects the presence of a specific sodium-dependent glutathione transporter at the BBB.[35]

Several larger oligopeptides have higher BBB permeabilities than would be predicted from their molecular weight and lipophilicity,[35] such as Leu-enkephalin and delta sleep inducing peptide. This observation, as with glutathione, reflects the presence of carrier-mediated transport at the luminal (blood-facing) membrane of the BBB.[35] It should be noted, however, that for Leu-enkephalin, peptidase activity may prevent the appearance of intact peptide in the brain parenchyma.[35]

It is now evident that the BBB can selectively transport a variety of oligo- and polypeptides.[3,5,19,35] In terms of small oligopeptides, the BBB expresses many different solute carriers that transport organic compounds.[7] These transporters often have a wide range of substrates and overlapping substrate specificities. The affinity of these different transporters for different types of peptides has not been examined in detail. However, the organic anion-transporting polypeptide-2 (Oatp2) has affinity for the opioid peptide [D-pen^{2,5}]enkephalin (DPDPE). Oatp2 is believed to act as a bidirectional transporter on both the luminal and abluminal (brain-facing) membranes of the BBB, and to participate in DPDPE uptake into the brain.[7] Human OATP transports DPDPE and deltorphin II.[7] For larger peptides and polypeptides, which are outside the scope of this chapter, transcytosis is an important mechanism for blood to brain transport.[3,5,19,35]

Brain to Blood Transport at the BBB

In the past decade, considerable attention has been focused on efflux transporters at the BBB, particularly in relation to P-glycoprotein (Pgp) and its role in preventing the access

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

of a wide range of drugs into the brain. The brain:blood concentration ratio of the opioid peptide DPDPE after systemic administration is 3- to 4-fold greater in mice deficient in Pgp.[6] This effect of Pgp on peptide distribution, however, probably is limited to those peptides that are relatively lipophilic. An analog of Leu-enkephalin, H-Tyr–D-Ala–Gly–Phe–D-Leu–OH (DADLE), does not seem to be significantly effluxed from the brain by Pgp, but the cyclic prodrugs of DADLE are.[18]

Other efflux transporters at the BBB can also affect the distribution of peptides. Thus, peptide transport system (PTS)-1 clears Tyr-MIF-1, Met-enkephalin, and oxytocin from the brain.[5] Somatostatin and its analogs also have a saturable efflux system that is separate from PTS-1.[5] PTS-6 also clears peptides from the brain at the BBB, but the size restriction of that transporter is unclear as it has so far been shown to transport only large peptides, pituitary adenylate cyclase-activating peptide and derivatives.[4] Such transporters may play an important role in clearing endogenous neuropeptides from the brain, but they may also play an important role in limiting the entry of neuroactive peptides (endogenous or exogenous) from the blood to the brain.

PEPTIDASES AT THE BBB

The cerebrovasculature expresses a wide range of enzymes that degrade peptides including carboxy-, amino-, and endopeptidases.[3,33] Some of these enzymes may be enriched both with respect to brain and with respect to systemic capillaries. The metabolic substrates for such peptidases include a wide range of compounds including enkephalins, neurotensin, bradykinin, angiotensin I and II, substance P, endothelin, dynorphin, luteinizing hormone releasing hormone, growth hormone releasing factor, and kallidin.[33] Along with the low passive diffusion across the BBB, the presence of these peptidases on the cerebrovasculature may aid in preventing the entry of potentially neuroactive peptides into the brain from the blood. It should be noted, though, that some peptides are vasoactive and neuroactive (e.g., angiotensin) and some peptidases may be present to limit vascular effects.

OLIGOPEPTIDE TRANSPORTERS AT THE CHOROID PLEXUS

Molecular Basis for Oligopeptide Transporter Heterogeneity

In mammals, the proton-coupled oligopeptide transporter (POT) family consists of four members (i.e., PEPT1, PEPT2, PHT1, and PHT2) and is responsible for the transport of small peptides/mimetics across biological membranes via an inwardly directed proton gradient and negative membrane potential.[12,21] The POT proteins vary in size from 572 to 729 amino acids and are predicted to contain 12 transmembrane domains, with the N- and C-termini facing the cytosol. The encoded proteins have many potential protein kinase recognition domains (i.e., 0–3 for PKA, 1–11 for PKC) and glycosylation sites (i.e., 2–7); however, their relevance has not been proven experimentally. Although PEPT1 and PEPT2 have high homology between species (about 80% in rat, rabbit, human, and mouse), the homology between these transporters for a given species is low (about 50%). Rat PHT1 and PHT2 have an amino acid identity of about 50%, but they show little homology to either PEPT1 or PEPT2 (<20%).

Tissue Distribution

PEPT1 is found primarily in the intestine and, to a lesser extent, in kidney.[12,21] It is a high-capacity, low-affinity transporter with *K*m values in the millimolar range. PEPT2 is the predominant POT in the kidney and, in contrast to PEPT1, is a low-capacity, high-affinity transporter with *K*m values in the micromolar range.[12,21] Together, PEPT1 and PEPT2 work in concert at the apical surface of epithelial cells to efficiently absorb and conserve protein digestive products arising in the intestine and kidney. However, PEPT2 has a wider tissue distribution that PEPT1 and, as demonstrated by immunolocalization in rats, is found extensively throughout the brain.[24] Although PEPT2 has its strongest expression in cerebral cortex, strong expression is also observed in the olfactory bulb, basal ganglia, cerebellum, and hindbrain. PEPT2 is also expressed abundantly in epithelial cells of the CP as well as in ependymal cells. This transporter is expressed exclusively on the apical membrane (i.e., CSF facing) of CP epithelia in both adult and neonatal animals. PEPT2 is differentially expressed in cerebral cortex as a function of age, with much greater levels in fetal and neonatal tissue than in adult. Moreover, PEPT2 is expressed in neurons (adult and neonate) as well as in astrocytes (neonate but not adult). The age-related decline of PEPT2 in cerebral cortex may reflect a loss of astrocytic PEPT2. There is no molecular or functional evidence for PEPT2 in endothelial cells of the BBB. Likewise, PEPT1 seems to be absent from brain. The apical expression of PEPT2 in CP suggests (along with functional studies; see below) that this transporter is involved in the export of neuropeptides, peptide fragments, and peptide-like drugs from CSF. Its expression in neurons and astrocytes further suggests that PEPT2 may play a role in regulating the concentration of neuropeptides in extracellular fluid.

Crystal Structure of a Prokaryotic Homolog of the POT Family

A significant discovery in advancing modern drug design and the targeted delivery of drugs within the body was made by determining the crystal structure of a prokaryotic peptide

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

transporter, $PeptT_{So}$, from *Shewanella oneidensis*.[16] This structure contains 14 transmembrane helices, was found in a ligand-bound occluded state, and shares a high degree of sequence similarity and functional characteristics with the human PepT1 and PepT2 proteins. Fundamental structural biology questions remain such as which residues are involved in protonation and peptide binding, how specificity is achieved within the binding pocket, and what does the structure look like for peptide transporters in different conformational states along the transport cycle. Once these, and other questions of broader biochemistry, are solved, it may be possible to engineer the targeted delivery of future drug molecules to the central nervous system where PEPT2 has a significant role in peptide/mimetic disposition and dynamics.

Basolateral Transporter

The cloning, membrane localization, and functional activity of PEPT2 in CP epithelium have provided the fundamental basis for how peptides/mimetics are transported from CSF into the cell. However, the precise nature of the basolateral peptide transporter in CP is yet to be resolved (as is also the case in the kidney and intestine). Still, a low-affinity transporter was observed for glycylsarcosine (GlySar) uptake at the basolateral membrane of rat CP epithelial cells.[26] It has been suggested[30] that a single facilitative peptide transporter is expressed at the basolateral membrane of Caco-2 cells, and that PEPT1 and the basolateral peptide transporter cooperate in the efficient transepithelial transport of small peptides and peptide-like drugs. Thus, PEPT1 (at the apical membrane of intestine) mediates the active uptake of these substrates from the lumen against a concentration gradient, followed by the facilitated cellular efflux into blood down a concentration gradient. It is reasonable to conjecture that the same mechanism could apply for the transepithelial transport of peptides/mimetics across the CP. Notwithstanding this uncertainty, the CP basolateral transporter does not seem to be PEPT1.[24,26]

Intracellular Transporters

Information on the tissue distribution, cellular localization, and transport properties of the peptide/histidine transporters, PHT1 and PHT2, is limited. PHT1 transcripts are abundantly expressed in rat eye and brain, including the CP.[34] Moreover, PHT1 expressed in *Xenopus laevis* oocytes transports L-histidine with high affinity (K_m of 17 μM) and the dipeptide carnosine. In contrast, PHT2 transcripts are abundant in the rat lung, spleen, and thymus but detected faintly in brain.[22] Although the uptake of L-histidine and histidyl-leucine was observed when PHT2 protein was reconstituted into liposomes, the transport kinetics was not determined. PHT1 and PHT2 are unlikely to be involved in peptide/mimetic transport at the blood-CSF barrier (apical or basolateral membrane) because functional studies have failed to show inhibition of oligopeptide uptake by excess L-histidine.[12] Despite the uncertain function of PHT1 and PHT2 in the brain, they may have a role in the intracellular trafficking of small peptides, as suggested by lysosomal expression studies in rat PHT2-transfected BHK and HEK-293T cells.[22]

Larger Peptide Transporters

Three members of the organic-anion-transporting polypeptide (Oatp) gene family of membrane transporters have been shown to transport the δ-opioid peptides DPDPE (5 amino acids) and deltorphin II (7 amino acids).[7] Although rat Oatp1 and Oatp2 are localized at the apical and basolateral domains, respectively, of CP epithelium, Oatp2 is also expressed strongly at the BBB. Moreover, the human OATP (called OATP-A) exhibits especially strong expression in brain microvessels and capillary endothelial cells. These findings suggest that certain members of the Oatp/OATP gene family may play an important role in carrier-mediated translocation of opioid peptides across the mammalian BBB and BCSFB.

PEPTIDASES AT THE CHOROID PLEXUS

A wide range of peptidases have been identified at the CP.[3,28] Some are located on the blood vessels of the CP (e.g., angiotensin-converting enzyme) and may be involved in regulating vasoactive hormones. Others, however, are present on the epithelium plasma membrane and have a polarized distribution. Thus, both endopeptidase 24.11 and aminopeptidase N are found on the CP apical membrane. Both these peptidases cleave enkephalins (and other substrates). It is probable that such peptidases serve to keep the concentrations of such neuroactive compounds low in CSF. They may act in concert with PEPT2 present on the apical membrane, with PEPT2 clearing peptide fragments produced by peptidase action.

In addition to cleaving peptides present in the CSF, CP peptidases may be involved in preventing the entry of peptides from the blood to the CSF. Peptidases on the CP vasculature or the epithelial basolateral membrane could prevent access of neuroactive peptides to the CSF. In addition, intracellular CP peptidases may degrade peptides taken up by endocystosis and other processes. Thus, cathepsin D and tripeptidyl peptidase I are both present in the CP lysosomal compartment.[28]

PEPTIDE AND PEPTIDE-LIKE DRUG TRANSPORT AT THE BCSFB

Although our understanding of blood–CNS barriers has increased greatly over the past few years, a significant gap still remains in our appreciation of drug efflux transporters

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

and their role in affecting the CNS exposure and pharmacological response to nutrients, drugs, and potential neuropharmaceuticals. Because of its unique localization within the brain, PEPT2 may represent an important determinant of CNS exposure and response to peptide (or mimetic) drugs, as well as endogenous peptides and their "oligo" fragments (some of which may be pharmacologically active or toxic).

In Vitro Disposition at the BCSFB

Studies in adult rat CP whole tissue, neonatal rat CP epithelial cells in primary culture, and genetically modified mice showed that PEPT2, located at the apical (CSF facing) as opposed to basolateral (blood-facing) membrane, is the primary member of the POT family responsible for the removal of neuropeptides, peptide fragments, and peptide-like drugs from the CSF.[12,28] In particular, *Pept2*-deficient mice have marked reductions (≥90%) in their ability to transport GlySar, carnosine, and 5-aminolevulinic acid in CP whole tissue. Moreover, the CP uptake of cefadroxil (a β-lactam antibiotic), as determined in wild-type and PEPT2 null mice, is primarily mediated by PEPT2 (80–85%) and to a minor extent by organic anion transporters (10–15%) and nonspecific mechanisms (5%). This finding suggests that aminocephalosporins, which are recognized by PEPT2, may have reasonable access to the CSF but are rapidly removed by drug efflux transporters making them ineffective for the treatment of bacterial infections in the CNS. However, one must be careful in extrapolating the results with cefadroxil to other aminocephalosporin drugs. As reported by Kuroda et al.,[13] small differences in chemical structure can substantially influence the mechanism of drug efflux from CSF. For example, cefaclor (3-chloro in dihydrothiazine ring) is eliminated from rat CSF by a benzylpenicillin-sensitive mechanism distinct from OAT3, whereas cephalexin (3-methyl in dihydrothiazine ring) is removed by a GlySar-sensitive transporter, presumably PEPT2.

In Vivo Disposition at the BCSFB

The development of *Pept2* knockout mice[25] has afforded a unique opportunity to explore the *in vivo* disposition of peptides and peptide-like drugs. Initial "proof of concept" studies with GlySar (a hydrolysis/peptidase resistant compound) showed that PEPT2 ablation has a significant effect on dipeptide disposition. In particular, *Pept2* knockout mice have a 2-fold greater concentration of GlySar in CSF, despite having much lower blood concentrations (as a result of a greater clearance by the kidney).[17] Thus, the CSF-to-blood concentration ratio of GlySar is 4-fold greater in *Pept2* null animals as compared with that of wild-type controls ($p<0.001$; Fig. 1). In the absence of PEPT2, the CSF-to-blood ratio is about 0.9, indicating that GlySar can achieve concentrations in the CSF similar to

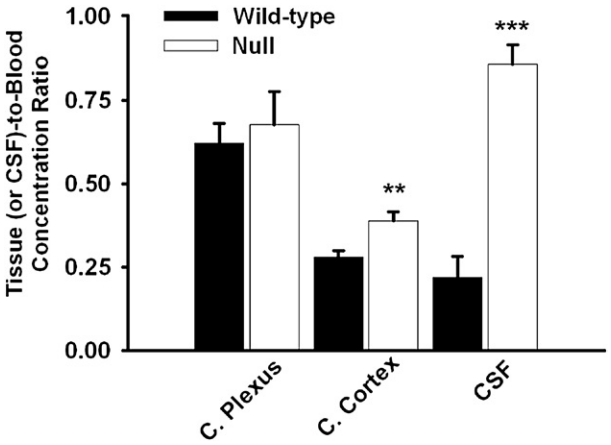

FIGURE 1 Tissue (or CSF)-to-blood concentration ratios of GlySar in the choroid plexus (c. plexus), cerebral cortex (c. cortex), and CSF of wild-type and PEPT2 null mice, 60 min after an intravenous bolus dose of dipeptide (0.05 μmol/g of body weight). Data are expressed as mean ± SE ($n=6$–7). $^{**}p<0.01$, and $^{***}p<0.001$ compared with wild-type mice.

that in blood. However, when PEPT2 is present, GlySar's persistence in the CSF is substantially reduced (i.e., CSF-to-blood concentration ratio of about 0.2). Although a modest 40% increase is observed in the cerebral cortex-to-blood concentration the ratio of GlySar in *Pept2*-deficient mice (i.e., 0.28 in wild-type vs. 0.39 in *Pept2* null animals, $p<0.01$; Fig. 1), there is no difference between genotypes in the CP-to-blood ratio (i.e., 0.62 in wild-type vs. 0.68 in *Pept2* null animals, $p>0.50$; Fig. 1). However, a substantial difference is observed in the CP-to-CSF concentration ratio of GlySar, where wild-type animals have a 5-fold greater tissue accumulation relative to medium at the transporter interface (i.e., 4.2 in wild-type vs. 0.8 in *Pept2* null animals, $p<0.01$).

Similar results were observed subsequently with the antibiotic drug cefadroxil in which the CSF-to-blood concentration ratio is 6-fold greater in *Pept2* knockout mice compared with that of wild-type animals.[23] Likewise, *Pept2* knockout mice have an 8-fold higher CSF-to-plasma concentration ratio of the dietary supplement carnosine after intravenous dosing (0.70 for null vs. 0.08 for wild-type mice).[11] By contrast, endogenous levels of carnosine are not different in the plasma (2.8 vs. 2.5 μM in null and wild-type mice, respectively) or CSF (8.9 vs. 8.6 μM in null and wild-type mice, respectively) for both genotypes. Taken as a whole, these findings clearly show that, under physiologic *in vivo* conditions, PEPT2 acts to efflux substrates from CSF into CP. It is also apparent that the body can adapt so that plasma and CSF levels of endogenous substrate (i.e., carnosine) are maintained during PEPT2 ablation. The nature of this adaptation remains unclear at present but deserves further attention. A proposed model for the transepithelial transport of di/tripeptides (and peptide-like drugs) in CP is shown in Fig. 2.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

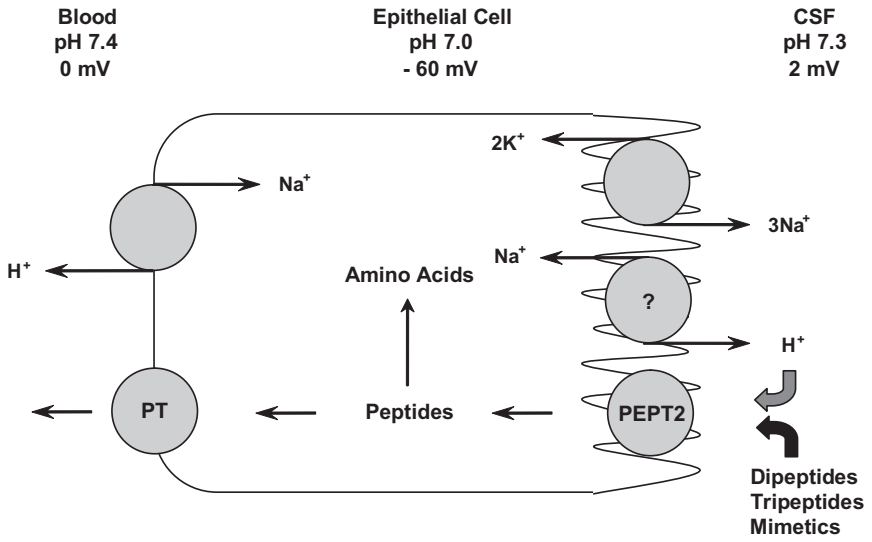

FIGURE 2 Proposed model for the transepithelial transport of di/tripeptides (and peptidomimetic drugs) in the choroid plexus. It is uncertain whether or not an acid microclimate (an area of low pH adjacent to the apical membrane) exists at choroidal brush border membranes, such as that observed in the intestine and the kidney. However, in the absence of a pH microclimate, accumulation could be driven by the negative membrane potential that exists in choroid plexus epithelium. Note that in the epithelial cells of the intestine and kidney, polarity of Na^+/K^+ ATPase and the Na^+/H^+ exchanger is reversed; still, PEPT2 is localized to the apical membrane. PT is the basolateral peptide transporter and PEPT2 is the apical proton-coupled peptide transporter.

Quantitative autoradiography of [^{14}C]GlySar in wild-type and *Pept2* knockout mice permits assessment of the parenchymal distribution of dipeptide in brain with high spatial resolution.[27] Autoradiographic analysis (performed 60 min after intracerebroventricular injection) shows that GlySar concentrations in the lateral, third, and fourth ventricle CPs are higher in wild-type than in *Pept2* null mice. Although GlySar uptake is higher in the ependymal–subependymal layer and septal region of wild-type mice, the half-distance of penetration into parenchyma is significantly less in *Pept2*-competent animals. The latter finding probably reflects the clearance of GlySar from interstitial fluid by neurons expressing PEPT2, which limits further penetration. A schematic illustrating as to how PEPT2 modifies the regional distribution of GlySar (and presumably other peptides and peptide-like drugs) in brain is shown in Fig. 3.

In Vivo Dynamics at the BCSFB

Regional modulation of peptide/mimetic disposition in brain by PEPT2 has relevance in pharmacology and toxicology. There is definitive evidence that PEPT2 can influence the antinociceptive response to a PEPT2 substrate, L-kyotorphin (L-KTP).[10] Specifically, the CSF efflux of L-KTP is slower in *Pept2* knockout mice than in wild-type animals, and this difference is reflected in greater L-KTP induced analgesia during PEPT2 ablation. In dose–response studies, the ED_{50} of L-KTP in *Pept2*-deficient mice is one-fifth the value of that observed in *Pept2*-competent mice (4 vs. 21 nmol, respectively). By contrast, the ED_{50} values of its diastereomer (D-KTP), a non-PEPT2 substrate, is not different between the two genotypes (9–10 nmol). The findings suggest that PEPT2 might function in the control of analgesia through the regulation of endogenous neuropeptides (and potential drug candidates) in the CSF or other compartments in brain. Another study showed a neuroprotective role for PEPT2 in modulating the toxicity of a heme precursor, 5-aminolevulinic acid (5-ALA).[9] This showed that survivability is reduced after high-dose acute administration and that neuromuscular function worsens after chronic dosing of 5-ALA in *Pept2* knockout mice. Pharmacokinetic studies indicate that CSF concentrations of 5-ALA are 8–30 times higher with PEPT2 ablation, suggesting that the greater toxicity of 5-ALA in *Pept2* knockout mice is because of changes in CSF (and presumably brain extracellular fluid) concentrations.

REGULATION OF PEPTIDE TRANSPORT

There is growing interest in the regulation of BBB and BCSFB transport and how that may affect brain drug delivery. Thus, BBB Pgp expression is affected by xenobiotics, stress, and disease states[15] and this will alter the brain distribution of peptide substrates of that transporter. Similarly, there is evidence that stress and disease can change BBB organic anion transport.[20]

The regulation of PEPT2 at the blood–CSF barrier has received limited attention. In this regard, mutations in the scaffolding protein PDZK1 can reduce the functional activity of PEPT2 in HEK293 cells,[29] although the mechanism of this interaction and relevance to brain function are unclear. Likewise, the serum- and glucocorticoid-inducible kinase SGK1 can enhance PEPT2 function and surface abundance

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

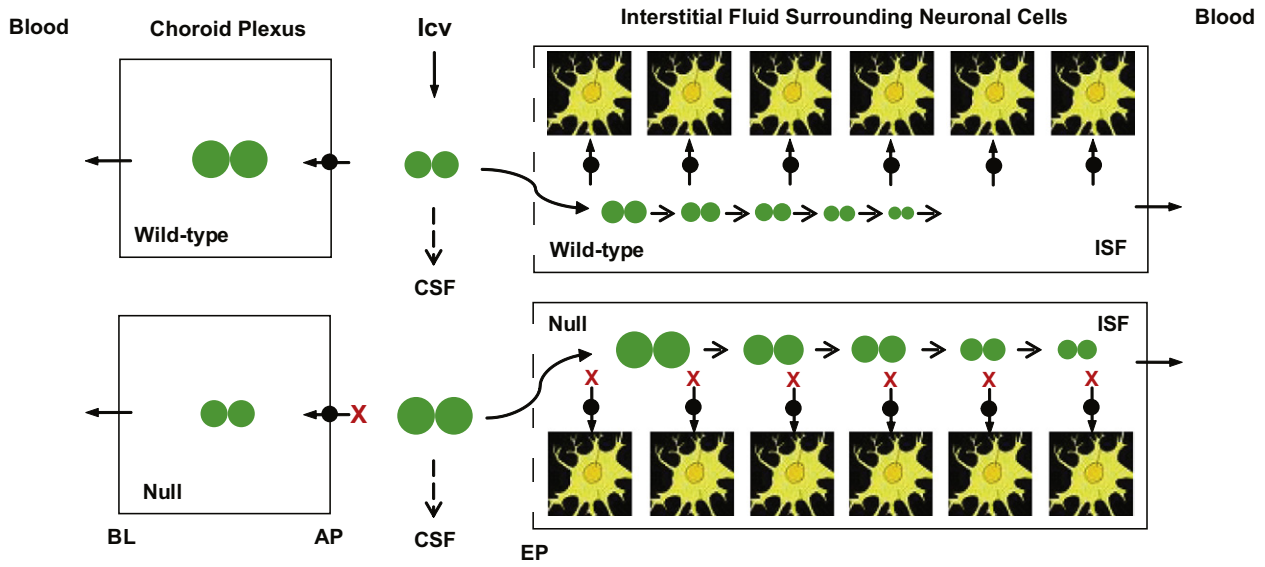

FIGURE 3 Schematic of how the proton-coupled oligopeptide transporter SLC15A2 (PEPT2 shown as ◄●–) affects the distribution of GlySar (displayed as dipeptide ●●) in different regions of the brain after an icv injection (adapted from Ref. 27). Interstitial fluid (ISF) concentrations of GlySar are reduced in wild-type mice because of PEPT2-mediated uptake in choroid plexus (CP), along with reduced coronal penetration of GlySar as it moves along the ISF–parenchymal axis and is taken up and trapped by PEPT2-containing neurons (shown as ✸). In null mice, substantially lower concentrations of GlySar are observed in CP epithelial cells, and higher concentrations of GlySar are observed in cerebrospinal fluid (CSF) and ISF surrounding the neurons. The solid arrows (——►) represent GlySar transport through membranes and the dashed arrows (- - ->) represent GlySar diffusion/bulk flow. Icv, intracerebroventricular; BL, basolateral membrane; AP, apical membrane; EP, ependyma (shown as dashed lines for both wild-type and null mice). The solid X symbols (X) represent lack of PEPT2 activity in the null mice.

in *Xenopus oocytes*,[14] but the nature of this interaction in neuronal function and disease is unknown. Finally, as discussed before,[24] PEPT2 is developmentally regulated in rat cerebral cortex and, as shown by immunolocalization studies, is expressed in rat neurons (neonate and adult) and astrocytes (neonate only).

SUMMARY

Although some peptides use specific transport systems at the blood–brain barriers to gain entry into brain, the low lipophilicity of many small peptides and the presence of peptidases at the BBB and BCSFB limit the entry of oligopeptides into the central nervous system. The presence of efflux transporters may further limit such entry. In particular, the activity of transporters such as Pgp and PTS-1 at the BBB, and PEPT2 at the BCSFB serves to clear neuropeptides, peptide fragments, and potential peptidomimetic drugs from the brain. As a result, a better understanding of efflux transport will be critical to the successful design, delivery, and targeting of neuropharmaceuticals. Moreover, such knowledge will facilitate insight into the regulation of endogenous neuropeptide activity.

Chapter 232

Opioid Peptides

Richard D. Egleton, Ken A. Witt and Thomas P. Davis

ABSTRACT

Opioid peptide research over the last 30 years has revealed considerable information regarding the function of the opioid receptors and their role in regulating pain and behavioral processes. Despite this, there remains a lack of viable peptide-based therapeutics capable of central nervous system action. This is largely because of the limited ability of opioid peptides to transverse the blood–brain barrier (BBB) intact. The BBB acts as a metabolic and transport barrier preventing peptide delivery to the brain. This chapter update addresses opioid peptide development for the enhancement of brain delivery.

INTRODUCTION

The *endogenous opioid system* modulates the perception of pain and many other behavioral responses (e.g. memory, pleasure, hunger) through a complex series of neuronal networks.[2] This system is regulated by three principle opioid receptor types (μ, δ, κ) expressed throughout the central nervous system (CNS). The endogenous substrates for these receptors (i.e. enkephalins, endorphins, endomorphins, and dynorphins) each have differential binding to the respective opioid receptor subtypes. Over the past two decades, numerous opioid peptide analogs have been synthesized. Although such peptides have led to a significant increase in the understanding of opioid receptors, none have shown to be a practical clinical alternative to morphine or other non-peptide-based therapeutics. Moreover, given the recent insights of opioid receptor action in various behavior processes,[2] there is a pressing need for viable receptor subtype-specific opioids for both treatment and study. Nevertheless, the development of CNS acting opioid peptides faces a significant hurdle, that being the BBB. The BBB plays a critical role in maintaining brain homeostasis, which it does through the interaction of three barrier systems: a physical barrier, a transport barrier (i.e. efflux mechanisms), and a metabolic barrier. These barrier systems directly impede peptide uptake into the brain. In this chapter update, we focus on studies evaluating opioid peptide drug delivery to the brain, within the context of the BBB. We further address how diseases may impact peptide drug uptake in the context of BBB alterations.

STABILITY

The metabolic stability of any drug is a primary factor in the determination of brain bioavailability. As opioid peptides are rapidly degraded by endogenous peptidases, one approach to enhancing BBB penetration is to increase the metabolic stability. This is highlighted by the study of Brownson et al. who showed that in the presence of enzyme inhibitors, transport of Met-enkephalin across an *in vitro* BBB was increased.[3] By contrast, there was no effect on the transport of metabolically stable opioid peptides,[3] indicating that metabolic stability is a vital first step toward improving peptide-based drug delivery to the brain. Furthermore, the Brownson study underscores the enzymatic activity of the BBB endothelium itself. Although not as metabolically active as the liver, the BBB endothelium does express enzymes capable of rapidly degrading peptide-based drugs, including a significant number of cytochrome P450 enzymes (Table 1).

Several strategies have been used to increase the metabolic stability of opioid peptides, such as insertion/addition of unnatural amino acids, cyclization of linear peptides, and glycosylation (see Ref. 31 for review of methods). One of the common features of opioid peptides is that they share a similar amino terminal sequence of Tyr-Gly-Gly-Phe-X. This amino acid sequence is believed to be essential for opioid receptor binding and activation. This makes the opioid peptides particularly sensitive to peptidase cleavage of the N-terminal TYR residue, as this cleavage will render the peptide inactive. A successful strategy for protecting the amino nitrogen amino acid is to replace the Gly at position 2 with a D-amino acid. Several amino acids have been used at this position, such as Ala (e.g. DAMGO, DADLE) and Ser (e.g. DSLET). Such amino acid substitutions when coupled with C-terminal amidation have shown to substantially enhance enzymatic stability.[24,28] Altering the structural design of a peptide via constrainment or bridging may also improve stability. A prime example is shown with the Met-enkephalin analog D-penicillamine (2,5)-enkephalin (DPDPE), which is constrained by a disulfide bridge. Not only does this design enhance stability

TABLE 1 Common Enzymes at the BBB

Peptidases (alternate names)
Angiotensin-Converting Enzyme (Peptidyl-dipeptidase hydrolase) (Peptidyl dipeptidase A) (Kinase II)
Aminopeptidase M (N)
Enkephalinase (Endopeptidase 24.11) (Neutral endopeptidase)
Endopeptidase (Endopeptidase 24.15)
Carboxypeptidase N (Kinase I)
Cytochrome P450s
CYP1A1, CYP1B1, CY2A6, CYB2B6, CYP2C, CYP2C9, CYP2E1, CYP2J2, CYP3A4, CYP4A11, CYP11B

with a serum and brain half-life of approximately 500 min but it also enhances selectivity and affinity for the δ-opioid receptor.[3] Another consistently applied method to increase stability is glycosylation. The addition of a carbohydrate moiety to a peptide (i.e. glycopeptide) may significantly impact the pharmacokinetic properties, not only improving metabolic stability but also increasing plasma half-life and membrane permeability.[31] Glycosylation of the opioid analog TY027 (Tyr-D-Ala-Gly-Phe-Met-Pro-Leu-Trp) by replacing the terminal Trp with a Ser-glycoside results in an increased metabolic half-life from 4.8 h to over 24 h (rat plasma evaluation).[35] Other sugar substitutions, such as fructose, also improve the metabolic stability, thus increasing the half-life of peptide drugs.[13] The principle caveat with opioid peptide glycosylation, or any other addition/modification, is that the placement of the moiety must occur at a location within the peptide so as not to interfere with the receptor binding.

Endomorphins (EMs) are endogenous opioid peptides that differ from the typical opioid structure. Instead of having the opioid receptor motif of Tyr-Gly-Gly-Phe-X, endomorphin-1 (EM-1) has a Tyr-Pro-Trp-Phe-NH_2 sequence, whereas endomorphin-2 (EM-2) has a Tyr-Pro-Phe-Phe-NH_2 sequence. They are also a bit unusual that instead of being full agonists at the opioid receptors (like the other endogenous opioids), they are partial agonists. The Pro in position 2 induces what has been described as a "kink" in the peptide structure that places the aromatic group at positions 1 and 3 into the correct alignment for binding to the μ-receptor. Initial studies replacing the Pro with a D-Pro also increased enzymatic stability but greatly reduced receptor binding affinity. An alternate strategy is to incorporate unnatural amino acids with six-membered heterocyclic rings, such as piperidine-2-, 3-, and 4-carboxylic acids, which mimic Pro. Perlikowska[23] showed that this substitution significantly increases metabolic stability in brain and subsequently increases intracerebroventricular analgesic activity.[22] Other research groups have found that conjugation of EM-1 with lipoamino acids such as 2-aminododecanoic acid increases the metabolic stability.[15] However, such conjugations tend to make the EM-1 too lipophilic and decrease delivery to the brain.[15] This highlights that increasing the metabolic stability of peptides is only one part of the equation for opioid peptide delivery to the brain.

TRANSPORT

Although numerous opioid peptide modifications have been explored to enhance stability and receptor selectivity, the question remains as to how these modifications affect the ability of the peptide to traverse the BBB. The nature of the BBB, with the presence of "tight junctions" with high transendothelial cell resistance, limits the paracellular entry of drugs into the brain. Thus, the transport of opioid peptides between endothelial cells is not viable. Beyond invasive methods, a number of structural/pharmacological modifications can be used to circumvent the BBB. Moreover, there are a number of transporters that can be targeted to enhance brain delivery (Fig. 1).

The number of hydroxyl groups within a peptide, and in turn hydrogen-bonding potential, dictates its partition coefficient. In this regard, the type of amino acids (polar vs. nonpolar) and their respective positions to one another dictates the overall lipophilicity of a peptide. Generally, moderately increasing the lipophilicity of a peptide drug promotes its ability to diffuse across the membrane. Historically, several different methods have been used to promote this, including methylation, halogenation, and reduction of hydrogen-bonding potential.[31] Methylation has shown to reduce hydrogen binding potential. Methylation [2,6-dimethyl-tyr] of the opioid peptide DPDPE has shown to result in enhanced bioavailability to the brain, resulting in a 10-fold increase in analgesia.[11] Tri-methylation of DPDPE was subsequently evaluated, with shifts in lipophilicity, BBB permeability, and an analgesic profile shown to be dependent on stereoconformation methyl groups.[34] Halogenation impact on lipophilicity and brain uptake is dependent on the conjugated halogen (i.e. Cl, Br, F). Addition of chlorine to DPDPE is particularly advantageous, increasing lipophilicity and BBB permeability with significant enhancement of analgesia.[29] A combination of a C-terminal chloro addition and an N-terminal guanidine addition (cationization), together with a D-Ala substitution in position 2 of EM-1, results in a guanidine- [D-Ala^2, *p*-Cl-Phe^4] EM-1 with substantial

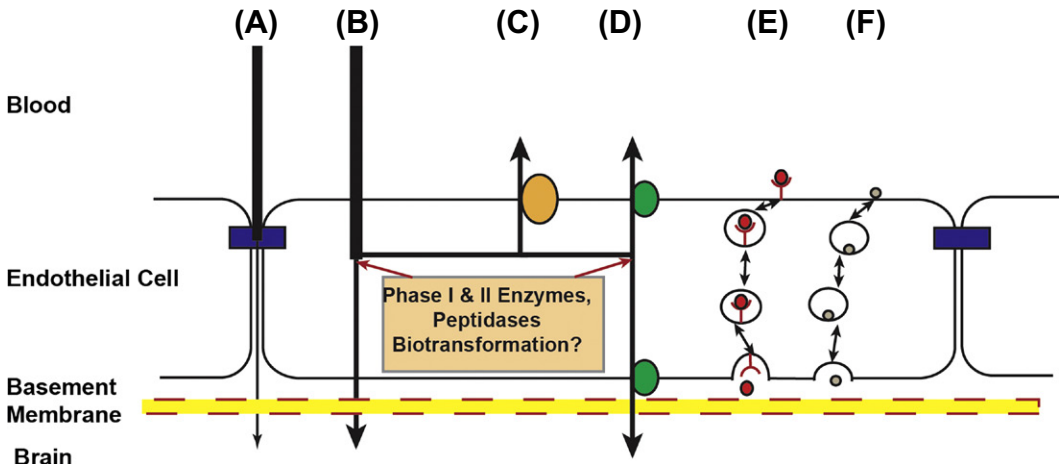

FIGURE 1 Potential transporter targets to improve opioid peptide delivery at the BBB. The transport systems at the BBB that have been targeted for increased opioid uptake include diffusion via increasing lipophilicity (B), masking efflux transport properties (C), targeting solute carriers (D), prodrugs/targeted immunoliposomes for receptor-mediated endocytosis (E), and changing charge/amphipacity for adsorptive-mediated endocytosis (F). We also have to take into account that the transporters can interact with each other and also with the metabolic barrier of the BBB. Additionally, the presence of phase-I and phase-II metabolic enzymes, and various peptidases, can turn a peptide into a substrate for the efflux transporters.

stability and 3-fold greater potency than the parent compound.[17] Such hybrid formulations using multiple methods to increase BBB permeability have great potential for future pharmacological use, yet the complexity of synthesis must be weighed against outcome benefits. For enkephalins, other lipophilic derivatives show promise not only in increasing metabolic stability, but also improving brain delivery. One evaluation showed that adding a synthetic lipid moiety such as 2-amino-D, L-octanoic acid hydrochloride (C8 lipoamino acid) or 2-amino-D, L-dodecanoic acid hydrochloride (C12 lipoamino acid) to the N-terminus of Leu-enkephalinamide increases lipophilicity and *in vitro* permeability.[4] Furthermore, in the subsequent *in vivo* evaluation, there was effective brain uptake of the C8-Leu-enkephalinamide via the nasal route.[4] The nasal route has significant advantages for delivery of highly lipophilic peptides as it avoids first pass metabolism through the liver, yields a high concentration of drug in the vicinity of the receptor, and reduces the potential of the compound from entering other organ beds. Although many strategies exist to enhance lipid solubility of opioid peptides, there are several limitations. Beyond maintenance of receptor activity and potential for enhanced peripheral distribution of the drug, there is also the potential for intracellular sequestration and enhanced affinity of efflux transporters at the BBB.

The BBB has a high level of efflux transporters [e.g. P-glycoprotein (P-gp), multidrug resistant protein (MRP), breast cancer resistant protein (BRCP)] that can prevent substances from entering the brain (Fig. 1). The substrate specificity for these transporters is rather broad and can be a considerable issue for opioid peptide delivery to the brain. Opioid peptides that are substrates for efflux mechanisms include a number of cyclized DADLE (Tyr-D-Ala-Gly-Phe-D-Leu) prodrugs. Cyclization of opioid peptides has been used to promote enzymatic stability and also maintain the peptide drug structure in a rigid conformation that can promote receptor binding. A strategy used by one group was to cyclize prodrugs of DADLE to enhance BBB permeability. However, in this case, the DADLE prodrug design enhanced its affinity for P-gp, one of the highest expressed ATP dependent efflux pumps expressed at the BBB.[20] Inhibitors of P-gp, such as cyclosporine, significantly increase the uptake of these DADLE prodrugs into the brain, showing this is indeed the key mechanism in inhibiting their uptake.[20] DPDPE, another cyclized peptide encephalin analog, is also a substrate for P-gp.[5] Administration of DPDPE to P-gp knockout mice, or in the presence of a P-gp inhibitor, increases brain accumulation of DPDPE and the analgesic response.[5] Several strategies have been used to mask opioids from efflux transporters. Pegylation (PEG) of DPDPE has been shown *in vitro* to mask the peptide structure from P-gp.[33] This modification improves brain distribution in mice and increases analgesia. Interestingly, the PEG seems to also act as a prodrug, improving the peripheral pharmacokinetics and promoting BBB entry. Once inside the brain, the PEG group is believed to undergo hydrolysis allowing the unconjugated DPDPE to act at the δ opioid receptor.[33] Other methods that have been used include the use of pluronic copolymer P85, which seems to inhibit DPDPE P-gp interaction as well. Regardless of the manner used, the critical aspect is to reduce efflux activity against the respective peptide, while maintaining BBB permeability and receptor affinity.

On the flipside, the BBB has several influx transporter mechanisms that can be targeted to improve brain delivery

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

of peptides. Many highly active influx mechanisms consist of transporters that work either via facilitative diffusion or via receptor-mediated processes (Fig. 1). The incorporation of linkers and/or modification of an opioid peptide to enhance the affinity for such nutrient transports have shown some success. The potent opioid peptide analog biphalin [(Tyr-D-Ala-Gly-Phe-NH)2], targets the large neutral amino acid (LNAA) carrier for uptake across the BBB, a transporter also used for L-DOPA.[1] However, some enkephalins use the saturable transporter, peptide transport system-1 (PTS-1) for efflux.[18] Another proposed strategy aimed to increase brain uptake of opioid peptides is via targeting the glucose-1 transporter (Glut-1). In one study, a group glycosylated the cyclic Met-enkephalin analog [D-Cys^{2,5},Ser^{6},Gly^{7}]-enkephalin to increase brain uptake by Glut-1.[9] Although this strategy did improve brain uptake and analgesia, the increased brain uptake of the glycosylated analog was shown not to be mediated via the glut-1 transporter, but via a yet unidentified saturable mechanism.[9] Nevertheless, other groups subsequently used this method on a series of different peptides and found similar improvements in brain penetration in rodents.[13,35] Interestingly, the glycosylated peptides that show the best analgesia in rats and mice do not lead to any significant improvements in CNS-mediated analgesia in primates.[8] This further highlights another fundamental caveat often overlooked that different transport systems exist across species, and thus evaluations of peptide modifications often needs to be evaluated in multiple models.

Targeting receptor-mediated transcytosis (RMT) is another heavily explored strategy to improve BBB uptake. In this regard, vector-based methods have shown some success. The principle of the vector approach is to couple a peptide to a substance (e.g. antibody/biologics) with affinity for a highly expressed BBB transporter. In this manner, the peptide is not only targeted to the BBB but also actually taken up across the membrane. One such study used a vector approach that bound the opioid peptide DALDA to an antibody targeting the transferrin-receptor.[14] The BBB expresses high levels of the transferrin-receptor, so this complex acts as a specific target for the brain endothelium. Compared with nonvector peptide, the brain uptake of vectorized-DALDA was increased 18-fold to reach 0.12% of the injected dose per gram tissue.[14] Although an effective method for delivering the peptide, this approach using an antibody or Fc-conjugate is rather expensive and may not be an economically viable for continuous drug delivery to the brain. Nevertheless, this method has shown utility for targeting liposomes to the brain and has been used for both delivery of chemotherapeutics and genetic material.[21]

Another delivery avenue is to take advantage of adsorptive-mediated endocytotic/transcytotic (AMT) processes. Although RMT is a highly specific means of transport, AMT is by definition a nonspecific process. In this regard, the AMT pathways of BBB may provide a more effective means for continuous transport of opioid peptides through the endothelial cytoplasm. AMT-based approaches include structural modification, cationization, glycosylation, and binding to various carriers/vectors (see Ref. 12 for full review). Several dermorphin analogs have been shown to undergo AMT at the BBB. Interestingly, for this class of opioid analogs, there seems to be some differential rates of AMT. Two dermorphin analogs, N-alpha-amidino-Tyr-D-Arg-Phe-betaAla-OH (ADAB) and N-alpha-amidino-Tyr-D-Arg-Phe-MebetaAla-OH (ADAMB) use AMT to penetrate the BBB. Their respective membrane uptake is inhibited by a range of endocytosis inhibitors and polycations, though not 2,4-dinitrophenol, or by decreasing the temperature to 4 °C. By contrast, the related dermorphin Tyr-D-Arg-Phe-beta-Ala-OH (TAPA) is inhibited by 2,4-dinitrophenol and has a greater rate of uptake than either ADAMB or ADAB.[6,7] Further, the half-saturation constant of TAAP is approximately three times that of ADAMB and ADAB, indicating that the transport affinity is much higher.[6,7] Another approach is to enhance the cationized state of the peptide, which contributes to an enhanced interaction with anionic sites of the BBB endothelium (i.e. glycocalyx) and thereby increase the potential for AMT uptake. Some examples involve the binding of cationic compounds such as spermine or putrescine, or via making the peptide structure more basic, such as for the dynorphin peptide analog E-2078.[12] AMT is also a potential mechanism for the increased uptake for glycosylated peptides. Some studies have shown that the least energy confirmation for a group of enkephalin glycopeptides is an amphipathic-like structure. It is possible that this increases the interaction with the membrane of the cells to increase uptake. Many glycosylated opioid peptides, including Met-enkephalins and β-endorphins, have shown enhanced enzymatic stability and increased BBB transport.[31] Although the AMT approach shows viability, there is the potential for enhanced peripheral distribution and increased serum protein binding.

Lastly, opioid peptides may be encapsulated via liposomes or nanoparticles for the enhancement of brain delivery. Liposomes consist of phospholipid bilayer that can act as a carrier for either hydrophilic or hydrophobic drugs. Such liposomes increase serum half-life, decrease clearance, and reduce toxicity a high drug concentrations.[31] A variation on the liposome approach is the use of self-assembling amphiphilic block copolymers (SAABCs). One example of an SAABC is P85, which is arranged in a triblock construct, consists of a central poly (propylene-oxide) block with attached poly (ethylene-oxide) blocks on each end. The hydrophilic blocks form hydrogen bonds with aqueous surroundings and form a tight "shell" around a hydrophobic core, allowing maintenance of a micelle structure on dilution. Hydrophobic drugs have an affinity for the core region, entrapping them and protected them

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

against enzymatic degradation and hydrolysis. Such formulations increase membrane transport and stability, while reducing immunogenicity, proteolysis, cellular efflux, and systemic clearance. The use of P85 with the opioid peptide analogs DPDPE and biphalin enhances analgesia, as well as inhibits P-gp and enhances BBB uptake *in vitro*[32] Nanoparticles have also been used to deliver opioids experimentally for a number of years. These are particularly useful for peptides such as EM-1 that has a short half-life. The benefit of nanoparticles is that if prepared with coatings, such as poly sorbate 80, they can readily cross the BBB and gradually release the peptide leading to a prolonged analgesia.[16]

BBB AND DISEASE, WILL IT CHANGE OPIOID PEPTIDE DELIVERY?

For many years, the BBB was considered to be a relatively static barrier. However, we now know that it is a highly flexible and dynamic barrier that can be modulated via physiological, pharmacological, and pathological signals. To date, several disease states have shown to influence the function of the BBB, including diabetes, Alzheimer's disease, acquired immune deficiency syndrome (AIDS), and Parkinson's disease.[10] Moreover, patients often require pain treatment over the course of such chronic diseases. The question is "How might drug transport be altered by disease and can opioids themselves alter BBB function?" Disease alters the expression and activity of ATP-binding cassette (ABC) transporters (e.g. P-gp, BCRP). TAT and other proteins, such as gp-120, which are regulated by the human immunodeficiency virus (HIV) are known regulators of BBB proteins, including P-gp.[31] Inflammatory pain has specifically shown to increase the expression of efflux transporters, potentially impacting the efficacy of opioids in producing centrally mediated analgesia.[25] P-gp has also been shown to be overexpressed at the BBB during morphine treatment, suggesting that the opioid drugs themselves have a direct or, more probably, an indirect action on efflux mechanism.[27] Changes in cerebral neurotransmitters during exposure to opioids and the release of cytokines during pain may well affect transporter synthesis. There is also evidence that opioids drugs can influence the BBB tight junctional proteins and increase paracellular permeability.[19] In an *in vitro* examination, a group investigated the effect of treating human brain microvessel endothelial cells (HBMEC) cells with morphine.[30] Morphine treatment led to increased paracellular permeability and decreased the expression of the tight junctional protein zona-occludens-1 (ZO-1). This increase in paracellular permeability by morphine was blocked by the use of the opioid receptor antagonist naltrexone. However, naltrexone only partially restored the expression of ZO-1. Conversely, in an *in vivo* study, in which rats were chronically treated with morphine for 12 days, paracellular permeability was significantly decreased, yet when withdrawn from morphine, significant increases in BBB permeability were observed in association with brain edema.[26] It is plausible that opioids may be producing the differential effects on paracellular permeability and P-gp via opioid receptors present on the endothelial cells of the BBB. Assessing the contribution of respective opioid receptors with regards to alterations in permeability and protein expression at the BBB may provide a significant insight into disease and treatment outcomes.

CONCLUSIONS

Opioid peptides have the potential to not only be valuable research tools but also be viable CNS acting therapeutics. Although the BBB remains a significant impediment, several delivery strategies show considerable promise in overcoming such obstacles. Therefore, rational drug design and customized delivery strategies must be tempered with a greater understanding of BBB dynamics in both health and disease.

Chapter 233

Peptide Delivery

Paul Kiptoo, Marlyn D. Laksitorini and Teruna J. Siahaan

ABSTRACT

The development of peptides as drugs for treating brain diseases has been hampered by the difficulty to deliver them through the blood–brain barrier (BBB). Therefore, there is an urgent need to develop methods to enhance peptide delivery through the BBB. Most peptides have unfavorable physicochemical properties for unrestricted permeation through the transcellular pathway of the BBB. Although some peptides can permeate through the paracellular pathway, this route of transport is limited by the presence of tight junctions. Paracellular permeation of peptides through the BBB can be enhanced by modulating the protein–protein interaction in the intercellular tight junctions by the use of Zot, occludin, and cadherin peptides. To improve permeation through the transcellular pathway, peptides can be modified to cyclic peptide prodrugs, which have better BBB permeation than that of the parent peptide. BBB permeation of peptides can be increased by improving peptide enzymatic stability and targeting saturable and receptor-mediated transport.

INTRODUCTION

Many peptide drugs have been developed as therapeutics to treat various brain diseases (i.e., Alzheimer's, Parkinson's, multiple sclerosis, brain tumors); unfortunately, the development of these molecules has been hampered by the limited ability to deliver them to the brain. The challenge of delivering peptides to the brain results from their difficulty in crossing the blood–brain barrier (BBB). Although some peptides may penetrate the BBB through the paracellular pathway,[19,35] paracellular penetration is constrained by the presence of tight junctions. The size of the peptide is one of the obstacles for diffusion through the paracellular pathway; normally, peptides have a hydrodynamic radius larger than 11 Å, and they cannot freely diffuse through tight junctions.[19] The porosity of the BBB paracellular pathway can be increased on disruption of the interaction of intercellular junction proteins.[35]

Most peptides have physicochemical properties (i.e., hydrophilicity, hydrogen-bonding potential, size) that make them less favorable for transcellular penetration through the BBB. The transcellular route of transport includes passive diffusion, passive diffusion modified by efflux pumps, receptor-mediated saturable transport, and non-receptor-mediated saturable transport. In regular passive diffusion, the peptide has to partition into the membranes on the blood side and subsequently enter into the cells; this is followed by partitioning into the membranes on the side of the brain before entering the brain environment. To make peptides more readily permeate via the transcellular pathway, the physicochemical properties of the peptide can be temporarily altered to favor membrane partition. An increase in lipophilicity is one major way to do this. Physicochemical properties of the peptide can be altered transiently by forming cyclic peptide prodrugs.[24] The formation of cyclic prodrugs has been shown to improve BBB penetration by opioid peptides.[2]

Another problem in peptide delivery to the brain is the presence of metabolic enzymes encountered in the blood and/or during crossing the BBB that prevents the parent peptide molecules from reaching the target site. Thus, improving peptide enzymatic stability can prolong its delivery to the brain. The presence of efflux pumps (i.e., P-glycoprotein (Pgp) and multidrug resistance proteins (MRPs)) on the BBB may also prevent the entry of peptides into the brain.[9] This chapter focuses on improving delivery of peptides to the brain through the paracellular route by modulation of the intercellular junctions and through the transcellular route by changing the physicochemical properties and enzymatic stability of the peptides. A few examples of the way that targeting saturable and receptor-mediated transport systems could be used to enhance permeation of a limited number of peptides are also discussed.

MODELS TO STUDY BRAIN DELIVERY OF PEPTIDES

Many *in vitro* and *in vivo* BBB models have been established for evaluating brain delivery of drug molecules including peptides. There is no single *in vitro* cell culture model that

can mimic the total properties of the *in vivo* BBB; nonetheless, many different *in vitro* BBB models have been very useful for preliminary evaluation or prediction of drug transport through the BBB. A good *in vitro* model should be easy to culture in a reproducible manner. These *in vitro* models normally have cellular architecture similar to that of the *in vivo* BBB, including tight junctions and transporters.[11] Rapid screenings of transport properties of drug molecules through the BBB have been conducted successfully with *in vitro* models, and the results from *in vitro* studies can be correlated to *in vivo* results.

To mimic the *in vivo* conditions, the model cell monolayer should have tight intercellular junctions with high transendothelial electrical resistance (TEER) to restrict the paracellular permeation of drug molecules. Unfortunately, it is difficult to mimic the *in vivo* cerebrovascular capillaries with a high TEER value (i.e., $>1000\,\Omega\,cm^2$). Although the bovine brain microvessel endothelial cell (BBMEC) monolayer is considered a good model for the BBB, it has a low TEER value (i.e., $60–200\,\Omega\,cm^2$); this model is suitable for studying transcellular transport of drugs. Its low TEER value reflects a leaky tight junction of the BBMEC monolayer; therefore, it is not a good model for studying the permeation of those peptides that penetrate the BBB via the paracellular pathway. By contrast, monolayer of porcine brain capillary endothelial cells is closer to the BBB *in vivo* situation with a high TEER value ($600–800\,\Omega\,cm^2$).[6] Because isolation of the BBMEC can be laborious, cell culture models such as bEND3 and bEND5 from immortalized brain endothelial cell lines were developed.[31] Similar to the BBMEC, these models are appropriate for studying drug uptake and efflux but not for studying paracellular transport because they have a low TEER ($60\,\Omega\,cm^2$). Madin–Darby canine kidney (MDCK) cell monolayers have also been used as an *in vitro* model to predict the passive transport of drug molecules through the BBB. Because MDCK has a tighter intercellular junction than BBMEC, it may be a better model for predicting the paracellular permeation of peptides through the BBB. Because the MDCK model does not express the proper efflux pumps on its surface, there are efforts to increase the expression of efflux pumps on the surface of MDCK cells.[8]

METHODS TO IMPROVE PARACELLULAR PEPTIDE DELIVERY THROUGH THE BBB

One way to improve brain delivery of peptides is by increasing their permeation via the paracellular pathway of the BBB. This can be done by modulation of the protein–protein interactions in the intercellular junctions of the BBB. Although there are many aspects of the structure and function of intercellular junctions that are not fully understood, it is clear that protein–protein interactions in the intercellular junctions are important in maintaining the integrity of the BBB.[35] The intercellular junction structure is divided into three regions—tight junctions, adherens junctions, and desmosomes. The tight junctions are located at the very top of the BBB close to the apical (AP) side or blood side and are mediated by transmembrane proteins such as occludins, claudins, and junctional adhesion molecules (JAM). Underneath the tight junctions is adherens junctions, which are mediated by calcium-dependent VE-cadherins and calcium-independent nectins.[35] Below the adherens junctions are the desmosmes, which contain desmocolline and desmoglein. The intercellular junctions are dynamic in nature and can assemble or disassemble during the physiological process. *In vitro*, the tight intercellular junction can be modulated by adjustment of the calcium concentration and use of peptides that inhibit protein–protein interactions. Next, the improvement of drug delivery (i.e., small molecules and peptides) through the BBB by disrupting protein–protein interactions in the intercellular junctions will be described.

Modulation of Cadherin–Cadherin Interactions

E-cadherin and VE-cadherin are found in the adherens junctions of the epithelial intestinal mucosa and vascular endothelial cells of the BBB, respectively. One hypothesis is that paracelluar permeation of large hydrophilic drugs (i.e., peptides) can be increased on modulation of cell-cell adhesion in the intercellular junctions by inhibiting protein–protein interactions.[18,19,23] It is proposed that the inhibition of protein–protein interactions increases the overall paracellular porosities of the intercellular junctions of the BBB. Thus, peptide molecules derived from the region of homophilic contact of the protein–protein interactions can be used to inhibit these interactions and loosen the intercellular junctions. An HAV hexapeptide (Ac-SHAVSS-NH_2) derived from the EC1 domain sequence of E-cadherin enhances permeation of ^{14}C-mannitol and ^{3}H-daunomycin through the BBB *in vivo*.[13] This result suggests that modulation of cadherin–cadherin interactions in the adherens junction can increase the porosity of the paracellular of the BBB.

Although VE-cadherin (cadherin-5) has been found in BBB microvessel endothelial cells,[29] anti-E-cadherin (DECMA-1) monoclonal antibody (mAb) can decorate the intercellular junctions of BBMEC monolayers[23] and block the single cell aggregation of BBMEC, suggesting the potential involvement of E-cadherin in the intercellular junctions.[18] Alternatively, the E-cadherin mAb has cross-reactivity with VE-cadherin. The alignment of VE-cadherin and E-cadherin shows that the VE-cadherin has the A**VIV**DK sequence instead of the S**HAV**SS found

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

in E-cadherin; however, sequence homologies are found between VE-cadherin and E-cadherin at the flanking residues to the AVIVDK and SHAVSS sequences, respectively (see the alignment of E-cadherin and VE-cadherin in Table 1).

Initially, the activity of HAV peptides derived from the EC1 domain of E-cadherin was evaluated for the inhibition of E-cadherin-mediated cell–cell adhesion in a single cell aggregation assay of BBMEC.[18] In this situation, BBMEC are trypsinized in the presence of calcium to acquire single cells.[23] The presence of calcium in the medium prevents the digestion of cadherins on the cell surface. The single cells are incubated with 1.8 mM of calcium in the presence of different concentrations of HAV peptides and anti-E-cadherin mAb as well as in the absence of peptide. In the absence of peptides or mAb, the aggregation of BBMEC single cells is observed. In the presence of HAV peptides and anti-E-cadherin mAb, less aggregation of BBME single cells is observed; the IC_{50} of the cell aggregation inhibitor is determined by counting the number of cell particles as a function of peptide concentration. The HAV-24 peptide (Table 1) is the most potent HAV peptide for inhibiting BBMEC aggregation, with an IC_{50} of 0.008 μM.[18] When HAV-24 is reduced to HAV6 (Table 1), the potency of HAV6 peptide in inhibition of BBMEC cell aggregation is dramatically reduced to 20 μM. These *in vitro* results suggest several possibilities. First, both E-cadherin and VE-cadherin have a role in the formation of intercellular junctions of the BBB. Second, if E-cadherin is present in the adherens junctions of the BBB, the HAV peptide and anti-E-cadherin mAb modulate the E-cadherin-mediated membrane-membrane contact on the BBB.[18,23] Third, if VE-cadherin but not E-cadherin is present in the adherens junctions of the BBB, modulation of the BBB by HAV peptide and anti-E-cadherin mAb interactions may result from binding or cross-reactivity of these molecules to VE-cadherin. Further studies are necessary to elucidate the roles of E- and VE-cadherins in the adherens junctions of the BBB and to determine the mechanism of action of HAV peptides in modulating the BBB.

HAV and ADT peptides are two different peptides derived from the groove and bulge regions of EC1 domain of E-cadherin (cadherin-1); these peptides modulate the intercellular junctions of cell monolayers (i.e., BBMEC, Caco-2, and MDCK).[14,18,20,23] In epithelial cells, the homotypic adhesion of Caco-2 single cells to modified Caco-2 cell monolayers is largely dependent on extracellular Ca^{2+} concentrations, and the calcium-mediated Caco-2 cell–cell adhesion can be inhibited by anti-E-cadherin mAb and E-cadherin peptides (HAV and ADT peptides), indicating that the cell–cell adhesion is mediated by E-cadherins.[14] In MDCK cell monolayers, HAV and ADT peptides lower the TEER values as well as improve ^{14}C-mannitol transport, indicating paracellular porosity can be increased on modulation of the cell–cell adhesion.[20] As mentioned previously, HAV hexapeptide enhances the permeation of ^{14}C-mannitol and [^{3}H]-daunomycin through the BBB of the *in situ* rat brain perfusion model.[13] In addition, HAV6 peptide administered in combination with verapamil, an efflux pump inhibitor, has a synergistic effect in enhancing the absorption of daunomycin through the BBB. Flanking residues on

the His–Ala–Val (HAV) sequence have an influence on the activity of HAV hexapeptides in inhibiting cadherin–cadherin interactions in cell aggregation and TEER evaluation assays. Mutation of some of the residues in Ac-SHAVSS-NH_2 peptide to alanine (i.e., Ac-SHAVAS-NH_2 and Ac-SHAVSA-NH_2) enhances the peptide activity in modulating the intercellular junctions of MDCK monolayers as measured by the lowering of TEER values and the enhancement of ^{14}C-mannitol.[13] The increase in ^{14}C-mannitol transport suggests that the peptides increase the paracellular porosity of the intercellular junctions on disruption of cadherin–cadherin interaction.

The potential mechanism of action of HAV peptides was evaluated in Caco-2 cell monolayers. Prolonged treatment with Ac-SHAVSS-NH_2 peptide (100 μM) for 24 h reduces the amount of E-cadherin protein in Caco-2 cells about 20%; however, there is no change in the E-cadherin gene expression.[1] Addition of HAV6 peptide to Caco-2 cell monolayers upregulates several different stress genes, including prostate differentiation factor, and several protective genes (i.e., ATP-binding cassette subfamily ABCA member 5, endothelin, and AMP-activated protein kinase alpha 2 catalytic subunit).[1] These results suggest that the mechanism of action of HAV6 peptide may involve not only disrupting the E-cadherin interactions in the intercellular junctions but also indirectly interfering with various intracellular pathways.[1]

Modulation of TJ Proteins by Occludin Peptides and ZOT Peptide

Occludin Peptides

Occludin and claudin are found in the tight junctions of biological barriers, and modulation of occludin interactions enhances the porosity of the tight junctions to allow molecules to penetrate biological barriers (i.e., BBB and intestinal mucosa barrier)[26] Occludin has four transmembrane helical domains and two extracellular loops with each loop containing 44 amino acid residues. Although none of the occludin peptides has been used to improve peptide delivery to the brain, it is useful to discuss the potential of occludin peptides in modulating the tight junctions of cell monolayers to increase paracellular permeation of hydrophilic molecules *in vitro*. Synthetic peptides called OCC1 and OCC2 from loop-1 and loop-2 of chick occluding, respectively, were evaluated in disrupting the tight junction integrity of *Xenopus* kidney epithelial A6 cell monolayers.[34] OCC2 but not OCC1 can modulate the tight junctions of the cell monolayers as reflected by the lowering of the TEER values of the monolayers. OCC2 increases paracellular penetration of large hydrophilic molecules (i.e., inulin, dextran-3000, and dextran-40,000) through the A6 cell monolayers.[34] The active OCC2 peptide has the thiol groups on both cysteine residues capped with acetamido-methyl groups; this protecting group prevents the formation of inactive OCC2 oligomers via a disulfide bond(s). A smaller fragment of the second loop of rat occludin (22 amino acid OCC2R, Table 1) could also disrupt the blood–testis barrier.[3,33] Tight junction modulation by OCC2 occurs via lowering of the total cellular levels of occludin, thus depleting the occludin molecules at the cellular boundaries of tight junctions. The lowering of occludin cellular level is not because of inhibition of occludin protein synthesis but to the faster turnover of occludin. OCC2 modulation of tight junctions does not change the distribution of E-cadherin and ZO-1 and ZO-2 proteins at the intercellular junctions.

Although the first loop of chick occludin (OCC1) does not show activity in the modulation of the tight junction of kidney epithelial A6 cell monolayers,[34] a 45-mer peptide called OP90–135 (Table 1) derived from the first extracellular loop region of human occludin modulates the intercellular junctions of the Caco-2 cell.[28] OP90–135 peptide lowers the TEER value of Caco-2 cell monolayers and improves ^{14}C-mannitol transport when added from the basolateral (BL) side but not from the apical (AP) side. The lack of modulatory activity from the AP side results from peptide metabolism at the AP side brush border.[28] It is also possible that, because of the large size of the peptide, OP90–135 cannot efficiently penetrate the tight junctions to modulate occludin–occludin interactions. OP90–135 was systematically shortened to OP90–103, and this peptide has better activity than OP90–135 in modulating the intercellular junctions. The modulatory activity of OP peptides is inhibited by dimer and oligomer formation. To overcome the oligomerization problem, the peptide was conjugated to the hydrocarbon (C-14) chain at the N-terminus to make "lipoamino" peptide (LIP-OP90–103). LIP-OP90–103 peptide has an 11-fold better activity than the parent peptide because LIP-OP90–103 does not form oligomers. By contrast, conjugation of the hydrocarbon (C-14) chain to the C-terminus of OP peptide does not improve the activity of the conjugate. In the future, it will be interesting to see whether OP peptides can be used to modulate the tight junctions of the BBB in *in vitro* and *in vivo* models.

ZOT Peptides

Zonula occludens toxin (Zot) and zonulin are proteins that can modulate the tight junctions of the intestinal mucosa and BBB to improve paracellular transport of large hydrophobic and hydrophilic drugs.[26,27] Zot is associated with Vibhrio cholerae and is involved in the opening of tight junctions in the pathology of cholera, causing passage

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

of water and electrolytes during cholera-associated diarrhea.[17] Zot enhances transport of small-to-large hydrophilic molecules (i.e., mannitol, polyethylene glycol 4000, and inulin) or small hydrophobic molecules (e.g., paclitaxel, acyclovir, cyclosporine A, and doxorubicin) across Caco-2 cell and BBMEC monolayers.[27] Oral delivery of insulin is improved by Zot administration, and the blood glucose is effectively reduced compared with the use of insulin alone. In cell culture, Zot peptide enhances paracellular permeation of ^{14}C-inulin more than that of ^{14}C-PEG4000 and the peptide is stable for 10 days.[4] This higher inulin permeation presumably results from the globular shape of inulin compared with the rod shape of PEG. However, the peptide is unable to enhance the permeation of FITC-dextran-10,000 through Caco-2 cell monolayers, suggesting that there is a cut-off limit on the paracellular opening created by the peptide.

In vivo, a 12-kDa fragment of Zot protein called ΔG administered intraduodenally via a cannula significantly increases (up to 57-fold) the C_{max} and AUC of drugs such as ritonavir and cyclosporin in the presence of protease inhibitors (30 mg/kg bestatin + 30 mg/kg captopril + 67 mg/kg leupeptin).[27] The need to include protease inhibitors results from the rapid *in vivo* enzymatic degradation of ΔG protein, but. protease inhibitors alone increase the transport of cyclosporine and ritonavir. These results suggest that a mixture of ΔG and protease inhibitors provides an alternative to enhance drug delivery through the biological barriers (i.e., intestinal mucosa and BBB).

The proposed mechanism of action of Zot and zonulin is that these molecules activate intracellular signaling related to protein kinase C (PKC) and phospholipase C and induce actin polymerization.[17] Zot peptides can modulate PKC to cause rearrangement of the cytoskeleton that alters the tight junction protein–protein interactions and loosens the tight junctions in a reversible fashion.[4] In the brain, the plasma membranes contain Zot receptors that bind to Zot and zonulin proteins, and these receptors have structural similarity with MRP-8 (14-kDa), which is a member of S-100 family of calcium-binding proteins.[17]

AT-1002 is a hexapeptide (FCIGRL) derived from the Zot sequence that can modulate the tight junctions *in vitro* and *in vivo* to enhance paracellular permeation of marker molecules.[10] Although AT-1002 has not been investigated for enhancing drug delivery to the brain, it improves oral absorption of low molecular weight heparin[21] and pulmonary delivery of salmon calcitonin.[10] The mechanism of action of AT-1002 in modulating the tight junctions was evaluated in Caco-2 and IEC6 cell monolayers. The tight junction modulation results from the rearrangement of the cellular cytoskeleton caused by the disruption of stress fibers, lowering of the actin filament, and the disappearance of ZO-1 protein from the "kiss" region of the tight junctions.[10] The alteration of the cytoskeleton can be correlated with the phosphorylation of ZO-1 protein at the tyrosine residue due to the activation of Src kinase.

FORMATION OF CYCLIC PEPTIDES TO IMPROVE TRANSCELLULAR DELIVERY THROUGH THE BBB

Often, the physicochemical properties of peptides contribute to their difficulty in penetrating the BBB via the transcellular pathway. This could result from the size and high hydrogen-bonding potential to water that limits their partitioning into cell membranes. One way to improve brain delivery of peptides is to modify their physicochemical properties. The idea is that passive transcellular transport of peptide involves peptide partition into cell membranes of vascular endothelial cell microvessels of the BBB. Peptide partitioning into cell membranes can be optimized by reducing the hydrogen-bonding potential to water, increasing the octanol/water partition coefficient, increasing molecular structure stability by forming a secondary structure, and/or reducing the hydrodynamic radius of the peptide. Lipid solubility is particularly important and serves to emphasize the role of membrane permeation for peptides without transporters. The physicochemical properties of peptide also could be modified by the formation of cyclic peptides or cyclic peptide prodrugs. The hypothesis is that the formation of a cyclic structure induces intramolecular hydrogen bonding to suppress the hydrogen-bonding potential to water. Lowering the hydrogen-bonding potential enhances the octanol/water partition coefficient (e.g., hydrophobicity) of the peptide to favor partition into cellular membranes of the BBB. The formation of a cyclic structure increases the propensity of the peptide to form a stable secondary structure such as beta- and gamma-turns and reduces the hydrodynamic radius of the peptide, which also favors penetration through the paracellular pathway of the BBB. Although formation of cyclic peptides may enhance the biological activity of some peptides, others can be active only in the linear form. Thus, formation of irreversible cyclic peptides may not be desirable for this class of linear peptides. To overcome this hurdle, a cyclic peptide prodrug method was developed in which the cyclic peptide prodrug is a transient molecule that can be converted into an active linear peptide at the site of action after it crosses the BBB.

A cyclic peptide prodrug can be constructed by linking the N- and C-termini via an enzyme-sensitive promoiety; however, the cyclic structure can also be generated by linking the backbone terminus (i.e., N- or C-termini) to the side chain or by linking side chain to side chain via a promoiety linker. The promoiety can readily be cleaved by an enzyme (i.e., esterase) to produce the parent peptide. Several

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

promoieties have been developed for the formation of cyclic peptide prodrugs, including acyloxy-alkoxy,[24] trimethyl-lock, coumarin,[30] and acyloxy-alkoxy coumarin linkers[2] (Fig. 1). The formation of cyclic peptide prodrugs has been applied to opioid peptides, delta sleep-inducing peptides (DSIP), and RGD peptides and peptidomimetics. In cell culture models of biological barriers (i.e., Caco-2 cell monolayers), cyclic peptide prodrugs penetrate the cell monolayer more readily (i.e., ~70 times) than the parent linear peptides. This suggests that the cyclic peptide prodrug has more desirable physicochemical properties for membrane partition than does the parent linear peptide. The cyclic prodrugs are readily converted by esterases to the parent linear peptides in the blood and tissues.[16] Structural studies indicate that cyclic peptide prodrugs normally have a stable secondary structure such as a beta-turn with an intramolecular hydrogen bond. They are also more hydrophobic and structurally more compact than the parent linear peptide. These structural properties contribute to their favorable transport properties through the transcellular pathway of the biological barriers.

The delivery of DADLE and its cyclic prodrugs (AOA-DADLE, OMCA-DADLE, and CA-DADLE) through the BBB has been determined by rat brain perfusion.[2] There is minimal brain disposition of DADLE and its cyclic prodrugs in the absence of a P-glycoprotein (Pgp) inhibitor, GF-120918. In the presence of GF-120918, the brain delivery of AOA-DADLE, OMCA-DADLE, and CA-DADLE is enhanced about 50, 170, and 460 times, respectively, compared with that of the parent DADLE. These results indicate that the cyclic prodrugs are recognized by Pgp to prevent their permeation through the BBB. The cyclic prodrugs have high metabolic stability, but they also have low bioconversion in the brain. The recognition of the DADLE cyclic prodrugs by Pgp results from the promoiety rather than the DADLE peptide. Different Pgp inhibitors (i.e., GF-120918, cyclosporine A (CsA), and PCS833) have different effects on enhancing permeation of cyclic prodrugs into the brain. GF-120918 has the highest impact on the permeation of cyclic prodrugs compared with CsA and PCS833; CSA and PCS833 have similar Pgp inhibitory activity.[22]

Several esterases are involved in converting cyclic prodrugs to the parent peptide, including carboxylesterase, cholinesterase, and acetylcholinesterase (AChE).[15] The cyclic prodrug should be stable while crossing the BBB and be converted by the esterase to parent peptide in the brain. AOA-DADLE, OMCA-DADLE, and CA-DADLE are stable crossing the BBB; unfortunately, they have low bioconversion in the brain, which is not a favorable property.[2] The optimal balance of stability in the blood stream and readability for enzymatic conversion has to be designed into the physicochemical properties of successful cyclic prodrugs. In other words, the

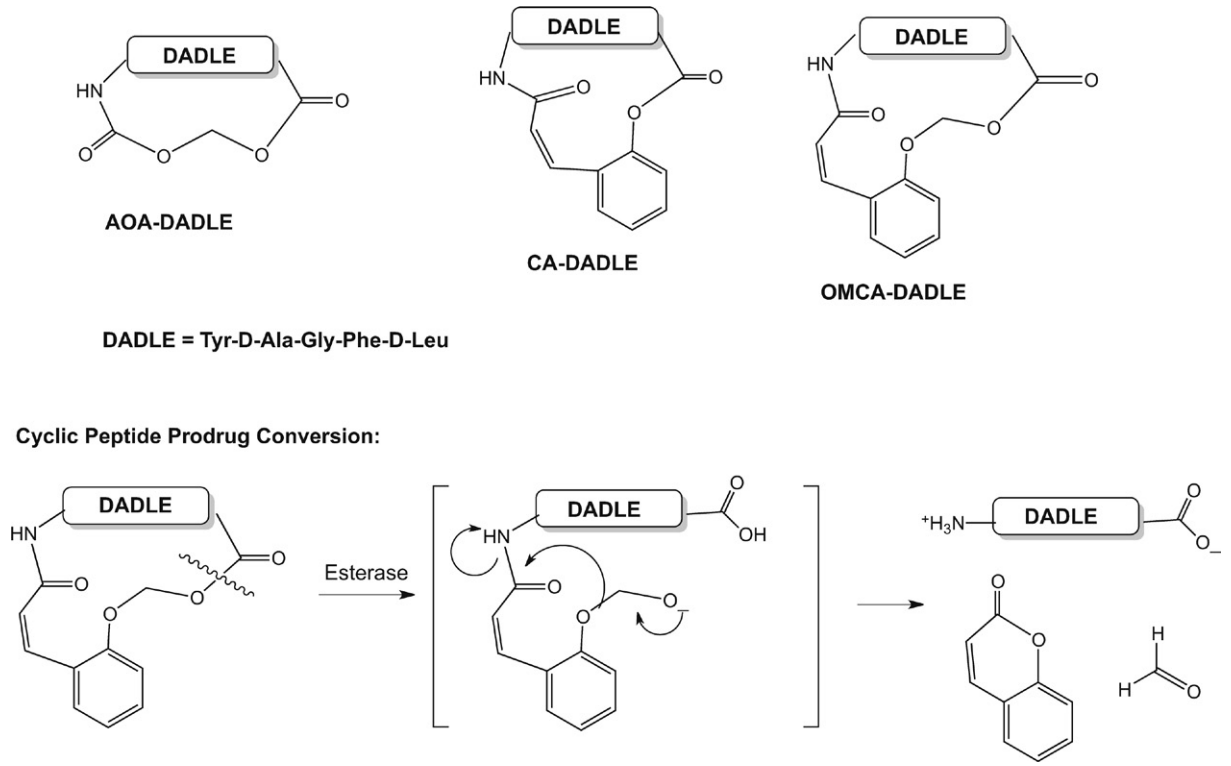

FIGURE 1 Structures of cyclic prodrug of DADLE with different promoeities, including AOA-DADLE, CA-DADLE, and OMCA-DADLE. The cyclic peptide prodrug can be converted to DADLE by esterase.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

cyclic prodrug should not be easily converted to the parent drug in the blood because that will produce hydrophilic linear peptides that pass less rapidly through the BBB. Conversely, the cyclic prodrug should be easily converted to the parent drug in the brain to produce its biological activity. It is known that esterase activity (i.e., carboxylesterase) is tissue dependent. In the case of DADLE cyclic prodrugs, the rate of hydrolysis in the brain is more pronounced than in plasma, and this rate depends on the chirality of the C-terminus amino acid. As predicted, the promoiety hydrolysis is more rapid when L-amino acid is the C-terminus rather than D-amino acid.

IMPROVING ENZYMATIC STABILITY

In addition to their physical barriers, peptides also suffer from enzymatic degradation in the blood, BBB, and brain. For example, the degradation of opioid peptides normally occurs in the extracellular space of the BBB and at the cytosol. Peptides can be degraded by endo- and exo-peptidases, and the rate of peptidase degradation is sequence dependent. Peptidase degradation can be prevented by acetylation and amidation of the N- and C-termini, respectively. Modifications of peptides by D-amino acid and cyclic peptide formation have been shown to slow peptide degradation.

Endomorphin-1 (Tyr–Pro–Trp–Phe–NH_2) is one of the more stable opioid peptides, and its degradation occurs at the peptide bond.[12] The C-terminal amidation prevents the degradation of endomorphin-1 by carboxypeptidases. In the brain preparation, endomorphin-1 is degraded by dipeptidyl peptidase IV (DPP IV) to produce a Tyr–Pro fragment. Endomorphin-1 is also degraded by aminopeptidase M (APM) from the N-terminus. Replacement of the L-Pro with D-Pro increases the enzymatic stability of endomorphin-1, but this modification lowers the activity. N-methylation of the peptide bonds of endomorphin-2 (Try–Pro–Phe–Phe–NH_2) could improve the enzymatic stability, but diminishes the biological activity. Replacement of the Pro with (NMe)Gly to give Tyr–(NMe)Gly–Phe–Phe–NH_2 improves the enzymatic stability and maintaining the activity. If pyperidine-2-carboxylic acid (Nip) replaces Pro-2 in endomorphin-2 to produce Tyr–Nip–Phe–Phe–NH_2, this modification enhances the enzymatic stability 10-fold in brain homogenates. Modification of the amino group of the Tyr residue to a guanidinium group in endomorphin-2 could also contribute to improved stability in brain homogenates.

Another strategy involves masking the enzyme cleavage site to improve metabolic stability. Endogenously produced Met-enkephalin (Tyr–Gly–Gly–Phe–Met) has a very short half-life ($t_{1/2} < 1$ min) because of rapid enzymatic degradation. A Met-enkephalin analog, DPDPE, formed through cyclization via two D-penicillamine moieties at positions 2 and 5, results in the formation of a conformationally strained peptide with increased metabolic stability ($t_{1/2} > 500$ min), leading to increased high BBB permeability and bioavailability.[32] However, subsequent studies showed that DPDPE had a significantly high clearance via the hepatic route because DPDPE is a substrate for many efflux pumps involved in billiary secretion, including Pgp and organic anion transporters (OATP).

TARGETING SATURABLE TRANSPORT SYSTEMS IN THE BBB TO IMPROVE DELIVERY INTO THE CNS

As indicated above, the presence of brain-to-blood saturable transport systems (efflux pumps) at the BBB is one of the major causes of low BBB permeability to peptides. In addition to the use of an enzyme inhibitor, one of the strategies is to counter the effect of efflux pumps such as Pgp is pegylation of the peptide. Polyethylene glycol (PEG) conjugation helps to reduce peptide affinity to Pgp. Masking of DPDPE with a PEG group reduces plasma clearance and increases brain uptake, thus leading to improved analgesia activity. Another peptide in which targeting saturable transport systems might be beneficial is the pituitary adenylate cyclase-activating polypeptide (PACAP). PACAP, a member of the secretin/glucagon/vasoactive intestinal peptides, is a pleuripotent peptide with neuroprotective, endocrine, and vasodilatory effects. *In vitro*, PACAP is neuroprotective in femtomole concentration amounts, but its brain uptake is limited by an efflux component of peptide transport system-6 (PTS-6). PTS-6 is identified as a β-F1 ATPase, and it is colocalized on the BBB endothelial cells with PACAP27, a C-terminal-truncated 27-aminoacid form of PACAP.[5] Inhibition of PTS-6 efflux with antisense to β-F1 ATPase increased PACAP concentration in the brain by increasing the uptake of peripherally administered PACAP and decreasing the loss of endogenously produced PACAP. *In vivo* findings show that treatment with antisense and PACAP27 improve cognition in a mouse model of Alzheimer's disease and reduced infarct size after cerebral ischemia.[5]

USE OF RECEPTOR-MEDIATED DRUG TRANSPORT TO IMPROVE PEPTIDE DELIVERY INTO THE BRAIN

Receptor-mediated drug transport involves the conjugation of a peptide and/or drug to a vector moiety, which has affinity for receptors of the target tissue to allow receptor-mediated transcytosis. Vectors that have been used include cationized albumin, liposomes, nanoparticles, and antibodies to receptors such as transferrin. Transferrin receptor is constitutively expressed at the BBB at higher levels than other capillary beds, and is involved in the transport of iron into the brain. The use of transferrin receptor has been investigated for the transport of various peptides across the BBB. For example, a murine monoclonal antibody to the rat transferring receptor OX26 has been successfully used to

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

increase brain uptake of proteins and peptides in a receptor-mediated manner. In the transport of brain-derived neurotrophic factor (BDNF), the administration of BDNF–OX26 conjugate directly after an ischemic incident prevented significant neuronal damage compared with that of BDNF or OX26 alone; this suggests that the protective effect of the BDNF–OX26 results from its increased ability to cross the BBB.[7] Receptor-mediated transport has also been investigated in the delivery of angiopep-2 peptide, whose sequence is derived from ligands that bind to low-density lipoprotein receptor-related protein-1 (LRP-1). LRP-1 is highly expressed in the brain endothelial cells, neurons, and astrocytes as well as in brain tumor cells and can be used to deliver drugs to the brain. *In vivo* injection of ANG1005, a conjugate of containing Angiopep-2 and the antineoplastic drug paclitaxel, inhibited growth of orthotopic human glioblastoma brain tumors in mice more potently than paclitaxel alone and significantly increased animal survival rate.[25] It is thought that the increased uptake of ANG1005 into the brain is due to ANG1005 bypassing Pgp efflux pumps and crossing the BBB via receptor-mediated transcytosis.[25] Although receptor-mediated transport represents a potent strategy, it has some disadvantages. First, the vector used for receptor-mediated transport could lead to potential steric inhibition of the peptide or drug at the target receptor. Second, not many peptides can be delivered via this mechanism. Third, when targeting by a vector such as the transferrin receptor, it is important to consider how it impacts the transport of the native substrate. Studies with OX26 showed that pretreatment of animals with OX26 reduced Fe-transferrin delivery across the BBB by 30–40%, suggesting that receptor-mediated transport should be used in a limited fashion or with potent peptides that require only limited delivery to the brain.

CONCLUSIONS

Peptide delivery into the brain is still very challenging. Some progress has been made in improving the peptide delivery through the paracellular pathways of the BBB by modulation of the tight intercellular junctions. However, there are serious safety issues that arise from nonselectively increasing the paracellular porosity of the BBB, and these need to be addressed. In the future, further investigation of mechanisms of action and tissue selectivity of peptides that modulate the intercellular junctions will be necessary. Further, the increase in pore size opening created by junction modulators has not been characterized, and the favorable shapes of molecules that can penetrate the paracellular pathway of the BBB are still unknown. Progress also has been made in improving transcellular permeation of peptides through the BBB by the formation of cyclic peptide prodrugs, increased lipophilicity, and enzymatic resistance. However, recognition of the promoiety by Pgp hampers the transcellular passive diffusion of cyclic peptide prodrugs, and the slow brain conversion of cyclic peptide prodrugs also needs further exploration. Therefore, there is a need to design cyclic prodrugs and other forms that are not recognized by Pgp and are readily converted to the parent peptide or active forms in the brain. Saturable and receptor-mediated transport systems have been used to improve the permeation of a limited number of peptides through the BBB.

Chapter 234

Acetylation

Qun Li, Iain J. Clarke and A. Ian Smith

ABSTRACT

Biologically active peptides and polypeptides are generated after proteolytic cleavage and other posttranslational modifications of precursor proteins. One of the most widely studied precursors is the prohormone precursor proopiomelanocortin (POMC), which gives rise to a number of peptide products with a range of biological activities. Interestingly, two of its posttranslational products (α-MSH and β-endorphin) belong to a very rare group of secreted, biologically active peptides that are acetylated. Acetylation of α-MSH enhances activity through increased biological stability, whereas acetylation abolishes activity of β-endorphin. These two peptides seem to have opposing roles in the regulation of energy balance, such that α-MSH inhibits feeding and β-endorphin stimulates feeding. Similarly, α-MSH stimulates reproduction, whereas β-endorphin is inhibitory. Thus, acetylation allows coordinate function of POMC-derived peptides, enhancing α-MSH function and reducing β-endorphin activity. The regulation of the relevant acetyl transferase enzyme(s), which remains to be identified, may provide a crucial regulatory point for the opposing physiological actions of these two peptides.

ACETYLATION OF BIOACTIVE PEPTIDES

Purification and molecular characterization of biologically active peptides have revealed that many are posttranslationally modified; this has a major effect on biological activity. Some commonly occurring posttranslational modifications include glycosylation of asparagine residues at the classic Asn-X-Ser/Thr sites, O-glycosylation of tyrosine residues, and the phosphorylation of serine residues. Less common peptide modifications include hydroxylation of lysine residues, serine octanoylation, sulfation, and finally, acetylation of N-terminal α-amino groups (serine and tyrosine) and, for α-MSH, the O-acetylation of the serine hydroxyl group. Since the discovery of an acetyl group at the amino-terminus of tobacco mosaic virus coat protein,[13] many acetylated proteins have been identified and characterized in animals and plants. For example, histone acetylation has been extensively studied; the lysine residues of histones undergo regulated acetylation and deacetylation, regulating the binding of these histones to DNA.[21,28] Acetylation is now considered a common modification of proteins in many organisms, and it has been suggested that more than half of the intracellular soluble proteins are N-acetylated. However, the acetylation of secreted bioactive peptides is considered a rare event. Indeed, only a handful of secreted proteins/peptides seem acetylated, and this group includes growth hormone where the acetylated form represents <5% total stored pituitary growth hormone and chaperonin 10;[4,29] in both of these, acetylation seems to have little impact on biological activity. Two other secreted hormones, α-MSH and β-endorphin, can be extensively acetylated and, for α-MSH, this can occur at two sites on the N-terminal serine residue (N,O) of the α-MSH molecule to produce diacetyl α-MSH.[15,31] Unlike chaperonin 10 and growth hormone, acetylation of α-MSH and β-endorphin has profound effects on biological activity.[19,32,33]

ACETYL TRANSFERASES

The acetylation of proteins and peptides is believed to be mediated by an acetyl transferase, which catalyzes the transfer of an acetyl group from a donor molecule, acetyl-CoA, to the target protein or peptide.[16] With respect to the mechanism of action, the acetyl transferases fall into two major classes. One class includes the enzyme that catalyzes acetylation of the newly synthesized peptide chain as it undergoes ribosomal synthesis. The enzymes in this class are likely ribosome and/or membrane bound. The second class of enzymes includes those that are responsible for processing bioactive peptides and mature proteins. For the second class of enzymes, it seems probable that different peptides and proteins are acetylated by substrate-specific enzymes. Glycine, alanine, serine, methionine, and aspartic acid are the preferred N-terminal amino acid of the α-N-acetylated proteins,[26] suggesting that the amino terminal residue may be a critical recognition site for these α-N-acetyl transferase(s).

DISTRIBUTION AND LOCALIZATION OF PEPTIDE ACETYL TRANSFERASE ACTIVITY

α-N-acetylation seems to occur in a tissue-specific manner given that different biological activities can be generated from one precursor molecule depending on the precise

pattern of processing, which in turn is dependent on the suite of enzymes coexpressed with the precursor in the cell/tissue of interest. One well-studied example of differential precursor processing is that of the prohormone precursor proopiomelanocortin (POMC). POMC is expressed in a variety of different tissues including, brain, pituitary, heart, and the immune system.[31] The intermediate lobe of the pituitary gland is a highly specialized tissue, consisting of a dense population of melanotropes, which are the major source of α-MSH and β-endorphin that is found in the blood stream.[15,31] POMC cells are also found in the arcuate nucleus of the hypothalamus, and these particular cells play a major role in the regulation of energy homeostasis.[11] In both these regions, α-N-acetylation of the POMC peptides occurs, and this is believed to be localized to the secretory vesicles.[16] Examples of this mechanism of vesicle-associated α-N-acetylation seem early in evolution and as such seem highly conserved.[10] Pulse-chase type experiments suggest that α-MSH and β-endorphin are acetylated in parallel.[15] Although this may be affected by the same α-N-acetyl transferase, the identity of the enzyme is not known.[16,33] Studies conducted >30 years ago by Glembotski[16] partially characterized an α-N-acetyl transferase activity in the neurointermediate lobe of both bovine and rat pituitaries. Subsequent studies by the same group showed a potential secretory vesicle location for this enzyme activity in the rat neurointermediate pituitary.[15] These studies also suggested that the enzyme is not membrane associated, has a pH optimum of 7.0, and the K_m value for the donor acetyl CoA is 8 μM. K_m values for the peptide substrates range from 11 to 286 μM. Other studies showed that β-endorphin 1–27 competitively inhibits the acetylation of α-MSH, suggesting that the same enzyme is responsible for acetylating endorphins and melanocortins.

The mapping of acetyl transferase activity indicated its presence in the pituitary and the brain, though activity and substrate levels are not always concomitant.[7] Finally, studies of intermediate lobe acetyl transferase activity suggest that both the POMC gene and the enzyme activity are coregulated.[25] Definitive studies to examine the expression, tissue location, subcellular distribution, and regulation of activity await the unequivocal identification and molecular characterization of the relevant acetyl transferase(s) involved in secreted peptide acetylation.

Both α-MSH and β-endorphin are generated after extensive posttranslational processing that involves the sequential action of several enzymes such as the prohormone convertases 1 and 2 (PC1 and PC2), carboxypeptidase E (CPE) and peptidyl α-amidating monooxygenase (PAM). This is detailed elsewhere in this volume. Although it remains possible that the amounts of the end products are determined by the activity of these processing enzymes, it is the acetylation of the peptides that finally determines activity or inactivity.

PATHOPHYSIOLOGY OF ACETYLATED AND NONACETYLATED α-MSH AND β-ENDORPHIN

Melanocortins

α-MSH is a well-characterized peptide that is secreted into the blood stream and stimulates skin pigmentation.[34] More recently, however, α-MSH has also been shown to play a pivotal role in regulating inflammation/immunomodulation,[6] reproductive function,[3] and energy homeostasis.[11] It should be noted that the POMC precursor also encodes β-MSH and γ-MSH. All three forms of melanocortins bind to the four (MC1R, MC3R, MC4R, and MC5R) of the five melanocortin receptor subtypes (MC1-5R). Although they have similar affinities for MCR3, their affinities to MC1R, MC4R, and MC5R differ.[14] In the periphery, MCR-1 is the effector for melanocortin action in skin, MCR-2 is the adrenocorticotropin receptor found in the adrenal glands, and MCR-5 is found in muscle, where it may mediate thermoregulation. MCR-3 and MCR-4 are found in the brain and have a major role in the regulation of food intake and energy homeostasis.[8,20] An elegant study by Bjorbaek and colleagues[18] showed that acetylation of α-MSH is required for full potency in terms of ability to suppress food intake (Fig. 1).

Despite the differences in potency between des-acetyl-α-MSH and its acetylated congeners, several studies have failed to find evidence for substantial differences in binding affinities for any of the MSH receptors.[30] The one factor that seems to address the apparent differences in potency between acetylated and des-acetylated MSH peptides is that in a biological environment, the acetylated form of α-MSH is much more resistant to proteolytic degradation than des-acetyl-α-MSH. Degradation of the des-acetylated form of α-MSH is initiated by amino-peptidases, and this occurs more rapidly than the metabolism of the acetylated

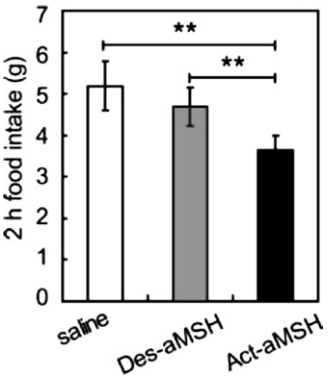

FIGURE 1 Mean (± SEM) food intake 2 h after an injection of des-acetyl-α-MSH (des-aMSH; gray column) or acetylated α-MSH (Acet-aMSH; black column) or vehicle (open column) into the third ventricle of rats ($n=6$) $^{**}P<0.005$. The figure is reproduced from Ref. (18) (permission requested). Note the stronger effect of the acetylated peptide.

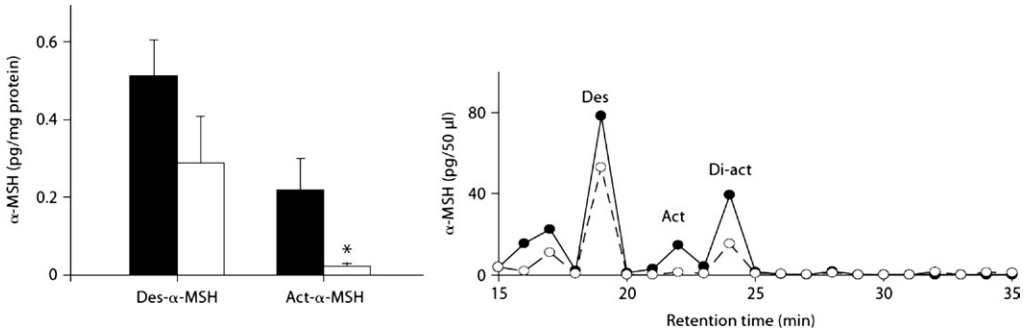

FIGURE 2 Mean (± SEM) levels of des-acetyl-α-MSH and acetylated α-MSH in the hypothalamus of sheep of normal (black columns) or lean body weight. *$P<0.05$ vs normal. The figure is reproduced from Ref. (2) with permission. High performance liquid chromatography was performed (right-hand panel) to separate the di-acetylated (Di-act), mono acetylated (Act) and des-acetylated forms of α-MSH (Des), before immunoassay.

forms of α-MSH. There is now some evidence to suggest that differences in specific G protein receptor-mediated activation of cellular signaling pathways may influence the relative functional activity of the different molecular forms of MSH.[33] Leptin stimulates the acetylation of α-MSH in the hypothalamus of rats [18] and in lean sheep, with low levels of leptin the acetylated form of α-MSH is reduced (Fig. 2).[2]

Endorphins

Although the 31-amino acid peptide β-endorphin was first characterized in 1976[22] after the isolation and amino acid sequencing of an opiate-like activity from camel pituitary, it was a series of studies in 1977, using both classical protein purification and cell free translation techniques[24,27] that showed that β-endorphin, β-LPH, and ACTH (which contains the α-MSH amino acid sequence) are synthesized in the ribosome as part of the same precursor molecule. The first study showing that β-endorphin was acetylated in the intermediate pituitary also showed that the acetylated form of β-endorphin lacked any opiate activity.[32]

The functions of β-endorphin have been extensively studied in the period after the identification of the endogenous opioids.[9] β-endorphin has analgesic properties with 20- to 30-fold greater potency than morphine;[23] this is a central function of the peptide, and the significance of peripherally circulating β-endorphin remains to be fully elucidated. It seems that the levels of β-endorphin in blood reflect cosecretion with α-MSH,[12] perhaps arising from the intermediate lobe, in the sheep at least. Acting centrally, β-endorphin stimulates food intake and inhibits the reproductive function.[5,17] It also modulates the function of most other neuroendocrine systems.[9,33]

The relative potency of acetylated and des-acetylated forms of the endorphins is primarily a function of receptor affinity. Modifications to both the N-terminus of β-endorphin (acetylation) and C-terminus (truncation) have quite profound effects on receptor binding.[1] Acetylation causes a dramatic, up to 1000-fold reduction in opiate binding efficiency, essentially rendering the peptide opiate inactive. C-terminal shortening, however, only marginally (~10-fold) reduces opiate receptor affinity.[1] The acetylated forms of β-endorphin simply do not bind significantly to either the k- or μ-type opiate receptors.[1]

CONCLUSIONS

Acetylation of α-MSH and β-endorphin has significant biological consequences in terms of melanogenesis; regulation of food intake; and reproduction, neural regeneration, and analgesia; these are detailed extensively.[33] Various endogenous and exogenous stimuli can impose physiological or pathological changes via the acetylation process, as indicated above for α-MSH. Thus, for α-MSH and β-endorphin, which have opposing activities, acetylation may represent a crucial switch whereby the physiological activities of these two peptides can be posttranslationally regulated.

Chapter 235

Carboxypeptidases E and D

Lloyd D. Fricker

ABSTRACT

Most bioactive peptides are produced from proteolytic processing of precursors. In many cases, the processing sites contain basic amino acids (Lys, Arg), which are cleaved by proprotein convertases to generate processing intermediates containing C-terminal basic amino acids. These intermediates are rarely biologically active, and removal of the C-terminal basic residues is necessary to produce the mature form. Although the proprotein convertase gene family contains nine members in mammals, the metallocarboxypeptidase gene family contains 25 mammalian members. However, only two of these are believed to function in the generation of bioactive peptides within the secretory pathway. Carboxypeptidase E is the primary peptide-producing enzyme; it is active within secretory granules. Carboxypeptidase D also contributes to peptide processing but plays a minor role in the production of most neuropeptides; this enzyme is primarily located in the trans-Golgi network, cycles to the cell surface, and returns to the trans-Golgi.

NAME AND HISTORY

Carboxypeptidase E (CPE) was originally discovered in enkephalin-containing chromaffin vesicles of the adrenal medulla and was renamed enkephalin convertase for publication.[10] The original name of CPE was used once it became clear that the enzyme was involved in the production of many neuroendocrine peptides and was not specific for enkephalin. CPE is also known as carboxypeptidase H, among its other names. For many years, CPE was believed to be the only carboxypeptidase involved in neuroendocrine peptide processing. However, mice lacking CPE activity resulting from a naturally occurring point mutation produce low levels of many neuroendocrine peptides.[2,6,14,18,35] Although the low levels of peptides in these mice supported the idea that CPE is the carboxypeptidase involved with the biosynthesis of most neuroendocrine peptides, the finding that low levels of mature peptides are still produced in the absence of CPE raised the possibility of an additional peptide-processing carboxypeptidase. This led to the discovery of carboxypeptidase D (CPD).[23]

CPD is occasionally referred to as metallocarboxypeptidase D to distinguish it from serine carboxypeptidase D, an unrelated enzyme. CPD was independently discovered in 1995 by three separate groups working in distinct areas. One group identified and characterized bovine CPD based on its enzymatic properties.[23] A duck protein named gp180 was identified by its ability to bind avian hepatitis B virus particles, and when the cDNA was cloned and sequenced, gp180 was found to be a homolog of CPD.[13] A third group was working on the *Drosophila silver* gene mutation, which was originally discovered in 1918 and caused reduced viability, altered pigmentation, and a pointed wing shape. The *silver* gene was found to represent the *Drosophila* homolog of CPD.[19] Soon after the initial discovery of CPD, homologs were found in humans,[26] rats,[34] and other organisms.

FUNCTION IN PEPTIDE BIOSYNTHESIS

CPE functions in the cellular secretory pathway where it is the primary carboxypeptidase involved in the biosynthesis of neuroendocrine peptides such as insulin and enkephalin, as well as many others. CPE functions after endopeptidases, such as proprotein convertase 1 (also known as proprotein convertase 3) and proprotein convertase 2, cleave the peptide precursor into intermediates containing C-terminal basic residues (these endopeptidases are covered in another chapter in this section of the Handbook). Additional roles for CPE have been described, such as a role in prohormone sorting, but this function is controversial and not supported by numerous studies. CPE is found in all vertebrate animals and many other species, including *Caenorhabditis elegans*. This is consistent with its broad role in the biosynthesis of neuroendocrine peptides. However, *Drosophila* do not have an ortholog of CPE, and instead rely on CPD, which is alternatively spliced in this species to produce a number of short forms, some of which resemble CPE in terms of enzyme properties. Most bioactive peptides described in other chapters of this volume require CPE for their production, including vasopressin, oxytocin, thyrotropin-releasing hormone, gonadotropin-releasing hormone, somatostatin, neuropeptide Y, melanocyte-stimulating hormone, cocaine and

amphetamine transcript-derived peptides, cholecystokinin, several tachykinins, enkephalins, dynorphins, nociceptins, and insulin. Other peptides also require CPE for their production, such as peptides derived from VGF, chromogranins A and B, secretogranin 2, 7B2, and proSAAS.[35]

Carboxypeptidase D has a broad tissue distribution and is believed to function primarily in the Golgi in the processing of proteins that transit the secretory pathway. Many secreted or cell-surface proteins require proteolytic processing at specific sites containing multiple basic residues; examples include the insulin receptor, and many of the molecules that serve as extracellular messengers (growth factors and neuroendocrine peptides). Endopeptidases such as furin initially cleave the precursors to the C-terminus of the basic amino acids, and the subsequent removal of these basic residues from the C-terminus of the intermediate is accomplished by CPD. Although the primary role of CPD is the processing of proteins, rather than neuropeptides, CPD is able to process peptides and proteins. The limiting factor is whether the endopeptidase processing occurs early enough in the secretory pathway for the intermediates to be exposed to CPD. For example, if furin or another proprotein convertase cleaves a neuropeptide precursor in the Golgi, then the intermediates will be exposed to CPD, and this enzyme will trim off the basic residues. However, CPD is not present in secretory granules, so if the prohormone processing occurs later in the pathway within the maturing granules, then CPD will not have access to the intermediates and cannot act on them. Because most neuropeptides are processed within the secretory granules, CPE was therefore predicted to function as the major carboxypeptidase in their biosynthesis, with CPD playing only a minor role. This prediction was borne out by the analysis of peptides in brain, pituitary, and other tissues of animals lacking CPE activity (described in another chapter in this section of the volume).

GENERAL PROPERTIES

CPE and CPD are both members of the same subfamily of metallocarboxypeptidases, named the N/E subfamily (after the first two enzymes discovered in this family, carboxypeptidase N and CPE). In addition to CPE, CPD, and carboxypeptidase N (a plasma enzyme), there are two other active enzymes in this subfamily: carboxypeptidase M, which is an extracellular membrane-bound enzyme, and carboxypeptidase Z, an extracellular matrix-bound enzyme. Three other members of this gene subfamily have no detectable carboxypeptidase activity (named CPX1, CPX2, and AEBP1/ACLP); these proteins are predicted to fold into the basic metallocarboxypeptidase structure but lack critical active site residues. CPE and CPD share approximately 50% amino acid sequence similarity and have many properties in common as well as some fundamental differences.

CPE is a single-chain protein of 52–56 kDa that contains an active site zinc ion. Although the crystal structure has not been determined, the structure of CPE has been modeled based on the crystal structure of one of the domains of CPD.[1] The two structures are similar, except for minor differences in the lengths and positions of the loops that shape the entrance to the active site.[1] The overall structure of CPE includes an approximately 300 residue domain that has homology to all 25 members of the M14 metallocarboxypeptidase gene family (i.e. eight members of the N/E subfamily and all members of the other three subfamilies). Following the general metallocarboxypeptidase domain, CPE contains an approximately 80 residue transthyretin-like domain (Fig. 1). Both the

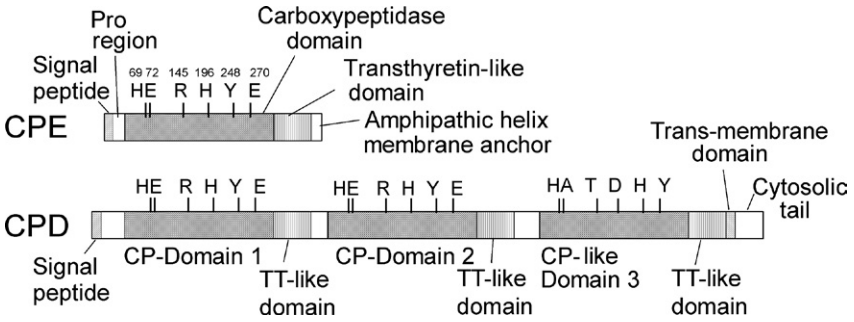

FIGURE 1 Schematic diagram of CPE and CPD, showing the various domains. CPE has an N-terminal signal peptide, a short proregion (which does not regulate enzyme activity, in contrast with most pro-domains), a carboxypeptidase domain with sequence and structural homology to carboxypeptidases A and B, a transthyretin-like domain that has structural homology but not sequence homology to the protein transthyretin, and a C-terminal domain that seems to form an amphipathic helix and bind the full length form of CPE to membranes. All forms detected in tissues lack the N-terminal signal peptide. Most forms lack the proregion, and soluble forms lack the C-terminal region. CPE is also modified by N-linked glycosylation at two distinct sites (not shown). Amino acids critical for Zn^{2+} binding (H69, E72, H196), substrate binding (R145, Y248), and catalytic activity (E270) are indicated; the numbering system is that of the active form of bovine carboxypeptidase A, by convention in the field. CPD has a signal peptide, two active carboxypeptidase (CP) domains and one inactive carboxypeptidase-like (CP-like) domain; each of these is followed by a transthyretin (TT)-like domain. CPD is membrane-bound through a transmembrane-spanning domain located near the C-terminus, followed by an approximately 50–60 residue C-terminal cytosolic tail. The CP domains face the interior of the Golgi, away from the cytosol. A number of N-linked glycosylation sites are present in the luminal part of the protein, and palmitate is added to the cytosolic tail at sites located near the transmembrane domain (not shown).

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

general carboxypeptidase domain and the transthyretin-like domain within CPE are present in CPD and all other members of the N/E subfamily (carboxypeptidases M, N, Z, and three related proteins that have no detectable carboxypeptidase activity). Although the 80 residue transthyretin-like domain is not conserved in the other three subfamilies of metallocarboxypeptidases, most other family members have a comparable region of 80–100 amino acids that forms a beta-sheet-rich structure, even though there is no amino acid sequence homology among these domains between the different subfamilies.

In addition to the common metallocarboxypeptidase domain and transthyretin domain found in all members of the N/E subfamily, CPE contains a unique C-terminal domain of approximately 30 amino acids that is not found in other metallocarboxypeptidases.[8] The C-terminal domain of CPE directs association of CPE with membranes, and variable proteolysis of the C-terminal region gives rise to soluble forms of CPE. The membrane-association of CPE seems to be as a peripheral membrane protein not as a transmembrane protein.[30] It has been proposed that CPE is anchored to membranes via a transmembrane domain.[4] However, there is no suitable sequence on CPE that corresponds to a transmembrane-spanning domain.[8] Furthermore, numerous studies have shown that CPE is released from membranes with an intact C-terminus by moderate to high pH treatments,[5,7,16] this is not compatible with the transmembrane mechanism of attachment. Therefore, the peripheral association of CPE through an amphipathic C-terminal helix is more likely to be correct, based on the numerous published studies, although the possibility that CPE forms a novel type of interaction with membranes cannot be ruled out.

In addition to the C-terminal membrane-binding region, a form of CPE detected in cells and tissue contains a 14 residue extension on the N-terminus. This form, named "proCPE" shows full enzymatic activity.[16] The function of the 14 residue propeptide is not known; it does not influence enzyme activity or sorting to the secretory pathway. CPE is also known to undergo additional posttranslational modifications; it is glycosylated on two Asn-Xaa-Ser/Thr sites found in the protein. Glycosylation does not seem to affect enzyme activity, and the function of this modification remains unknown.

CPD is unique from CPE, and all other members of the metallocarboxypeptidase gene family, in several ways. First, CPD is the only member of the M14 metallocarboxypeptidase family that is a type 1 transmembrane protein. Second, carboxypeptidase D contains three distinct carboxypeptidase-like domains, the first two of which are enzymatically active, whereas the third is not (Fig. 1). This feature of two active carboxypeptidase domains followed by a third inactive domain and then a transmembrane domain and cytosolic tail is found in CPD proteins from *Drosophila* to humans. Because of the three carboxypeptidase domains, CPD is a large protein with a molecular weight of approximately 180 kDa in most species.[23,24] The first two metallocarboxypeptidase domains have 40–50% amino acid identity with other members of the CPD subfamily. The third domain shows slightly less homology to the other members of the subfamily, and lacks one or more residues believed to be critical for catalytic activity.[13,26,34] The C-terminal cytosolic tail of CPD directs the retention of this protein in the trans-Golgi network. This 50–60 residue domain is highly conserved among vertebrates, with only two conservative differences between ducks and humans. Although the sequence of the C-terminal tail of vertebrate CPD shows little amino acid sequence similarity with *Drosophila* CPD, the general domains are conserved between *Drosophila* and vertebrates.[29,31,33] These include acidic clusters, di-Leu motifs, and other motifs thought to be important for the trafficking of CPD from the trans-Golgi to the cell surface and back to the trans-Golgi.

The crystal structures of the first and second carboxypeptidase domains of duck CPD have been determined.[11,27] There is considerable structural homology between each carboxypeptidase domain of CPD and all other members of the larger metallocarboxypeptidase family. The first and second carboxypeptidase domains of CPD each contain a zinc atom, which is required for catalysis. The zinc-binding residues, the active site residues, and most of the substrate-binding residues are conserved among CPD and other metallocarboxypeptidases. Like CPE, after each of the carboxypeptidase domains in CPD is an 80-residue domain that folds into a β-sandwich that resembles the topology of transthyretin and other proteins.[11,27] Even though the third carboxypeptidase-like domain of CPD is inactive, modeling shows a generally similar structure as the catalytically active carboxypeptidase domains of CPD, including the presence of a transthyretin-like domain.[1] The function of this transthyretin-like domain in CPD (or in CPE and related subfamily members) is not currently known, although it is essential for activity; deletions of any portion of this domain lead to inactive enzyme. Thus, it has been proposed to function in protein folding.

SUBSTRATE SPECIFICITY AND REGULATION OF ACTIVITY

CPE removes C-terminal basic residues (i.e. Arg, Lys) from a variety of substrates, with only weak activity toward C-terminal His and no detectable activity toward nonbasic residues.[10,22] Most residues are well tolerated in the penultimate (P1) position, with Met the most favorable and Pro the least favorable. The Pro–Arg bond is slowly cleaved, with a rate that is orders of magnitude slower than substrates with other P1 residues.[3,22] CPE is much more active toward tripeptides than dipeptides, and longer peptides are also efficiently cleaved.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Like CPE, CPD also removes C-terminal Lys or Arg residues from a variety of substrates, with no detectable activity toward nonbasic residues.[23] Both the first and second domains of CPD prefer an Ala in the penultimate position.[15] As with CPE, CPD also shows higher activity with tripeptides than with dipeptides. CPD has been assayed with the same substrates previously developed for CPE.[23] The first and second domains of CPD differ in their pH optima; the first domain of CPD is maximally active at neutral pH whereas the second domain is preferentially active at the acidic pH 5–6 range. The first and second domains of CPD also show different preferences for C-terminal Lys and Arg residues. The first domain cleaves C-terminal Arg residues more efficiently than Lys residues, whereas the second domain cleaves Lys residues as efficiently as Arg residues.

A number of different substrates have been used to detect CPE and CPD. Some of the assays make use of a solubility change that the peptide undergoes when the basic residue is removed from the C-terminus of the substrate (Dns-Phe-Ala-Arg; [^{3}H] Bz-Phe-Ala-Arg; or [^{125}I] Ac-Tyr-Ala-Arg). Once the basic residue is removed, the products readily partition into organic solvents such as chloroform from an acidic aqueous phase. Assays based on the extraction of the product into organic solvent permit the rapid analysis of a large number of samples. This assay is much faster than other assays developed for CPE that use HPLC or thin-layer chromatography to separate the product from the substrate.

The assays for CPE and CPD are not specific for these enzymes and will also detect other carboxypeptidases that cleave Arg and endopeptidases that cleave the substrate. The assay can be performed at pH 5.5 to minimize the contribution from cellular peptidases that are optimal at neutral pH values, but at pH 5.5, the assay will detect lysosomal enzymes that cleave the substrate. To increase the specificity of the assay for CPE and CPD, the assay can be performed in the presence and absence of selective inhibitors such as guanidinoethylmercaptosuccinic acid; this compound selectively inhibits metallocarboxypeptidases and not the lysosomal carboxypeptidases or various endopeptidases found in a cell. Unfortunately, the various assays do not allow for the discrimination of CPE versus CPD. However, it is possible to separate these two enzymes by partial purification on a substrate affinity column.[23] CPE elutes from *p*-aminobenzoyl-Arg-Sepharose when the pH is raised to 8, whereas CPD remains bound at this pH and is eluted with a competitive ligand such as Arg.[23]

CPE activity is optimal at pH 5.0–5.5, and activity falls off dramatically with increasing pH due to a change in K_m. It is likely that the sensitivity of CPE to pH over the range 5.5–7 serves as a mechanism for CPE to become activated when it moves from the neutral pH of the Golgi to the mature secretory vesicles (internal pH of 5–5.5). By contrast, CPD shows a broad pH optimum resulting from the two distinct carboxypeptidase domains that are active; the first domain is active at neutral pH, whereas the second is maximally active at acidic pH. Thus, CPD is able to function in the Golgi (where the pH is slightly acidic), on the cell surface (where the pH is neutral), and in the endocytic pathway (where the pH is acidic).

Both CPE and CPD are stimulated by millimolar concentrations of Co^{2+} and inhibited by 1,10-phenanthroline and by transition-state inhibitors and thiol-directed reagents such as *p*-chloromercuriphenylsulfonate and $HgCl_2$. None of these compounds or ions is thought to be involved in the physiological regulation of CPE or CPD. One ion that may play some role in the regulation of CPE is Ca^{2+}. CPE has a binding site for Ca^{2+}, and this ion affects the stability of CPE. However, the effect is small and Ca^{2+} does not seem to substantially affect enzyme activity. Increasing concentrations of Ca^{2+}, together with decreasing pH, cause the aggregation of CPE, which may contribute to the sorting of CPE into the regulated secretory pathway.

DISTRIBUTION/LOCALIZATION

The distribution of both CPE and CPD is consistent with broad roles for these enzymes in the production of numerous biologically active peptides. CPE is most abundant in brain, pituitary, and pancreatic islets, and it is also present in many other neuroendocrine tissues. At a subcellular level, CPE is enriched in peptide-containing secretory granules and is cosecreted along with the bioactive peptides.

The distribution of CPD is broader than that of CPE, consistent with a role in the processing of many proteins that transit either the regulated or constitutive secretory pathways.[29,31,33] CPD is found in virtually all tissues examined.[24,34] Within cells, CPD is enriched in the trans-Golgi network and is also found in immature secretory vesicles but not in mature secretory granules. Although CPD has been reported to exist within purified secretory granules, it is present in only a small subset of these granules and this presumably corresponds to the immature granules.[17,29,33] CPD cycles to the cell surface via a constitutive secretory pathway and returns to the trans-Golgi network via an endocytic pathway.[29,31,33] Cell surface CPD is enzymatically active and cleaves peptides containing C-terminal Arg residues, thereby releasing free Arg. It has been proposed that this Arg can then be a substrate for nitric oxide synthesis; treatments that lower the levels of cell surface CPD or which inhibit CPD enzyme activity have been shown to reduce the production of nitric oxide in cell culture systems.[12]

PATHOPHYSIOLOGICAL IMPLICATIONS

A spontaneously arising mouse mutation, named the *fat* mutation, represents a point mutation within the coding region of the *Cpe* gene.[14] This mutation causes a Ser to

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

be replaced with a Pro, and this change eliminates CPE enzyme activity. The resulting mutant form of the protein is degraded in the early secretory pathway, before packaging into secretory vesicles.[32] Mice homozygous for the *fat* mutation have very low levels of the mature forms of most neuropeptides and greatly elevated levels of C-terminally extended peptide processing intermediates.[2,6,14,18,35] This result is consistent with the role of CPE activity in the production of many neuroendocrine peptides, and is described in more detail in another chapter in this section of the handbook. Mice with the *fat* mutation show juvenile-onset obesity, greatly reduced fertility, and other behavioral and physiological abnormalities.[9,25] Mice with a gene disruption in *Cpe* have been created and characterized; the phenotype of mice with a disruption of the *Cpe* gene is essentially the same as the phenotype of the *fat* mice.

A number of variants of human *CPE* have been found. A study of 269 Japanese subjects found three nucleotide variants, but none of these altered the amino acid sequence.[28] A study of 945 Ashkenazi subjects found five different single nucleotide polymorphisms.[3] Two of these variants altered the amino acid sequence, one of which was a highly-conserved residue (Arg283). The variant found in the Ashkenazi population encoded a Trp in this position (R283W). The enzymatic properties of the R283W form of CPE were examined; the *V*max of the R283W variant was reduced about 10-fold compared with that of wild-type CPE.[3] The R283W variant form of CPE was less stable to heat denaturation than that of wild-type CPE.[3] Although this variant may contribute to some cases of obesity and/or diabetes, the prevalence of the variant in the human population is too low to explain the vast majority of human obesity or diabetes.

The CPD gene is not associated with any known genetic mutations in humans or mice. A number of mutations have been found in the CPD ortholog in *Drosophila*.[21] Severe mutations of *Drosophila* CPD are lethal, with no survivors past the third instar stage;[20] these severe mutations do not produce any CPD protein. Mutations within the second carboxypeptidase domain of *Drosophila* CPD are viable; these mutants produce short forms of CPD that correspond to the first carboxypeptidase domain and this is sufficient to rescue the lethality. However, *Drosophila* mutants that lack the long CPD forms have altered wing shape and changes in behavior, suggesting that the full-length membrane-bound forms of CPD perform different functions than do the shorter forms of CPD produced in *Drosophila*.[21]

LATER FINDINGS

Despite having been discovered approximately 30 years ago, CPE is still yielding new insights. CPE is inhibited by catecholamines. Because the levels of catecholamines that are inhibitory to CPE are within the physiological range of their concentrations within adrenal medullary chromaffin granules, this raises the possibility that the production of bioactive peptides is controlled by endogenous levels of catecholamines. CPE is implicated in cancer, although the forms of CPE that seem to correlate with cancer are missing in their N-terminal region and therefore are not routed to the secretory pathway. Because CPE requires disulfide bond formation, and is inhibited when treated with agents that disrupt disulfide bonds, it is not probable that CPE produced in the cytosol will be enzymatically active. Still, there may be alternative roles for CPE protein that do not require enzyme activity. Another emerging area is the characterization of the behavior of mice lacking CPE activity because of the *fat* mutation. Originally reported to be overweight and sterile, they have additional behavioral problems, as expected for the broad role of neuropeptides in many neurological processes. Further studies to identify the peptides responsible for each of the aberrant behaviors in the mice lacking CPE activity may identify novel roles for existing peptides or novel neuropeptides.

CPD is also still revealing many new insights. One unsolved mystery is the reason for the unusual domain structure, with two carboxypeptidase domains and one carboxypeptidase-like domain present in CPD from human to *Drosophila*. In *C. elegans*, only two of these domains are present; the first is predicted to be enzymatically active, the second is predicted to be inactive based on the absence of critical active site residues. Therefore, the presence of an inactive carboxypeptidase-like domain seems to be an essential part of CPD function. Transgenic *Drosophila* lines have been created, which express forms of CPD that lack the inactive carboxypeptidase-like domain, or which have this domain replaced with one of the active domains. All of these lines show greatly reduced viability, compared with transgenic *Drosophila* in which constructs contained the inactive carboxypeptidase-like domain. These results support the hypothesis that this inactive carboxypeptidase-like domain has a function, and further studies are necessary to identify this function.

Chapter 236

Disulfide Bond Formation

Gautam Rajpal and Peter Arvan

ABSTRACT

'Spontaneous' disulfide bond formation is critically dependent on the local environment, and multiple host-cell gene products provide the environmental and compartment-specific control in which these reactions take place. In the secretory pathway of cells, rather than being spontaneous, disulfide bond formation in biologically active peptides is primarily catalyzed, by protein disulfide isomerase (PDI)-like oxidoreductases. *In vitro* studies provide a solid understanding of the spectrum of enzymatic capabilities of PDI and related family members. However, these *in vitro* studies cannot replicate the oxidoreductase working environment within the secretory pathway. In the yeast endoplasmic reticulum (ER) – which may be a more oxidizing environment than in the ER of mammalian cells – there is strong evidence that PDI facilitates disulfide bond formation in exportable protein substrates, with some evidence supporting a role for PDI in disulfide reduction or isomerization. In mammalian cells, the literature has tended to group PDI-like family members as if they were a single protein, but more recent evidence points to the idea that the distinct PDI-like family members are subspecialized for somewhat different (albeit overlapping) *in vivo* functions. This probably reflects differences in their relative redox setpoints, alterations/modifications of their catalytic CXXC sequences and neighboring residues, differences in their hydrophobic pockets for substrate binding and chaperone function, and differences in their ER resident partners that provide substrate specificity and function. A case in point is for proinsulin folding in pancreatic beta cells: *in vitro* results support a role for PDI in proinsulin disulfide bond formation while thus far limited results in beta cells provide no direct support for this view. As PDI-like family members may play roles in the pathogenesis or amelioration of disease, further work is needed to elucidate their respective roles in the spectrum of oxidoreductase activities in the context of their native working environment.

INTRODUCTION

Disulfide bonds are made in nearly one-third (7000) of the proteins in the eukaryotic proteome,[11] many of which are destined for contact with the relatively nonreducing extracellular environment as secretory or cell surface proteins. Disulfide bond formation involves a reaction between the sulfhydryl (SH) side chains of two cysteine residues: an S^- anion from one sulfhydryl group acts as a nucleophile, attacking the side chain of a second cysteine to create a disulfide bond, and in the process releases electrons (reducing equivalents) for transfer. Proper disulfide bonds provide stability to a protein, decreasing further entropic choices that facilitate folding progression toward the native state by limiting unfolded or improperly folded conformations. An increase in stability of the native structure resulting from the formation of a particular disulfide bond has been said to be directly proportional to the number of residues between the linked cysteines, i.e. the larger the number of residues in the 'disulfide loop,' the greater the stability provided to the native structure.[22]

The chemistry of protein disulfide bond formation is directly influenced three key factors: 1) the spatial accessibility/physical proximity of the partner cysteine residues forming the disulfide bond; 2) the difference between the pK_a of the involved thiol groups and the pH of the local environment (with lower pH limiting reactivity and higher pH favoring increased reactivity); and 3) the redox environment (with lesser reactivity under more reducing conditions and greater reactivity under more oxidizing conditions).[22] As the latter two factors are environmentally controlled, specific cellular compartments have evolved within cells to facilitate disulfide bond formation. In bacteria, disulfide bonds in bioactive peptides and polypeptides of the secretory pathway are formed in the periplasm; in eukaryotes, such (poly)peptides tend to acquire their disulfide bonds in the endoplasmic reticulum (ER) although disulfide bond formation can occasionally occur at other sites (including extracellularly). The ER is a vastly more common site than the cytosol (which is very rarely the site of disulfide bond formation) because the ER intralumenal environment is more oxidizing than that of the cytosol.[1] The redox environment is at least partly reflected by the ratio of oxidized glutathione (GSSG) to reduced glutathione (GSH), which in the case of the ER (and periplasm), is shifted in favor of GSSG.[1]

THE CONCEPT OF SECRETORY PATHWAY CATALYSIS OF DISULFIDE BOND FORMATION

Although disulfide bonds can form spontaneously (albeit very slowly) via molecular oxygen or directly via GSSG as an electron acceptor, the main mechanism of disulfide bond formation in the secretory pathway seems to involve enzymatic catalysis, via oxidoreductase proteins bearing a catalytically active thioredoxin domain motif: CXXC (where 'X' residues tend to be hydrophobic amino acids) that is responsible for disulfide bond transfer from oxidoreductase to substrate.[11] (A thioredoxin domain, stemming from thioredoxin proteins, a class of redox proteins found in all organisms, consists of a βαβαβαββα fold motif.) In secretory proteins that contain more than one disulfide bond in their final structure, the formation of these bonds is typically not a linear process, insofar as their order of formation may vary *en route* to the native state. In general, newly synthesized secretory proteins have preferred folding intermediates (such as has been become well known from *in vitro* folding studies of ribonuclease and bovine pancreatic trypsin inhibitor[22]). Oxidoreductases may help to promote a particular folding pathway both by selective disulfide catalysis and by acting as molecular chaperones that limit off-pathway folding choices. Once a transient intramolecular disulfide bond has formed within the CXXC motif of the oxidoreductase, the catalytic event proceeds via a transient mixed-disulfide bond between the amino-terminal cysteine of the CXXC and the substrate protein, which is then resolved by completion of an intramolecular disulfide bond formed within the substrate protein (Fig. 1) in a process facilitated by both the carboxyl-terminal cysteine of the CXXC motif and neighboring residues that influence the CXXC redox potential. Catalyzed disulfide bond formation occurs very rapidly, with dynamic sampling and release of substrate proteins by oxidoreductase enzymes.[2,10] The reaction catalyzing disulfide transfer to the substrate protein does not result in a net loss or gain of disulfide bonds, as a reduced CXXC motif is regenerated in the disulfide transfer process, i.e. the transfer reaction involves oxidation of the substrate protein concomitant with reduction of the thioredoxin motif in the oxidoreductase. Thus, within the ER, there is a net flow of electrons from substrate proteins to oxidoreductases that catalyze disulfide bond formation. In the ER of eukaroyotes, protein disulfide isomerase (PDI) is the most prominent and most evolutionarily conserved of the oxidoreductases – but there are at least 21 PDI-like family members[11] – several of which shall be touched upon later (Table 1).

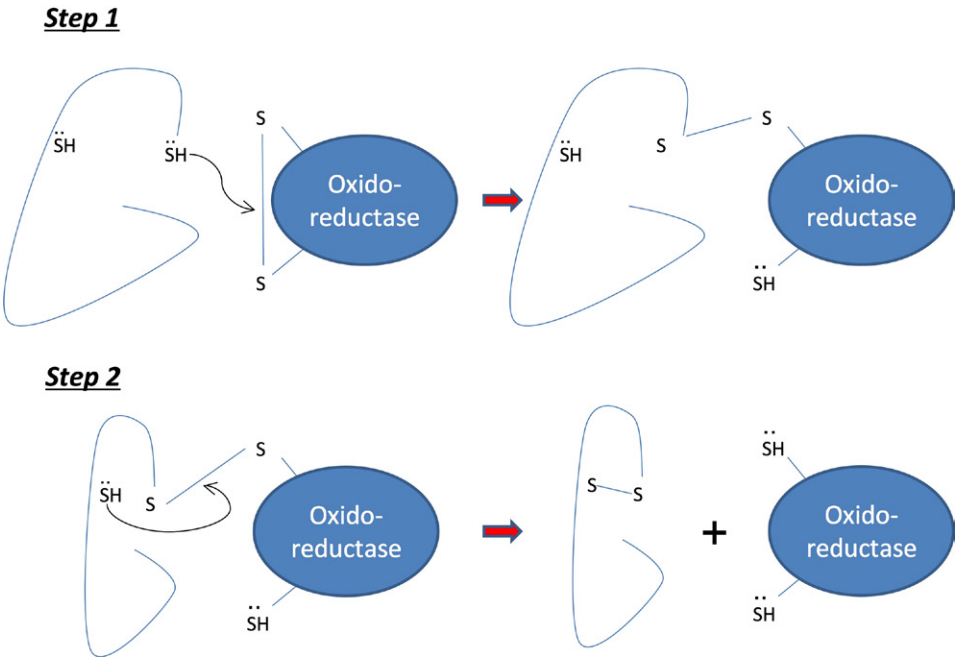

FIGURE 1 Oxidoreductase-catalyzed disulfide bond formation. In this diagram, the ER oxidoreductase (oval) oxidizes a secretory protein substrate (shown schematically, as a line, at *left*). In the first step, a sulfhydryl group in the substrate attacks a disulfide bond in the thioredoxin motif (CXXC) within the oxidoreductase, creating a transient mixed-disulfide bond between the two proteins. In the second step, folding changes in the substrate bring another cysteine sulfhydryl moiety into proximity with the mixed disulfide. The nucleophilic attack results in the formation of an intramolecular disulfide bond, creating a disulfide loop structure within the substrate, and leaving the CXXC motif of the oxidoreductase as reduced thiols (electrons represented by dots). This will require reoxidation in order that another round of catalyzed disulfide bond formation may proceed.

The secretory pathway operates as a protein manufacturing and export company. Once properly folded, the most recent cohort of oxidized secretory proteins is exported, only to be immediately followed by a new cohort of incoming (newly synthesized) secretory proteins – and these new polypeptides begin their 'life' with a full complement of reduced cysteine thiols. In order to bring about another round of substrate protein oxidation, the catalytic oxidoreductases must again form a transient intramolecular disulfide bond within their CXXC motif(s); thus, they must become reoxidized. In bacteria, secretory protein oxidation by the disulfide bond formation family ("Dsb") of proteins begins with DsbA catalyzing initial disulfide bond formation in substrates. DsbA is reoxidized by electron transfer to the periplasmic membrane-bound DsbB (from which electrons are subsequently 'unloaded' to ubiquinone that is finally reoxidized by the respiratory chain involving molecular oxygen as the terminal electron acceptor[22]). In the secretory pathway of eukaryotes, the various ER oxidoreductases also must become reoxidized, and this is an extremely active area of ongoing investigation. What is clear is that PDI (encoded by the P4HB gene) can be specifically reoxidized by Endoplasmic Reticulum Oxidoreductin-1 (ERO1), an ER membrane–associated protein that serves as the functional analog of bacterial DsbB. In yeast, ERO1 was first identified because its genetic deletion resulted in a phenotype in which exportable proteins lacked disulfide bonds.[7] Indeed, ERO1 was found to form a transient mixed disulfide with PDI and yet ERO1 seemed unable to interact directly

TABLE 1 Mammalian PDI-like Family Members

	Gene name	Protein	Thioredoxin domains	Catalytic motif sequence
1	**P4HB**	**PDI**	**4 (2)**	**CGHC, CGHC**
2	**PDIA3**	**ERp57**	**4 (2)**	**CGHC, CGHC**
3	**PDIA4**	**ERp72**	**5 (3)**	**CGHC, CGHC, CGHC**
4	**PDIA6**	**P5**	**3 (2)**	**CGHC, CGHC**

12	ERp90	ERp90	5 (0)	None
13	TXNDC5	ERp46	3 (3)	CGHC, CGHC, CGHC
14	PDILT	PDILT	4 (2)	SKQS*, SKKC
15	Agr-2	Agr-2	1 (1)	CPHS
16	Agr-3	Agr-3	1 (1)	CQYS
17	TMX1	TMX1	1 (1)	CPAC
18	TMX2	TMX2	1 (1)	SDNC
19	TMX3	TMX3	3 (1)	CGHC
20	TMX4	TMX4	1 (1)	CPSC
21	TMX5	TMX5	1 (1)	CRFS

Gene names (first column) and protein alias (second column) are shown. The total number of thioredoxin domains in each gene product is indicated, with the number of catalytically active domains listed in parentheses. The specific CXXC sequences are listed in the last column; note that for PDILT (line 14) the SKQS motif bears strong resemblance to the A domain of PDI and is listed under the catalytic motif sequence, although it does exhibit catalytic activity. Family members highlighted with gray background signify transmembrane proteins and the first five members in large font denote those whose functions are specifically mentioned within the text. The bolded oxidoreductases are mentioned specifically in the text and the asterisk denotes a motif that cannot form a disulfide bond.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

with exportable protein substrates.[8] Moreover, overexpression of ERO1 itself cannot rescue perturbation of disulfide bond formation resulting from PDI knockout, strongly suggesting that, at least in *Saccharomyces cerevisiae*, oxidized PDI is required for ongoing disulfide bond formation in secretory proteins and ERO1 is required for the catalytic reoxidation of PDI.[8] From these and additional studies performed in higher eukaryotic cells and animals,[5] ERO1 proteins are now considered to be one of the major catalysts of disulfide bond formation in the ER lumen[27] – although still under active investigation are possible important roles for other oxidizers of lumenal ER oxidoreductases and substrate proteins – including oxidized glutathione (discussed above) plus additional enzymes (discussed below).[1]

TRANSFER OF REDUCING EQUIVALENTS FROM THE ER LUMEN TO THE CYTOSOL

ERO1, containing a variant of the thioredoxin motif known as a cysteine triad, provides a mechanism for delivery of reducing equivalents back to the cytosol, leading ultimately to molecular O_2.[27] In the case of the mammalian gene product, whereas the last two cysteines of the amino-terminal cysteine triad (residues C94 and C99) of ERO1 catalytically transfer a disulfide bond to the active site of PDI, the last two cysteines of the carboxyl-terminal triad (residues C394 and C397) of ERO1 are used to transfer reducing equivalents to FAD^+.[3] Reducing equivalents are internally shuttled within ERO1 from C94/C99 to C394/397, to make ready C94/C99 for another round of disulfide bond formation. The reduction of FAD^+ to $FADH_2$ (which, in the cytosol, can transfer these reducing equivalents to molecular oxygen as the terminal electron acceptor) is accompanied by formation of hydrogen peroxide (H_2O_2) in the ER, as a byproduct.[27] The stoichiometry is such that for every ERO1-catalyzed disulfide bond, one molecule of H_2O_2 is generated.

As H_2O_2 is one form of reactive oxygen species (ROS), the catalytic activity of ERO1 has been considered a contributor to cellular oxidative stress that is seen as an undesirable outcome,[27] although this has been debated.[1] New studies indicate that Peroxiredoxin 4 (PRDX4) links the reduction of cytoplasmic hydrogen peroxide to additional disulfide bond formation in PDI-like oxidoreductases of the ER lumen.[4,35] In the process of reducing H_2O_2, PRDX4 becomes chemically oxidized at the carboxyl-terminal cysteine of its CXXC motif, followed by formation of a mixed-disulfide bond that is transferred to PDI or other PDI-like oxidoreductase. Notably, mice bearing a double knockout of ERO1α and ERO1β (the two mammalian ERO1 genes) are still able to generate disulfide bonds in secretory proteins with only a minor delay, but a triple knockout of ERO1α, ERO1β, and PRDX4 displays a more severe oxidative folding defect.[35] In addition to PRDX4, PDI peroxidases GPX7 and GPX8 also reduce cytoplasmic H_2O_2 and may promote disulfide bond formation in the ER lumen, although these molecules are relatively understudied.[4]

Vitamin K–dependent OxidoReductase (VKOR) is another protein that can receive reducing equivalents from PDI-like family members. VKOR is an ER transmembrane protein that catalyzes reduction of Vitamin K epoxide to hydroquinone (a cytoplasmic co-factor needed for gamma-glutamyl carboxylation of newly synthesized blood clotting factors in the ER [of hepatocytes][30]), allowing the CXXC motif in VKOR itself to become oxidized. VKOR can then in turn receive reducing equivalents from PDI-like oxidoreductases, as shown by 'disulfide trap mutants' of oxidoreductases bearing the active site cysteine mutation CXXA that allows for creation/capturing of a stable mixed-disulfide complex with VKOR.[26]

Quiescin–Sulfhydryl Oxidase (QSOX), another potent source of direct disulfide bond oxidation in substrate proteins (in a manner entirely independent of PDI-like oxidoreductases), uses molecular oxygen as its terminal electron acceptor to very potently generate disulfide bonds directly in substrate proteins (preferentially over those in PDI-like family members), and produces H_2O_2 as a byproduct.[12] In yeast, the overexpression of QSOX, a monomeric flavoprotein, can rescue mutant phenotypes of *ero1* null mutants. Yet the physiological role of QSOX *in vivo* remains unknown because of its low expression level and its apparent localization in the Golgi complex rather than the ER where most secretory protein disulfide bonds are believed to form.

PROPER DISULFIDE BOND FORMATION IN THE SECRETORY PATHWAY MAY ALSO INCLUDE DISULFIDE REDUCTION AND ISOMERIZATION

Even after disulfide bond formation in the secretory pathway, there are times when existing disulfide bonds must be broken within the ER (or periplasmic space of bacteria). For example, initial disulfide bond formation may involve cysteine mispairing, leading an exportable protein into a nonnative 'off-pathway' conformation. Such mispaired disulfide bonds need either to be broken (reduced) or isomerized to native pairings. In higher eukaryotes, the large number of distinct PDI-like oxidoreductases makes it all the more likely that subspecialization exists among family members to function more as oxidases or more as reductases for specific substrates – even as all members must cycle their catalytic CXXC motifs between oxidized and reduced states. Although this is largely unproven in higher eukaryotes, it is plausible that evolution may have divided catalysts of disulfide bond formation versus disulfide reduction or isomerization into distinct gene products, because such specialization might allow for greater functionality. Even in bacteria, isomerization activity is carried out by

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

DsbC and DsbD, which tend not to assist in initial disulfide bond formation within substrates.[23]

Nevertheless, PDI – which is certainly associated with disulfide bond formation in yeast and ER reoxidation after reductive stress in higher eukaryotic cells[1] – can also be clearly shown to exhibit disulfide isomerase activity. Indeed, disulfide isomerization catalyzed by PDI was one of the observed activities reported by Anfinsen in his Nobel prize-winning study of the *in vitro* refolding of denatured ribonuclease. By contrast, there are other agents, such as QSOX (and others, described below), that do not seem to be capable of reduction or isomerization of disulfide bonds in secretory proteins – providing support for the notion of specialization of enzymes in the secretory pathway primarily dedicated to substrate oxidation rather than to isomerization or reduction.

THE FAMILY OF PDI-LIKE ER OXIDOREDUCTASES

As PDI is the prototypic ER oxidoreductase, it is worth briefly reviewing its structure–function relationships. A 55-kDa protein containing two catalytic thioredoxin (a and a') domains, PDI also contains two noncatalytic (b and b') domains arranged as a–b–b'–a' (Fig. 2). The noncatalytic b and b' domain (and its following linker region) tend to contain hydrophobic pockets that contribute importantly to low-affinity binding of a wide variety of substrates.[10] The low affinity allows PDI to "sample" many potential substrates and thereby to potentially direct rapid catalysis – within the ER, the apparent K_m of the enzyme for a given substrate is at least as much about protein sampling as it is about catalytic activity. The a and a' domains may also contribute to substrate recognition.[10] PDI and many other members of the PDI-like family of ER oxidoreductases also contain the 4 amino acid carboxyl-terminal KDEL-like sequence that functions as a Golgi retrieval signal to enrich these proteins within the ER. With the combination of its four domains, PDI can also function as a molecular chaperone – preventing aggregation of proteins – in addition to its function as an enzyme. In yeast, catalytically-dead PDI rescues the lethal PDI null phenotype, suggesting that PDI's essential role in the ER goes beyond its role in disulfide bond formation.[18] Thus, it is thought that through both its catalytic and noncatalytic activities, PDI can minimize kinetic traps – helping to eliminate 'dead-end' folding intermediates.

Other PDI-like family members differ in length and activity, but share the common thioredoxin-like-fold,[1] being grouped on the basis of their content of a, a', b, or b' homology domains. The noncatalytic b and b' domains are often not well defined; moreover, some PDI-like family members are entirely noncatalytic as they contain no "a-domain" bearing a CXXC motif (a Ser residue is often substituted in place of Cys) – nevertheless, these family members assist in protein folding of substrates.[25] For a list of PDI-like ER oxidoreductases, please see Table 1. This broad family of PDI-like ER oxidoreductases displays a diversity of functions that continues to be discovered. As a complete review of all family members and their putative functions is beyond the scope of this Handbook, we will confine ourselves to a few limited examples. ERp57, like PDI, has structural units that include two redox-active a and a' domains.[11] However, for ERp57, the noncatalytic b domain contains no substrate-binding hydrophobic pocket. Instead, the positively charged noncatalytic domain of ERp57 seems to be specialized for interaction with the negatively charged tip of the P-domain of lectin-like chaperones calreticulin and calnexin – it is for this reason that ERp57 substrates almost exclusively comprise glycoproteins.[16] ERdj5 has been shown to function mainly as a reductase, breaking disulfide bonds in misfolded proteins.[29] ERp72 can act on the same protein substrate as PDI, yet ERp72 does not have an identified hydrophobic domain, and its phenotypic effects tend to be opposite to those of PDI. In one such example, PDI has been found to act as an unfoldase that enhances the retrotranslocation of cholera toxin from the ER lumen to the cytosol, whereas

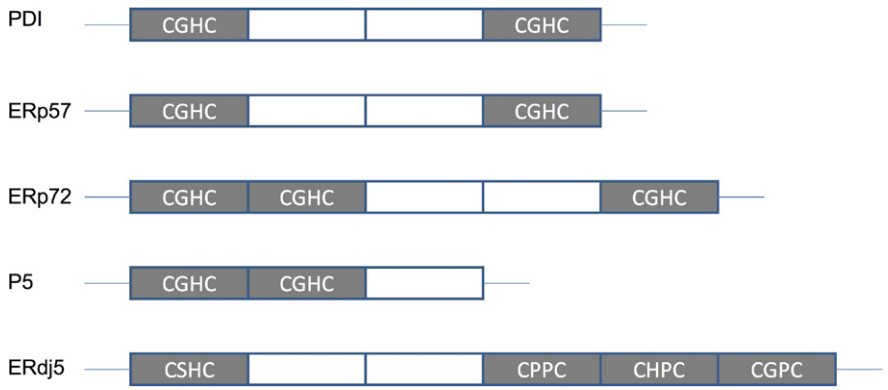

FIGURE 2 Domain structure of selected ER oxidoreductases. Schematic of PDI-like family members, comprising "A"-type thioredoxin domains that are catalytically active (shown in gray), and "B"-type noncatalytic thioredoxin-like domains.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

ERp72 limits cholera toxin retrotranslocation.[6] ERp72 and another PDI-like oxidoreductase, P5, have been found to complex with the molecular chaperone BiP (GRP78) and may also be involved in recognition of misfolded protein cargo. PDILT (restricted to testis) and PDIp (restricted to pancreas) interact with endogenous substrates specific to those tissues.[11] Overall, existing results tend to support the view that different ER oxidoreductases are selective about their choice of substrates – the central issues (besides cell type–specific gene expression) include their relative abundance in the ER, the molecular organization, and structure of their catalytic and noncatalytic domains, their redox potential (relative ease of reduction vs. oxidation of the catalytic CXXC), and the availability of ER resident partner proteins for the oxidoreductase that may bring it into close proximity with selective substrate proteins.

SELECTIVE ACTIVITIES OF OXIDOREDUCTASES WITHIN THE ER ENVIRONMENT

Although PDI-catalyzed substrate (re)folding has been extensively characterized *in vitro*, there remains little data on the role(s) of PDI-like oxidoreductases *in vivo*. It has been reported that siRNA-mediated knockdown of PDI in the HepG2 hepatocyte cell line results in a modest retardation in oxidative folding of various substrates. The effect is enhanced when combined with simultaneous knockdown of other oxidoreductases such as ERp57, resulting in delayed substrate exit from the ER – with the authors suggesting functional redundancy among members of the PDI-like family of ER oxidoreductases.[24] Conversely, it has previously been shown that siRNA-mediated depletion of ERp57 in mouse L cells causes a delay in the oxidative folding of MHC class I heavy chain and a delay in the export of class I molecules from the ER[33] – and ERp57 knockout mice die in utero, believed primarily to represent a B cell defect in the formation of MHC class I peptide-loading complexes.[9] Thus, it would seem that other ER oxidoreductases cannot adequately replace this essential physiologic function of ERp57. Likewise, neither ERp72 nor ERp57 can support normal retrotranslocation of cholera toxin A1 polypeptide from the ER to the cytosol – a function that seems to be facilitated selectively by PDI.[6] Indeed, PDI overexpression stimulates ER-Associated Degradation (ERAD, a process involving retrotranslocation for proteolysis via the ubiquitin–proteasome pathway) of mutant thyroglobulin, while ERp72 overexpression decreases ERAD rate for the same mutant.[6] Taken together, these examples suggest that ER oxidoreductases exhibit distinct behaviors within the ER. Nevertheless, multiple ER oxidoreductases are induced by ER stress (also known as the Unfolded Protein Response, or UPR), and deficiency of a variety of different ER oxidoreductases (including ERdj5) can sensitize cells to ER stress-mediated apoptosis[28] – at least in part resulting from deficiency of disulfide reductase activity that is needed for the ERAD process.[5,29]

OXIDATION OF SPECIFIC BIOACTIVE PEPTIDE SUBSTRATES WITHIN THE ER: THE CASE OF PROINSULIN

PDI has been studied with regard to disulfide bond formation within proinsulin/insulin; indeed, this is perhaps the best-studied example of a protein substrate for which PDI interaction has been analyzed both *in vivo* and *in vitro*. Proinsulin is the secretory polypeptide precursor to biologically active insulin. Insulin comprises two peptide chains (B and A), linked by two disulfide bonds [C(B7)–C(A7), and C(B19)–C(A20)]. Proinsulin is a single-chain molecule in which the two insulin chains are contiguous because of the presence of a 35-amino acid connecting peptide (C-peptide) plus flanking cleavage sites that are endoproteolytically excised in the final processing events leading to the synthesis of active insulin. Thus, after cleavage of the signal peptide, the proinsulin primary sequence, beginning from the amino terminus of the molecule, sequentially encodes B-chain, C-peptide, and A-chain.

Human proinsulin, produced as an 86-residue peptide (along with a 24-residue signal peptide that is cleaved), contains three intramolecular disulfide bonds: the two noted above interlink the B- and A-chains while a third is contained entirely within the A-chain [C(A6)–C(A11)]. Each of the three bonds is ultimately essential to the biological activity of insulin. In pancreatic beta cells, on folding to the native state (that includes of course the proper disulfide pairings), proinsulin exits the ER and is delivered to the Golgi complex from which newly made secretory granules are first formed – the compartment in which processing from proinsulin to insulin takes place. Ultimately, the insulin granules migrate to the periphery of beta cells to ready themselves for exocytosis in response to secretory stimuli such as elevated blood glucose.

The proinsulin gene product is just one member of the large insulin/IGF superfamily, each sharing the 3-disulfide structure. Multiple members of this family, including both IGF-I and IGF-II, have a branched protein folding pathway that can lead to distinct disulfide-linked final structures – including structures with fairly similar thermodynamic stability – although only one of these disulfide isomers (the native form) has optimal bioactivity.[13]

Quality control in the ER, mediated via recognition of nonnative structures by ER chaperones (and oxidoreductases), is designed to limit ER export of secretory protein substrates that are biologically inactive due to conformational immaturity (i.e.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

"unfolded") or from having formed inappropriate 'dead-end' folding products (i.e. "misfolded"). In this regard, the three disulfide bonds of proinsulin are not equal in importance. Specifically, without the C(B19)–C(A20) interchain disulfide bond, proinsulin is incompetent for export from the ER, indicating recognition and retention of the "open structure" by ER quality control mechanisms. Likewise, absence of the C(B7)–C(A7) interchain disulfide bond both impairs thermodynamic stability and dramatically decreases secretability. However, selective absence of the intrachain C(A6)–C(A11) disulfide bond creates only a modest structural perturbation of proinsulin (or insulin) and does not impair secretion.[21]

B/A-chain alignment is critical to achieving the C(B19)–C(A20) and C(B7)–C(A7) pairings. Early work suggested that biosynthesis of a single-chain insulin with direct contiguity of B- and A-chains (i.e. lacking C-peptide) results in efficient secretion of a structure isomorphous with native 2-chain insulin; however, it had not been appreciated that certain nonnative disulfide isomers (identifiable by abnormal mobility on nonreducing Tris–tricine–urea–SDS-PAGE) could also be secreted – as is known for other members of the IGF superfamily. In reality, such a protein is quantitatively misfolded, proving that, in addition to the primary sequence of B- and A-chains, a linking peptide between these chains is actually required for proper insulin disulfide bond formation in the ER,[21] which may represent an evolutionary pressure to retain the C-peptide that is otherwise of limited biological function.

Not only does improper disulfide bond formation critically perturb insulin function, it also seems to be linked to a chain of events that leads to full-blown diabetes with loss of pancreatic beta cell survival. This is quite a curious situation, as complete deletion of up to three of the four wild-type proinsulin-encoding alleles from the mouse genome (or loss of expression of one of the two wild-type alleles from the human genome) does not cause diabetes or beta cell death.[20] However, the presence of mutant proinsulins bearing cysteine substitutions inexorably leads to this autosomal-dominant phenotype. An interesting structural feature of wild-type proinsulin is that the C(B7)–C(A7) disulfide bond is nearly exposed at the surface of the molecule[14] potentially rendering it susceptible to persistent thiol attack. In fact, recent evidence suggests that the presence of "*Akita* proinsulin," a mouse mutant bearing the C(A7)Y substitution, blocks the secretion of coexpressed wild-type proinsulin and results in the production of aberrant disulfide-linked protein complexes in the ER that contain both wild-type and mutant gene products.[20] Moreover, studies of certain additional proinsulin coding sequence mutations (including those altering residues other than the cysteines themselves), leading to the syndrome of "Mutant INS-gene–induced Diabetes of Youth" (MIDY), also result in improper disulfide bond formation that triggers the same diabetes phenotype as that seen in the *Akita* mouse.[19] These findings validate a sensitive role of proper disulfide bond formation not only for the substrate itself, but also for innocent bystander proteins that may come under attack by coexpressed proteins that bear exposed, reactive cysteine thiols.[20] It is believed that proinsulin dimerizes in the ER[15]; what remains to be established is whether misfolded proinsulin triggering dominant-negative blockade of innocent bystander substrates is restricted exclusively to bystander proinsulin or may also have an impact – either through inappropriate mixed-disulfide bonds, or via a generalized ER stress response – on any other cysteine-bearing secretory proteins that happen to be coexpressed in the same ER.

PDI can catalyze the formation of proinsulin disulfide bonds *in vitro*,[31] yet the physiological role of PDI in the ER of pancreatic beta cells remains unknown. There are data that do not support the notion of PDI as a facilitator of the oxidative maturation of proinsulin in pancreatic beta cells. Specifically, overexpression of PDI in beta cell lines results in a decrease in insulin content and secretion, while proinsulin accumulates intracellularly (presumably in the ER).[32] Although it is possible that PDI overexpression can result in nonspecific effects, the results imply an apparent PDI-mediated inhibition of proinsulin export from the ER, which in turn suggests a probable defect in the proinsulin folding process. ERO1β has been reported to function as the primary oxidoreductin in pancreatic beta cells,[34] and, as described in detail above, ERO1 accepts reducing equivalents from PDI (and some other PDI-like family members[1]) to allow the ER oxidoreductases to form a catalytic disulfide bond that can be transferred to exportable protein substrates. Impaired expression of the ERO1β gene produces a phenotype – both in mouse islets and in cultured pancreatic beta cells –similar to that seen upon PDI *overexpression*, i.e. there is a delay in the ER exit of proinsulin with lower beta cell insulin content and lower insulin secretion.[17,34] Unlike in yeast, knockdown or deletion of PDI gene expression is not lethal to higher eukaryotic cells – undoubtedly because of the presence of many other PDI-like family members that can partially or fully replace its function.[24] Thus, based on the foregoing discussion, it is now essential that PDI knockdown or gene deletion in pancreatic beta cells be directly examined for its effects on proinsulin disulfide bond formation. In this way, we should finally be able to decide whether, in a cellular biological/physiological context, PDI is directly responsible for receiving reducing equivalents from proinsulin.

CONCLUSIONS

Proper disulfide bond formation is essential for the folding stability and export of numerous secretory proteins, including bioactive peptides. Several related genes have evolved to assist in the process of disulfide bond formation. In the

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

yeast *S. cerevisiae*, five PDI-like family members have been identified whereas in mammalian systems at least 21 different PDI-like family members have been discovered. What remains unclear, however, is the spectrum of secretory protein substrates that each PDI-like protein participates in assisting, and whether, for a given family member, the assistance actually operates primarily in disulfide bond formation or disulfide isomerization or even reduction of its preferred substrate(s). As this field of investigation grows, the possibility emerges that some of the PDI-like ER oxidoreductases may specialize in unfolding protein substrates to assist in ERAD – while other PDI-like family members may operate in an entirely noncatalytic yet important way for secretory protein folding and export. As a case in point, for a protein as well studied as proinsulin/insulin, the oxidoreductase(s) that primarily assist(s) in nascent disulfide bond formation in the ER, has(ve) not yet been identified. In addition to probable substrate preferences of distinct PDI-like family members, a new appreciation is developing for ER redox proteins that contribute primarily to controlling the proper compartmental milieu while other gene products operate directly on the secretory protein substrates. Multiple pathways operate in parallel in the generation of secretory protein disulfide bonds, including proteins that are not classic members of the PDI-like family of oxidoreductases. An understanding of the specific functions of PDI-like family members in the *in vivo* folding of proinsulin and other bioactive secretory peptides is expected to emerge over the coming decade.

Chapter 237

Ghrelin *O*-Acyltransferase (GOAT)

Masayasu Kojima and Hideko Ohgusu

ABSTRACT

Ghrelin is a gastric peptide hormone in which serine[3] (threonine[3] in frogs) is modified, primarily by an *n*-octanoic acid; this modification is essential for ghrelin's activity. The enzyme that transfers *n*-octanoic acid to the third serine residue of the ghrelin peptide has been identified and named (GOAT) ghrelin *O*-acyltransferase. GOAT is the only known enzyme that catalyzes acyl modification of ghrelin; it specifically modifies the third amino acid serine (or threonine) and does not modify other serine residues in ghrelin peptides. GOAT prefers *n*-hexanoyl-CoA over *n*-octanoyl-CoA as the acyl donor, although in the stomach, the *n*-octanoyl form is the main acyl-modified ghrelin.

INTRODUCTION

Ghrelin is a peptide hormone that is secreted from the stomach in response to hunger and starvation and serves as a peripheral orexigenic signal transmitting information to the brain and encouraging consumption of food.[1,10] Both intravenous and subcutaneous injections of ghrelin stimulate the hypothalamic arcuate nucleus, an important region in the control of appetite, via the vagus nerve.

Ghrelin has been identified in almost all vertebrate species thus far examined, including both mammalian and nonmammalian species, for example, frogs, birds, and fish.[9] In its active form, ghrelin bears an acyl modification at the third amino acid (serine in most species; threonine in the frog). This acyl modification is necessary for ghrelin to bind to the ghrelin receptor, GHS-R, and for it to exert biological activity.[8] The structure of ghrelin, particularly that of the acyl-modified regions, is highly conserved throughout all vertebrate species. The fatty acyl group that is used for the modification of ghrelin is primarily *n*-octanoic acid. The enzyme that transfers *n*-octanoic acid to the third serine residue of the ghrelin peptide was identified in 2008, and named GOAT.

NAME AND HISTORY OF GOAT

Ghrelin is the first and only known case of a peptide hormone modified by a fatty acid, and this acyl modification is essential for ghrelin's activity.[8] The enzyme that catalyzes this acyl transfer to ghrelin was identified in February 2008, when two independent groups reported the identification of GOAT (Fig. 1).[3,14]

The group led by Brown and Goldstein from The University of Texas Southwestern Medical Center searched the genome database and identified several orphan acyltransferases, meaning that the functions of the enzymes had not been clarified.[14] The authors expressed both ghrelin and putative enzyme cDNAs in a cell culture system, and examined the production of acyl-modified ghrelin. They finally identified (MBOAT4) membrane-bound *O*-acyltransferase as the GOAT that made the acyl modification of the ghrelin peptide.

Another group from Eli Lilly also identified several candidate acyltransferases in the genome database, and suppressed their expression by siRNA in TT cells, a thyroid medulla carcinoma cell line in which acyl-modified ghrelin is endogenously expressed.[3] They also identified MBOAT4 as the GOAT responsible for ghrelin's acyl modification. The group created MBOAT4 knockout mice and confirmed that ghrelin was not acyl-modified in the knockout mice.

Thus, MBOAT4 is the GOAT that catalyzes transfer *O*-acyl acid to the hydroxyl group of serine[3] (Ser[3]).

FUNCTIONS OF GOAT IN GHRELIN PROCESSING

The main molecular form of ghrelin in the stomach is a 28 amino acid peptide, in which Ser[3] is *n*-octanoylated. GOAT is the only known enzyme that catalyzes acyl modification of ghrelin. GOAT specifically modifies the third amino acid (serine) and does not modify other serine residues in human ghrelin. When the serine residues at the second, sixth and 18th amino acid positions in ghrelin are replaced by alanine, Ser[3] is still correctly modified by *n*-octanoic acid.[14] However, when the Ser[3] is replaced by alanine, GOAT cannot modify the peptide. The third amino acid of frog ghrelin is threonine, and is modified by *n*-octanoic acid just as Ser[3] is in other ghrelins.[7] When the third amino acid serine of rat

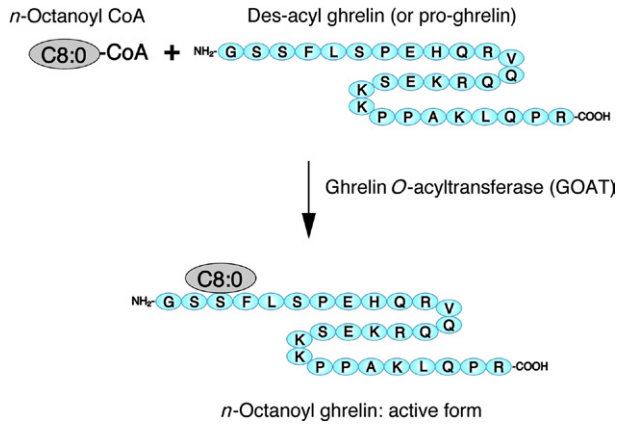

FIGURE 1 Des-acyl ghrelin (or proghrelin) is modified with an acyl acid (mainly *n*-octanoic acid) by GOAT to produce active ghrelin.

ghrelin is replaced with threonine, GOAT can modify the replaced threonine using *n*-octanoic acid.[14] Thus, the presence of serine or threonine as the third amino acid is important for *n*-octanoyl modification of ghrelin, and GOAT can modify not only serine but also threonine residues.

PROPERTIES

General Properties of GOAT

GOAT is a membrane-bound enzyme with multiple transmembrane domains. The number of membrane-spanning regions remains controversial and has been reported as eight (Yang et al.)[14] or five (Gutierrez et al.).[3] GOAT is a member of an acyltransferase family that includes at least 16 acyltransferase enzymes. Among these proteins, only GOAT has the ability to acyl-modify ghrelin. Just as ghrelin is present in all vertebrate species, GOAT is also found in mammals, birds, and fish.

The acyl group that is used for ghrelin modification is not a free acid but is instead a CoA-conjugated form.[12] The ghrelin modification reaction does not occur with free fatty acids or a mixture of free fatty acid and CoA.

Structure

The GOAT amino acid sequence is highly conserved among vertebrate species (Fig. 2). Amino acids 300–340 contain the acyltransferase catalytic region;[4] however, the role of other regions has not yet been revealed. The putative catalytic asparagine and histidine residues are conserved not only in mammalian GOAT but also in chicken, zebrafish, and *Xenopus tropicalis* GOATs.

Molecular Weight

The amino acid length of six mammalian GOATs (human, mouse, rat, chimpanzee, cow, and horse) is 435; the predicted molecular weights are 49,585 (human), 49,749 (mouse) and 49,877 Da (rat). The amino acid lengths of nonmammalian GOATs are 424 (chicken), 415 (zebrafish), and 429 (*X. tropicalis*); the predicted molecular weights are 47,345 (chicken), 47,495 (zebrafish), and 49,971 (*X. tropicalis*).

Effects of Detergents on GOAT Activity

Treatment of the membrane fraction with CHAPS or Tween 80 preserves GOAT activity.[12] By contrast, treatment with other six detergents (Triton X100, Lubrol, NP40, Brij96v, Triton X45 and NP9) attenuate or abolish GOAT activity. These results indicate that CHAPS and Tween 80 stabilize the conformation of GOAT and are useful for the solubilization of this protein.

STIMULATION OF GOAT

GOAT activity is enhanced by incubation with long-chain fatty acyl CoA in the GOAT reaction.[15] The GOAT reaction is stimulated equally by myristoyl-CoA (C14:0), palmitoyl-CoA (C16:0), and oleoyl-CoA (18:1). These long-chain fatty acids stimulate GOAT activity by inhibiting deacylation of *n*-octanoyl ghrelin.

Inhibitors

The pentapeptide derived from the ghrelin N-terminal peptide (GSSFL-NH_2, GSAFL-NH_2, GSSFL-COOH) inhibits *n*-octanoyl modification of ghrelin.[15] Moreover, when this peptide bears an *n*-octanoyl modification (GSS(C8:0) FL-NH_2), it also inhibits GOAT. In particular, when Ser^3 is replaced with (S)-2,3-diaminopropionic acid (Dap) and modified by *n*-octanoic acid, the pentapeptide potently inhibits the acyl modification activity of GOAT. [Dap]octanoyl-ghrelin (1-5)-NH_2 also exhibits potent GOAT inhibiting activity.

A synthetic bisubstrate inhibitor for GOAT, GO-CoA-Tat, has been developed (Fig. 3).[2] GO-CoA-Tat consists of three components: octanoyl-modified N-terminal 10 amino acid ghrelin peptide (GO), coenzyme A (CoA), and a Tat peptide, which is an 11 amino acid oligomer HIV Tat-derived peptide sequence intended to enhance cell penetration. Intraperitoneal injection of GO-CoA-Tat inhibits the production of acyl-modified ghrelin and suppresses body weight gain. Moreover, GO-CoA-Tat increases insulin concentration and improves glucose tolerance by lowering glucose concentration. Thus, GO-CoA-Tat may be a clinical target for the treatment of metabolic diseases, such as diabetes mellitus and obesity.

SUBSTRATE SPECIFICITY OF GOAT

Peptide Substrates

Not only the 28 amino acid des-acyl ghrelin but also the 94 amino acid proghrelin (human) can be acyl-modified by GOAT.[14] In fact, proghrelin is octanoylated before it is

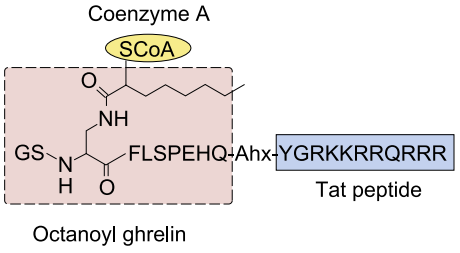

FIGURE 3 Structure of GOAT inihibitor, GO-CoA-Tat. Ahx, aminohexanoate, is the linker between ghrelin peptide and Tat peptide. Tat peptide is used for enhancing cell penetration.

cleaved to form mature 28 amino acid ghrelin.[17] These results indicate that although des-acyl ghrelin can serve as a substrate for GOAT, the acyl modification of ghrelin does not require previous protease processing.

With synthetic ghrelin N-terminal peptides, the minimum length of ghrelin peptide that can be acyl-modified by GOAT has been determined.[12] The synthetic N-terminal peptides used for these studies were shorter than des-acyl ghrelin and their C-termini had α-amide structures.

Immunoreactive octanoylated ghrelin concentration in the reactions revealed that the longer 8 amino acid peptide is acylated to 100-fold more efficiently than the shorter 4 amino acid peptide, and 4-fold higher than the 5 amino acid peptide. Because the amount of GOAT-treated 4 amino acid peptide produced (GSSF-NH_2) was very low, there was a possibility that the *n*-octanoyl modification of the 4 amino acid peptide was not a GOAT-specific reaction, but was instead a nonenzymatic reaction. However, in the absence of GOAT enzyme solution, no *n*-octanoyl modified peptide is produced.

These results indicate that these five synthetic peptides serve as substrates for GOAT and can be modified by *n*-octanoic acid. Thus, a peptide as short as four amino acids constitutes the core motif for substrate recognition by GOAT.

As described above, GOAT specifically modifies the third residue, serine or threonine. Interestingly, when the first amino acid (glycine) or the fourth amino acid (phenylalanine) is replaced by alanine, Ser^3 is not acyl-modified; however, replacements of Ser^2, Leu^5, Ser^6, or Pro^7 by Ala do not have an effect on the acyl modification.[14] In addition, N-terminal addition of two amino acids (Ser-Ala) significantly suppresses the acyl modification of Ser^3 of ghrelin. These results indicate that three amino acids in the N-terminus (Gly^1, Ser^3, and Phe^4) are important for the acyl modification reaction.

Acyl Donors

GOAT can use a wide range of substrates for acyl modification of ghrelin, ranging in size from acetic acid (C2:0) to tetradecanoic acid (C16:0).[3] However, the main molecular form of gastric ghrelin is modified by *n*-octanoic acid, and other acyl-modified forms of ghrelin are found only at low levels.

GOAT can modify des-acyl ghrelin peptide not only with *n*-octanoyl CoA, but also with other medium-chain acyl groups, such as *n*-hexanoyl-CoA and *n*-decanoyl-CoA. By contrast, very little acyl-modified products result from reaction with long-chain fatty acids. Kinetic studies using des-acyl ghrelin and three medium-chain acyl-CoAs as the acyl donor (*n*-hexanoyl-CoA, *n*-octanoyl-CoA and *n*-decanoyl-CoA), indicate that the order of the activities (as evaluated by *Vmax*/*Km*) is *n*-hexanoyl-CoA > *n*-octanoyl-CoA > > *n*-decanoyl-CoA.[12] The *Km* values for *n*-hexanoyl-CoA and *n*-octanoyl-CoA are 294 and 13.6 μM, respectively. Thus, GOAT prefers *n*-hexanoyl-CoA to *n*-octanoyl-CoA as the acyl donor. However, the concentration of *n*-hexanoyl ghrelin in the mouse stomach is very low relative to *n*-octanoyl ghrelin. Nishi et al. reported that ingestion of glyceryl trihexanoate drastically stimulates the production of *n*-hexanoyl ghrelin in the stomach.[11] This observation supports the idea that GOAT prefers *n*-hexanoyl-CoA as an acyl donor. These results indicate that the content of *n*-hexanoyl-CoA in the stomach may be lower than that of *n*-octanoyl-CoA, and these concentration differences may determine the relative production rates and concentrations of various acyl-modified ghrelins.

Multiple Acyl-modified Forms of Ghrelin

Several forms of acyl-modified ghrelin peptides have been isolated. In human, these can be classified into four groups by the type of acylation observed at Ser^3: nonacylated, octanoylated (C8:0), decanoylated (C10:0), and decenoylated (C10:1).[5] Additionally, there are several different acyl-modified forms of ghrelin in cat stomach: C8:0, C10:0, C10:1, C10:2, C13:0, C13:1.[6]

Because of its broad spectrum of acyl group substrates, GOAT is probably responsible for the transfer of all these modifications onto des-acyl ghrelin peptides.

REGULATION OF ACTIVITY

Ions

The following metals have no effect on GOAT activity: Mg^{2+}, Ca^{2+}, Na^+, and K^+. However, Fe^{2+} and Cu^{2+} potently inhibit GOAT activity.[12] GOAT activity is completely blocked >5 mM Fe^{3+} or 0.5 mM Cu^{2+}. EDTA and EGTA have no effect on GOAT activity, indicating that the enzyme has no absolute requirement for cations.

pH

The optimal pH for maximal specific activity of GOAT is 7.0–7.5 (Fig. 4).[12] The specific activity decreased rapidly <pH 6.5 and >pH 8.5.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

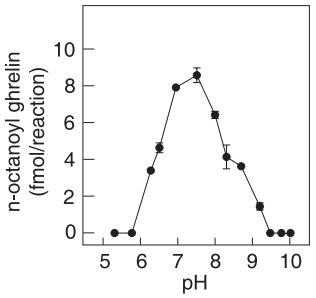

FIGURE 4 pH dependence of GOAT activity. *n*-Octanoyl ghrelin production activity was measured using standard assay conditions. *n*-Octanoyl ghrelin concentrations were measured by active ghrelin ELISA Kit. Results are expressed as the means ± S.D. ($n = 3$). The following buffers were used: 50 mM MES (pH 5–7), Tris-HCl (pH 7.5–8.5), and $NaHCO_3$ (pH 9–10).

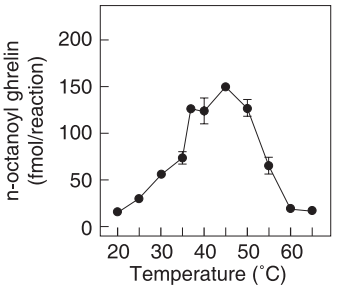

FIGURE 5 Optimal temperature of GOAT activity.

Because the optimal pH of the processing protease PC1/3 is rather acidic, and the pH value in the secretary granules is also acidic (pH 5–6), the acyl modification of ghrelin should occur before protease processing. In other words, it is probable that ghrelin will be modified before it matures, as preproghrelin and proghrelin. Indeed, proghrelin has been shown to be modified by *n*-octanoic acid.[14] Thus, acyl modification precedes protease cleavage.

Optimal Temperature

The optimal GOAT reaction temperature is 37–50 °C (Fig. 5).[12] GOAT still retains some enzyme activity at 55 °C, but the activity is abolished at temperatures >60 °C.

Distribution and Localization

The tissue distribution of GOAT is similar to that of ghrelin.[3,14] GOAT mRNA is most highly expressed in the stomach, followed by the small intestine and colon. GOAT mRNA is also expressed in testis, pancreas, total brain and especially in the hypothalamus. Ghrelin and GOAT are colocalized in the stomach.[13] However, there is a subset of ghrelin-immunoreactive cells in the stomach that do not contain GOAT mRNA.

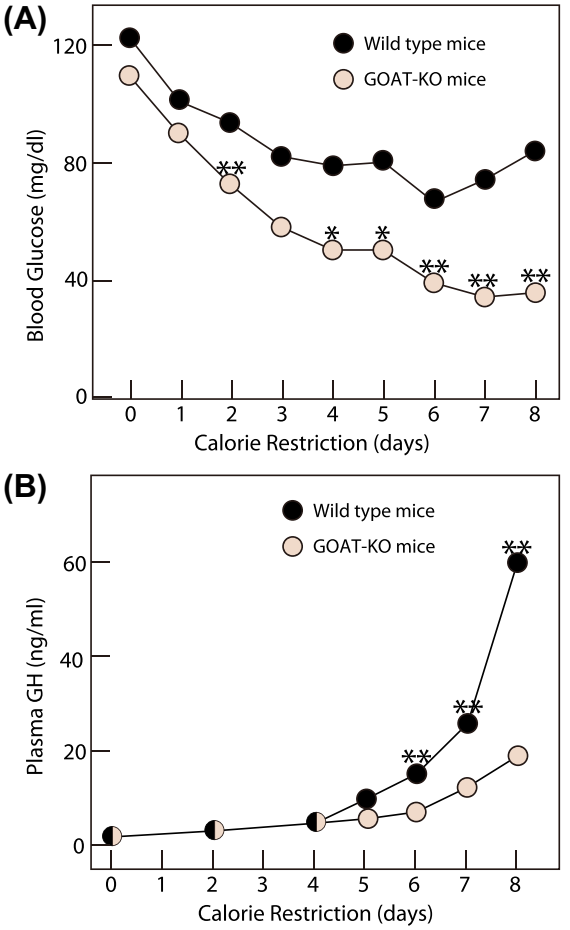

FIGURE 6 Blood glucose and plasma GH levels in 60% calorie-restricted mice. (A) Blood glucose levels in WT mice are stable after 4 days, whereas in GOAT-KO mice, they continue to decrease. (B) Plasma GH concentrations in GOAT-KO mice increase much more slowly than those of WT mice after 4 days. (These figures are modified from Reference 17.)

PATHOPHYSIOLOGICAL IMPLICATIONS

The growth and body weight of GOAT-KO mice are similar to those of WT mice when the GOAT-KO and WT mice are fed normal or high-fat diets. Under 60% caloric restriction, body weight and body fat are suppressed in both WT and GOAT-KO mice for the first four days, and their fasting blood glucose levels are decreased.[16] After four days of restriction, the blood glucose level in WT mice is maintained steadily at 58–76 mg/dl; however, the glucose level of GOAT-KO mice decreased gradually and reached 12–36 mg/dl after seven days (Fig. 6A). Under these conditions, WT mice showed normal activity, whereas GOAT-KO mice were close to death. In addition, the plasma GH level of the calorically restricted WT mice gradually increased, whereas the increase in plasma GH levels in the calorically restricted GOAT-KO mice was lower than that of WT mice (Fig. 6B). Ghrelin or GH injections into the calorically restricted GOAT-KO mice returned plasma glucose concentration to the normal level and prevented death.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

These results indicate that under highly calorically restricted conditions, ghrelin maintains normal plasma GH concentrations and prevents death. It is not clear whether ghrelin-KO and ghrelin receptorKO mice exhibit the same phenotypes as GOAT-KO mice.

Chapter 238

Glutaminyl Cyclases

Holger Cynis, Stephan Schilling and Hans-Ulrich Demuth

ABSTRACT

Posttranslational modifications such as glycosylation, amidation, or phosphorylation play an important role for the maturation of peptides and proteins. Frequently, the modifications alter their bioactivity and stability *in vivo*. Besides C-terminal modification by peptidylglycine alpha-amidating monooxygenase (PAM), the N-terminal modification by a 5-oxo-prolyl (pyroglutamyl, pGlu)-residue has been described for many peptide hormones and proteins, for example, thyrotropin-releasing hormone (TRH), gonadotropin-releasing hormone (GnRH), neurotensin, and fibronectin. The pGlu-residue originates from intramolecular cyclization of N-terminal glutamine and glutamate residues. This reaction is facilitated by glutaminyl cyclases (QC, isoQC, EC 2.3.2.5) and is found in bacteria, plants, and animals. Similar to C-terminal amidation, N-terminal pGlu-formation is important for the stability and/or bioactivity of the respective substrates. In addition to their important role in hormone function, several pGlu-peptides and proteins have been implicated in human disorders, such as Alzheimer's disease or monocyte-driven inflammatory disorders making glutaminyl cyclases attractive targets for drug discovery.

N-TERMINAL pGLU-MODIFICATION OF PEPTIDES AND PROTEINS

pGlu-Peptides of Plants

In plants, a few pGlu-modified proteins have been described. Most of these proteins are functionally related to plant defense reactions, for example, chitinases and glucanases. In addition, selected pathogenesis-related proteins (PR) are modified by an N-terminal pGlu-residue (Table 1). The role of the N-terminal pGlu-residue is unknown in either case, but because of the co-upregulation of proteases on infection, it might exert a stabilizing function to ensure stability of the respective pGlu-peptide in a highly proteolytic environment.

pGlu-Peptides of Invertebrates

In accordance with the distribution of glutaminyl cyclases among invertebrates and vertebrates, a broad spectrum of pGlu-peptides with differing functions have been described. The lowest metazoans, which contain pGlu-peptides, are cnidarians such as the sea anemone *Anthopleura elegantissima*. This organism expresses a number of pGlu-modified neuropeptides, and some of them were found to induce muscular constriction and were, therefore, considered as neurotransmitter or neuromodulators[30] (Table 2). Also, in the maritime snail *Aplysia californica*, pGlu-modified neuropeptides could be isolated. However, their specific functions remain unclear[9] (Table 2).

Among arthropods, a significant number of pGlu-peptides with different functions have been described so far. In this regard, Attacin-C is part of the immune response of *Drosophila melanogaster* showing antimicrobial activity against Gram-negative bacteria.[19] Further, the adipokinetic hormone of different arthropod species, for example, of *Locusta migratoria*, is a neuropeptide with importance for energy homeostasis. It is released when the insect flies and ensures the mobilization of fatty acids and carbohydrates from the fat body. In addition, pGlu-peptides are important components of the venom of arachnids. pGlu-discrepin, an irreversible potassium channel blocker inhibits potassium currents of cerebellar granule cells of rats and has been isolated from the venom of the scorpion *Tityus discrepans* (Table 2). Likewise, the Brazilian armed spider *Phoneutria nigriventer* also injects potent venom. By mass spectrometric analysis, this cocktail contains several pGlu-modified peptides structurally related to tachykinin peptides. Although detailed functional analysis of these peptides are lacking, it seems that these peptides are able to induce a constriction of the small intestine of guinea pigs, a function, which was described for tachykinin peptides[16] (Table 2). The role of the N-terminal pGlu-residue for the above-mentioned invertebrate pGlu-peptides is still unknown. However, it is tempting to speculate, that at least the pGlu-peptides in venom might have a stabilizing function to ensure a long bioactivity after injection.

In analogy to pGlu-peptides in venom of arachnids, the poison gland of the colubrid snakes *Boiga irregularis* and *Boiga dendrophila* generates a mixture of pGlu-peptides.[15] Therefore, the appearance of pGlu-peptides in animal venom is an evolutionary conserved hallmark among different phyla.

pGlu-Peptides of Vertebrates

The neuropeptides TRH and GnRH probably represent the best studied pGlu-peptides from vertebrates (Table 3). Both are formed in the hypothalamus and regulate the hypothalamus–pituitary–thyroid (TRH) and hypothalamus–pituitary–gonadal axes (GnRH), which are responsible for energy homeostasis and reproduction, respectively. TRH stimulates the release of prolactin and thyroid-stimulating hormone (TSH) from the anterior pituitary and is also known as a neurotransmitter and neuromodulator. The pGlu-residue of TRH is essential for its bioactivity.[1]

GnRH stimulates the release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from the anterior pituitary. The N- and C-terminal amino acids are essential for receptor binding and the activation of the GnRH-receptor is facilitated via the N-terminal region. The most important residues for activation are His^2 and Trp^3, but $pGlu^1$ might also be involved.[31] In addition, the presence of the N-terminal pGlu-residue increases the circulation half-life of TRH and GnRH suggesting a stabilizing function presumably by protection against aminopeptidase cleavage.[24] Additional human pGlu-neuropeptides are neurotensin and orexin A.

Besides pGlu-hormones such as gastrin-17 leading to the gastric release of hydrochloric acid (Table 3) and fertilization promoting peptide (FPP), a TRH analog with importance for sperm fertilization (Table 3), pGlu-peptides and proteins play a pivotal role in the human immune system. This is mainly attributed to pGlu-chemokines such as "monocyte chemoattractant proteins" (MCPs) leading to the attraction of immune cells to inflamed tissues.

Chemokines are grouped on the basis of conservation of cysteine residues in the N-terminal region. Accordingly, the peptides constitute the four classes "C-," "CC-," "CXC-," and "CX_3C-." Among those, CCL2 (MCP-1) represents the best studied CC-chemokine showing a high potential to attract monocytes. On stimulation, CCL2 is released by a variety of cell types, such as endothelial cells, fibroblasts, smooth muscle cells, or neuronal cells. After secretion, CCL2 is bound by glycosaminoglycanes of the extracellular matrix building up a gradient pointing toward the inflamed tissue. In addition, CCL2 is connected to vascular endothelial cells leading to the recruitment of monocytes to the subendothelial space. The N-terminal pGlu-residues of human MCPs are essential for their bioactivity and stability. Mature pGlu-CCL2 has a higher potency to activate its main receptor CCR2 and, therefore, possesses a higher potential to attract monocytes compared with immature Gln-CCL2.[4] In addition, the N-terminal pGlu-residue protects CCL2 and its family members CCL7, CCL8, and CCL13 against proteolytic degradation by aminopeptidases such as dipeptidylpeptidase 4 (DP4) and aminopeptidase P (ApP). Interestingly, artificial elongation of the N-terminal

sequence or truncation by aminopeptidases leads to a loss of bioactivity of all MCPs, highlighting the importance of the pGlu-moiety.[4,18] Thus, the pGlu-residue mediates stabilizing and activating functions in human pGlu-MCPs.

pGlu-Amyloid Peptides as Exceptional Cases with Relevance to Pathophysiology

In contrast to the vast majority of peptides, in which the pGlu-moiety is generated from a glutaminyl precursor, pGlu is formed from N-terminal glutamic acid in few peptides. The cyclization reaction is also accelerated by glutaminyl cyclases[6] but apparently as a slow and physiologically irrelevant side reaction. Evidence for a QC-catalyzed cyclization of glutamyl residues came from analysis of human amyloid peptides. First hints toward pGlu-formation from Glu were obtained by studies on hormonal peptides. Neuronal extracts of *A. californica* catalyzed the conversion of a glutamyl- into a pGlu-residue.[9] Furthermore, analysis of the cleavage products of proopiomelanocortin (POMC), namely, β-lipotropin and the joining peptide revealed a partial pGlu-formation from N-terminal glutamate. However, this pGlu-formation seems to lack functional consequences underlining the role of an irrelevant side reaction to most of the proteins.[2]

In amyloid peptides, however, the pGlu-formation potently influences the biophysical properties, which likely contributes to the pathophysiology of disease. The neurodegenerative disorders Alzheimer's disease (AD), familial British dementia (FBD), and familial Danish dementia (FDD) are characterized by progressive accumulation of such pGlu-peptides[10,20] (Table 3). The pGlu-modification of Aβ renders the peptides more toxic and leads to an increase of the aggregation propensity. Therefore, pGlu-Aβ might contribute to the formation of initial aggregates, mediating disease progression.[29] In FBD, pGlu-ABri is deposited in the brain parenchyma and peripheral deposits, whereas the unmodified glutamate precursor is found in the circulation.[11]

Apparently, the pGlu-modification contributes to the deposition, in turn highlighting a gain of toxic potential for certain pGlu-modified amyloid peptides.

GLUTAMINYL CYCLASES

Glutaminyl Cyclase (QC, QPCT, EC 2.3.2.5)

Glutaminyl cyclases are aminoacyltransferases catalyzing the intramolecular cyclization of N-terminal glutaminyl- and glutamyl residues under the concomitant release of ammonia or water, respectively[27] (Fig. 1). This reaction has been described in prokaryotes and eukaryotes. The first QC was isolated in 1963 from the latex of the tropical plant *Carica papaya*. Twenty-four years later the first mammalian enzyme was identified in bovine pituitary extracts. In addition, a prokaryotic QC from *Streptococcus bovis* was described in 1993. Bacterial/plant and animal QCs catalyze the same reaction. The proteins, however, do not share structural homology. Apparently, animal QCs evolved from ancestral zinc-dependent aminopeptidases, and both proteins share the typical α/β-hydrolase fold. By contrast, the homologous plant and bacterial QCs form a separate protein family, the polypeptides adopt an all-β conformation.[8]

Homologous plant QCs were identified in *Arabidopsis thaliana* and *Solanum lycopersicum*.[28] Mammalian QCs were described and characterized from bovine, rat, mouse, and human sources.[17,21,22,33] In addition, QCs from arthropods (*D. melanogaster*) and serpents (*Bioga spec.*) were reported.[15,25] Because of the broad distribution of pGlu-peptides and QCs among phyla, it is tempting to speculate, that QCs are conserved in most of the metazoan species.

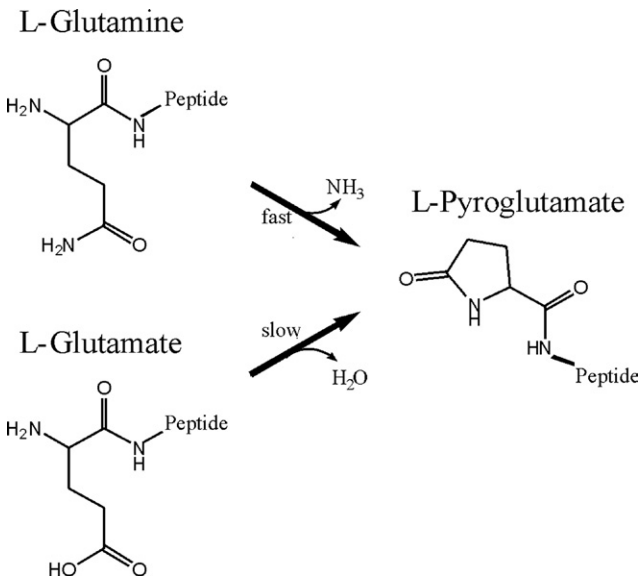

FIGURE 1 Cyclization of N-terminal glutaminyl- and glutamyl residues into pyroglutamate.

Mammalian QCs are monomeric glycoproteins of approximately 40 kDa. QCs are primarily expressed in neuronal tissue, such as cerebral cortex, striatum, and hippocampus.[5] In addition, QC expression and activity were identified in a broad range of cell lines in culture.[7]

QC is directed to the endoplasmatic reticulum (ER) by an N-terminal signal peptide. The enzyme passes the Golgi complex, is packed into secretory granules, and transported to the plasma membrane, where it is secreted from the cell. In hypothalamus, QC is colocalized with its substrates TRH and GnRH in dense core secretory granules. Apparently, those are transported together along the tractus hypothalamo hypophysialis.[3] Similarly, studies point toward cotransport and cosecretion of QC and Aβ-peptides from the entorhinal cortex to the hippocampus. The mechanism might have implications for formation of pGlu-Aβ containing deposits in Alzheimer's disease.[12] Support for the cosecretion and conversion of QC substrates within secretory granules is also obtained from QC knockout mice. Homozygous mice are fertile and do not show any overt abnormalities. The animals show a mild form of hypothyreodism, which is probably caused by reduced TRH production. Other hormonal cascades are apparently not affected, suggesting a therapeutic window for QC inhibition and clinical applications.[24]

Animal QCs are single-zinc metalloenzymes, which are inactivated by metal-chelating compounds such as 1, 10-phenantroline or dipicolinic acid. Animal QCs and the bacterial aminopeptidases (MEROPS ID: clan MH, family M28) share a conserved zinc-binding motif (H-D-E-D-H) (Fig. 2). However, in contrast to QCs, two zinc ions are coordinated in the active site of the aminopeptidases. The presence of one zinc ion in the active site of QC was confirmed by total X-ray fluorescence spectroscopy (TXRF), atomic absorption spectroscopy and X-ray crystallography.[14,27] The metal ion is coordinated by D^{159}, E^{202}, and H^{330} in human QC. The zinc ion represents the primary interaction site of competitive QC inhibitors. The most potent compounds contain imidazole or benzimidazole moieties as metal-binding groups. The interaction between the imidazole and the active site zinc ion was confirmed by cocrystallization of QC with imidazole derivatives such as 1-vinylimidazole.[14]

A characteristic feature of QCs from plants and animals is relaxed substrate specificity. The substrate spectrum ranges from peptide surrogates, such as glutamine-β-naphthylamine to protein substrates, for example, CCL2(1–76).[4,26] Moreover, QC also converts β-homoglutamine or glutamic acid. In contrast to glutamine, however, the conversion of glutamate into pyroglutamate proceeds with significantly reduced velocity. Apparently, N-terminal glutamic acid is only converted with uncharged γ-carboxyl and α-amino groups. The reaction shows a pH optimum at pH 5.2–6.5, which contrasts with the mildly basic pH optimum of QC-catalyzed cyclization of glutamine.[23]

Iso-Glutaminyl Cyclase (isoQC, QPCTL, EC 2.3.2.5)

The presence of a QC isoenzyme was postulated for bovine spleen first; however, an enzyme could not be isolated. A genomic homology search led to the identification and isolation of different QC isoforms from *D. melanogaster*, highlighting the possibility of the presence of mammalian QC isoforms.[25] Consequently, an isoenzyme of human and mouse QC (isoQC) was isolated and characterized.[5] Human QC and isoQC represent homologous proteins sharing a sequence identity of 45%. The catalytically important zinc-binding motif (D–E–H) is conserved in all mammalian isoQCs (Fig. 2). Inhibition studies using heterocyclic metal-binding compounds supported a zinc-dependent catalysis of isoQCs, which was later substantiated by TXRF analysis and X-ray crystallography.[34] Likewise, the X-ray structure of QC and isoQC shows conspicuous similarity.[13]

Interestingly, the N-terminal parts of QC and isoQC display rather low homology mediating differential subcellular localizations of the sister enzymes. Initial studies suggest retention of isoQC in the Golgi complex, which is mediated by a signal anchor. By contrast, the N-terminus of QC contains a secretion signal, which is cleaved in the mature, secreted protein.[5] (Fig. 2).

Similar to QC, isoQC shows broad substrate specificity *in vitro*, although the absolute catalytic proficiency is lower. Studies *in vivo* suggest, however, a differential substrate

conversion by QC and isoQC. For instance, by using QC and isoQC knockout mice, it could be shown that pGlu-CCL2 is generated by isoQC. Apparently, QC does not contribute to CCL2 maturation. Although further studies are required, the subcellular localization and substrate processing appear to significantly influence whether a substrate is converted by QC or isoQC.[4] A comparison of isoQC expression in different tissues reveals an equal distribution among CNS and peripheral tissues contrasting the pronounced expression of QC in neuronal tissue. Many pGlu-hormones are formed in the late secretory pathway, requiring prohormone convertase cleavage before N-terminal cyclization. Because secretory granules apparently do not contain isoQC, pGlu-hormone maturation might represent the major function of QC. By contrast, isoQC topology shows similarities to glycosyltransferases, with a short cytosolic N-terminus, a transmembrane helix and a large luminal catalytic domain suggesting a major function of isoQC in ubiquitous, "house-keeping" protein maturation.

Although the formation of pGlu is obviously catalyzed in plants, bacteria, and animals, N-terminal glutaminyl residues tend to form pGlu spontaneously. *In vitro* studies reveal a rate of 10^{-6} s^{-1} or even higher, which suggests half-lives of hours to days.[32] The nonenzymatic cyclization of glutamine might be accelerated by anions such as phosphate or borate. The spontaneous cyclization of glutamine probably causes a residual pGlu formation even in the excess of specific inhibitors in cell culture experiments.[4] In comparison with glutamine, the spontaneous cyclization of N-terminal glutamic acid proceeds at rates, which are three orders of magnitude lower. QC accelerates this reaction by a factor of 2.2×10^5 revealing a lower but reliable proficiency for glutamate substrates *in vitro*.[32]

The spontaneous cyclization of glutaminyl precursors, resulting in a formation of pGlu-peptides and proteins independent of QC or isoQC activity, probably contributes to the very mild phenotypes of the knockout mouse models. These studies support, in turn, current endeavors to develop inhibitors of the enzymes as therapeutics in neurodegenerative disorders.

Chapter 239

In Silico Search for Biologically Active Peptides

Mariko Nishiyama, Munehiro Ishii, Shuichi Hirose, Hiroyuki Yamazaki and Sadao Kimura

ABSTRACT

Reverse pharmacology and orphan receptor strategy have successfully unraveled many endogenous compounds including peptides for orphan GPCRs, combined with a variety of screening assays. However, there are still >100 orphan GPCRs, and their ligands and functions remain to be identified for fundamental and clinical research. Many screening methods to deorphanize orphan GPCRs have so far been developed and successfully used, while few practical methods to predict novel ligand candidates have been reported. A potentially useful approach to predict bioactive peptide candidates may be the use of bioinformatics, based on information of public database of protein amino acid sequences derived from human genome sequence project. In this chapter, we describe an outline for systematic in silico prediction of bioactive peptide candidates with a C-terminal amide.

BACKGROUND OF GPCR DEORPHANIZATION

According to the reported data of the human genome sequence, approximately 800 genes are indicated to encode G protein-coupled receptors (GPCRs).[9,22] Excluding presumed odorant receptors and pheromone receptors (~400 GPCRs), there exist around 400 typical GPCRs in the human genome. Among them, about 100 GPCRs, whose endogenous ligands are still unknown, are called "orphan receptors."[1,4,6,8,23] A wide variety of chemicals are identified as ligands for GPCRs, including amines, amino acids, peptides, proteins, nucleosides, nucleotides, Ca^{2+} ions, and lipids. Among GPCRs for known ligands, the ratio of peptide receptors to nonpeptide receptors is approximately 90:100.[1] If the same ratio is assumed among orphan receptors, potentially about 50 peptide receptors may remain to be deorphanized, although it might be a little overestimated.

Formerly, the conventional approach of GPCR investigation was the first to discover natural ligands, then to search and identify their receptors, next to analyze the characteristics of the various compounds that inhibit binding of the ligand to the receptor, and finally to develop novel therapeutics relating to the receptor. However, in recent years, other strategies have been widely accepted in orphan receptor research. One such approach is to search the ligands in natural tissue extracts by monitoring responses of cells expressing orphan receptors (orphan receptor strategy),[11,15–17] and another one is to identify the ligands by combining orphan receptors and chemically known compounds whose receptors are unknown (reverse pharmacology strategy).[2,3,21] Both approaches have been successfully applied so far. In these 15 years, ligands for >60 GPCRs have been newly identified. Hunting of endogenous ligands for the remainder of the orphan GPCRs now becomes the target of intense worldwide severe competition between pharmaceutical industries, universities, and academic institutes, to develop novel therapeutic agents.[4,8,23] About 45% of the top selling drugs target GPCRs.[24]

In the usual methods to search for peptide ligands, extracts from animal tissues are used as sources of peptides. However, in the cases of peptides whose content in tissues is extraordinarily low, or which are expressed only at extremely limited sites, this method with tissue extracts may fail to identify the endogenous ligands. Peptides existing abundantly in tissues with potent biological activities may have already been identified easily, so that peptides with only trace or unique activities remain unknown.

PREDICTION OF BIOACTIVE PEPTIDES: BIOSYNTHETIC PATHWAY OF BIOACTIVE PEPTIDES AND THE EMPIRICAL CLEAVAGE RULES

N-terminal and C-terminal Structures of Bioactive Peptides

Bioactive peptides, including peptide hormones, neuropeptides, and neurotransmitters, are initially synthesized

Handbook of Biologically Active Peptides. http://dx.doi.org/10.1016/B978-0-12-385095-9.00239-6

as precursor proteins, usually called "preprohormones." In this chapter, we use the term "preprohormone" for precursors of all kinds of bioactive peptides that may have various sizes and functional properties. Each preprohormone is cleaved into the signal peptide and the remaining part, "prohormone," containing bioactive peptide sequences. The presence of the signal peptide suggests that bioactive peptides are secreted to play physiological roles. The prohormones are further processed by proprotein convertases and carboxylpeptidases to yield mature bioactive peptides (Fig. 1). Although each prohormone possesses a distinct primary sequence, proteolytic processing occurs at dibasic amino acid residue sites that commonly flank the amino (N)- and carboxyl (C)-termini of bioactive peptides within their precursors. Then, the dibasic residues at the C-terminal are removed by carboxylpeptidases to produce mature bioactive peptides. Lys-Arg (KR) or Arg-Arg (RR) are the dibasic pairs most often found at the cleavage sites of known bioactive peptides.[7,18] However, processing also occurs at the dibasic residue sites Lys-Lys and sometimes Arg-Lys (Table 1). Processing occurs at monobasic Arg sites in certain cases, such as procholecystokinin, provasopressin, and prosomatostatin. For bioactive peptides with a C-terminal α-amide, including thyrotropin-releasing hormone, substance P, gastrin, oxytocin, and vasopressin, a specific sequence, Gly-Lys-Arg (GKR) or Gly-Arg-Arg (GRR) is located at the C-terminal sites of the bioactive peptides (Fig. 1). The glycine (Gly) residue in these sequences is catalyzed by amidation enzymes (peptidylglycine α-amidating monooxygenase and peptidylamido-glycolate lyase)[5,14] and serves as the amide donor for C-terminal amidation, that is essential for exerting most biological activity.

Biochemical Characteristics of Bioactive Peptides and Their Precursors

To predict bioactive peptides by in silico methods, we introduced several criteria for the characteristics of preprohormones deduced from full-length cDNA and genomic DNA sequences. (1) Each preprohormone should contain a signal peptide at the N-terminal site. (2) Preprohormones should not have membrane-spanning motifs in their sequences. (3) Peptide candidates produced from preprohormones should belong to the following six groups.

We classified bioactive peptides into six groups based on their specific sequences of the N-terminal and C-terminal sites franking mature bioactive peptides (Table 2). In type A, each peptide contains a most frequently cleaved signal, the dibasic pair (KR or RR) at both N- and C-terminal sites. Type B peptides contain an N-terminal dibasic pair and an amide signal, GKR or GRR, at the C-terminal. As shown in the following section, in the final version of the criteria in our in silico search of bioactive peptides, the dibasic pairs of KR and RR are accepted as processing sites and those of KK

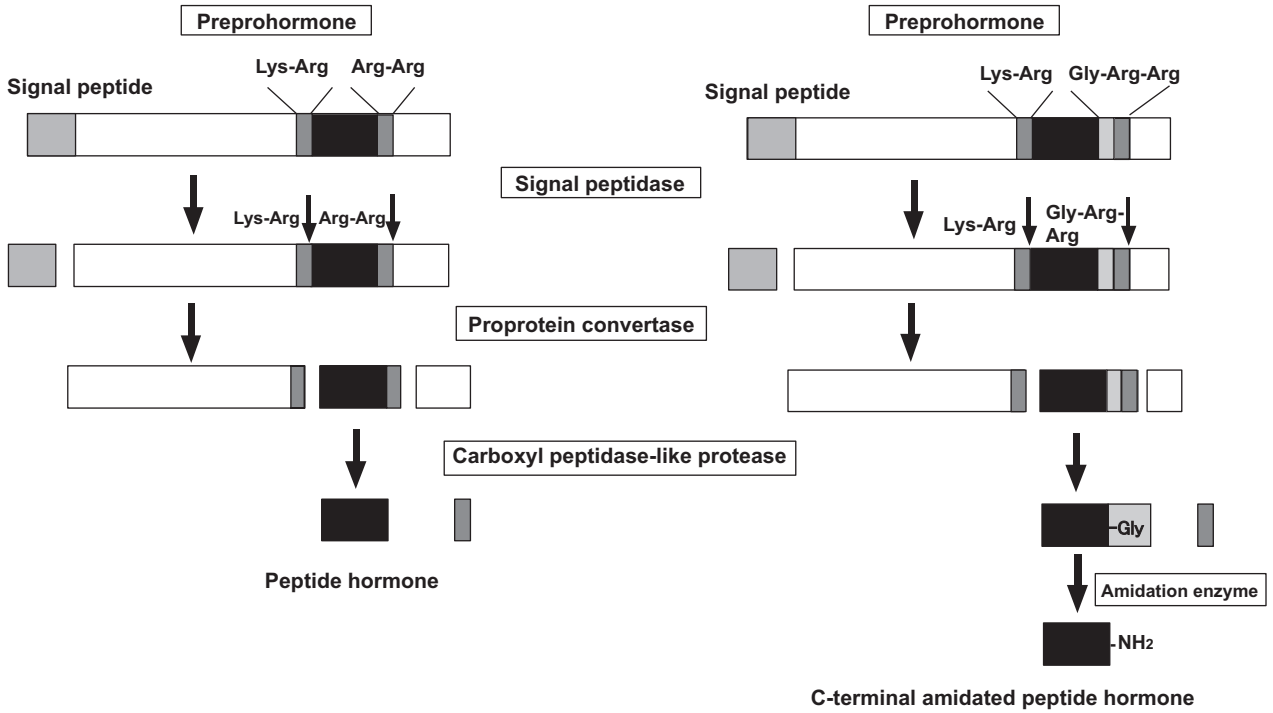

FIGURE 1 A schematic representation of preprohormone precursors and their posttranslational processing. Arrows indicate where prohormone convertases cleave the C-terminal side of a dibasic pair site (Lys-Arg, Arg-Arg, or Gly-Arg-Arg). C-terminal amides of mature peptide hormones are produced from Gly by amidation enzymes (peptidylglycine a-amidating monooxygenase and peptidylamido-glycolate lyase).

TABLE 2 Classification of Bioactive Peptides with a Dibasic Pair at the N- or C-terminal

Cleavage type	Pattern*	Step 1	Step 2	Step 3	Known bioactive peptides†
Type A	([KR]R-**peptide**-[KR]R)	15,848	3,815	327	3
Type B	([KR]R-**peptide**-G[KR]R)-**amide**	1,789	1,789	170	16
Type C	([KR]R-**peptide**-[KR]n-STOP)	7,425	916	130	5
Type CA	([KR]R-**peptide**-G[KR]n-STOP)-**amide**	638	638	78	3
Type D	(signal peptide-**peptide**-[KR]R)	5,896	726	108	0
Type E	(signal peptide-**peptide**-G[KR]R)-**amide**	709	709	104	13
	No. of bioactive peptide candidates	32,302	8,593	917	40
	(C-terminal amide type peptides)	3,136	3,136	352	32
	(Non-C-terminal amide type peptides)	29,168	5,457	565	8

Step 1: 6 ≤ **peptides** ≤60, **precursors** ≤ 300, Cys residues (0, 2, or 4).
Step 2: calculated from precursors with a C-terminal amide (including sequence overlapping).
Step 3: Lys-Arg and Arg-Arg in mature peptide sequences, no overlapping sequences.
**G = Gly, K = Lys, R = Arg, [KR] = K or R,* n = *0-n.*
†Predicted numbers of known bioactive peptides.

and RK are omitted, because our analyses on the sequences of about 140 known bioactive peptides precursors showed that most of the peptides are processed at the dibasic pairs KR or RR, and not KK or RK at N- and C-terminal cleavage sites (Table 1). Similarly, only GKR and GRR are accepted as C-terminal cleavage sites of amide type peptides. On the other hand, the four types of dibasic pairs are found almost equally in the population of peptide candidates simply extracted in silico from the DNA databases. Type C peptides and type CA peptides contain an N-terminal dibasic pair and a stop signal at C-terminal. Type D peptides possess a signal peptide at N-terminal and a dibasic pair at C-terminal. Similarly, type E peptides possess a signal peptide and a C-terminal amide signal. Further, analysis of known bioactive peptides indicates their biochemical properties; (1) preprohormones consist of 50–300 amino acid residues, (2) most of the mature bioactive peptides are 6–60 amino acids in length (Fig. 2) and contain 0, 2, or 4 Cys residue(s).

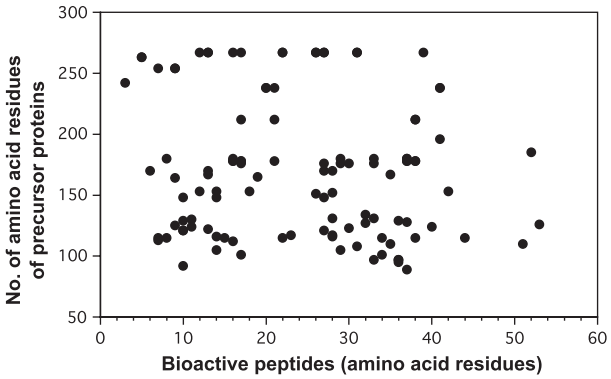

FIGURE 2 Relationship of the number of amino acid residues between mature peptide hormone and their preprohormone precursors. The number of amino acid residues of 94 peptide hormones and their precursors are indicated. Most of peptide hormones and their precursors contain <60 and 300 amino acid residues, respectively.

PREDICTION OF BIOACTIVE PEPTIDE CANDIDATES

Extraction of Protein Precursors

We used sequence information from three databases, Ensembl, IPI (International Protein Index), and H-InvDB (H-Invitational Database) (Table 3). In February 2006, we obtained about 25 million protein sequences with overlapping. Removal of overlapped sequences gave us about 200,000 protein sequences. Next, to extract the probable secreted precursors, we further applied the two criteria into our original soft program; (1) preprohormones contain a signal peptide, judged by SignalP and (2) contain no membrane-spanning region, judged by their membrane retention signal analyses. We finally obtained 33,119 proteins as starting precursor proteins for in silico prediction of bioactive peptide candidates (Table 3).

Extraction of Bioactive Peptide Candidates by Pattern Matching Methods

We started in silico analysis using 33,119 protein sequences to obtain bioactive peptide candidates matching to six groups of bioactive peptides (Table 2). We first tried a pattern matching analysis with a simple criterion that bioactive

peptides contain dibasic residues (KR, RR, RK, KK) at their N- and C-terminal sites. Surprisingly, enormous numbers of about 300,000 peptide candidates were obtained, suggesting that we need the more specific criteria based on biochemical features empirically obtained from biosynthetic pathways (Table 1). Next, we introduced several criteria into the computer program; (1) 6 ≤ amino acid residues of bioactive peptides ≤60 amino acids in length, (2) 50 ≤ amino acid residues of precursor proteins ≤300 amino acids in length, (3) number of Cys residues in a peptide sequence is 0, 2, or 4. These criteria gave us 32,302 peptide candidates with overlapping (C-terminal amide-type peptides 3,136; non-C-terminal amide-type 29,168) (step 1 in Table 2). We judged that these candidate numbers are still too many for making peptide libraries by chemical synthesis. Thus, we tried to limit the candidate proteins to those containing peptides with C-terminal amide sequences, for example, GKR, GRR, and G-stop (step 2 in Table 2). Further, we added two criteria; (4) bioactive peptide candidates not containing dibasic pair sequences (KR, RR, KK, and RK) within their mature peptide sequences, and (5) N- and C-terminal cleavage sites are KR or RR (as mentioned above, step 3 in Table 1). Finally, 352 C-terminal amide-type and 565 non-C-terminal amide-type peptide candidates were obtained (step 3 in Table 2). Among these predicted candidates, 32 peptides of C-terminal amide type and 8 peptides of the nonamide type matched known bioactive peptides, indicating that the prediction method described above may be practically useful. The number of finally predicted candidates may be acceptable for preparing a synthetic peptide library for screening. A part of these predicted peptides is now commercially available from PharmaDesign, Inc. (PharmaGPEP series, http://www.pharmadesign.co.jp/eng/index.html).

PERSPECTIVES

Screening methods used to search for biologically active ligand among the predicted peptide candidates were not described in this article because of the limited space. In signaling of many orphan GPCRs, it is difficult to specify the responsible type(s) of G protein α subunits and to choose adequate assay procedures. Therefore, multiple assay procedures are often combined for screening. Identification of a true ligand for an orphan receptor and elucidation of its physiological and pathophysiological roles require that researchers have much patience.

Discovery of novel peptide ligands is decreasing in recent years. It has also been pointed out by some investigators that an orphan GPCR and a known receptor can form a heterodimer. If so, in such situations, the orphan receptor itself might have no specific endogenous ligand and only serve as a regulatory protein through the dimer formation.[12,13] However, as described above, through the systematic in silico prediction method based on the information of the opened protein database, the number of amide type peptides predicted as GPCR ligand candidates may not be too many. A combination of well-established expression systems of orphan GPCRs and adequately tuned assay procedures may hopefully lead to the discovery of novel ligands. In contrast, as to nonamide type peptide candidates predicted from the systematic in silico search, the number of the predicted peptides are still too many for practical screening, and future development of more effective and more reliable prediction methods is awaited to find a more limited number of peptide candidates of good quality. For the detection of endogenous bioactive peptides whose tissue content is very low, development of multiple assay systems has been improved in recent years, and for identification of the detected peptides, technical sensitivity has been increased dramatically by the introduction of mass spectrometry. However, to overcome the difficulties for peptides whose tissue content is very low, or which is expressed at very limited sites, it may be necessary to improve in silico prediction methods by bioinformatics.[10,13,19,20]

Because identification of novel ligands of orphan GPCRs is inevitable to clarify a novel mechanism in biological regulation, continuous efforts are required to discover novel ligands. For this purpose, improved methods to predict peptide ligand candidates, together with improved screening technique, may be a powerful tool for researchers.

Chapter 240

New Mass Spectrometric Approaches for Uncovering Neuropeptides

Xiaowen Hou and Jonathan V. Sweedler

ABSTRACT

Neuropeptides are a diverse group of cell-to-cell signaling molecules; because of their chemical complexity and wide range of physiological concentrations, their characterization requires analytical techniques with low detection limits and high information content. Recent developments in mass spectrometry (MS)-based technologies, integrated with appropriate sample preparation and separation protocols, have enabled the characterization of hundreds of neuropeptides in a broad range of model organisms, from invertebrates to mammals. Sample sizes also vary widely, from single cells to whole animals. The wealth of knowledge about neuropeptides acquired using MS includes identity and quantity, localization and distribution, and temporal and spatial variation. In addition to providing lists of brain peptides, MS analysis now helps elucidate their function. With ongoing improvements in the figures of merit for MS-based profiling and sampling techniques, more rapid, sensitive, accurate, and higher-throughput approaches are emerging that enhance our understanding of neuropeptides.

INTRODUCTION

Neuropeptides, a broad class of structurally diverse cell-to-cell signaling molecules, are involved in a myriad of biological processes. Synthesized as protein precursors, they undergo complex enzymatic processing, are packaged into vesicles, and can be transported long distances to their cellular release sites. Many prediction programs are available that help identify cell-to-cell signaling peptides by predicting prohormone cleavage sites.[32] However, because the final bioactive peptide products are determined by the particular enzymes present and the order in which they act, and because they vary in a brain- and context-specific manner, it is difficult to confirm final products without measuring them. As one example, the cleavage of prohormones at basic amino acid (lysine and arginine) sites is common, but only a fraction of such sites are actually cleaved.[32] Although prediction methods are useful, oftentimes empirically measuring the peptide presence using mass spectrometry (MS)-based methods is required.

MS, assisted by separation techniques such as liquid chromatography (LC), offers the capability to fractionate and characterize complex samples to determine their chemical constituents. Since one of its first successes in characterizing thyrotropin-releasing hormone,[4] MS characteristics have advanced dramatically, leading to recent discoveries of large numbers of brain peptides in many animal models.[12,24] In addition to being used to unambiguously identify and characterize neuropeptides and their posttranslational modifications in complex biological systems—without previous knowledge of the peptide sequences—MS can also provide information about neuropeptide level changes under various physiological conditions. Further, recent advances in localization and imaging approaches have been combined with several MS platforms to reveal the distribution of neuropeptides in tissue slices and even whole animals.

No single method works equally well for all samples. Instruments vary in their analytical capabilities; thus, selection of the appropriate MS platform depends on many factors. These may include the characteristics of the peptides of interest (e.g. peptide charge states, mass range of detection), the experimental goals (e.g. peptide identification, quantification, or distribution), and the number of samples to be examined. Several MS technologies are available: electrospray ionization (ESI), quadrupole-time of flight (Q-TOF), ion trap (IT), matrix-assisted laser desorption/ionization (MALDI)-TOF, Fourier transform ion cyclotron resonance (FT-ICR), and others.[2,24]

When measuring peptides in a brain sample, one typically characterizes hundreds of peptides. Which ones are neuropeptides and what are the other peptides present? Although prohormones often encode multiple peptides, only a portion of these peptides are involved in cell-to-cell

Copyright Elsevier 2024

signaling. It has been suggested that the other peptides provide charge neutrality during acidification of the dense core vesicle, aid in correct folding and disulfide bond formation of their corresponding prohormones, and even participate in receptor localization. Another important point is that only a fraction of the peptides in a vesicle are expected to be *bone fide* neuropeptides. Contributing to the complexity of peptide measurements, one typically obtains a snapshot of prohormone processing (peptide formation), storage, and degradation. Thus, one can expect that the final products, as well as the processing intermediates and degradants, will be present in the sample. It should also be kept in mind that the tissue isolation process may lead to further degradation or other changes in the peptide forms.

Consequently, a peptidome measurement can result in long lists of peptides, only a fraction of which are involved in cell-to-cell signaling (and hence, only a fraction of which are neuropeptides). One can design sampling protocols to obtain information on function, transport, release, distribution, and changes in abundance based on treatments. In this chapter, we provide an overview of various MS-based approaches for uncovering neuropeptides by following their dynamics from transport to release, and from localization to heterogeneity, as well as their level changes based on physiological perturbations. The sample types range from single cells to whole animals. These measurements allow one to focus on specific sets of peptides based on their form, release, and level change or distribution, information that advances neuropeptide research.

MS-BASED NEUROPEPTIDE DISCOVERY

Peptide Transport Studies

Among the numerous peptides identified by MS, only a subset are expected to be transported long distances such as from a soma down nerves, and it is this subset of transported brain peptides that is more likely to function in cell-to-cell signaling. The ability to isolate subcellular structures associated with the transport process (vesicles) or release (synapses) results in fractions containing specific sets of peptides, thereby facilitating the identification of the localized neuropeptides. These transport studies can address questions such as: "Which neuropeptides are transported?" "Which endogenous neuropeptides are cleaved and generated in vesicles via *in vivo* events?"

Many approaches are available to examine these issues. One option is to ligate living nerve tissue between the central nervous system and periphery so that the ends of the nerve can be sampled after a suitable delay. Increased peptide levels can be observed at the nerve end toward the peptide source and reduced levels from the end located toward the destination of the peptides. A simple technique is to place the entire nerve onto a sample plate for the direct measurement of peptides by MALDI MS.[23] Alternatively, the nerve sample can be homogenized in peptide extraction solutions, such as acidified acetone, acidified methanol, or HCl.[35] The resulting solution contains a variety of peptides that were being transported when the nerve was isolated. These samples oftentimes are subjected to several clean-up steps (e.g. desalting) or separation by LC or other techniques, before identification by MS. Just as with the approach described above with nerves, one can isolate individual neurons for direct analysis via MALDI MS; this allows one to discriminate peptide patterns among soma, dendrites, and axons.[19,29] and thus determine which peptides are transported.

Another intriguing approach is to look for peptide packaging by isolating vesicles, such as large dense core vesicles, or to isolate specific locations such as synaptosomes. Typically after tissue or brain isolation, secretory vesicles are separated and collected through differential and sucrose density gradient centrifugations,[13] while synaptic components are enriched by subcellular fractionation.[27] These processes reduce the chemical complexity of the samples by concentrating the more abundant molecules in these fractions. The fractions are then homogenized in extraction solutions to recover peptides, followed by separation and MS identification. A variety of MS platforms have been used to detect and sequence the peptides from these subcellular compartments, or to create sets of peptides determined to likely play a role in cell-to-cell communication.[13,16,27] As another example, vesicles and synaptosomes from a region of interest have been isolated before and after a treatment (e.g. morphine administration); the changes in peptide levels determined by MS reflect the effects of the treatment.[27] Techniques used to accomplish these measurements are detailed later (see Peptide Quantification).

Peptide Release Studies

Cell-to-cell signaling peptides must be released from the cell under a stimulation condition in order to affect other cells. Which peptides are released, what are their forms on release, and under what conditions are they released? For example, upon various stimulations, the posterior lobe of the pituitary releases hormones such as oxytocin and vasopressin, while the anterior pituitary secretes other growth and reproductive hormones. The integration of MS measurements with *in vitro* and *in vivo* sampling approaches allows the characterization of peptide release; several examples of measuring peptide release are discussed below.

In vitro sampling of release has been reported using tissues from individual neurons and neuronal clusters in invertebrates[15] and from mammalian brain slices.[14] The stimulation and releasate collection are performed *in vitro* or ex vivo and the releasate profiles typically characterized by off-line MALDI-TOF MS. Once released, the peptides

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

are diluted by orders of magnitude as they diffuse into the cellular media. Many techniques have been developed to improve neuropeptide recovery and to provide spatial information on the location of release. By using a solid-phase extraction (SPE) material embedded within pipettes or micrometer-sized beads to collect releasates, as shown in Fig. 1A, the peptides are collected and concentrated before their measurement. After desalting with water rinses, peptide analytes are eluted from the SPE material or beads for subsequent MS analysis. Because of its high sensitivity and tolerance for impurities, MALDI MS is often used for these measurements. In MALDI MS, the eluents are cocrystallized with a matrix (e.g. alpha-cyano-4-hydroxycinnamic acid), ionized with a laser, and the resultant ions analyzed by the appropriate mass analyzer. MALDI MS requires minimal sample preparation due to its high tolerance for salts and other background molecules. This approach provides high-quality mass profiles, allowing one to measure multiple released peptides and their posttranslational modifications (Fig. 1B). Because of these characteristics, MALDI MS has been widely implemented in peptide release studies.[14,15,18] Furthermore, by collection of releasates from various locations using these beads (Fig. 1C), or over a time course (Fig. 1D), spatial and temporal information is added to the chemical release profiles. To improve the detectability of this approach for specific peptide categories, several SPE collection columns have been developed, such as a micron-scale porous polymer monolithic column, which provides both high binding capacity and spatial resolution.[18]

Microdialysis is a well-used brain sampling technique that has been combined with MS and other separation techniques to examine the extracellular fluid of animals *in vivo*, including brain tissues and the cerebrospinal fluid.[26,28] A microdialysis probe can be used both to collect endogenous compounds (e.g. peptides) and administer exogenous substances, such as drugs, directly and locally into the tissue regions of interest. The system includes a pump to perfuse the probe with a physiological salt solution (perhaps with a drug) while the device collects compounds that diffuse from the extracellular space across the membrane; the heart of the approach is the semipermeable membrane that allows molecules smaller than a selected size to be sampled (Fig. 2A).[6] To provide optimum sampling efficiency, the probe needs to be carefully designed (e.g. the membrane material and size), and the experimental parameters well controlled (e.g. the composition of the perfusion fluid, the perfusion flow rate, temperature).[26] As shown in Fig. 2B, the probe can be placed in a freely moving animal to monitor intracerebral neuropeptide release.[17] SPE materials have also been incorporated into probes to further concentrate and/or desalt the releasates before MS analysis. MS enables mass

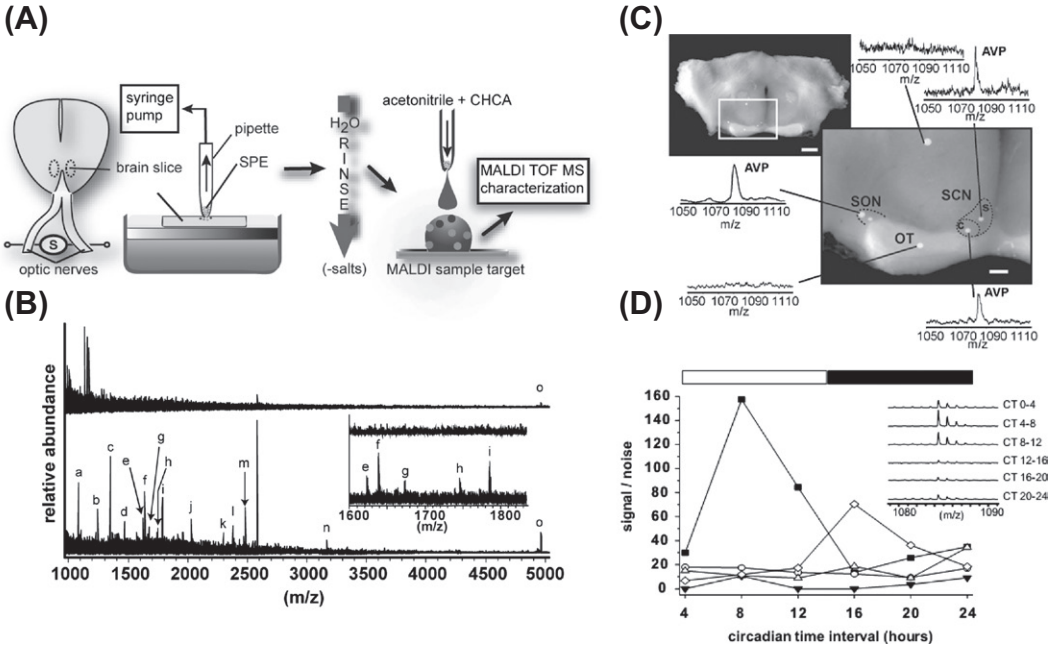

FIGURE 1 MS-based approaches for collecting peptide release from brain slices. (A) Solid-phase extraction pipette sampling allows the spatially resolved collection of released peptides and their subsequent characterization via MALDI-TOF MS. CHCA is alpha-cyano-4-hydroxycinnamic acid. (B) MALDI-TOF MS characterization of releasates before (upper panel) and after (lower panel) simulation. Peptide peaks are labeled as (a) to (o) and identified in the original work.[14] (C) Spatially resolved release of arginine vasopressin (AVP) peptide from a brain slice was performed by placing individual beads onto the slice, and then removing them for subsequent MS characterization; the beads were placed on four regions—suprachiasmatic nucleus (SCN), supraoptic nucleus (SON), anterior hypothalamic nucleus (AHP), and optic tract (OT). (D) Temporal release of five endogenous peptides over a time course of 24 h. The inset shows the release of AVP at 4-hour intervals. CT is circadian time. See color plate 63.

spectral comparisons between samples collected before, during and after the application of the selected stimuli, or over a specific time course, or at different tissue locations, all of which provide insights into the temporal and spatial chemistry occurring *in vivo*. Although accurate mass measurements are useful, more confident identifications require tandem MS capabilities. Because the number of peptides that can be fragmented by MS over a specific time period is limited, hyphenating MS to small-volume separations reduces sample complexity, yielding larger numbers of peptides that are identified via tandem MS. The combination of chemical, temporal, and spatial information on peptides that can be revealed by MS-based approaches, demonstrate the power of this technology as a discovery tool. For example, the peptide little SAAS is released from the suprachiasmatic nucleus at one time of day and directly affects circadian phase at that time of the day.[14]

Peptide Localization and Distribution Studies

Peptides often have sparse and highly localized distributions that change during development, treatment, and in some cases, even during specific behaviors. Methods that provide localization details are valuable to understanding peptide function and, in fact, optical imaging via microscopy has established that peptides have complex distributions within the brain. The caveat with microscope-based imaging is that selective and specific probes are often required to image specific peptides. By contrast, mass spectrometry imaging (MSI), which combines mass spectrometric approaches with imaging technologies, does not require preselection or labeling of analytes. It has been used to examine a range of biological tissues and provides both chemical and spatial information for known and unknown molecules, including neuropeptides.[5,9] Another advantage of MSI compared

with traditional microscopy is that the distribution of a wide range of compounds can be obtained in a single experiment. The direct analysis of tissue samples and the minimal sample preparation requirements are also beneficial. Figure 3A illustrates a typical MSI procedure, from sample preparation to data analysis. Experimental animals are selected and the regions of interest (e.g. brain, spinal cord, nerves) are isolated and dissected out under physiological conditions. A slice of tissue is sectioned via a cryostat and then placed onto a MALDI target plate, incorporating additional sample preparation steps as needed, for example, sample stretching to improve spatial resolution.[34] After matrix application, mass spectra are acquired in an ordered array of positions across the sample. Selected ion images of neuropeptides are reconstructed by plotting the MS signal intensities with the *x*, *y* coordinates of each spot (Fig. 3B). Peak assignments are made either by mass-matching or via subsequent tandem MS. The localization of tens to hundreds of peptides can be imaged at spatial resolutions from the low micron to hundreds of microns size range, depending on the instrumental and protocol figures of merit.

For obtaining quality images of peptides with MSI, one has to rely heavily on choosing the appropriate sample preparation protocols, selected according to sample type, mass range of interest, and desired spatial resolution and sensitivity. Several measurement approaches can be considered, such as stigmatic imaging,[1] oversampling,[20] and stretched sampling.[34] Because each MS platform provides unique capabilities, choosing the right system is also important. MALDI MS is well suited for imaging peptides with a wide range of masses at spatial scales from single cells[29] to whole animals,[21] while secondary ion mass spectrometry, or SIMS imaging is often used to study peptides with lower molecular weight masses (usually <700 Da) at higher spatial resolution.[34] Other ionization techniques, such as ESI and desorption electrospray ionization, or DESI, are alternative approaches.[33]

Single-Cell Neuropeptide Studies

Neurons are heterogeneous cells with distinct chemical compositions and functions, even among adjacent cells. With optimized sample preparation protocols and appropriate MS platforms, individual larger neurons can be rogated;[19,22,30,31] however, such measurements are not common. Because the neuropeptide complement varies in a cell-specific fashion, the analysis of single cells tends to reduce sample complexity and prevent the dilution of a specific neuropeptide with contents from nearby cells. Therefore, neuropeptides present at high local levels, but low global abundances are more easily detected.

Many single-cell analyses use MALDI MS; as mentioned previously, it is tolerant of salts. It is also tolerant of lipids, compatible with solid samples, has excellent detection limits, and requires minimal sample preparation. An overview of single-cell MALDI MS is illustrated in Fig. 4. After animal dissection and single-cell isolation under physiological conditions, single cells are positioned onto the target plate, and an appropriate MALDI matrix is applied. This approach has successfully been used to assay large invertebrate neurons to mammalian cells, with cell sizes ranging from several to hundreds of microns.[30] These approaches are becoming higher-throughput, capable of identifying rare novel neuropeptides, and placing the resulting information

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

into the context of the specific functions of individual neurons, and of following the cell-specific changes of peptide levels resulting from disease and exposure to drugs.[31]

Peptide Quantification

Details about which peptides are present within a brain region or tissue, including how these peptides are affected by the administration of drugs, gene knockout, or behavioral changes,[12] advances our understanding of peptide function. Quantitative peptidomic approaches that use MS-based methodologies allow us to compare changes in the relative amounts of many peptides simultaneously. There are several common MS-based approaches for quantifying peptides that use isotopic labeling[3,7,8,11,25] and label-free methods;[10] the general procedures are illustrated in Fig. 5. For isotopic labeling, the extracts from control and experimental samples are labeled with either light or heavy labeling reagents, which create labeled peptides with the same structure but a mass difference. Suitable isotopic labeling reagents should provide high reactivity and efficient labeling, stably labeled peptides during sample preparation and MS measurement, the coelution of differentially labeled peptides from commonly used LC columns, and a mass difference large enough for peak recognition and differentiation; these characteristics help ensure more reproducible and accurate results. Two types of "universal" reagents are widely employed for peptide labeling: one targets the N-terminus and the ε-amino group of lysine residues (e.g. succinic anhydride and trimethylammoniumbutyryl), and the other targets the C-terminus (e.g. methanol).[12] After labeling, samples are combined and simultaneously measured, with the MS instrument allowing the "identical" peptides to be differentiated; the difference in peptide abundance is quantified by determining the ratio of differentially labeled peaks in the same mass spectra (Fig. 5C).

Label-free measurements require fewer sample preparation steps after peptide extraction, and the samples are individually analyzed using LC–MS to obtain separate mass spectra for comparison (Fig. 5B). Because this approach handles samples separately throughout the process, it is essential to maintain experimental consistency during peptide extraction and sample preparation, and to carefully select the proper MS platform and parameters to obtain reproducible and comparable results. Although label-free quantification tends

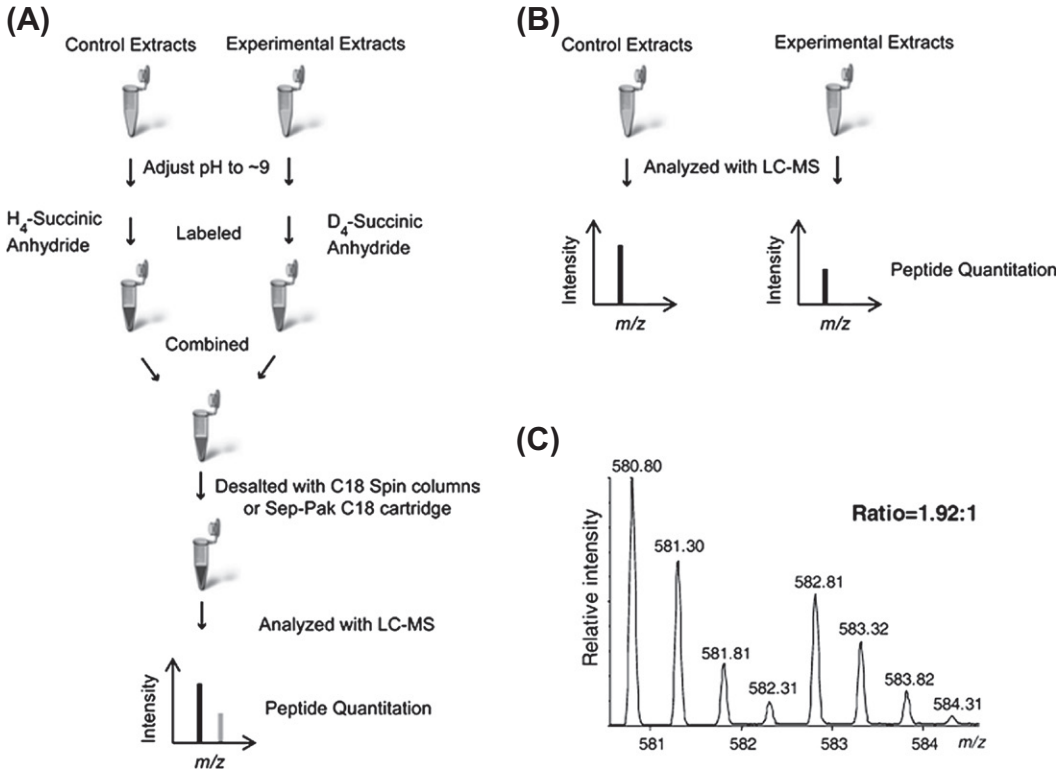

FIGURE 5 Neuropeptide quantification workflow with representative mass spectra shown. (A) Labeling approach from sample preparation and succinic anhydride labeling to LC–MS data analysis. (B) Label-free approach from sample preparation to LC–MS data analysis. (C) MS spectra of bradykinin standards differentially labeled with succinic anhydride (molecular weight = 1059.55 with masses 1159.62 (labeled with hydrogen)/1163.66 (labeled with deuterium) after labeling; charge state +2). to work well for quantifying peptides in the smallest-volume samples and peptides in low abundance with no theoretical limitation to the number of samples being compared, labeling approaches combine the samples at an earlier stage and may thus provide a more accurate quantification. The current availability of labeling reagents for quantitative peptidomics allows a comparison of up to four samples,[3,25] but the development of optimized reagents may lead to the ability to label more samples in parallel. Both labeling and label-free approaches have been successfully applied to investigate the correlation of peptide level changes in examining foraging behavior in honey bees[3] and the effects of drug exposure[7,11] and food deprivation and exercise[8] in mice. We expect such peptide studies to continue.

CONCLUSIONS

Significant advances in the integration of MS measurement methods with various sampling techniques have combined to collect dynamic, temporal and spatial information for neuropeptidomics research. As a result, the number of peptides discovered from a range of model organisms has dramatically increased over the past decade, shedding light on potential neuropeptides in the context of their biological environments. The emergence of more advanced MS platforms capable of unambiguous peptide identification, lower detection limits, higher information content and higher-throughput, in concert with the continuous development of more localized and activity-dependent sampling techniques, will further advance our understanding of these important cell-to-cell signaling molecules.

Chapter 241

Peptide Degradation (Neprilysin and Other Regulatory Peptidases)

Anthony J. Turner and Natalia N. Nalivaeva

ABSTRACT

Turning off peptide signaling is principally mediated by a group of cell-surface peptidases whose active sites face the extracellular space (ectopeptidases). Two groups of metallopeptidases are the best characterized as peptide degrading enzymes: the neutral endopeptidase or neprilysin (NEP) family and the angiotensin-converting enzyme (ACE) family. NEP and its homologs are important in degrading both brain peptides (e.g. enkephalins, tachykinins) and cardioactive peptides (e.g. atrial natriuretic peptides). They also metabolize the Alzheimer amyloid β-peptide (Aβ). In the cardiovascular system, ACE and ACE2 act to counterbalance each other in controlling angiotensin peptide levels and may also participate in the metabolism of other peptides. Prolyl-directed peptidases such as dipeptidyl peptidase IV and prolyl oligopeptidase play highly specific roles in peptide metabolism. This chapter summarizes current developments in our understanding of the roles and the regulation of these key mediators of peptide signaling, their roles in disease and as potential therapeutic targets.

INTRODUCTION

Proteolysis, which regulates the production and removal of biologically active peptides, represents a key biological process underpinning events from fertilization, through development to cell death. The ubiquity and diversity of peptidases are indicated by the existence of some 28,000 specific peptidases and their homologs characterized in >6000 known organisms (http://merops.sanger.ac.uk/). In the human genome of approximately 24,000 protein-coding genes, 686 genes of putative peptidases are known alongside 423 of noncatalytic homologs. Many of these are orphan peptidases for which the biologically active peptide substrates have not yet been identified. Such a profusion of proteolytic events requires specifically controlled regulation. Hence, although genes for peptidases constitute about 2.8% of the human genome, a significantly higher number (7.4%) of genes encode protein inhibitors of peptidases.

The term "peptidase" refers to enzymes that hydrolyze peptide bonds and, as such, all known biologically active peptides represent potential substrates for these enzymes. According to the location of the peptide bond cleaved by the peptidases, they are conventionally subdivided into "endopeptidases" that cleave the bond within the polypeptide chain, or exopeptidases that release amino acids from the N- or C-terminus of the substrate. However, some peptidases, e.g. angiotensin-converting enzyme (ACE), can fulfill both endopeptidase and exopeptidase functions. The physiological role of peptidases is very diverse. In general, peptidases do not cleave their substrates at random but participate in very well-controlled, specific processing of peptide molecules. The term "limited proteolysis" was originally introduced by Linderstrøm-Lang to distinguish the restricted specificity of certain peptidases, particularly those involved in posttranslational modification of proprotein precursors, from the random proteolysis accompanying protein digestion and degradation.

All peptidases have been divided into six classes (metallo-, serine, cysteine, aspartic, threonine, and glutamate peptidases) with cysteine-, serine-, and metallopeptidases representing the major categories. A seventh class involving asparagine peptidases has recently been reported.[24] Aberrant functioning of these peptidase genes is implicated in such diverse pathologies as inflammatory and cardiovascular diseases, cancer, and neurodegeneration. Understanding the normal functional roles of peptidases and their regulation and restoration in disease is hence important for the design of novel and selective therapeutics.

This chapter is focused primarily on two major families of zinc peptidases participating in the specific degradation of biologically active peptides. The prototypes for these peptidases are neprilysin (neutral endopeptidase, NEP) and ACE. The roles of peptidases directed specifically toward prolyl residues are also reviewed. Table 1 summarizes the diversity of peptide substrates hydrolyzed by this cohort of enzymes.

TABLE 1 Typical Biologically Active Peptides Degraded by Peptidases Discussed in this Chapter

Substrate	Peptidase
Adrenomedullin	NEP
Amyloid β-peptide	NEP, NEP II, ECE-1, IDE, ACE
Amyloid precursor protein intracellular domain (AICD)	IDE
Angiotensin I	ACE, NEP, ACE2, POP
Angiotensin II	ACE2, NEP, POP
Apelin	ACE2
Atrial natriuretic peptide	NEP, IDE
β-Endorphin	IDE, POP
Big endothelin-1	ECE-1, ECE-2, NEP, NEP II
Bradykinin	ACE, ECE-1, ECE-2, IDE, NEP, APP2, POP
Brain natriuretic peptide	IDE
Cholecystokinin-8	ACE, NEP
Corticotropin	ACE, NEP
Dynorphins	NEP, IDE, ECE-2
Endomorphin	DPP IV, NEP
Enkephalins	NEP, ACE
Endothelin-1	NEP
Gastrin	NEP
Ghrelin	ACE2
Glucagon-like peptide-1	DPP IV
Gonadoliberin-1	ACE, POP
Insulin	IDE
Insulin-like growth factor I	DPPIV
Insulin-like growth factor II	IDE
Luliberin	NEP, ACE
Neuropeptide Y	DPPIV, NEP, APP2
Neurotensin	ACE, ACE-2, ECE-1, ECE-2, NEP, POP
Oxytocin	NEP, POP
Somatostatin	NEP, ECE-1, IDE
Substance P	NEP, ACE, DPPIV, ECE-1, ECE-2, POP
VIP	NEP, ACE, IDE

NEUTRAL ENDOPEPTIDASE (NEPRILYSIN) FAMILY

Name and History

Neprilysin activity was first characterized from rat kidney brush border membranes as an enzyme hydrolyzing insulin B chain at neutral pH, and hence termed "neutral endopeptidase" (NEP), although it plays no role in the physiological insulin inactivation, which is mediated by another peptidase, insulin-degrading enzyme (IDE). NEP is a zinc metallopeptidase resembling the bacterial enzyme thermolysin, including its sensitivity to the inhibitor, phosphoramidon. NEP has a diverse range of biological roles and hence has been rediscovered in different proteolytic contexts. For example, after the discovery of the enkephalins, NEP was rediscovered in brain as a membrane enzyme hydrolyzing these opioid peptides and was termed enkephalinase. It is also the principal enzyme inactivating many other neuropeptides (e.g. substance P) and cardioactive peptides (atrial natriuretic peptide (ANP) family) and hence represents the first general "neuropeptidase." NEP plays an important role in the immune system where it is referred to as the common acute lymphoblastic leukemia antigen (CALLA or CD10), although its substrate(s) have not been identified. NEP also contributes to the metabolism of the Alzheimer amyloid β-peptide (Aβ) in the brain.[12] The human genome contains at least seven NEP-like enzymes, including the biosynthetic enzyme endothelin-converting enzyme (ECE-1). The family is even more abundant in Drosophila (24 predicted members) and *Caenorhabditis elegans* (22 members).[4] NEP is also known as MME, for membrane metalloendopeptidase, in the Human Gene Nomenclature database.

Properties

NEP is exclusively localized to the plasma membrane (type II integral membrane protein) with the active site facing the extracellular space (ectoenzyme) where it is poised to inactivate circulating peptides. It is a glycoprotein of approximately M_r 90,000. The enzyme is classified as a "gluzincin" peptidase with the typical His-Glu-Xaa-Xaa-His (HEXXH) zinc-binding motif. The glutamate in this motif (Glu^{584} in the human enzyme) is essential for catalysis and an additional glutamate (Glu^{646}) constitutes the third zinc ligand. NEP is an archetypal peptidase rather than proteinase because it generally only hydrolyzes peptides up to about 50 amino acids long. The 3D structure of the NEP catalytic domain in complex with its inhibitor phosphoramidon has been deduced aiding the design of novel inhibitors and providing a better understanding of its substrate specificity and catalytic mechanism.[20] The active site region is restricted in size preventing access of large peptides and hence explaining its oligopeptidase nature.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

In general, NEP hydrolyzes peptidases on the amino-terminal side of hydrophobic residues, e.g. the Gly[3]-Phe[4] bond of enkephalins, giving it a very broad specificity for known biologically active peptides although its physiologically validated substrates are more restricted. In addition to opioids, tachykinins, and the ANP family, it inactivates endothelins, bradykinin, and somatostatin. Other NEP substrates include glucagon, the vasoactive intestinal peptide family and adrenomedullin. NEP may also regulate bone metabolism through its presence on the surface of human osteoblasts and its ability to metabolize osteogenic peptides such as calcitonin and calcitonin gene-related peptide. Because inhibition of NEP can, in theory, potentiate the action of any of its peptide substrates, much emphasis has been directed toward developing novel and potent NEP inhibitors, with thiorphan originally being synthesized as an inhibitor of its enkephalin-hydrolyzing activity, and this is still the most commonly used NEP inhibitor. Many others have subsequently been developed as potential therapeutics in cardiovascular disease by prolonging the actions of ANP. The combined actions of NEP and ACE inhibitors have improved benefits over ACE inhibitors alone. The prodrug of thiorphan, acetorphan (racecadotril), is an effective antidiarrheal agent through its potentiation of the antisecretory effects of enkephalins in the intestine. However, the NEP substrate that has attracted by far the most interest over the last decade has been the Alzheimer amyloid-β peptide (Aβ).

Distribution/Localization

NEP and its homologs are widely distributed enzymes in the animal kingdom reflecting the general need for terminating the action of circulating regulatory peptides. Many invertebrate peptides are inactivated by NEP-like peptidases where it often plays a role in development and reproduction. In *C. elegans*, NEP seems to be an effector of locomotion. In mammals, the enzyme is particularly abundant in the kidney where its expression levels in brush border membranes are several orders of magnitude higher than in brain synaptic membranes. It is also highly expressed in the reproductive system (testis, ovary), although its functional role is unknown. Elsewhere NEP, although widespread, is expressed at much lower levels.

In the brain, NEP inactivates peptide neurotransmitters, especially opioid and tachykinin peptides, after their release into the synapse. Given the role of these peptides in pain mechanisms, NEP inhibitors have antinociceptive actions. However, most attention has been focused on the role that NEP plays, alongside other peptidases such as ECE, insulin-degrading enzyme, and possibly ACE, in detoxifying the Aβ peptide that predisposes to Alzheimer's disease (Fig. 1). The susceptibility of Aβ is perhaps not surprising given the

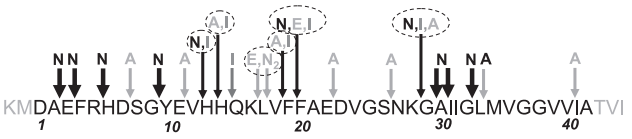

FIGURE 1 Main cleavage sites of amyloid-β peptide by peptidases. The Aβ-(1–42) sequence is shown in black with the flanking amino acids of the amyloid precursor protein (APP) shown in gray. The principal peptidases involved in Aβ peptide metabolism are indicated in black and the other activities in gray. N, neprilysin; N_2, neprilysin-2; A, angiotensin-converting enzyme; E, endothelin-converting enzyme-1; I, insulin-degrading enzyme. Letters in circles indicate peptidases that cleave Aβ at the same site.

specificity of NEP, as it is a highly hydrophobic peptide. Indeed, under normal conditions there is considerable evidence that Aβ itself may be a regulatory peptide, and it is only in pathological conditions when it accumulates excessively that it becomes toxic. This process is enhanced in aging because there is a well-documented age-related decline in NEP expression. The levels of brain Aβ are hence increased in NEP-deficient mice. NEP expression is also diminished after periods of ischemia or hypoxia. Infusion of an NEP inhibitor into rat brain leads to a significant accumulation of the more neurotoxic Aβ42 peptide, and hence, upregulation of NEP has been proposed as a potential therapeutic strategy in Alzheimer's disease.[12,18] NEP gene transfer can decrease amyloid-like pathology and cognitive decline in transgenic mice.[16] Given the potential of NEP inhibitors to increase brain Aβ levels and hence to induce Alzheimer's disease-like symptoms, interest in the development of novel NEP inhibitors as potential cardiovascular therapeutics has considerably diminished.

In the brain, NEP is mainly localized on neuronal cells, especially in the striatonigral pathway consistent with its role in turning off opioid peptide and tachykinin signaling, and it is also located in the hippocampus, where it functions to inactivate somatostatin and in cortical regions where it may also act to degrade Aβ . The enzyme is also present on activated astrocytes and on Schwann cells in the peripheral nervous system where it may function in nerve development and/or regeneration.

Unlike many proteases, NEP is not synthesized in an inactive proenzyme form and is not generally regulated by endogenous inhibitors although sialorphin, the peptide product of the *Vcsa1* gene, has been reported to inhibit the enzyme *in vivo*.[26] In most tissues, much of the NEP expression is constitutive but recent demonstration of epigenetic regulation of NEP has opened up the possibility of new approaches to control NEP levels in brain.[3,21] The Aβ peptide is formed by proteolytic processing of the amyloid precursor protein (APP). Another metabolite of APP is its intracellular domain (AICD), a 50–59 amino acid peptide, which can be translocated to the nucleus where it can bind to the NEP promoter (and promoters of some other genes) displacing

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

histone deacetylases which act as transcriptional repressors, and hence upregulating gene expression.[3] This effect seems to be mediated preferentially by the neuronal isoform of APP (APP695).[2] Through a related mechanism, histone deacetylase inhibitors such as trichostatin A and valproic acid, can enhance NEP expression *in vitro* and *in vivo* and may therefore have therapeutic value in Alzheimer's disease.[3]

NEP is an important diagnostic marker in certain forms of childhood leukemia and has also been implicated in cancer progression, particularly of the prostate. NEP gene transcription is androgen-regulated in androgen-responsive tissues. Hence, the downregulation of NEP through hypermethylation of the promoter contributes to androgen-independent progression of prostate cancer because of a reduced ability to metabolize mitogenic peptides, particularly endothelin-1. NEP may also be important in the development of obesity and its expression levels associate with insulin resistance and the metabolic syndrome.[28]

Related Peptidases

Seven NEP-like proteins have been identified in the human genome.[4] Most of these are of unknown biological function, and their substrate specificity is unclear. The most close in similarity to NEP is a peptidase referred to as NEP II in the rat, "soluble secreted endopeptidase" (SEP) or NEP-like 1 (NL1) in the mouse, or MMEL2 (human). The best-characterized NEP homologs are the endothelin-converting enzymes (ECE-1, ECE-2). ECE-1 participates in the conversion of big endothelin to the vasoactive peptide, endothelin-1 (see the chapter on Cardiovascular Peptides and below). ECE-2 probably plays a role as a processing enzyme in the biosynthesis of regulatory peptides and can process such peptides at non-classical processing sites. Mice deficient in ECE-2 have learning and memory deficits and show abnormal responses to morphine and have altered peptide levels in the spinal cord.[17]

NEP II was first identified in mice deficient in ECE-1 as a potential endothelin-processing enzyme.[11] Although it is the most similar peptidase to NEP, it has many distinct properties; for example, it occurs as both a soluble, secreted enzyme and an alternatively spliced form retained in the endoplasmic reticulum. NEP II is particularly localized to neuronal populations in the brain and spinal cord and is also abundant in reproductive tissue—male mice deficient in NEP II show reduced fertility. Originally, NEP II was reported to have a broad repertoire of substrates, similar to those for NEP itself,[12] although its physiological role apart from male fertility, remains unresolved. However, rodent NEP II exhibits a much wider substrate specificity than the human enzyme.[33] For example, only substance P and angiotensin I are hydrolyzed at comparable rates by human NEP and NEP II.[33] The inhibitor thiorphan is also more potent toward NEP than NEP II. A physiological role for NEP II has emerged alongside NEP in the degradation of Aβ peptide. NEP II has now been shown to contribute significantly to Aβ degradation both *in vitro* and *in vivo* in gene knockout and transgenic studies (Fig. 1).[9]

ECE-1, like NEP, is a membrane-bound metalloprotease, which is found at the cell surface and is also present in the trans-Golgi network and endosomal system. The early history of ECE-1 discovery is summarized in Ref. 30. ECE-1 and NEP are both inhibited by phosphoramidon, but ECE-1 is relatively insensitive to the action of thiorphan. ECE-1 is undoubtedly the principal enzyme generating endothelin-1 from its inactive precursor, big endothelin. However, it is capable of hydrolyzing a wide range of biologically active peptides with a specificity broadly similar to that of NEP, although peptides smaller than hexapeptides (e.g. enkephalins) are hydrolyzed poorly, if at all. Among peptides hydrolyzed by ECE-1 are angiotensin I, atrial natriuretic peptide, bradykinin, calcitonin, calcitonin gene–related peptide (CGRP), neurotensin, somatostatin peptides, and substance P. A unique role for ECE-1 in peptide metabolism is its ability to degrade neuropeptides (e.g. CGRP, tachykinins, somatostatin peptides) within endosomes to control receptor recycling.[25] This property is consistent with an acidic pH optimum for the enzyme. ECE-1 can also hydrolyze the amyloid peptides $A\beta_{1-40}$ and $A\beta_{1-42}$ at three major cleavage sites (Fig. 1) and seems to have a physiological role in Aβ metabolism as shown in mice deficient in the peptidase.[7]

In addition to its cardiovascular role ECE-1 is important developmentally, especially for neural crest development, again through its ability to generate endothelin-1. ECE-1 has also been implicated in numerous cancers: thyroid, ovarian, endometrial, lung, colon, and especially prostate. Indeed, it has been shown that siRNA-mediated knockdown of ECE-1 reduces prostate cancer cell invasion in culture.[14]

THE ACE FAMILY (ACE AND ACE-2)

As described in the angiotensin chapter in the Cardiovascular Peptides section of the book, ACE was identified >50 years ago by Leonard Skeggs and colleagues as the enzyme responsible for converting angiotensin I into the vasoconstrictor peptide, angiotensin II (termed hypertensins I and II at that time). In parallel, it inactivates the vasodilator and inflammatory peptide bradykinin, which is the most favorable peptide substrate for ACE, being hydrolyzed approximately 25 times more efficiently than is angiotensin I. Hence, the inhibition of ACE has a powerful antihypertensive effect, and the enzyme has therefore been a major cardiovascular target for many years leading to the development of numerous potent and specific inhibitors (e.g. captopril, lisinopril). The catalytic activity of ACE is predominantly as a "peptidyl dipeptidase" or carboxydipeptidase, removing

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

dipeptides from the C-terminus of a susceptible peptide substrate. However, ACE can act as an endopeptidase in the hydrolysis of some peptides (e.g. both substance P and luteinizing hormone-releasing hormone), although far less efficiently. ACE is a type I integral membrane protein and zinc metallopeptidase with the typical HEXXH zinc-binding motif, which is expressed on the surface of both endothelial and epithelial cells. Mammalian ACE exists as two distinct forms, arising from the use of alternative promoters. The simplest is the testis-specific form of ACE, which is essential for male fertility, and which carries a single zinc-binding and catalytic domain. Elsewhere in the body, the somatic form of ACE has arisen by gene duplication and has two homologous but not identical active sites (N-domain and C-domain sites) with an overall M_r of 150–180 kDa. Hence the two sites differ somewhat in substrate specificity and inhibitor sensitivity. For example, the hemoregulatory peptide Ac-Ser-Asp-Lys-Pro (AcSDKP) and angiotensin-(1-7) are preferred substrates of the N-domain catalytic site whereas angiotensin I is mainly metabolized by the C-domain. A soluble form of ACE exists in serum and other body fluids and is derived from the membrane form of ACE by proteolytic shedding (for a review on ACE see Ref. 13).

Elucidation of the structure of ACE eluded investigators for many years because of the heavy glycosylation of the glycoprotein hindering crystallization. It was not until 2003 that the first X-ray structures of ACE were determined for the testicular form with and without inhibitor (lisinopril) bound.[19] Analysis of the structures has revealed that ACE most closely resembles a neurotensin-degrading zinc endopeptidase known as neurolysin rather than NEP, or carboxypeptidase A, on whose structure the design of ACE inhibitors was originally based. Subsequent structure determination of the N-domain[1] has allowed comparisons of the two active sites and aided the development of domain-selective inhibitors.

An unexpected substrate identified for ACE has been the Aβ peptide with the enzyme apparently cleaving the Asp^7-Ser^8 bond of $A\beta_{1–40,}$[10] although this did not seem to fit with the known specificity of ACE. Subsequently, other sites of cleavage have been identified within Aβ, including the ability of ACE to convert $A\beta_{1–42}$ to $A\beta_{1–40}$, which is more consistent with its carboxydipeptidase specificity[35] (Fig. 1). This cleavage would be beneficial in removing the more toxic $A\beta_{1–42}$ species. This study also showed that treatment of transgenic mice that develop Alzheimer-like pathology with an ACE inhibitor significantly increased the deposition of brain $A\beta_{1–42}$. However, there is no epidemiological evidence that human patients on ACE inhibitor therapy are any more prone to the development of Alzheimer's disease.

The only known functional homolog of ACE in humans was discovered in 2000 through genomics-based approaches.[29] ACE2, like ACE, is a transmembrane glycoprotein but with only a single catalytic site equivalent to the C-domain of ACE. Although ACE2 is highly similar in sequence to ACE around the active site, it displays a somewhat different substrate specificity and is not sensitive to inhibition by ACE inhibitors. ACE2 behaves as a simple carboxypeptidase removing a single C-terminal amino acid from a susceptible substrate. Hence, angiotensin I is converted to angiotensin-(1–9) by ACE2 rather than to angiotensin II (angiotensin-(1–8)). However, ACE2 acts much more efficiently on angiotensin II converting it to the vasodilatory angiotensin-(1–7) and hence serving to counterbalance the actions of ACE (see the section on Cardiovascular Peptides in this Handbook). Angiotensin-(1–7) can also be formed directly from angiotensin I through the action of NEP. Of 126 biologically active peptides tested as ACE2 substrates, only 11 were hydrolyzed by the enzyme, the most efficient being angiotensin II, apelin-13, and dynorphin A-(1-13).[32] Apelin-13 may be a physiologically relevant ACE2 substrate. A number of potent and specific ACE2 inhibitors have been reported, of which the first were the non-peptide inhibitor, MLN-4760, and a peptide identified from phage library screening, DX600.

INSULIN-DEGRADING ENZYME (INSULYSIN, IDE)

Insulin-degrading enzyme (IDE, insulysin) is another zinc endopeptidase involved in the degradation of biologically active peptides although it differs substantially from the ACE and NEP families in location and catalytic mechanism. IDE was originally isolated as an enzyme regulating plasma levels of insulin, hence its name, and is therefore seen as of potential significance as a therapeutic target in diabetes. In addition to insulin, IDE can hydrolyze a number of biologically active peptides including insulin-like growth factor II, tumor growth factor-α, and atrial natriuretic peptide.[27] Another important peptide substrate of IDE is the amyloid precursor protein intracellular domain, AICD, which acts as a transcriptional regulator controlling the expression of NEP and some other genes as discussed above.[3] IDE also degrades somatostatin, a neuropeptide that declines in aging and Alzheimer's disease.[5] Unlike the other peptidases described above, IDE is mainly a soluble cytoplasmic enzyme although it also exists as a secreted form.[34] There is also a splice-variant of IDE targeted to mitochondria. The mechanisms responsible for the subcellular targeting and secretion of IDE remain unresolved. The secreted form of IDE seems to play a role in the metabolism of Aβ peptide, was the first such peptidase identified and remains as a well validated Aβ-degrading enzyme from both *in vitro* and *in vivo* studies, including the use of transgenic approaches.[18] Hence, IDE is also seen as a potential target for upregulation in the treatment of Alzheimer's disease.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

IDE differs from ACE and NEP in possessing an inverted zinc-binding motif (His-Xaa-Xaa-Glu-His) and shows unusual allosteric behavior with small peptides. The structural solution of IDE[27] has shown the active site to be enclosed within a flexible clamshell-like structure and ATP is required to facilitate the opening of the catalytic chamber. Until recently, there were no potent and specific IDE inhibitors to facilitate studies of the role of the enzyme in the metabolism of biologically active peptides but rationally designed inhibitors based on the structural information have now been produced which confirm the role of IDE in regulating insulin signaling.[15] Such inhibitors may well have potential for the treatment of type 2 diabetes.

PROLINE-DIRECTED PEPTIDASES

Numerous biologically active peptides are partially protected from exopeptidase degradation by the presence of highly conserved prolyl residues especially at or near to the peptide N- and C-termini. Hence, very specific peptidases are required to initiate their metabolism because the conformational constraint imposed by the cyclic imino structure of proline hinders proteolysis.[31] The Xaa-Pro sequence is present at the N-terminus of >100 biologically active peptides or proteins, including peptide hormones, neurotransmitters, immunopeptides, and kinins. The best-characterized prolyl peptidase is the cell-surface serine peptidase, dipeptidyl peptidase IV (DPP IV) which, as its name suggests, hydrolyzes a dipeptide from the N-terminus of peptides provided that the second residue is a proline (or less favorably an alanine or serine). DPP IV is therefore one of only a few enzymes that have specificity directed toward prolyl residues. DPP IV was originally described as a rat liver enzyme releasing naphthylamine from Gly-Pro-2-naphthylamide and postulated to be involved in collagen metabolism. However, it was unable to cleave collagen and its physiological role remained unclear. Subsequent studies showed it to be an abundant peptidase of the renal and intestinal brush borders although it is present on most cell types. It is identical with the T cell-activating antigen (CD26) and, on T cells, it associates with the immunodeficiency-related protein adenosine deaminase via a cluster of charged amino acid residues. It is a type II membrane protein with only a short cytoplasmic tail (six residues) with the bulk of the enzyme facing the extracellular space where it can participate in the metabolism of a diverse range of biologically active peptides. DPP IV is also found as a soluble protein in serum whose levels are altered in cancer and some other diseases. The soluble form is most probably shed from the membrane-bound form although the protease responsible for this process is unknown. The enzyme is discussed in further detail, especially in relation to the immune response in this Handbook (see the chapter in Immune/Inflammatory Peptides section).

DPP IV is a typical serine peptidase, and a member of the "prolyl oligopeptidase" family, possessing the catalytic triad residues Ser/Asp/His (in rat $Ser^{631}/Asp^{709}/His^{741}$) and the enzyme functions as a homodimer and can also form functional tetramers. The crystal structure reveals that each subunit consists of two domains, an α/β-hydrolase domain and an eight-bladed β-propeller domain[23] with the catalytic site located in a cavity formed between the two domains both of which participate in substrate/inhibitor binding. The human DPP IV gene consists of 26 exons and, unusually among serine proteases, the nucleotides that encode the active site sequence (Gly-Xaa-Ser-Xaa-Gly) are split between two exons. DPP IV may play a digestive role in the digestion and uptake of prolyl-containing peptides. Most interest has focused, however, on the role of the enzyme in metabolizing biologically active peptides. In this capacity, it can either generate active peptide from a precursor, convert one active peptide to another with different receptor specificity (e.g. peptide YY or neuropeptide Y), or inactivate peptides. It is the latter role that has allowed the development of DPP IV inhibitors as the first new therapeutic class of orally active antihyperglycemic drug for type 2 diabetes mellitus for a long time through the ability of DPP IV to inactivate incretin hormones (glucagon-like peptide-1; glucose-dependent insulinotropic peptide).[6] Almost 50 biologically active peptides have been identified as substrates for DPP IV most of which have the N-terminal Xaa-Pro sequence, but some have Xaa-Ala or less commonly Xaa-Ser.

Another cell-surface peptidase capable of hydrolyzing peptides with a penultimate N-terminal prolyl residue is aminopeptidase P (APP2 to distinguish it from a cytosolic prolyl aminopeptidase, APP1). The enzyme removes the N-terminal residue leaving a free prolyl residue at the N-terminus. Examples of good substrates include bradykinin and neuropeptide Y. The specific inhibitor, apstatin, can reduce blood pressure by potentiating the action of bradykinin. A prolyl residue in the third position of a substrate renders the peptide resistant to the action of DPP IV (e.g. bradykinin, Arg-Pro-Pro-…). APP2 is a zinc peptidase and is unusual among cell-surface peptidases in being anchored to the cell surface via a glycosyl-phosphatidylinositol membrane anchor.

Unlike DPP IV and APP2, which are exopeptidases, another prolyl peptidase functions as an endopeptidase and can hydrolyze a wide range of small (<30 amino acids) biologically active peptides, at least *in vivo*. This is a serine peptidase originally known as postproline cleaving enzyme or proline endopeptidase, which cleaves peptides on the carboxy-terminal side of prolyl residues. It is now known as prolyl oligopeptidase (POP) and was originally implicated in oxytocin metabolism. Other potential substrates include substance P, angiotensins, bradykinin, β-endorphins, neurotensin, and thyrotropin releasing hormone (TRH). To evaluate the role of POP, numerous potent and relatively specific

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

small molecule inhibitors have been developed, which exhibit a number of interesting physiological properties, for example, in enhancing memory, which is perhaps consistent with vasopressin also being a substrate for the enzyme. There are many reports that POP may have a role in psychiatric and neurodegenerative diseases although it does not seem to play a role in Aβ metabolism.[22] The evidence for a physiological role for POP in peptide degradation is, in most cases, lacking (see Ref. 8 for review) and a topological problem is that POP is a cytosolic enzyme and therefore unlikely to interact with circulating peptides. Another related proline-specific peptidase (acylpeptide hydrolase), which can be secreted from neuronal cells, may however contribute to Aβ metabolism.

Two specific areas where POP may also participate are in inositol phosphate signaling, and in angiogenesis and hence progression of malignancies. POP is able to enhance inositol phosphate signaling and cell sensitivity to lithium acting via the enzyme inositol polyphosphate phosphatase and hence regulate gene expression. POP is also able to cleave thymosin-β4 to generate the hemoregulatory peptide AcSDKP, itself a substrate for the N-domain of ACE (see above). Both AcSDKP and POP activity are substantially increased in certain malignancies.

CONCLUSIONS

Unlike the high specificity of ligand–receptor interactions, peptidases that degrade biologically active peptides tend to have multiple substrates, and hence, relatively few are needed to control the circulating levels of the multiplicity of such peptides described in this Handbook. They mostly exist as cell-surface ectoenzymes, or in a soluble, secreted form. The properties of some of the key ones, especially of the neprilysin family, have been described in this chapter, as well as methods for manipulating their activity. Structures are now available for most of these peptidases allowing rational design of potent and specific inhibitors. The promiscuity of these peptidases might suggest that inhibiting their activity could have undesirable side effects. However, in practice, this does not seem to be the case, as best exemplified by ACE inhibitors. NEP inhibitors also have a role to play in many conditions, although their chronic use could potentially lead to a build-up of brain Aβ peptide. There still remain numerous orphan peptidases, however, for which their physiological peptide substrates remain to be identified. Comparative *in vivo* peptidomic approaches in animals deficient in a particular peptidase now provide a powerful tool to categorize physiological substrate profiles for individual enzymes. We can expect to have a much clearer picture of the roles of peptidases in the metabolism of biologically active peptides in the next few years.

Chapter 242

Peptidomics of Mice Lacking Peptide Processing Enzymes

Jonathan H. Wardman and Lloyd D. Fricker

ABSTRACT

Neuropeptides and most other biologically active peptides are produced from precursors through limited proteolysis. The major endopeptidases implicated in neuropeptide biosynthesis include prohormone convertase 1 (PC1, also known as PC3) and prohormone convertase 2. After endopeptidase cleavage, most peptides require the action of carboxypeptidase E to remove the basic C-terminal residues. Each of these various peptide-processing enzymes has been studied by purification and characterization of the activity with a variety of peptide substrates. An additional approach to study these enzymes has involved the generation of mice lacking each enzyme, by gene disruption and/or by mutation, and then the analysis of this disruption on the peptidome of the mouse brain. These peptidomic approaches are described in this chapter.

INTRODUCTION

For an enzyme to be considered a peptide-processing enzyme, it must meet several criteria. First, the enzyme must be expressed in the tissues where the neuropeptide is produced, and within that tissue it must be present in the correct subcellular compartment. For neuropeptide biosynthesis, this means that the enzymes should be present within the neuroendocrine system and localized to the secretory pathway, specifically the immature and mature secretory granules. Second, the enzyme must have the correct properties when purified and tested with substrates. These properties include pH optima and ion regulation, and substrate specificity. Finally, conclusive proof that the enzymes function in peptide processing requires the demonstration that elimination of enzyme activity has an effect on peptide levels. Thus, analysis of peptides in knockout mice, or in mice that lack enzyme activity due to a genetic mutation, is a critical step in defining each enzyme's function.

The major processing enzymes in the production of most biologically active neuropeptides are the prohormone convertases (PCs, which are also known as proprotein convertases), and carboxypeptidase E (CPE). There are two PCs that play a major role in neuropeptide production; these are PC1 (which is also known as PC3, and abbreviated as PC1/3) and PC2 (described in detail in other chapters in this section of the book). Other PCs that contribute to the production of some neuropeptides include furin and related enzymes that are present in the trans-Golgi network. However, furin and most other trans-Golgi enzymes are excluded from the secretory granules where the majority of neuropeptide precursor processing takes place. For example, the trans-Golgi enzyme carboxypeptidase D can participate in the processing of some neuropeptide precursors, but most of the carboxypeptidase processing is believed to occur through the action of CPE, which is present in the maturing secretory granules. Some bioactive peptides require a C-terminal amide group for biological activity; this is catalyzed from precursors containing a C-terminal glycine residue via the action of peptidylglycine-alpha-amidating monooxygenase (PAM). Many bioactive peptide hormones require this modification, but fewer neuropeptides are C-terminally amidated.

Knockout mice for PC1/3 and PC2, CPE, and PAM have been created and characterized using a variety of techniques.[4,6,9,27] In addition, mice lacking CPE activity because of a naturally occurring mutation have been studied.[15] Of these mice, the PAM knockout mice are embryonic lethal, thus limiting the analysis; all others are viable. The individual phenotype of each knockout or mutant line is described below, in the section describing the results of the peptidomic analysis. Each of these enzymes is also the subject of a separate chapter in this section of the handbook.

QUANTITATIVE PEPTIDOMIC TECHNIQUES

Peptidomics is defined as the analysis of peptides within a biological sample. In general, peptidomics approaches are similar to proteomics techniques, except that most peptidomic studies do not treat the samples with digestive enzymes that are usually included to make the analysis of proteins easier (by converting the proteins into peptides). By avoiding the digestive enzyme step, the endogenous forms of the peptides can be identified by mass spectrometry. Technically, it is not possible to detect all peptides that are present in a sample due to the limitations of the detection method. In most biological samples, the range of peptide levels from the most abundant to the least abundant can span many orders of magnitude, while the range of typical mass spectrometers is only a few orders of magnitude due to problems associated with background and ion suppression. In addition, some peptides do not ionize well. Peptides with no positively charged groups will not be detected in the positive-ion mode of the mass spectrometer, which is more commonly used and more sensitive than the negative ion mode. Some biologically active peptides, such as thyrotropin releasing hormone, are not detected by peptidomics studies, presumably because of the size (three amino acids).

Despite these limitations, peptidomics is ideally suited for the analysis of the peptidome of mice lacking peptide-processing enzymes. In particular, the use of quantitative peptidomics techniques to compare the relative levels of peptides in mutant mice versus wild-type littermates provides an ideal system to examine the biological role of the peptide-processing enzymes. Peptidomics studies can rapidly detect hundreds of peptides in a single experiment and generally reveal the precise forms of each peptide.[1,8,10,19,21] This is in contrast to radioimmunoassays (RIAs) that require considerable time for the generation and characterization of the antisera, and these antisera are rarely specific for a single form of a peptide and usually detect N- and/or C-terminally extended forms. Additional studies are required to verify that the peptide detected by RIA corresponds to a particular form of the peptide. By contrast, the mass of a peptide determined by modern mass spectrometers can be determined within a fraction of a Dalton, much less than the differences between forms of a peptide due to altered processing.

A variety of quantitative approaches have been used to compare the relative levels of peptides among two or more samples. One approach uses isotopic labels in which a peptide-modifying reagent is tagged with different numbers of stable isotopes. Our laboratory has tested a variety of reagents that modify amine groups; most peptides contain one or more free amines, and so this is a convenient way to label the most number of peptides. The ideal labels for quantitative peptidomics are those based on trimethylaminobutyric acid (TMAB), with the amine-reactive form of the label produced as the N-hydroxysuccinimide (NHS) ester (Fig. 1). It is possible to synthesize the TMAB tags in five isotopic forms that differ by 3 Da between each form; this enables comparison of up to five different samples in a single experiment.[14] This technique has been used to examine the peptide levels in mice lacking peptide-processing enzymes, relative to the levels of these peptides in control wild-type mice.[22–24]

CPE-DEFICIENT MICE

Mice with a naturally occurring point mutation within the CPE gene were initially detected in the 1970s, although it took decades before the genetic analysis was performed and the mutation identified. The mutant mouse was named *fat* because of the increased adiposity of these mice. Subsequent to the identification of *Cpe* as the gene containing the mutation, the mouse was renamed $Cpe^{fat/fat}$.[15] These mice also show greatly impaired reproduction and are generally sterile due to an inability to mate properly. Using RIAs, many peptides were found to be greatly affected by the mutation of CPE.[7] In most cases, the mature form of the peptide was present at much lower levels in the $Cpe^{fat/fat}$ mouse brain or pituitary, compared with that of wild-type mouse tissue. Exceptions to this are mainly the C-terminal prohormone peptides, which do not require CPE for biosynthesis. In a few situations, the peptide-processing intermediates were examined by RIA in the $Cpe^{fat/fat}$ mice and found to be greatly elevated. However, these studies were difficult to do because most antisera did not readily distinguish between the form of the peptide containing the C-terminal basic residue (i.e. the processing intermediate) and the form lacking this residue (i.e. the mature form). Therefore, peptidomics analysis of $Cpe^{fat/fat}$ mouse brain and pituitary is an ideal way to examine the relative levels of hundreds of neuropeptides and the peptide-processing intermediates.

The TMAB labels were used for peptidomic analysis of relative levels of peptides in $Cpe^{fat/fat}$ mice, compared with that in wild-type mice. In addition, to comparing the variability of these peptides among replicates of wild-type mice, controls were performed in which peptidomic analysis of groups of wild-type mice was compared with that of other wild-type mice. This analysis showed low variability of the peptides among control groups, in contrast to the difference between peptide levels in $Cpe^{fat/fat}$ mice versus wild-type mice.[23] To visualize these differences, summary plots of the peptidome were generated from the previously published data. For these plots, the raw data was plotted, with each dot corresponding to the ratio for a peptide observed in one of the experiments. This ratio was either the comparison of one wild-type mouse sample to another wild-type mouse sample (Fig. 2, top panels) or the comparison of one $Cpe^{fat/fat}$ mouse sample with a wild-type mouse

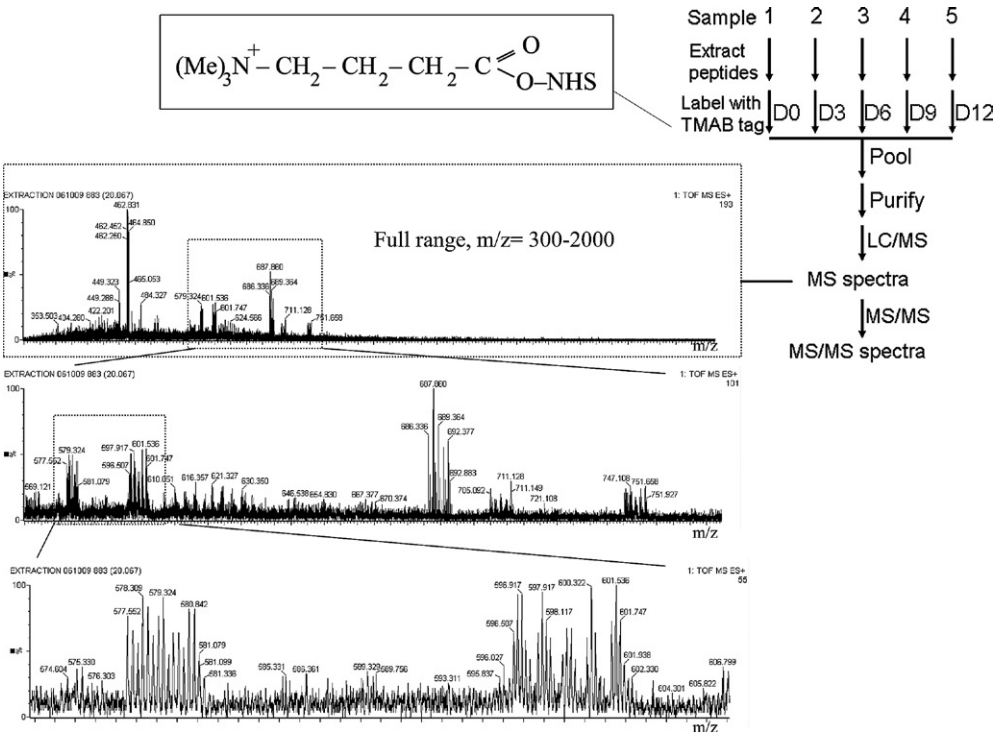

FIGURE 1 Quantitative peptidomic scheme using trimethylaminobutyric acid (TMAB) tags activated with *N*-hydroxysuccinimide (NHS). The synthesis of the TMAB labels and incorporation of these labels into the peptides have been recently described.[14] In general, the labeling is done early in the process of peptide extraction and purification so that losses of peptide during purification steps do not contribute to variation in the peptide levels between samples. Once peptides are labeled and pooled, the similar chemical nature of the different isotopic tags means that all forms will show equal recoveries on the subsequent purification steps. Analysis is typically performed by running the samples on liquid chromatography (HPLC) followed directly by on-line electrospray mass spectrometry. The resulting mass spectra show groups of peaks that differ by 3 Da, each representing a different form of the TMAB label. The intensity of each of these peaks reflects the levels of peptide in the original samples, thus providing a relatively rapid measurement.[14] The mass spectrometer also provides sequence information of peptides selected for fragmentation and further mass spectrometry of the product ions, which are referred to as MS/MS spectra. From these MS/MS spectra, it is often possible to determine the sequence of the peptide. Thus, the quantitative peptidomic approach provides relative quantification and identification of hundreds of peptides in a single sample. Figure copyright 2011, Lloyd Fricker, reprinted with permission.

sample (Fig. 2, bottom panels). Each experiment was run with multiple replicates, and with many brain regions; for original data, see supplemental tables with the original published report.[23] To generate the summary plots shown in Fig. 2, all ratio values for a particular comparison (i.e. wild-type versus wild-type, or *Cpe*$^{fat/fat}$ versus wild-type) were combined into a single column on a spreadsheet. If a peptide was found in multiple replicates, or in different brain regions, each time the peptide was found, it appeared in the spreadsheet. Then, the combined list of all ratio values was sorted from low to high and plotted. The *y*-axis is the ratio of each data point, while the *x*-axis represents the rank order of that peptide in the replicate.

The summary plots show the relative low variability when peptides are compared among different wild-type mice, with most of the ratio values around the theoretically expected 1.00 (Fig. 2, top). This is true both for peptides derived from secretory pathway proteins (i.e. neuropeptide precursors) as well as peptide derived from cytosolic or mitochondrial proteins (Fig. 2, top left versus top right). By contrast, the summary plots for peptides in the *Cpe*$^{fat/fat}$ mice, relative to the wild-type mice, show that the peptides derived from secretory pathway proteins are greatly affected by the absence of CPE activity (Fig. 2, bottom left). Approximately one-third of the peptides are not detected in the *Cpe*$^{fat/fat}$ mice (levels <10% of the wild-type level; this is the cut-off for the peptidomic analysis because of the detection limit for the typical peptide). These peptides represent CPE products that require this enzyme for the production of the majority of the peptide.[23] Another one-third of the peptides show ratios <1.0, but above the lower detection limit of 0.1; these peptides probably correspond to products of CPE that are also cleaved by CPD earlier in the secretory pathway.[23] Thus, the levels of these peptides decrease in the CPE-deficient mice, but they are still detected, reflecting the contribution from CPD. A large number of peptides are greatly elevated in the *Cpe*$^{fat/fat}$ mice, with ratios ≥10 indicating a 10-fold increase or more.

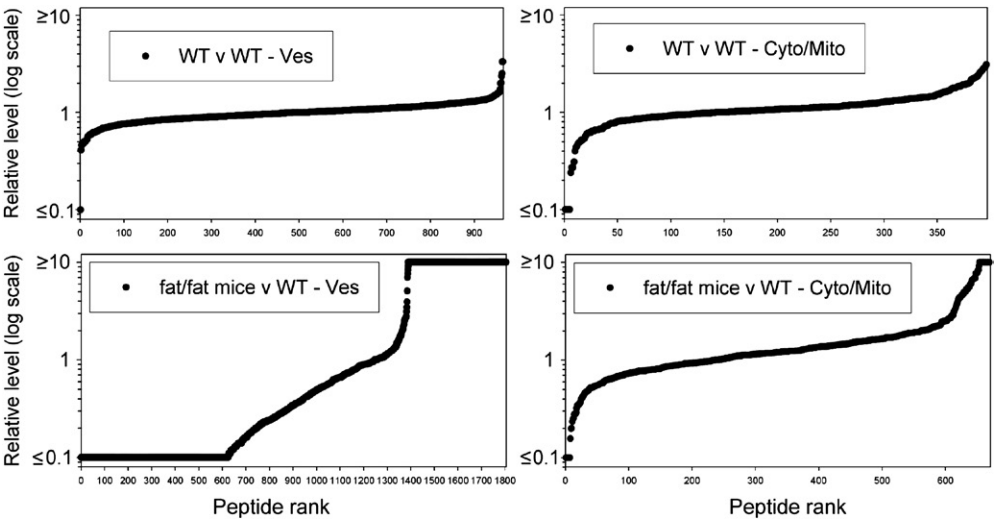

FIGURE 2 Summary plots of the peptidome of mouse brain. Top panels: Levels of peptides in one group of wild-type (WT) mice were compared with the levels of another group of WT mice to determine the general variability of the peptides among groups of mice. Bottom panels: Levels of peptides in *Cpe*$^{fat/fat}$ mice were compared with the levels in WT mice. Peptides were identified by MS/MS analysis. Plots of peptides from secretory pathway proteins (such as neuropeptide precursors) are shown in the left panels, and peptides derived from cytosolic or mitochondrial proteins are shown in the right panels. To generate these plots, the ratio of peptide levels, relative to the control group, were combined into a single column in a spreadsheet, sorted by relative order from lowest to highest, and then plotted. The *y*-axis represents the relative level (log scale), with the lowest values capped at 0.10 and the highest capped at 10 (i.e. any value <0.10 or >10 was plotted as 0.10 and 10, respectively). The *x*-axis for these plots represents the relative order of the peptide after sorting. Data were previously published.[13,23] Abbreviations: Ves, secretory pathway (vesicles); Cyto/Mito, cytosolic and/or mitochondrial. Copyright Lloyd Fricker, 2011; reprinted with permission.

Most of these peptides contain C-terminal Lys and/or Arg residues, and these peptides are not detected in the wild-type mice. Only a few peptides showed no change or a moderate increase in the *Cpe*$^{fat/fat}$ mice; these are generally C-terminal fragments of the prohormone precursor that do not require CPE for their biosynthesis.[23]

PC KNOCKOUT MICE

The prohormone convertases have been studied using many *in vitro* techniques, including purified recombinant enzymes, viral overexpression techniques, and several different neuroendocrine cell lines, including AtT-20 mouse adrenal corticotroph cells, PC12 rat pheochromocytoma cells, and others.[2,3,12,25,26] Despite the observation that both PC1/3 and PC2 cleave peptides at multibasic sites, each enzyme has its own preferences.[11,18,22] These peptidases are also expressed at varying levels in different neuroendocrine tissues, which can lead to tissue specific processing of a single precursor. Although *in vitro* enzymatic and cell biological methods are effective for understanding the basic properties of the prohormone convertases, studies on mice lacking the enzymes are needed to complement the *in vitro* studies.

The PC1/3 null mice exhibit severe developmental defects including abnormal growth, a phenotype probably resulting from incomplete processing of growth hormone-releasing hormone (GHRH).[27] PC1/3 mice are hyperproinsulinemic, though they exhibit normal glucose tolerance, likely due to the insulin-like effect of proinsulin.[27] Initial studies in the effects of the loss of PC1/3 on the mouse brain peptidome were performed using RIA. These studies reveal an essential role for PC1/3 in the processing of several mouse brain peptides, including those derived from the enkephalin precursor. These RIA studies reveal peptides processed specifically by PC1/3 for which PC2 could not compensate.[17]

Quantitative peptidomic techniques were used to compare the processing of peptides in the PC1/3 null mouse brain relative to their wild-type counterparts.[22] These studies used the stable isotopic TMAB tags for quantitative analysis and found that the lack of PC1/3 causes changes in the levels of many neuropeptide precursors. Among the peptides affected are some putative specific substrates of PC1/3, which show large decreases despite the presence of PC2. This study also reveals many peptides that are unchanged despite the lack of PC1/3, indicating that they are produced by another enzyme.[17] Further peptidomic studies performed using PC1/3 null mice examined the function of PC1/3 across several brain regions, including the hypothalamus, the amygdala, and the striatum, using multiple isotopic tags. One of the goals of the peptidomics study of PC knockout mice is to better understand the nature of the cleavage site of PC1/3 and to determine the amino acid sequences characteristic of specific PC1/3 substrates.[17] By observing the amino acids frequently found in the cleavage site of those peptides affected by the lack of PC1/3, and comparing those residues with those observed in peptides

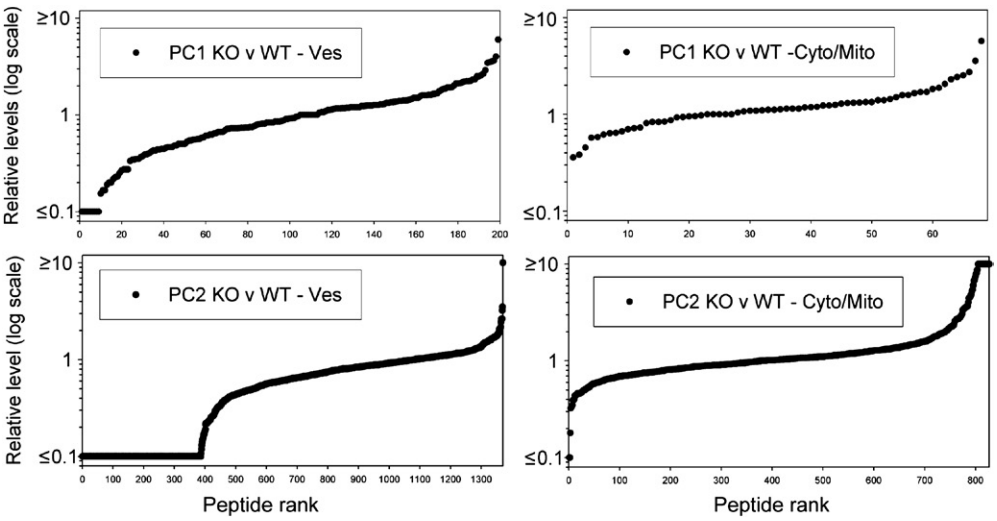

FIGURE 3 Summary plots of the peptidome of mouse brain, comparing PC1/3 knockout mice to WT mice (top panels) or PC2 knockout mice to WT mice (bottom panels). Both secretory pathway peptides (left) and peptides derived from cytosolic or mitochondrial proteins (right) are indicated. See Fig. 2 legend for explanation of the details of the plot and abbreviations. Data were previously published.[22,24] Copyright Lloyd Fricker, 2011; reprinted with permission.

specifically cleaved by PC2, it is possible to glean predictive sequence information for cleavage by each endopeptidase. This information in turn is useful in determining where and when in the secretory pathway the peptide is cleaved, both within the secretory pathway and among different cell types expressing different endopeptidase cohorts in the multiple brain regions examined.

These PC1/3 knockout studies reveal a few peptides that show a large decrease relative to wild-type mice (Fig. 3, upper left panel). These peptides that show a large decrease are presumably specific products of PC1/3 cleavage, as PC2 cannot make up for the lack of PC1/3 in these tissues. Many secretory pathway peptides are unaffected by the knockout of PC1/3, or only slightly affected, and this indicates that the enzyme does not have a unique role in the production of these peptides (Fig. 3, upper left panel). There are also several peptides that show an increase in the PC1/3 knockout animals, these probably being substrates of PC1/3 cleavage which increase because of the absence of PC1/3. Peptides derived from proteins found in the cytoplasm and mitochondria compartments show relatively low variability, with the majority of these peptides having a ratio value of approximately 1.00 (Fig. 3, top right panel), much like the wild-type vs. wild-type comparison (Fig. 2, top right panel).

PC2 null mice have also been studied to determine the specific contribution of this endopeptidase to peptide processing. The PC2 null mice exhibit retarded growth, despite being indiscernible from wild-type littermates at birth.[5] These mice also exhibit chronic fasting hypoglycemia and are deficient in circulating glucagon.[20] Quantitative peptidomic studies were performed with the PC2 null mice using the quantitative peptidomic technique previously described. In this case, hypothalami from wild type and PC2 knockout mice were compared using stable isotopic TMAB tags. Peptides from many secretory pathway neuropeptide precursors were identified.[16] Many of the peptides detected in wild-type mice are either undetectable in the PC2 knockout mice, or are present at levels ranging from 25 to 75% of wild-type levels (Fig. 3, lower left panel). The specifics of cleavage by PC2 were further characterized by comparing the residues most frequently found in the cleavage site of the incompletely processed peptides. The cleavage site residues in these substrate peptides must therefore be specifically cleaved by PC2, otherwise other prohormone convertases would have cleaved them in the absence of PC2. These comparative studies suggest that sequences with a Trp, Tyr, and/or Pro in the P1′ or P2′ position, or a basic residue in the P3 position, are particularly good PC2 substrates, versus other secretory pathway enzymes.[16] These studies were early indicators of the physiological specificity of propeptide cleavage by one endopeptidase versus another. Later, further quantitative peptidomic studies were performed with the PC2 null mice to better understand the physiological actions of PC2 in multiple brain regions, including the prefrontal cortex, hypothalamus, striatum, hippocampus, thalamus, and amygdala.[24] Like the previous studies, many of the peptides identified are undetectable in the tissues of the PC2 knockout mice, and another large percentage are significantly decreased. Only three peptides are increased significantly in the tissues of the knockout mice (Fig. 3, lower left panel).[24] This study serves to reinforce the broad role of PC2 in the processing of secretory pathway propeptides, but still maintains its redundancy with PC1/3 in many tissues. Cleavage

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

site analysis reveals similar sequence preferences for PC2 over other secretory pathway peptidases as observed in the hypothalamus across all tissues examined in this study.[24]

CONCLUSIONS

Taken together, quantitative peptidomic studies provide an important level of analysis that complements the other approaches to study enzymes and their peptide substrates. By themselves, the studies examining peptides in tissues of mice lacking processing enzyme activity do not provide a complete picture because of several issues. If, for example, the levels of a peptide change in the knockout mice, one interpretation is that the missing enzyme is responsible for the production of that peptide. Alternatively, it is possible that the change in peptide results from an indirect effect, where the missing enzyme affects a system that in turn causes the peptide to change. Likewise, if a peptide does not change in the knockout mice, one interpretation is that the enzyme does not participate in the production of that peptide. Alternatively, it is possible that the enzyme does play a role in the production of the peptide, but because of redundancy in the system, the absence of any one enzyme does not show a measurable change. Thus, although the *in vivo* analysis is important, it needs to be carefully interpreted and considered together with the *in vitro* studies on the capability of the purified enzymes to cleave peptides. Despite the caveats, the use of quantitative peptidomics to detect, quantify, and identify the peptides is a great advantage over conventional approaches for the detection and quantification of neuropeptides (such as RIAs) because of the large number of peptides that can simultaneously be measured with peptidomics, and the accuracy of the identifications based on precise mass values that distinguish between related forms of peptides, as occurs when processing enzymes are absent.

Chapter 243

Peptidomics Strategy for Discovering Endogenous Biologically Active Peptides

Kazuki Sasaki and Naoto Minamino

ABSTRACT

Assisted by nanoflow liquid chromatography, mass spectrometry (MS) permits a large-scale identification of endogenous peptides on a chromatographic timescale for an organism whose genome sequence is available. In analogy with other "-omics" disciplines, a systematic study of such peptides is collectively referred to as peptidomics. Although MS seems to be an appealing technique for identifying previously uncharacterized peptide hormones or neuropeptides, comprehensive peptidomics of brain or endocrine tissues does not lead to a fruitful outcome. The rapid metabolism of bioactive peptides should also be considered. This chapter describes the concept of "secretopeptidome" that we have proposed, and some of our peptidomic strategies to discover mammalian biologically active peptides through secretopeptidome mining. Functions of the novel bioactive peptides identified with this approach will also be discussed.

MASS SPECTROMETRY IN ENDOGENOUS PEPTIDE RESEARCH

Discovery of biologically active peptides, whatever approaches are taken, remains a great challenge in life science. Aside from an in silico search for peptides homologous to biologically active peptides, most studies have involved activity-guided purification using specific biological or biochemical assays in conjunction with liquid chromatography (LC), and Edman degradation for sequence determination and subsequent cDNA cloning with established molecular biology techniques. In the 1990s, mass spectrometry (MS) was adopted to profile peptides in biological samples, where in most cases only dominant peaks were identified on the basis of the measured mass values corresponding to known biologically active peptides.[6] The impact of MS to differentiate peptides by one mass unit was acknowledged but was not suitable to discovery-oriented approaches at that time.

The introduction of mass spectrometers capable of tandem mass spectrometry (MS/MS) inspired peptide researchers in many aspects. By using genome sequence data, MS/MS provides digital information that helps to identify a peptide sequence, along with the identification and localization of accompanying posttranslational modifications. There are obvious advantages of MS/MS over conventional methods; we need not remove peptide N-terminal blocking or purify a peptide of interest to near homogeneity. Earlier this century, the term peptidomics was advocated to study the full complement of endogenous peptides, or the peptidome.[5,25] Initial studies intended for biomedical or agrochemical applications have been published.[5,22,25,26] Peptidomics absolutely requires that every endogenous peptide be analyzed in its native form to understand how the peptide is generated through precursor processing and then degraded by proteases/peptidases. The analysis of peptides present in complex mixtures is promoted by LC–MS/MS, which has become a key technology indispensable to peptidomics. With the available genome information, LC–MS/MS elucidates hundreds of peptide sequences of a target organism on a chromatographic timescale. In current peptidomics laboratories worldwide, LC–MS/MS is conducted on a nanoflow LC column connected on-line with a high-performance tandem mass spectrometer. The state-of-the-art mass spectrometers enable mass measurement within a mass accuracy of 2 ppm in a routine LC–MS/MS experiment[23] (Table 1).

Early peptidomics studies concerned the identification of endogenous peptides in the rat and mouse hypothalamus and pituitary, but they suffered from an overwhelming number of peptide fragments derived from cytosolic proteins or major contaminating proteins like albumin and hemoglobins. Most of these peptides were produced as a result of protease activation that occurs postmortem and/or during tissue extraction and sample preparation.[15] Some solutions to this problem include heat denaturation such as focused

LC–MS/MS for sequence identification was performed on an LTQ-OrbiTrap mass spectrometer, with a mass accuracy within 2 ppm. Peptides are listed in elution order. Mr(obsd), observed monoisotopic mass value of the peptide; Mr(calc), theoretical monoisotopic mass value of the indicated sequence. The N-(N-term) and C-terminal (C-term) flanking 10 amino acids (columns 4 and 6) are shown and marked as follows: closed boxes with white letters indicate typical PC1/3 or PC2 consensus cleavage sites containing consecutive basic residues or canonical C-terminal amidation motifs; dark gray boxes, PC1/3 or PC2 consensus cleavage sites containing basic residues at P4, P6, or P8 positions; pale gray boxes, sites having basic residues at P1 but not at P2, P4, P6, or P8 positions. "Signal" indicates that the peptide is adjacent to its signal sequence. "C-term" indicates that the peptide C-terminus is the end of the precursor. Ac-, N-terminal acetylation; -NH_2, C-terminal amidation; <Q, pyroglutamic acid. Oxidized methionines are underlined in column 5. CGRP, calcitonin gene-related peptide; CT, calcitonin; GRP, gastrin-releasing polypeptide; PC2, prohormone convertase 2; SCG2, secretogranin II; SCG3, secretogranin III; SST, somatostatin; TMSB4X, thymosin β-4 X-linked; TMSB10, thymosin β-10. "CT/CGRP" indicates that the peptide is shared by CT and CGRP precursors.

microwave irradiation of the rodent brain[4,26] or heat stabilization of tissues after sampling.[27] In so doing, nonsecretory peptides identified in the tissue peptidome were decreased in number.[8] Still, most of the identified peptides turned out to be fragmented peptides derived from highly expressed neuropeptide precursors, far from tracking the processing sites of known neuropeptides described to date. This results from the limited performance of MS and MS/MS technologies; relatively abundant and/or smaller peptides (<2000 Da) are more readily detected by MS, and larger ones (>3500 Da) are difficult to identify by MS/MS regardless of signal intensity. Owing to the advances in mass spectrometers, however, the upper mass ceiling that is accessible to MS/MS has now stretched well beyond 3500 Da to encompass larger peptides. In any case, it had become clear that additional strategies would be required to discover biologically active peptides. Given that such peptides are of a secretory nature, an important lesson from the early studies is that we should investigate analytes that are believed to be least contaminated with non-secretory peptides. From here on, we will describe in chronological order how we have improved our peptidomic strategy and the newly identified peptides over the course of our study.

PEPTIDOMIC IDENTIFICATION AND BIOLOGICAL VALIDATION OF NOVEL C-TERMINALLY AMIDATED PEPTIDES: NEUROENDOCRINE REGULATORY PEPTIDES (NERPs)

Nearly half of the biologically active peptides found in the nervous and endocrine systems possess a C-terminal alpha-amide group.[7] This posttranslational modification has long been considered a hallmark of such peptides, because for many of them it is important or essential for bioactivity.[10,19,28,32] In 1978, Tatemoto and Mutt developed a chemical derivatization method to identify C-terminally amidated peptides, leading to the discovery of galanin, peptide tyrosine tyrosine, neuropeptide Y, peptide histidine isoleucine,

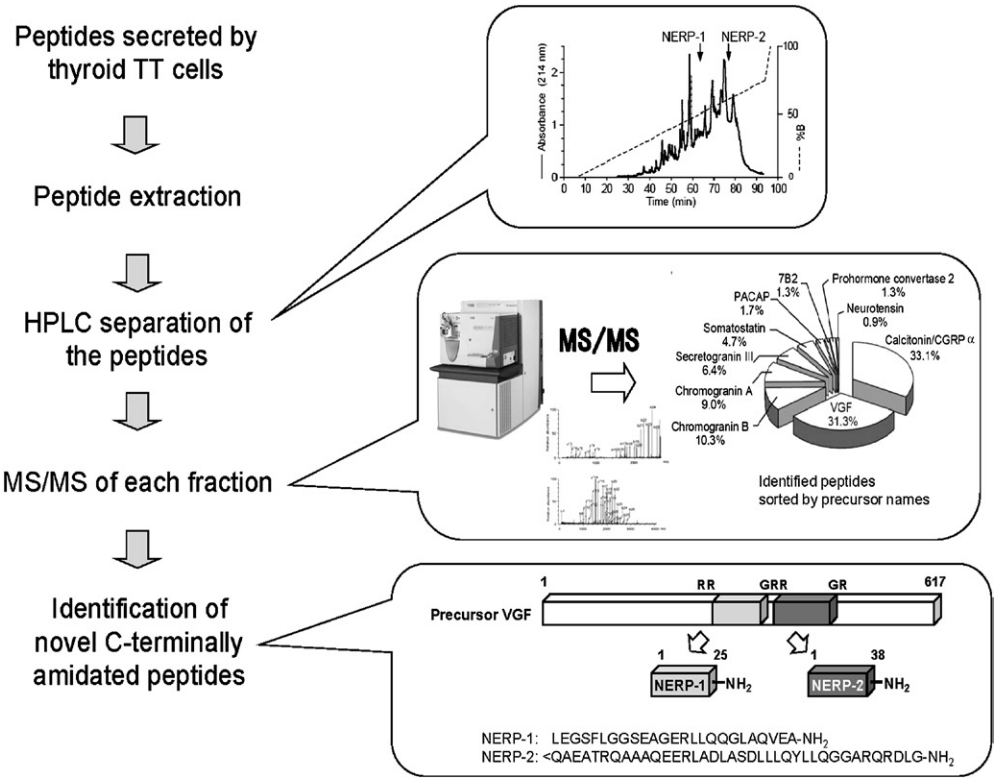

FIGURE 1 MS/MS identification of NERPs. Peptides secreted by the human medullary thyroid carcinoma TT cell line were separated by HPLC into 50 fractions, each of which was subjected to MS/MS. Two previously uncharacterized C-terminally amidated peptides, derived from the neurosecretory protein VGF, were identified and designated NERPs. Rat NERPs were inferred from the corresponding sequences and subsequently confirmed by mass characterization of peptides reactive to antibodies recognizing the amide groups.

and pancreastatin.[28] In invertebrates, the structure of a cardioexcitatory substance from a molluscan ganglion was determined to be the tetrapeptide FMRF-NH2.[19] Since then, many FMRFamide-related peptides have been isolated from various invertebrate species. The peptides that crossreact with an antiserum directed against FMRFamide have been purified from bovine brain extract.[32] With the advent of the postgenome era, an in silico search for unknown members of the RFamide family in the human database led to the discovery of two RFamide-related peptides.[10]

To identify unknown C-terminally amidated peptides independently of any specific amide structure, we used MS/MS techniques to analyze a complex mixture of peptides secreted by TT cells, a human thyroid medullary carcinoma cell line[31] (Fig. 1). A total of 233 peptides were identified, of which 15 underwent C-terminal amidation, including intact calcitonin (CT), intact calcitonin gene-related peptide (CGRP) and a series of N-terminally truncated forms of CGRP. In addition, we were able to identify two novel amidated peptides with monoisotopic masses of 2677.4 and 4062.2, both of which arise from distinct regions of the neurosecretory protein VGF. The former (VGF[281-306]-NH2) and the latter (VGF[310-347]-NH2) were designated neuroendocrine regulatory peptide (NERP)-1 and NERP-2, respectively.[31] Because peptidomics of rat brain fell short of identifying NERPs, the tissue extract was immunoprecipitated with antibodies recognizing each amide structure. By molecular characterization of the major immunoprecipitates, it was concluded that, according to the rat VGF sequence, NERP-1 and NERP-2 occur as 25- and 38-amino acid C-terminally amidated peptides, respectively.[31] For both the peptides, both N- and C-termininal ends are cleaved at the general motif $((K/R)-(X)_n-(K/R)\downarrow$, where $n=0$, 2, 4, or 6 and X is any amino acid other than Cys) recognized by prohormone convertase (PC)1/3 and PC2,[3] indicating that they represent *bona fide* endogenous peptides generated through VGF processing. Fricker and colleagues reported that PC2 is at least in part involved in the processing of NERP-1 (identical between rat and mouse) in their quantitative neuropeptidome analysis of PC2 knockout mice,[33] which is discussed in a different chapter of the Peptide Biosynthesis/Processing section of this book.

The *Vgf* gene was first cloned in rat pheochromocytoma PC12 cells stimulated with nerve growth factor.[12] It was also independently identified as a gene associated with human neuroblastoma differentiation.[17] The encoded protein is expressed in neurons and endocrine cells and composed

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

of 615 amino acids in human and 617 amino acids in rodents.[13] It is stored in dense core granules and secreted through the regulated pathway.[13,21] Before the identification of NERPs, a couple of peptides recognized by antibodies raised against the C-terminus of rat VGF had been reported and shown to possess biological activity;[1,2,11,13,30] TLQP-62/VGF[556–617] and AQEE-30/VGF[588–617] enhance synaptic activity in a whole-cell patch clamp recording on rat hippocampal cells,[1] and AQEE-30 and LQEQ-19/VGF[599–617] enhance penile erection on injection into the paraventricular nucleus (PVN) of male rats.[13] Centrally administered AQEE-30 elicits a robust antidepressant response in mice.[11] Using the antibody raised against the N-terminus of TLQP-62, Bartolomucci and colleagues have identified TLQP-21/VGF[556–576], which increases energy expenditure by stimulating autonomic activation of adrenal medulla and adipose tissues.[2] By contrast, NERPs were identified by MS/MS without using antibodies, showing that peptidomics contributes to peptide research from a different standpoint.[31]

Because NERPs were discovered using a "peptide-first" approach, we began with immunohistochemical studies to identify NERPs expressing cells in the rat nervous system.[31] Cell bodies strongly immunostained with NERP antibodies were found in the supraoptic nucleus (SON) and the PVN, the hypothalamic nuclei where vasopressin neurons and oxytocin neurons reside. By immunofluorecence microscopy, NERPs were found to be colocalized with vasopressin rather than with oxytocin.[31] This colocalization was confirmed by immunogold electron microscopy at the secretory granule level.[31] In situ mRNA hybridization showed that VGF expression was concomitantly upregulated with vasopressin in rats not allowed access to water.[31] These findings suggest a functional relationship between NERPs and the antidiuretic hormone vasopressin. In rats receiving central injection of NERPs, NERPs in a dose-dependent manner suppress the increase in plasma vasopressin levels that is normally induced by central administration of hypertonic NaCl or angiotensin II.[31] The sustained increase in vasopressin levels caused by dehydration was also decreased by icv injection of NERP-1 or NERP-2. Further, NERPs antibodies significantly reverse the plasma vasopressin suppression induced by acute water loading, suggesting that NERPs function as endogenous peptides to regulate vasopressin secretion.[31] These inhibitory effects of NERPs on vasopressin secretion have also been confirmed on hypothalamic explants. C-terminal glycine-extended NERPs had no such activity. This suggests that the C-terminal amide groups are also important to NERPs, as reported in many biologically active peptides.[7,31]

NERP-2 immunoreactivity was also found in the lateral hypothalamus (LH).[29] The LH serves as a center for controlling feeding, as damage to the area causes reduced food intake. In the LH, orexin and melanin-concentrating hormone (MCH) are expressed in distinct neuronal populations.[20] We found that NERPs were colocalized with orexins, rather than MCH, suggesting a functional relationship between NERPs and orexins. In support of this, VGF mRNA was upregulated in the LH of rats fasted for 48 h but returned to basal levels after re-feeding.[29] Centrally administered NERP-2 induced Fos activation in a subset of LH orexin neurons.[29] It was also found that centrally administered NERP-2 stimulates feeding behavior, body temperature, and locomotor activity in a dose-dependent manner, the effects not observed with either NERP-1 or C-terminal glycine-extended NERP-2.[29] These effects were considered orexin-dependent because the enhanced food intake was canceled by the central administration of neutralizing antibody to orexins or selective antagonists to the orexin receptor. More specifically, the NERP-2-stimulated feeding did not occur in orexin-knockout mice.[29]

Vgf knockout mice exhibit reduced body weight gain and increased oxygen consumption as compared with that of wild-type littermates.[9] This phenotype suggests that VGF or VGF-derived peptides function in the regulation of energy homeostasis. To date, VGF-derived peptides that are shown to be involved in energy homeostasis are catabolic TLQP-21 and anabolic NERP-2. Given the complexity of VGF processing, the observed phenotype of the *Vgf* knockout mice cannot be explained solely by the two peptides that seem to centrally modulate metabolic functions in opposite directions. However, we should not jump to a conclusion that the principal role of NERP-2 in the central nervous system is to enhance feeding. This is inferred from the research history of orexin, which is implicated in NERP-2 functions; orexin, as its name implies, had received attention because of its orexigenic effect, but is now recognized as a neuropeptide that physiologically regulates sleep and wakefulness through interactions with the nervous systems that are closely related with emotion, reward and energy homeostasis.[20,29]

The distribution of NERPs in humans was studied by immunohistochemistry.[14] NERPs immunoreactivity was also found in the human SCN and PVN. In the islets of the pancreas, NERPs are colocalized extensively with insulin, partially with glucagon, and do not overlap with somatostatin. In addition, NERPS immunoreactivity is found in the thyroid CT-producing cells and the gastrin-producing cells of the gastric antrum.[14] Molecular characterization of NERPs in these locations has shown that the major forms of NERP-1 and -2 are identical to those originally identified from the TT culture supernatant.[14,31] These observations suggest as yet unknown biological functions of NERPs in the endocrine system.

ELUCIDATING PRECURSOR CLEAVAGE SITES BY SECRETOPEPTIDOME ANALYSIS

The identification of NERPs made us realize two critical points in pursuing peptidomics-based discovery studies. First, although endoproteolytic and exoproteolytic cleavages cannot be distinguished with a given sequence alone, we need to opt for samples highly rich in secretory peptides that retain endoproteolytic cleavage sites. This is because large-scale identification of such peptides has the potential to reveal precursor processing sites, which in turn should be helpful to predict the generation of candidate bioactive peptides. Second, C-terminal amidation of a target peptide does not guarantee that it is biologically active. Actually, we had gone through many hit-or-miss experiments to elucidate the aforementioned biological actions of NERP.[31] We will describe a solution to the second point later, and we now turn to the first one.

Investigating a carefully isolated peptide source is all the more important, as LC–MS/MS is an unbiased analysis automatically conducted without knowing the nature of an analyte in advance. In this regard, peptides localized in the secretory granules of neurons and endocrine cells are believed to be the most ideal target, which can be quickly recovered in supernatant after an acute secretagog challenge in a noninvasive manner.[23] As proof-of-principle study, we investigated a complex mixture of peptides secreted by TT cells that received a secretagog challenge for 2 min.[23] A total of 400 peptides were identified, of which 395 (99%) arose from 20 secretory precursor proteins having signal peptides.[23] Of note, 19 precursors are known to be processed in the regulated secrsetory pathway and fell into three categories: (1) peptide hormone and neuropeptide precursors such as proCT, proCGRP, progastrin-releasing peptide, propituitary adenylate cyclase-activating polypeptide, prosomatostatin, proenkephalin A, proneuromedin U, proneuropeptide W, and proghrelin; (2) granin-like proteins such as chromogranins A, B, and C, secretogranin III, 7B2, proSAAS, and VGF; (3) enzymes involved in peptide hormone processing such as PC1/3, PC2, and peptidyl-glycine alpha-amidating monooxygenase.

We examined N-terminal and C-terminal cleavage sites of the 395 peptides to see if they fit the general motif recognized by PC1/3 and PC2[23] (Table 1). Such consensus sites were found in 299 peptides, which revealed many processing sites of known peptide hormone precursors. No less importantly, monobasic sites, defined here as the sites containing basic residues at P1 but none at P2, P4, P6, or P8 position, were found in 98 peptides, including those previously shown to be cleaved by PC1/3 or PC2.[23] Overall, these findings indicate that the complement of peptides harvested after a stimulatory challenge well reflects the precursor processing in the regulated secretory pathway, and suggest that comprehensive analysis of such peptides contributes to the understanding of precursor processing. Thus, we have advocated the term secretopeptidome, to distinguish from conventional peptidome studies (Fig. 2).[23] Using this scheme, peptide hormones and neuropeptides stored in secretory granules have been consistently recovered from several established cell lines of endocrine origin, including intact or N-terminally or C-terminally truncated peptides of proadrenomedullin, proopiomelanocortin, prourocortin III, progalanin, proluteinizing hormone-releasing hormone type II, proneurotensin, and proapelin.

The peptide processing map of precursor VGF is shown in Fig. 3, where the peptides identified in the TT secretopeptidome were aligned across the precursor sequence. Consisting of several clusters of many peptides sharing either N-termini or C-termini, this map highlights major endoproteolytic cleavage sites of the precursor. Although the cell-type-specific processing should be considered, processing sites deduced through the map are for the most part in agreement with the processing pattern of rat VGF that has been elucidated using conventional

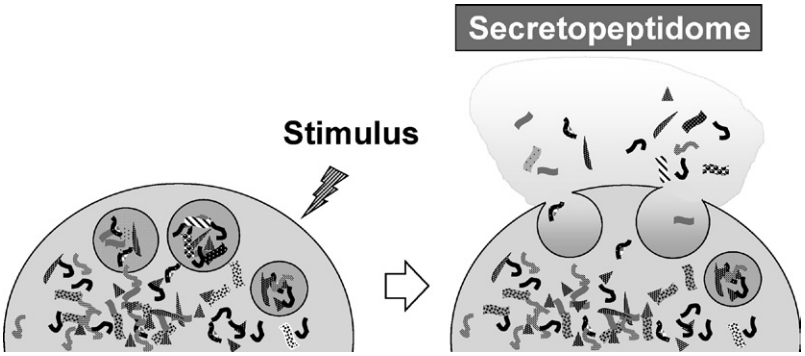

FIGURE 2 The secretopeptidome concept. Peptides stored in the secretory granules of neurons and endocrine cells can be harvested in culture supernatant on secretagog stimulation in a noninvasive manner. Accumulated information about the sequenced peptides is used to predict the generation of endogenous peptides as a result of endoproteolytic processing.

antibody-dependent biochemical methods in the brain and gut of rat.[16] Furthermore, we are made aware that even if peptides are quickly harvested (2 min after a stimulation challenge), they are attacked by numerous endopeptidases or exopeptidases. These findings also caution us about assessing peptide amounts by radioimmunoassays using a limited set of antibodies.

A UNIVERSAL PEPTIDOMICS STRATEGY FOR DISCOVERING ENDOGENOUS BIOLOGICALLY ACTIVE PEPTIDES

On the basis of findings obtained with secretopeptidome mining, we have proposed a universal approach to simultaneously screen for bioactive peptides and their target tissues.[24] This takes advantage of the common features of known peptide hormones and neuropeptides, i.e. strong interspecies homology and frequent use of calcium as a second messenger. The workflow for this strategy is illustrated in Fig. 3. As proof-of-principle study, >150 distinct VGF-derived peptides were identified by LC–MS/MS in the TT secretopeptidome and mapped to the precursor sequence to deduce endogenous peptide forms from the sequence ladders.[24] Peptides showing sequence identity between human and mammals (at least rodents) are selected and synthesized for candidate peptides. Candidates are tested on an ex vivo calcium assay using tissue pieces from transgenic mice expressing the calcium indicator protein aequorin.[24] Tissues are cut out as 1- to 2-mm^3 dices and incubated with coelenterazine, a type of luciferin, for 3 h, then sequentially challenged with medium, test peptide, known secretagogue, and finally with the detergent Triton X-100. Secretagogs used are ATP, angiotensin II, and bradykinin, but other peptides can be used. Triton X-100 is used to lyse cells and confirm the generation of functionally active aequorin complexed with coelenterazine. If a receptor for the target peptide uses calcium and is expressed at appreciable levels in a test tissue sample, a calcium transient is detected as emitted blue light on a luminometer. Because this calcium assay is performed on tissues consisting of heterogeneous cell types, we are more likely to get a hit as compared with cell-based assays. Another advantage is the broad applicability to various tissues or organs, including those not amenable to *in vitro* culture. This approach led to the discovery of human VGF[177-206] and [485-503], designated NERP-3 and NERP-4, which evoke a calcium response in the pituitary and hypothalamus.[24] The natural occurrence of these

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

peptides was also confirmed by immunoprecipitation-mass spectrometry and the tissue neuropeptidome analysis of PC2 knockout mice.[33]

FOCUSED SECRETOPEPTIDOME MINING: DISCOVERY OF ANTIMICROBIAL PEPTIDE AMP-IBP5

Next, we conducted secretopeptidome mining to search for cationic peptides.[18] Many antimicrobial peptides (AMP) contain multiple internal basic residues, a physicochemical property necessary for them to interact with target microbe's negatively charged cell wall. A secretopeptidome from the human islet cell line QGP-1 was enriched for highly charged peptides using cation exchange chromatography. In this peptidomic survey, a novel intramolecular disulfide-linked 22-residue C-terminally amidated peptide was identified and designated as AMP-IBP5 (antimicrobial peptide derived from insulin-like growth factor-binding protein 5).[18] It was so named according to its potent antimicrobial activity against six of the eight microorganisms tested, which is equal to or even better than the representative mammalian AMPs β-defensin-2 and cathelicidin.[18] AMP-IBP5 is identical at the amino acid level between humans, rats, mice, pigs, and cows. Natural occurrence of this peptide as the originally isolated form has been confirmed by MS of major immunoreactive peptides from rat brain and intestine. Consistent with its identification as a C-terminally amidated peptide, AMP-IBP5 is flanked by the canonical amidation motif GRKR. It is presumed that the site GRKR↓G first undergoes endoproteolytic cleavage (=precursor processing) by PC1/3 or PC2, followed by carboxypeptidase E-mediated removal of RKR. As in many C-terminally amidated peptides, the exposed glycine serves as a donor of the amide group. The N-terminal cleavage site MVPR↓A has no basic residue at either P2, 4, 6, or 8 position and is regarded as atypical for PC1/3 or PC2 cleavage; however, the cleavage C-terminal to a single arginine by PC2 has been reported with the N-terminus of neuromedin C, MYPR↓G, using a quantitative peptidomics approach by comparing the neuropeptide profiles between PC2 knockout mice and wild-type mice.[33] Although we have evidence that several peptides are cleaved from IGFBP-5 at the consensus motif of PC1/3 and PC2, complete sequence identity between mammals is restricted to the AMP-IBP5 sequence.

IGFBP-5 is a well-known secreted protein regulating cellular availability of the binding partners' insulin-like growth factors. Our peptidomics study is the first to show that IGFBP-5 undergoes processing to generate a biologically active peptide.[18] The observation that secretagog stimulation causes a 5- to 10-fold increase in immunoreactive AMP-IBP5 in culture supernatant of two different endocrine cells suggests that AMP-IBP5 is also sorted into the regulated secretory pathway granules.[18]

The fact that the peptide has an intramolecular disulfide bond means that a pair of cysteine residues involved in IGFBP-5 disulfide formation has been experimentally identified. Like many proteins, the overall disulfide connectivity of parent IGFBP-5 remains to be elucidated. In current public databases, each of the two cysteines of IGFBP-5 has been assigned a different disulfide linkage on the basis of sequence homology to the IGFBP family members IGFBP-4 and -6. This means that AMP-IBP5 is in principle beyond the reach of in silico prediction that is dependent on the current databases. It is also noteworthy that because of the presence of multiple basic residues, the peptide escapes identification in current bottom-up proteomics, again illustrating the benefit of peptidomics.[18]

CONCLUSIONS

It is envisaged that forthcoming improvements to related technologies (bioinformatics, LC–MS/MS, sample preparation techniques) will enable in-depth secretopeptidome analysis and have a far-reaching impact on peptide biology. Whatever elegant approaches may be developed for peptide discovery, they will not detract from the value of peptidomics in peptide research.

Peptidylglycine Amidating Monoxygenase (PAM)

KS Vishwanatha, Richard E. Mains and Betty A. Eipper

ABSTRACT

Amidation, a terminal modification in peptide biosynthesis, often increases the affinity of the peptide for its receptors and retards proteolytic degradation. Peptide amidation involves the sequential action of two enzymes. Peptidylglycine α-Hydroxylating Monooxygenase (PHM, EC 1.14.17.3), a copper, ascorbate and molecular-oxygen-dependent monooxygenase, catalyzes the stereospecific hydroxylation of the glycine α-carbon of the peptidylglycine substrate. Peptidyl-α-hydroxyglycine α-Amidating Lyase (PAL, EC 4.3.2.5) then catalyzes the cleavage of the C–N bond linking the α-hydroxyglycine to the penultimate amino acid, generating the α-amidated peptide and glyoxylate. In many primitive species, PHM and PAL are encoded by separate genes. In mammals, both enzymes are part of PAM (Peptidylglycine α-Amidating Monoxygenase), a bifunctional integral membrane protein. Genetic elimination of *Pam* causes embryonic lethality. Mice with a single *Pam* gene exhibit deficits in thermal regulation, anxiety-like behavior, and fear-based learning. PAM plays a role in maintaining copper homeostasis and in coordinating luminal and cytosolic events.

NAME AND HISTORY

About half of all known bioactive peptides terminate with a C-terminal α-amide. Amidated peptides are produced from peptidylglycine precursors by peptidylglycine α-amidating monooxygenase (PAM).[11] This posttranslational modification is often essential for receptor binding and may also increase peptide half-life in the circulation. Peptidylglycine-α-amidating monooxygenase (PAM) is required for the biosynthesis of all α-amidated peptides.[11] In the first step of the α-amidation reaction, the α-carbon of Gly is hydroxylated by peptidylglycine α-hydroxylating monooxygenase (PHM; EC 1.14.17.3) (Fig. 1). This reaction requires copper, molecular oxygen, and ascorbate. In the second step of the reaction, peptidyl-α-hydroxyglycine α-amidating lyase (PAL; EC 4.3.2.5) catalyzes an N-dealkylation reaction, generating amidated product and glyoxylate. At alkaline pH, the lyase reaction occurs spontaneously. The first *in vitro* assay for PAM was developed in 1982.[5] PAM was purified from bovine neurointermediate pituitaries in 1986, cloned in 1987, and first crystallized in 1997.[26]

A key step in the development of an assay for the biosynthesis of α-amidated peptides came from the sequencing of cDNAs encoding peptide precursors and the realization that α-amidated peptides were always derived from peptidylglycine precursors (Fig. 1). Amidated peptides play critical roles in *Planaria* and *Cnidarians*, creatures with a simple nerve net, as well as in mammals, flies and parasites like *Schistosoma*. Amidated peptides are produced in a similar manner in each of these organisms. A bioinformatically identified secretory protein whose predicted proteolytic cleavage sites generate a product with a C-terminal glycine is highly likely to generate a secreted product whose C-terminus is α-amidated.

The earliest studies of PAM revealed its similarities to dopamine β-monooxygenase (DBM, EC 1.14.17.1), the enzyme that converts dopamine into norepinephrine; the catalytic core of PHM [PHMcc; rat PAM(42–356)] is 28% identical to the corresponding region of DBM. Conservation of exon/intron junctions and eight of the ten Cys residues in PHMcc show their evolutionary relationship. The Cys residues, which form essential disulfide bridges, are conserved across species. PHM and DBM define a family of copper-dependent monooxygenases that includes at least one additional member, monooxygenase X (MOX), which resembles DBM more closely than PHM.[27]

FUNCTION OF PAM IN PEPTIDE BIOSYNTHESIS

PAM functions at a very late stage of the peptide biosynthetic pathway (Fig. 1). For most prohormones, endoproteolytic cleavage by a prohormone convertase followed by exoproteolytic trimming by carboxypeptidase E is required to produce a peptidylglycine substrate for PHM (Fig. 1). The subtilisin-like endoproteases Prohormone Convertase 1/3 (PC1/3) (Chapter 245 in this section of the book) and Prohormone Convertase 2 (PC2) (Chapter 246) are often

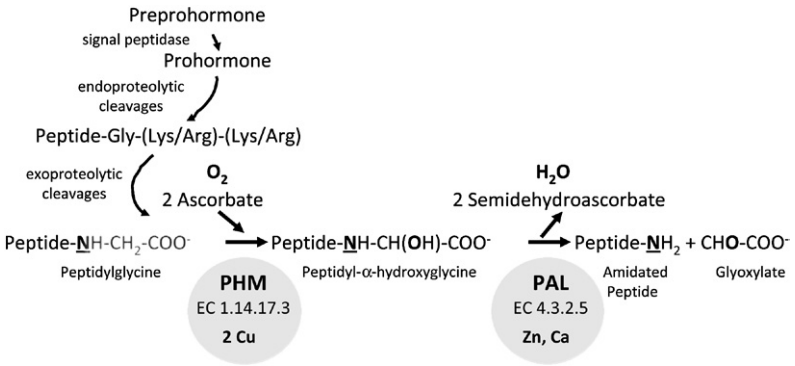

FIGURE 1 Peptide amidation is a two-step reaction. After cotranslational removal of the N-terminal signal sequence from the preprohormone, subsequent modifications occur in the lumen of the secretory pathway. The newly synthesized cargo moves through the Golgi complex and into immature secretory granules, which undergo a maturation process that involves luminal acidification. Peptidylglycine α-hydroxylating monooxygenase (PHM) catalyzes the stereospecific α-hydroxylation of the α-carbon of Gly residues at the C-terminus of peptides generated by endoproteoloytic and exoproteolytic cleavage of prohormones. Peptidyl α-hydroxyglycine α-amidating lyase (PAL) catalyzes cleavage of the C-N bond. Molecular oxygen, O_2; N of Gly α-NH_2 group, N.

responsible for producing reaction intermediates in which Lys or Arg is the C-terminal residue. Removal of C-terminal Lys and Arg residues is catalyzed by carboxypeptidase E, a carboxypeptidase B-like exopeptidase (Chapter 235). If a Gly residue is exposed after these endo- and exoproteases have acted, the active site of PHM can accommodate a wide variety of peptidylglycine substrates. Ubiquitin, a cytosolic protein not normally exposed to PAM, terminates with a C-terminal Gly and can be amidated by PAM.[21]

PAM substrates derived from prohormones do not generally become available until late in the biosynthetic pathway. Based on the ability to visualize α-amidated products in electron micrographs of corticotroph tumor cells, amidation occurs primarily in the low pH environment of immature secretory granules. Because copper is delivered to the lumen of the secretory pathway by the P-type ATPases ATP7A and ATP7B, which are localized to the trans-Golgi Network (TGN), it may be that PHM is first loaded with copper in this region of the cell.[23] If so, PHM would not be catalytically competent even if presented with a peptidylglycine substrate earlier in the secretory pathway. In many tissues, very little precursor (peptidylglycine) is detected in tissue lysates and the amidated product is by far the major form secreted. In a few cases, the peptidylglycine substrate for PHM can be detected in lysates and after secretion. For example, pyro-Glu-His-Pro-Gly, the precursor to TRH, is more prevalent than TRH (pyro-Glu-His-Pro-NH_2) in hypothalamus[4] and both oxytocin-Gly and gastrin-Gly are readily detected in serum.[27] It is interesting that –Pro-Gly (TRH) and –Gly-Gly (oxytocin) are poor substrates in test tube assays of PAM activity.

PROPERTIES OF THE PHM DOMAIN OF PAM

The catalytic cores of PHM and PAL have been crystallized,[26,27] revealing key features of their active sites (Fig. 2). Recombinant PHM and PAL secreted by stably transfected Chinese Hamster Ovary cells were used for these studies. PHM is the only member of the PHM/DBM/MOX family that has been crystallized. Crystallographic analysis of oxidized PHMcc, reduced PHMcc, oxidized PHMcc with bound substrate and reduced PHM with a slow substrate in the presence of molecular oxygen has revealed a great deal about the way in which molecular oxygen is used to catalyze the α-hydroxylation of glycine. In all the structures examined, PHMcc adopts the same overall structure, with only small differences in the conformation of several active site side chains and in the coordination geometry of the Cu-binding sites.

PHMcc has two domains, each about 150 residues long (Fig. 2). Despite having little sequence identity, the N- and C-terminal domains of PHMcc each contain a similar eight-stranded antiparallel β-sandwich. The two domains are connected by a three-residue linker. Each domain has a single Cu-binding site. The Cu-binding site in the N-terminal domain (Cu_H or Cu_A) is formed by three His residues (His^{107}-His^{108} and His^{172}). Three disulfide bonds anchor loops in domain I without linking the two major β-sheets. The Cu-binding site in the C-terminal domain (Cu_M or Cu_B) is formed by two His residues and a Met (His^{242}, His^{244}, Met^{314}). Two disulfide bonds connect the two sheets of the C-terminal β-sandwich.

Although connected by only a single strand, the N- and C-terminal domains are closely associated through a large, well-conserved hydrophobic interface. This interdomain interface is further stabilized by a hydrogen-bonded antiparallel β-sheet that links the two domains. A large, solvent-filled cleft separates the Cu_H site in N-terminal domain from the Cu_M site in the C-terminal domain. The two Cu ions, which must both participate in the reaction, are separated by an 11 Å cleft, with no evidence that they move closer together during the reaction.

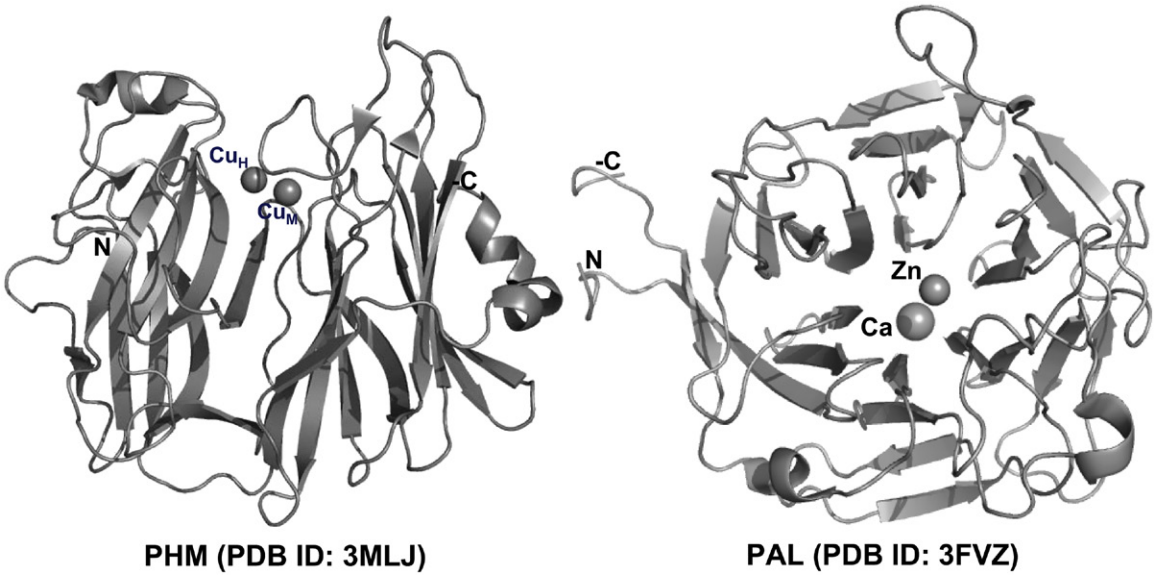

FIGURE 2 The catalytic cores of PHM and PAL. The structures determined for oxidized PHMcc without bound substrate[26] and PALcc without substrate[7] are shown. Bound metal ions are indicated. The N- and C-terminal ends of the polypeptide chains are indicated. The peptide substrate binds near Cu_M in PHMcc and near the Zn in PALcc. A linker region of variable length connects PHMcc to PALcc in PAM. In membrane PAM, a short linker region connects PALcc to an α-helical transmembrane domain.

The PHM Reaction

Much remains to be learned about the reaction catalyzed by PHM, but certain features are clear; kinetic studies indicate that the peptidylglycine substrate must bind before molecular oxygen can interact with PHM, perhaps limiting the production of reactive oxygen intermediates.[28] Molecular oxygen binds to the Cu_M site. The amino acid that will be α-amidated interacts with Met^{314} and several residues situated in the β-strand that extends beyond Met^{314}. Crystallization of reduced PHMcc with N-acetyl-diiodotyrosyl-D-threonine, which serves as a very slow substrate, clarifies two critical roles played by the C-terminal Gly. The α-carbon is positioned near the Cu_M site, placing the hydrogen to be extracted close to the molecular oxygen bound at this site; L-amino acids cannot occupy this position. In addition, the Gly carboxylate is bound to the guanidinium group of Arg^{240} in a bidentate salt bridge.

Although peptides terminating with hydrophobic amino acid amides are more common than peptides terminating with charged amino acid amides (-Lys-NH_2, -Arg-NH_2, -Asp-NH_2, -Glu-NH_2), PAM can catalyze the production of all 20 amino acid amides. The open nature of the active site is consistent with its ability to accommodate a variety of substrates. PHM catalyzes N-dealkylation, O-dealkylation and sulfoxidation reactions of nonpeptide substrates.[21] Purified recombinant PAM efficiently converts fatty acyl glycines, ranging in length from N-formyl to N-arachidonyl, into fatty acyl amides through an *N*-acyl-hydroxyglycine intermediate. PAM also catalyzes the conversion of nicotinuric acid into nicotinamide and glutathione into γ-Glu-Cys-NH_2.[21] Access of potential substrates to PAM is clearly critical in determining which of these reactions actually occur *in vivo*.

Ascorbate is the preferred reductant *in vivo*, but other single electron donors can support the α-hydroxylation reaction. PHM is absolutely dependent on copper; no other metal can replace it. For the reaction to proceed, both Cu_H and Cu_M must be reduced. PHM functions most effectively at pH 4.5 to pH 5.5, the pH observed in mature secretory granules.

PHM activity can be assessed with peptidylglycine substrates that are labeled with [^{125}I] or with a fluorescent tag; substrate and product are separated by RP-HPLC or by phase separation.[19] An oxygen electrode can be used to quantify PHM activity when large amounts of enzyme are available.[3,12] The manner in which the Cu_H and Cu_M sites interact with molecular oxygen to catalyze the α-amidation reaction remains a subject of intense interest and debate.[3,12,28]

PROPERTIES OF THE PAL DOMAIN OF PAM

The initial purification of peptide amidating activity from bovine neurointermediate pituitaries yielded soluble 45 kDa PHM. The existence of PAL became clear when the cDNA encoding PHM was found to encode a larger integral membrane protein and the properties of purified PHM were found to be distinctly different from those of the amidating activity in tissue lysates. A stable, protease resistant PAL catalytic core [PALcc; rat PAL(498–820)] was defined and expressed in CHO cells. Like PHMcc, disulfide bonds play

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

a critical role in PALcc. A single Zn(II) is bound to three conserved His residues in the active site and a single Ca(II) plays an essential structural role[7] (Fig. 2). Chelators of divalent metals (e.g. EDTA, EGTA) inactivate PALcc.

Crystallization of PALcc reveals a six-bladed β-propeller, with its blades positioned around a central cavity (central pore).[7] Each blade contains four antiparallel β-strands, with the first strand at the center of the propeller and the fourth strand at the outer edge. The loops connecting strand 4 of one blade to strand 1 of the next blade and the loops connecting strands 2 and 3 of each blade form the "cup" of the β-propeller. As in other β-propeller-enzymes, the cup encompasses the active site Zn(II). Loops 2–3 of the first blade contains 20 residues, significantly longer than the equivalent loop in the other blades. This long first blade loop provides a tryptophan (Trp^{538}) that creates a hydrophobic pocket for the substrate and may also provide a surface that can interact with the PHM domain when both catalytic domains occur in a bifunctional PAM protein.

The PAL Reaction

PAL activity has been quantified using [^{125}I]-labeled α-N-acetyl-Tyr-Val-α-hydroxyglycine or α-OH-hippuric acid.[21] Purified PALcc exhibits an acidic pH optimum, although significant activity is observed at neutral pH. The K_m for α-N-acetyl-Tyr-Val-α-hydroxyglycine is 38 ± 13 μM, slightly higher than the K_m of PHM for α-*N*-acetyl-Tyr-Val-Gly (10 ± 2 μM). The active site of PALcc contains an essential Tyr residue, which is situated near the bound Zn. Unlike PHMcc, which can lose its bound Cu and can later be reconstituted with additional copper, the metals in PALcc seem to play an essential structural role.[7]

THE PAM GENE

In *Drosophila melanogaster*,[17] sea anemone (*Calliactis parasitica*), and *Schistosoma mansoni*, PHM and PAL are encoded by separate genes. The two *Drosophila* PAL genes are not always expressed with PHM, suggesting that PAL may function independently. The *Planarian* genome encodes PHM, but a PAL ortholog has not yet been identified.[1] The *Caenorhabditis elegans* genome encodes a bifunctional PAM and a monofunctional PAL. As in mammals, the pond snail (*Lymaea stagnalis*) and the frog (*Xenopus laevis*)[27] genomes encode integral membrane proteins with both PHM and PAL domains. In *Lymnaea*, a single type-1 membrane protein contains four independent, functional PHM domains followed by a single PAL domain.

In several species, tissue-specific alternative splicing generates multiple isoforms of PAM; the major splice variants of rat and human PAM are compared in Fig. 3. The rat PAM gene consists of 27 exons and encompasses >160 kb of genomic DNA.[24] Rat PAM-1, the longest isoform, is a

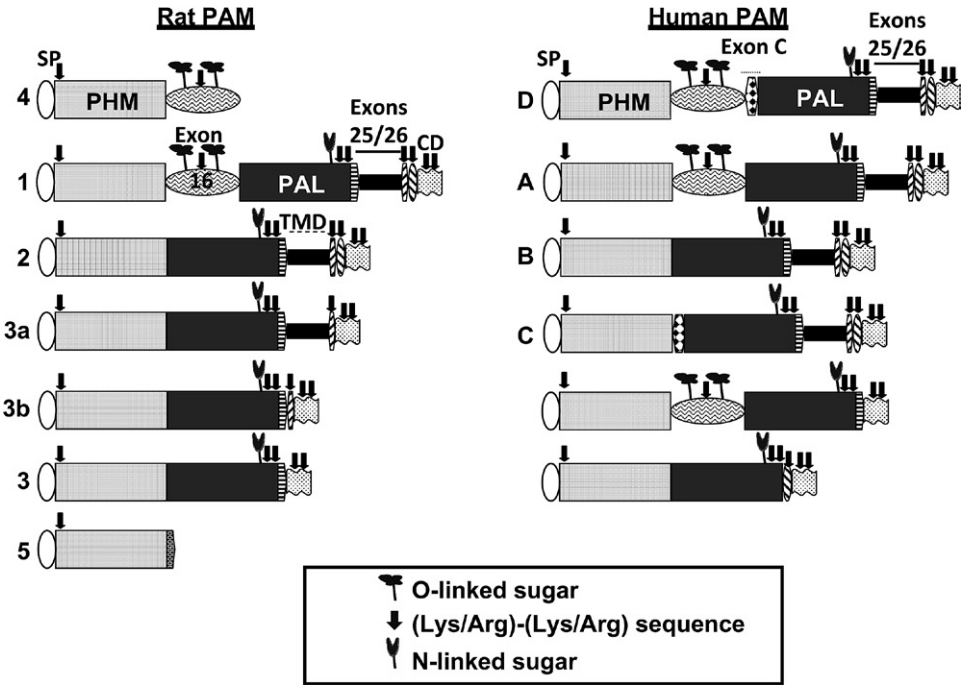

FIGURE 3 Isoforms of rat and human PAM. The splice variants of rat *Pam* and human *PAM* are shown. Inclusion of the exon that encodes the transmembrane domain generates a type-1 integral membrane protein. After removal of the signal sequence, tissue-specific cleavage at pairs of basic residues can generate soluble forms of PHM, PAL, and PAM, which are secreted along with the amidated peptides they create.

976 amino acid protein with a molecular weight of 108,650. The N-terminal signal sequence is followed by a 10 amino acid proregion that assists in folding but is not essential. N-glycosylation at a single site in the PAL domain and O-glycosylation at multiple sites in the linker region between PHM and PAL (exon 16) result in a PAM-1 protein with an apparent molecular weight of about 120,000. The 86 amino acid cytosolic domain (CD) of PAM is unstructured, highly phosphorylated and essential for the trafficking of PAM in the biosynthetic and endocytic pathways.[29]

Alternative splicing of the PAM gene is tissue specific and developmentally regulated. Splicing determines whether PAM will be an integral membrane protein or a soluble protein (Fig. 3). Splice variants lacking the exon that encodes the transmembrane domain are soluble and will be secreted along with their peptide products during exocytosis. As discussed below, membrane PAM that appears on the cell surface after exocytosis undergoes endocytosis and can return to the TGN and re-enter secretory granules.

Like other proteins in the lumen of the secretory pathway, PAM proteins are subject to endoproteolytic cleavage in the linker regions that connect the catalytic cores to each other and to the transmembrane domain (Fig. 3). In rat PAM, exon 16 includes a pair of basic amino acids that can be cleaved by prohormone convertases, releasing soluble PHM and creating membrane PAL. Splice variants that lack exon 16 are resistant to endoproteolytic cleavages that separate PHM from PAL. That a region equivalent to exon 16 occurs in *Lymnaea* and in *Xenopus* suggests that this region serves an important function.

Orthologs of PAM, DBM, or MOX have not yet been detected in bacterial, archaeal, or yeast genomes, suggesting that this family of copper-dependent monooxygenases may have evolved with multicellular organisms.

Properties of the Bifunctional PAM Protein

The catalytic functions performed by PHM and PAL are performed by PAM, with slight differences in pH optimum and kinetic parameters. Despite attempts to show substrate channeling from PHM to PAL, there is no evidence to support this suggestion.[22] Evidence for very low levels of the peptidyl-α-hydroxyglycine intermediate produced by PHM in tissue lysates was recently obtained using mass spectroscopy.[35]

The structure of PAL latches its N- and C-termini in close proximity[7] (Fig. 2). In a bifunctional PAM protein, the linker that joins the catalytic cores of PHM and PAL would be expected to place the domains in close proximity. In membrane PAM, PALcc is followed by a membrane spanning α-helix. The "latch"-like arrangement of the N- and C-termini of PALcc places PHMcc close to the membrane, where it might be well positioned for receipt of electron equivalents from cytochrome b_{561} and Cu(I) from ATP7A or ATP7B.

As discussed below, the presence of the transmembrane domain places the C-terminus of PAM in the cytosol, where it can interact with cytosolic trafficking machinery in a manner that reflects the actions of cytosolic factors and the luminal milieu. Regulated intramembrane proteolysis in the endocytic pathway is believed to release a soluble fragment of PAM (sf-CD) that accumulates in the nucleus, where it affects gene expression.[13,29]

REGULATION OF PAM ACTIVITY

Expression of PAM mRNA is regulated in a tissue-specific manner. In the melanotropes of the intermediate pituitary, the expression of PAM falls in response to the inhibitory effects of dopaminergic agonists, as does expression of proopiomelanocortin. In the anterior pituitary, the expression of PAM is increased by hypothyroidism and decreased by hyperthyroidism. Electroconvulsive shock increases the expression of PAM and increased production of amidated peptides, along with expression of its target peptides in the hippocampus.

The ability of PAM to function is dependent on the availability of copper and ascorbate in the secretory pathway. It is not clear that the availability of either copper or ascorbate is normally used to regulate PAM function. Lumenal pH is believed to play an important role in PAM function, with little PHM activity at neutral pH and effects of pH on the conformation of PAM that are believed to affect trafficking. Cleavage of membrane PAM to create PHM increases its catalytic activity and is believed to play a role in the activation of PAM and increased production of amidated peptides in response to hypoxia.[31]

Distribution/Localization: Sites of PAM Expression

Sites of PAM expression have been mapped using *in situ* hybridization, enzyme activity, and antibodies. In the adult rat, PAM expression is the highest in atrial myocytes, pituitary endocrine cells, and in subsets of neurons. However, PAM expression is not limited to classical neuroendocrine tissues. PAM is also expressed in airway and olfactory epithelia, endothelial cells, chondrocytes of bronchial cartilage, smooth muscle cells, brain ependymal cells, and astrocytes.[27]

In the brain of adult rats, transcripts encoding PAM are found in virtually all major brain areas with the exception of the cerebellum. A broad distribution of PAM in the CNS is consistent with its role in the synthesis of all α-amidated neuropeptides and the presence of α-amidated neuropeptides in all major brain areas. High levels of PAM mRNA and immunoreactivity are found in the hypothalamus,

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

hippocampus, and cortex. The magnocellular hypothalamic neurons of the SON and PVN, well known for their synthesis of vasopressin and oxytocin, exhibit the highest levels of PAM mRNA in the rat brain.[30]

During development, PAM transcripts first appear in decidualizing uterine endometrium and myometrial smooth muscle; later, PAM expression is apparent in the cardiogenic region. PAM expression in the central nervous system exhibits a complex developmental pattern. Non-neuronal cell populations that express especially high levels of PAM include limb mesoderm and the mesenchyme adjacent to nasal, maxillary, palatal, and dental epithelia during tissue fusion and remodeling. Expression of PAM is detectable in many neuroendocrine tumors, and amidated peptides may contribute to tumor growth as autocrine growth factors.[16]

In *Drosophila*, PHM is one of the genes expressed when DIMM, a basic-helix-loop-helix protein, turns on expression of key components of the regulated secretory pathway.[25] In *Planaria*, PHM is expressed in brain, eyes, and ventral nerve cord.[1] In *Cnidarians*, genes encoding the precursors to many amidated peptides are expressed in very discrete locations for defined periods of time; it is not yet clear whether the expression of PHM is coordinated with peptide precursor expression in this organism.[34]

DISTRIBUTION/LOCALIZATION: BIOSYNTHETIC AND ENDOCYTIC TRAFFICKING OF PAM

In cells that store peptides in secretory granules, PAM is largely localized to those granules. Cell-type-dependent cleavage of the different isoforms of PAM generates soluble PHM, soluble PAL, and soluble PAM, which are secreted along with the stored peptides (Fig. 4). In cells in which membrane PAM is a major product, PAM is inserted into the plasma membrane at the time of exocytosis. PAM is rapidly removed from the cell surface by endocytosis; very little PAM is found on the cell surface at steady state. PAM that enters the endocytic pathway can be returned to the TGN for reentry into secretory granules or it can be degraded. The endocytic trafficking of PAM is responsive to copper levels and involves regulated entry of PAM into the intraluminal vesicles of the multivesicular bodies (Fig. 4).

INHIBITORS OF AMIDATION

Because amidated peptides can serve as autocrine growth factors in lung cancer and contribute significantly to the acute inflammatory response in conditions such as

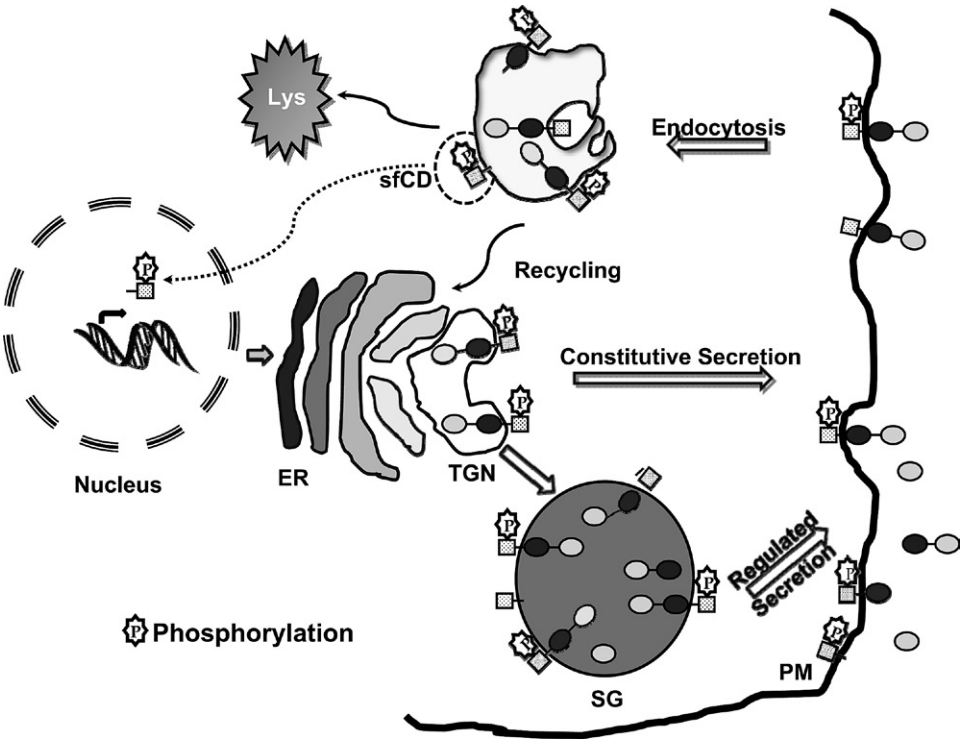

FIGURE 4 Biosynthetic and endocytic trafficking of PAM: generation of sf-CD. Membrane PAM enters regulated secretory granules when it exits the trans-golgi network (TGN). In the regulated secretory granules, PAM can undergo prohormone convertase-mediated cleavage, generating soluble PHM, membrane PAL, soluble PAL, soluble PAM, and transmembrane/CD fragments. On exocytosis, the soluble proteins are secreted, and the membrane proteins undergo endocytosis. Experiments with antibodies to the lumenal domains of PAM and surface biotinylation show that endocytosed PAM can return to secretory granules. It can also undergo regulated intramembrane cleavage, generating sf-CD, which accumulates in the nucleus. PAM-CD is unstructured and multiply phosphorylated. Both the biosynthetic and endocytic trafficking of PAM are regulated by CD phosphorylation and dephosphorylation.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

rheumatoid arthritis, PAM inhibitors have been sought.[16] In addition, PAM plays a role in the proliferation of androgen-independent prostate cancer. Homocysteine-extended peptides, acetopyruvate, pyruvate-extended amino acids, (4-methoxybenzoyloxy) acetate, *d*- and *l*-styrylglycine-extended peptides, and mimosine inhibit PAM with IC_{50} or K_i values of ≥100 μM.[20]

Both 4-phenyl-3-butenoic acid and 5(acetylamino)-4-oxo-6-phenyl-2-hexenoic acid inhibit PAM activity in serum.[2] Detailed studies of DBM facilitated the development of mechanism-based PHM inhibitors.[21] By the use of α-unsaturated thioacetic acid derivatives, such as *trans*-styrylthioacetic acid, as enzyme-activated inhibitors of horse serum PHM, it was shown that a radical rather than a reactive sulfoxide was formed as the PHM-inactivating transient species,[6] similar to that postulated for 4-phenyl-3-butenoic acid.

Hippurate analogs, *S*-(2-phenylthioacetyl)thioglycolate and *S*-(4-methylthiobenzoyl) thioglycolate, which have highest affinity for PAM, have been used as lead compounds in inhibiting the growth of human androgen-independent prostate cancer DU 145 cells.[21] Disulfiram, used as an alcohol deterrent, chelates copper and inhibits PHM, reducing the levels of amidated peptides in adult rat pituitary and cerebral cortex. *In vivo* studies of phenylbutenoic acid have shown a decrease in serum PHM activity and decreased inflammatory responses against carrageenan.[27]

Because PAL may not play an essential role in the production of amidated products, there have been fewer attempts to develop inhibitors of this enzyme. Potent inhibitors of PAL include pyruvate-extended *N*-acetyl amino acids and 2, 4-dioxo-5-acetamido-6-phenylhexanoate.[27]

PATHOPHYSIOLOGICAL IMPLICATIONS

Genetic Manipulation of PAM—Knockout Flies and Knockout Mice

Elimination of the PHM gene in *Drosophila* results in larval death;[17] in insects, >90% of the neuropeptides are α-amidated and non-amidated precursors accumulate in the absence of PHM. Mice lacking a functional PAM gene do not survive past embryonic day 15, exhibiting severe edema and malformed vessels.[9] The total absence of amidation activity in these embryos supports the conclusion that PAM is the sole source of amidation activity.

Perhaps more importantly, mice heterozygous for the PAM gene ($PAM^{+/-}$) are viable, fertile, and show no gross motor abnormalities. Tissues from $PAM^{+/-}$ mice have half the normal level of amidation activity. As they age, $PAM^{+/-}$ mice show signs of adiposity and impaired glucose utilization.[9] They are unable to maintain their body temperature when placed into a cold environment, largely because of their inability to vasoconstrict peripheral vessels.[4] $PAM^{+/-}$ mice exhibit an increase in anxiety-like behavior and a deficit in short- and long-term contextual and cued fear conditioning.[14] Although the levels of TRH-Gly were elevated in the hypothalami of $PAM^{+/-}$ mice, the effect was small and peptidomic analyses of the pituitaries of $PAM^{+/-}$ mice revealed the accumulation of peptidyglycine precursors without significant depletion of amidated products.[35] As discussed below, the deficits in $PAM^{+/-}$ mice are believed to reflect alterations in the ability of the PAM protein to fulfill its noncatalytic roles, including a role in copper homeostasis.

Genetics and Environment: Copper and Ascorbate

To function, PAM requires molecular oxygen, reduced ascorbate and copper. In humans, both ascorbate and copper must come from dietary sources; rodents can synthesize ascorbate. To be used by PAM, both ascorbate and copper must be delivered into the lumen of the secretory pathway, a process that requires the participation of multiple additional genes.

Members of the SVCT2 family of high-affinity Na^+-dependent ascorbate transporters are highly enriched in neurons, neuroendocrine cells, exocrine cells, osteoblasts, and endothelial cells.[27] These antiporters use the Na^+ gradient to concentrate ascorbate in the cytosol. In anterior pituitary endocrine cells, cytosolic ascorbate levels are 2–5 mM; secretory granule levels can be ten-fold higher, although the mechanism by which ascorbate gains entry to the secretory pathway remains unclear.

Ascorbate is converted into semidehydroascorbate when it donates a single electron to Cu(II), forming Cu(I); production of one mole of amidated peptide consumes one mole of ascorbic acid. Cytochrome b_{561}, an integral membrane protein, shuttles reducing equivalents from the cytosol across the secretory granule membrane. A close association of Cytochrome b_{561} and PAM is apparent in *Planaria*, with coexpression of these genes.[1] Mutation of *Drosophila* cytochrome b_{561} (*nemy*) results in defects in memory retention and an inability to amidate neuropeptides.[15]

Several agents capable of single electron transfer can reduce Cu(II) bound to PHM to Cu(I); however, reactions using ascorbic acid as the reductant result in the highest PHM activity in both *in vivo* and *in vitro* assays. This lack of reductant specificity in PHM is further supported by the observation that no ascorbate binding site was identified in crystals of PHM analyzed in the presence of high levels of ascorbate.[27]

As discussed above, copper plays an essential role in the ability of PHM to use molecular oxygen. Although many proteins bind copper, the number of cuproenzymes is small. Unlike ceruloplasmin, which binds copper tightly and is degraded in its apoform, copper is rather loosely bound to PHM. Copper is lost during the purification of PHM and

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

can easily be replaced; the affinity of PHM for Cu(II) is estimated to be approximately 0.06 μM. The structure of PHM is sensitive to the presence of copper[26,32] and the endocytic trafficking of PAM is affected by the availability of copper.[10]

Delivery of copper to the secretory pathway involves uptake in the gut, transport through the circulation and across the blood–brain barrier, uptake across the plasma membrane, chaperone binding, transfer to a P-type ATPase, and transport into the secretory pathway. Although many of the key players in whole body copper homeostasis are known, much remains to be learned about their control.[18] Mutations in ATP7A, an X-linked gene, cause Menkes Disease. In the mottled-brindled mouse, a model of Menkes Disease, peptide amidation is severely compromised.[23,33] Although cytosolic copper is known to bind to a variety of chaperones, little is known about the handling of copper in the lumen of the secretory pathway.

LATER FINDINGS

Role of PAM as a Luminal Domain Sensor

Analysis of corticotroph tumor cells engineered to allow control of PAM expression reveals the ability of membrane PAM to alter cytoskeletal organization and diminish the endoproteolytic processing and regulated release of proopiomelanocortin products.[8] Kalirin, a Rho GDP/GTP exchange factor for Rac1 and RhoG, and Uhmk1, a Ser/Thr kinase that phosphorylates the CD of PAM, were identified through their ability to interact with the CD of PAM. Regulated intramembrane proteolysis of PAM by γ-secretase produces a soluble fragment of the cytosolic domain (sf-CD), which accumulates in the nucleus in a phosphorylation-regulated manner.[13] Microarray analysis reveals the ability of PAM to increase the expression of a subset of genes in AtT-20 corticotroph tumor cells; included in this set of PAM-regulated genes is aquaporin 1 (*Aqp1*), a protein known to play an essential role in secretory granule biogenesis.

Role of PAM in Copper Homeostasis

Several deficits observed in $PAM^{+/-}$ mice are reversed by supplementary dietary copper.[4] In addition, similar behavioral deficits appear in wild-type mice kept on a mildly copper-deficient diet. $PAM^{+/-}$ mice consuming copper-supplemented water regain the ability to maintain body temperature in the cold, and copper-deficient wild-type mice lose the ability to do so. Similarly, the increase in anxiety-like behavior observed in $PAM^{+/-}$ mice is eliminated when they are provided with copper-supplemented water, and copper-deficient wild-type mice show an increase in anxiety-like behavior. Q-PCR analysis of atrium and pituitary reveals tissue-specific effects of PAM heterozygosity on the expression of the plasma membrane copper transporter Ctr1, the cytosolic copper chaperone Atox1 and ATP7A. The fact that copper affects the trafficking of membrane PAM and the conformation of PHM may contribute to the altered copper homeostasis observed in $PAM^{+/-}$ mice.

Role of PAM in Hypoxia

Intermittent hypoxia, which occurs during sleep apnea, is known to affect the synthesis of neurotransmitters in the central and peripheral nervous systems; in particular, neuropeptide signaling is altered. Analysis of brainstem lysates of adult male rats exposed to intermittent or continuous hypoxia shows that intermittent, but not continuous hypoxia, results in increased PHM activity; levels of amidated substance P and amidated neuropeptide Y are also increased, without an increase in PAL activity.[31] The increase in PHM activity is the result of increased proteolytic processing of membrane PAM and is blocked by an antioxidant that prevents the generation of reactive oxygen species.

Chapter 245

Prohormone Convertase 1/3

Mirella Vivoli and Iris Lindberg

ABSTRACT

The prohormone convertase PC1/3 is a eukaryotic serine protease that initiates the neuroendocrine-specific proteolytic cleavage of peptide hormone and neuropeptide precursors. Within the regulated secretory pathway, PC1/3 is synthesized as a glycosylated and sulfated precursor which undergoes initial rapid propeptide cleavage followed by further C-terminal cleavages in the later stages of the secretory pathway, resulting in a variety of PC1/3 forms differing in size, charge, and activity. PC1/3 has a propensity to oligomerize, which reduces its activity. PC1/3 interacts with the neuroendocrine protein proSAAS, which represents a highly potent natural inhibitor of this enzyme. Gene disruption experiments, and the many naturally occurring human mutations, support the involvement of PC1/3 in pathological conditions such as obesity, diabetes, opportunistic diseases, and hypercholesterolemia, making PC1/3 a potentially strong target for drug design. Recent studies are directed toward the development of potent and specific inhibitors.

DISCOVERY AND GENERAL FEATURES OF PC1/3

Many secretory proteins and peptide precursors are subjected to intracellular limited proteolysis, a process essential for acquisition of bioactivity. The enzymes responsible for this intracellular cleavage have been characterized in molecular and functional terms and belong to an evolutionarily conserved family of serine proteases related to the bacterial enzyme subtilisin and the yeast processing protease kex2 or kexin (reviewed in Ref. 28). In humans, PC1/3 is encoded by the *PCSK1* gene located on chromosome 5 and consists of 14 exons. Because of the homology of their catalytic domains to that of the bacterial enzyme subtilisin, these enzymes have been termed subtilisin-like proprotein convertases (SPCs or PCs).[28] Thus far, seven mammalian PCs have been identified, and their nomenclature has been standardized as follows: PC1/3 (previously known as PC1, PC3 and sPC3); PC2; furin; PACE4; PC4; PC5/6; and PC7/8 (previously known also as sPC7, LPC, and PC8). All these enzymes specialize in the cleavage of basic residues within the general motif Arg-$(X)_n$-Arg↓ where n = 0, 2, 4, 6 and X is any amino acid except Cys or Pro. Two other enzymes, subtilisin/kexin-like isozyme-1 (also known as SKI-1 and site-1 protease) and PCSK9, which perform cleavages at hydrophobic residues (reviewed in Ref. 30), are also present within the secretory pathway. The conservation of catalytic domains among these enzymes suggests a common evolutionary origin for PC genes; over time, ancestors of these enzymes have probably undergone duplications, insertions, translocations, and/or deletions to generate the current family.

PC1/3 was cloned in 1991 as the third PC to be identified; as early as 1988, Hutton and colleagues described a proinsulin-processing enzyme in insulinoma granules, which they termed "Type I proinsulin converting endopeptidase," which was later identified as PC1/3.[28] Analysis of the tissue expression and cellular localization of the cloned enzyme confirmed that this enzyme is found in dense core secretory granules within neuroendocrine tissues where it plays a pivotal role in the processing of neuropeptide and endocrine precursors. In this chapter, we review essential information concerning PC1/3, focusing on the work of the last decade.

PEPTIDE BIOSYNTHESIS AND PROCESSING: PC1/3 FUNCTION

Peptide hormones and neuropeptides are initially generated as relatively large precursors that require activation through a series of posttranslational processing events occurring during transit through the regulated secretory pathway. These processing reactions begin in the lumen of endoplasmic reticulum, and continue within the various secretory pathway compartments and the maturing secretory granules. The initial processing reactions consist of the removal of signal peptide, core glycosylation (which is relatively infrequent), and proper folding. Proteolytic cleavage of precursors most often occurs at single/double basic residues, such as Lys–Arg and Arg–Arg, and is believed to begin in the trans-Golgi network; PC1/3 cleavage often initiates this proteolysis. Within the secretory granules, intermediate-sized and final peptide products are subjected to additional exoproteolytic cleavages at C-terminal basic residues by

carboxypeptidase E.[13] In certain cases (depending on primary sequence), further terminal modifications can occur, such as C-terminal amidation, N-terminal acetylation, pyroglutamylation, phosphorylation, and/or sulfation; these modifications may be required to render the final peptide products biologically active (reviewed in Ref. 26). In contrast to the secretion of liver proteins into the bloodstream, which proceeds constitutively, the release of mature peptides from endocrine and neuroendocrine cells requires the presence of a cell-specific stimulus, such as depolarization (nerve cells) or high glucose levels (pancreatic beta cells). During a still poorly understood sorting process occurring in the trans-Golgi network, processed hormones and/or neuropeptides are condensed into immature secretory vesicles, which gradually become more acidic due to the presence of a proton pump within the membrane. This decrease in pH probably facilitates the final enzymatic steps of precursor maturation, as many of the posttranslational processing enzymes have an acidic pH optimum. Finally, after a stimulus event, a portion of docked mature vesicles fuses with the plasma membrane, resulting in the release of mature peptides into either the circulation or the synaptic cleft.

Work from several laboratories has confirmed that PC1/3 accomplishes the initial physiological processing of proopiomelanocortin (POMC), the common precursor for the melanocortin-related peptides ACTH/α-MSH, β-MSH, and γ-MSH and the opioid peptide β-endorphin. In anterior pituitary corticotrophs, which are highly enriched in PC1/3, POMC undergoes an ordered sequence of proteolytic cleavages beginning with PC1/3 action. This proteolysis yields ACTH, the N-terminal region of POMC, and β-lipotropin. In intermediate lobe melanotrophs, which contain both PC1/3 and PC2, different POMC products are generated via the sequential action of these enzymes (Fig. 1).[32] Differential tissue-specific processing by the two enzymes yields a variety of biologically active peptides involved in diverse cellular functions.

Many other peptide hormone and neuropeptide precursors are now known to be cleaved by PC1/3, including proinsulin, pancreatic and intestinal proglucagon, proghrelin, prosomatostatin, propancreatic polypeptide, progastrin, proparathyroid hormone, proenkephalin, prodynorphin, proluteinizing hormone-releasing hormone, and prorenin (reviewed in Ref. 6); most of these have been identified and quantified in PC1/3 knockout mouse brains subjected to quantitative peptidomics techniques[33] (see the Peptidomic chapters in this section of the book). It is probable that other precursor substrates remain to be discovered.

PROPERTIES OF PC1/3

General Properties

Similarly to other members of the eukaryotic subtilisin family, PC1/3 contains four domains: the propeptide, the catalytic domain, the P or Homo B domain, and the carboxy-terminal domain. Like subtilisin, this protease is activated through an autocatalytic cleavage of the N-terminal

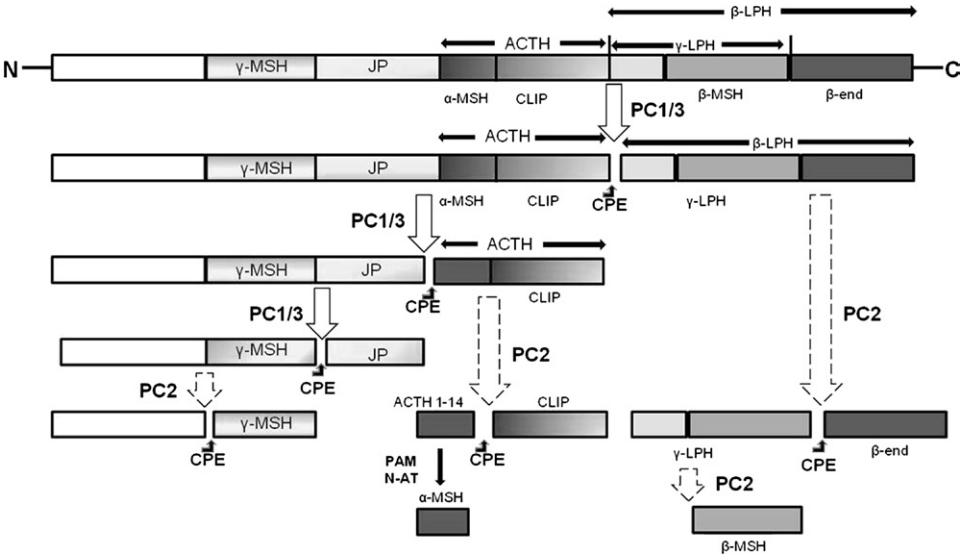

FIGURE 1 POMC processing by PC1/3 and PC2 in the pituitary. The POMC precursor, already modified by phosphorylation and glycosylation, is first cleaved by PC1/3 (shown with solid arrows), which results in a N-terminal segment containing the peptides γ-MSH (melanocyte-stimulating hormone), JP (*joining peptide*) and ACTH (adrenocorticotropic hormone), and β-LPH (β-lipotropin). After any internal proteolytic cleavage, C-terminal basic residues are removed by carboxypeptidase E (CPE; shown with black bent arrows). In tissues that contain PC2, such as the intermediate pituitary, further cleavage (shown with dashed arrows) generates ACTH 1–14, α-MSH, γ-MSH, γ-LPH, and β-endorphin (β-end). Additional terminal modification of ACTH 1–14 then occurs, consisting of CPE trimming, amidation, carried out by peptidyl α-amidating monooxygenase (PAM), and acetylation by an unknown N-acetyl transferase (N-AT).

propeptide. As shown in Fig. 2 (top), the catalytic domain, featuring the serine–histidine–aspartic acid catalytic triad, which performs catalytic action, lies adjacent to this N-terminal domain. The P or Homo B domain of approximately 150 amino acids is the carboxy terminal to the catalytic domain; this domain is believed to assist in correct protein folding, to contribute to enzyme stability, and also to contribute to calcium and pH dependence.[6] Lastly, the carboxyl-terminal domain probably plays a role in cellular routing (reviewed in Ref. 6).

Both proPC1/3 and its prohormone substrates are subjected to similar posttranslational processing reactions and travel together through the regulated secretory pathway of neuroendocrine tissues. During translation, preproPC1/3 is inserted into the lumen of the endoplasmic reticulum, where the 27 residue signal peptide is removed. The resulting proPC1/3 zymogen of approximately 94 kDa then undergoes very rapid autocatalytic cleavage of the proregion, resulting in an 87-kDa form. The evidence for such a mechanism derives from several studies showing that mutations at the PC1/3 active site result in a failure of the enzyme to undergo both propeptide cleavage and oligosaccharide maturation; it is probable that this poorly folded precursor remains in the endoplasmic reticulum, destined for degradation.[16] PC1/3 (87 kDa), which has three Asn-X-Ser/Thr N-glycosylation sites, is then decorated by sugars and moves into the Golgi apparatus, where it is subjected to additional posttranslational modifications, such as terminal glycosylation and sulfation. Whether the cleaved propeptide (which is a potent inhibitor of the enzyme) remains associated with the mature enzyme during transport is unclear; this occurs for furin, which does not become fully active until it reaches acidic compartments in which it undergoes internal propeptide cleavage and dissociation (reviewed in Ref. 26). It is however clear that once 87-kDa PC1/3 arrives in the slightly acidic trans-Golgi network, it acquires the ability to initiate prohormone cleavage; cleavage continues in the immature and mature secretory granule (reviewed in Ref. 6). Additional proteolytic modification of PC1/3 takes place in the secretory granules; this consists of intermolecular proteolysis of the C-terminus and results in the formation of the 74 and 66 kDa truncated forms of PC1/3, as shown in Fig. 2 (top). The 66-kDa form exhibits much higher specific activity but also lesser stability (reviewed in Ref. 6). This truncation event is apparently extremely important to the physiology of PC1/3, as shown by the introduction of mutations that block the removal of the carboxy-terminal tail which

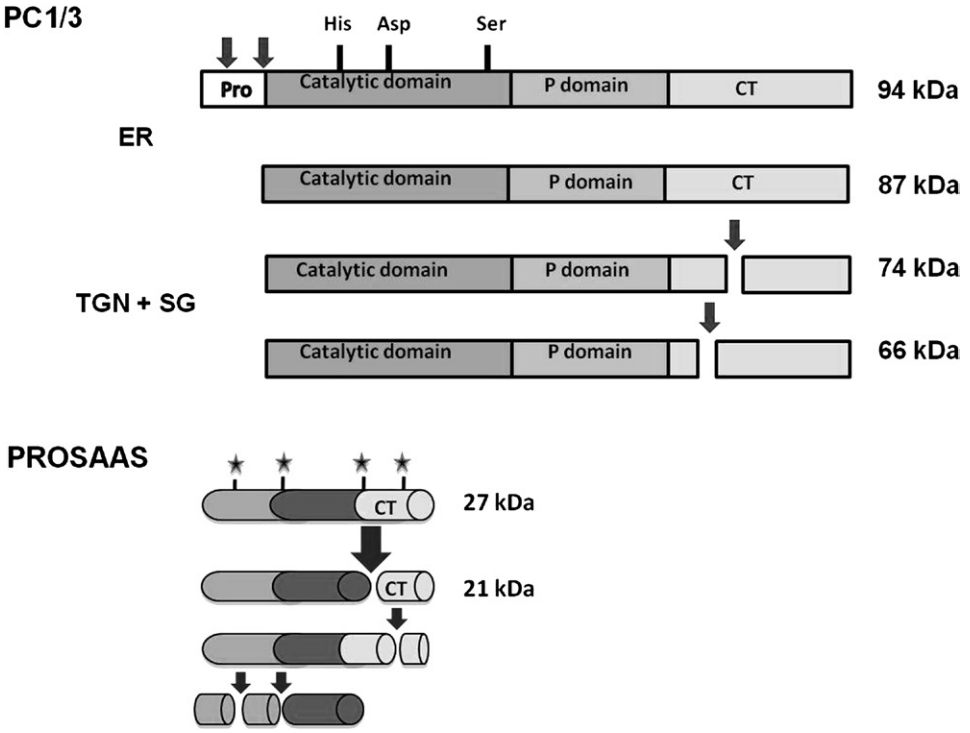

FIGURE 2 Schematic representation of the domains of PC1/3 (top) and proSAAS (bottom). Top: Pro, propeptide domain; catalytic domain, which contains the catalytic triad His, Asp and Ser; P domain (also known as "middle" or Homo B domain); and CT, the carboxyl-terminal domain. ER, endoplasmic reticulum; TGN, trans-golgi network; SG, secretory granules. Known cleavage sites are shown with arrows. Bottom: The 27-kDa form of the PC1/3 binding protein proSAAS, formed after cleavage of the signal peptide, is cleaved first at the furin cleavage site separating the 21 kDa from the CT peptide domains (shown with larger arrow); further cleavages then liberate potential bioactive peptides (shown with smaller arrows). As in Fig. 1, CPE is required to remove carboxy-terminal basic residues. Stars depict dibasic cleavage sites.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

prevent full enzyme activation (and also result in abnormal cellular localization).[24] The carboxy-terminal region behaves as a bimodal regulator of PC1/3 activity:[27] it can function either to stimulate the conversion of the 87-kDa form into the more active 66-kDa form, or to inhibit PC1/3 autocatalytic cleavage in the early secretory compartments. The carboxy-terminal domain also clearly stabilizes the enzyme, and plays a role in routing of the enzyme to the secretory granules.[24] One group has provided evidence to support transmembrane insertion of PC1/3,[23] whereas its categorization as a transmembrane protein[2] has been refuted by others.[31]

After the publication of the cDNA sequence of PC1/3, the production and characterization of recombinant PC1/3 became possible using overexpression methods. Indeed, recombinant PC1/3 is now obtainable from several sources, including methotrexate-amplified transfected CHO cells, transfected L-cells, vaccinia virus-mediated overexpression, and baculovirally mediated insect cell expression (reviewed in Ref. 6). Recombinant PC1/3 is easily assayed using the fluorogenic substrate pGlu-Arg-Thr-Lys-Arg-aminomethylcoumarin (AMC); recent results show that tissue PC1/3 can also be assayed if (1) tissues are homogenized in the presence of general protease inhibitors; (2) general protease inhibitors are present in the assay mixture to block the much more active cellular enzymes capable of cleaving the convertase substrate; and (3) the specific inhibitor LLRVKR is used to block nonspecific activity, which is then subtracted from the total. The assay is described in Ref. 17.

Substrate Specificity

Previous *in vitro* and *in vivo* studies support the idea that PC1/3 represents the first enzyme involved in the production of larger intermediates from precursor proteins (unlike PC2, whose action generates small peptides from those larger intermediates). Common procedures to analyze the substrate specificity in a cellular context are coexpression of PC cDNA with a target precursor; antisense studies; and/or gene knockout experiments. By contrast, *in vitro* experiments with purified enzymes generally use kinetic measurements in which the purified PC is incubated with either a recombinant precursor or a synthetic fluorogenic peptide substrate. A generally accepted general model of enzymatic cleavage (Schecter and Berger nomenclature) depicts substrate amino acids designated as P1, P2, P3, P4, etc. proceeding in the N-terminal direction from the scissile bond; similarly, the residues proceeding in the C-terminal direction from the scissile bond are designated P1′, P2′, P3′, P4′, etc. Both *in vitro* and *in vivo* studies show that PC1/3 processes prohormone and neuropeptide precursors C-terminally to a pair of basic residues (occupying the P1 and P2 positions), or, rarely, to a single arginine. A comparison of cleavage sites within peptide precursors, coupled with the known occurrence of given residues at different positions, enables certain conclusions to be made as to the preferred substrate specificity of PC1/3 (reviewed in Ref. 6). Briefly, an aliphatic residue, such as Leu, Ile, Val, Met, or Thr, almost never occurs at the P1′ position within substrates; it is also very rare to find a Pro in the P1′ or the P2 position, which impairs both recognition and cleavage; moreover, Arg, Lys, Asp, or Glu are also rarely present at position P1′ or P3′. In addition, Cys or His have thus far rarely been found in the close vicinity of the scissile bond, as shown in a human proalbumin synthetic peptide, where the presence of such amino acids prevents PC1/3 cleavage. This result is consistent with the idea that these residues are unfavorable when occurring close to a PC1/3 cleavage site.[21] Moreover, other *in vitro* studies using recombinant enzyme have also shown that PC1/3 prefers substrates with positively charged amino acids, particularly Arg, at positions P2, P4, P6, or P8. For example, the replacement of these arginines with Lys or Orn in the synthetic substrate acetyl-Arg-Ser-Lys-Arg-AMC results in decreased catalytic efficiency due to an increased K_m.[20] In the substrate human proparathyroid hormone substitution of the natural residue Arg at position P4 with Val does not affect cleavage rate; however, in human proalbumin, peptide substitution by Arg at the same subsite increases cleavage velocity by fivefold,[21] suggesting that substrate context affects the role played by Arg at the P4 position. The specificity of PC1/3 has been investigated *in vitro* using pGlu-Arg-Thr-Lys-Arg-AMC as fluorogenic substrate. Because its K_m value for PC1/3 is in the micromolar range (varying from 8 to 23 μM), catalytic cleavage of this substrate is clearly very inefficient compared with that of other proteolytic enzymes such as trypsin and even the yeast convertase kex2. K_m values observed with larger peptide substrates are also in the micromolar range, indicating that catalytic inefficiency is an intrinsic property of PC1/3 rather than a substrate effect. Interestingly, decreased affinity for shorter peptides has been observed, often occurring with an increase of V_{max} (which compensates for decreased affinity and results in similar overall catalytic efficiency).[5] These findings suggest that PC1/3-mediated processing is not greatly influenced by substrate length. Although this work begins to illuminate the substrate specificity of PC1/3, in the absence of the availability of a crystal structure, further studies are necessary to define the relative contribution of each residue lining the catalytic pocket to the minimal and maximal substrate recognition sites.

Regulation of Activity

The specific activity of PC1/3 is 50–80 times lower than that of PC2, suggesting considerable room for regulatory mechanisms. Despite the critical importance of PC1/3 in the

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

bioactivation of neuropepetide precursors and prohormones, regulatory mechanisms affecting activity have not yet been completely elucidated. Similar to the other convertases, the enzymatic activity of PC1/3 is highly dependent on the presence of calcium and is inhibited by chelators such as EDTA (reviewed in Ref. 26); the known calcium gradient within the secretory pathway may thus control PC1/3 activity. Truncation of PC1/3 also clearly plays a role in controlling PC1/3 activity. Recombinant PC1/3 is obtained as three enzymatic forms differing in length at the C-terminus; as described above, removal of the carboxy-terminal fragment has a major impact on enzymatic properties, such as pH optimum, calcium dependence and enzyme stability (reviewed in Ref. 6). The pH optimum of the 87-kDa form is in the range of 5.5–6.5, and this form of the enzyme requires 2 mM concentrations of calcium for maximal activity. Truncation of 87-PC1/3 to the 66 kDa species increases the optimal calcium concentration by several fold and decreases the pH optimum from 5.5 to 5.0.[26]

PC1/3 biosynthesis and activity can also be regulated by a binding partner, called proSAAS, a 21-kDa granin-like neuroendocrine secretory protein.[11] ProSAAS contains two domains, a large N-terminal domain and a C-terminal peptide domain (Fig. 2, bottom); like the PC2 chaperone protein 7B2, these domains are separated by a furin cleavage site. The C-terminal peptide represents a potent endogenous PC1/3 inhibitor *in vitro*. Although the N-terminal domain of 7B2 is critical for the expression of PC2 activity (see the next chapter), the N-terminal domain of proSAAS has no effect on PC1/3 activity *in vitro*. However, the expression of proSAAS N-terminal domain reduces the secretion of PC1/3 in both CHO cells stably expressing PC1/3, as well as in transiently-transfected HEK cells.[11] This reduction in secretion rate is reminiscent of chaperone protein action; for example, BiP overexpression is well known to delay the secretion of molecules through the secretory pathway. Overexpression of proSAAS blocks the dynamic maturation of newly synthesized POMC to ACTH, but paradoxically has little effect on the total cellular content of ACTH.[11] More work remains to be done to fully understand the physiological role of proSAAS interactions with PC1/3. Interestingly, further cleavage of proSAAS to smaller peptides occurs in certain tissues.[29]

PC1/3 can also be transcriptionally regulated; several studies have shown that the PC1/3 promoter contains binding sites for both STAT3 (signal transducer and activator of transcription 3) and Nhlh2 (nescient helix-loop-helix 2, a member of the large family of basic helix-loop-helix transcription factors); both are involved in hypothalamic PC1/3 expression. These transcription factors may also coordinately regulate transcription of PC1/3 following leptin stimulation.[12] PC1/3 expression is also dependent on activation of the CREB/cAMP system.[9] Lastly, PC1/3 is regulated on a translational level: for example, in pancreatic islets, glucose regulates both the synthesis of PC1/3 and its substrate proinsulin.[1]

Hoshino et al.[18] showed that recombinant and natural PC1/3 forms exist as multiple populations, differing not only in charge but also in size. These species consist of monomers, oligomers, and aggregates; the more acidic forms of PC1/3 consist of defined oligomers and aggregates, whereas the more basic PC1/3 forms are monomers and dimers. A variety of experimental techniques, such as gel filtration, radiation inactivation, and dynamic light scattering, support the idea that one of the active forms of PC1/3 is an 87-kDa homodimer. In addition, certain small peptides terminating in pairs of basic residues were found to both stabilize the 66-kDa form of PC1/3, and behave as activators of 87-kDa PC1/3. Because the carboxy-terminal domain differentiates the 66 from the 87-kDa form of PC1/3, it is likely that this domain contributes to stimulation, most probably by altering the conformation of 87-kDa PC1/3. Taken together, these findings suggest that oligomerization and allosteric peptide activation represent important factors involved in the regulation of PC1/3 activity; further study is required to elaborate the precise binding sites for these events.

Zandberg et al.[34] reported that N-glycosylation of PC1/3 affects zymogen activation and trafficking and influences prohormone processing. However, the probability that N-glycosylation dynamically controls these processes *in vivo* seems slight.

DISTRIBUTION/LOCALIZATION

Analysis of the mRNA expression of PC1/3 in rat tissues and cell lines by Northern blotting shows that PC1/3 is expressed in many tissues and cells containing secretory granules, including pituitary, adrenal gland, pancreatic islets, endocrine cells within the small intestine, in the gastric mucosa, and within the large luteal cells of the ovary. Although PC1/3-like transcripts of various sizes have been detected by Northern blot analysis in lung, skeletal muscle, and heart, the ability of these various transcripts to express PC1/3 has not been established. Moreover, small amounts of PC1/3 are also expressed in various cells of the immune system. The enzyme is not found in liver, kidney, and spleen (reviewed in Ref. 26).

PATHOPHYSIOLOGICAL IMPLICATIONS OF PC1/3 VARIANTS

The varied physiological roles of PC1/3 have been revealed through the characterization of gene knockout phenotypes in mice and by the discovery of mutations in human patients. PC1/3 misregulation would be predicted to lead to multiple hormone and neuropeptide deficiencies. Indeed, knockout of the PC1/3 gene in mice results

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

in severe developmental abnormalities, such as growth retardation and dwarfism, most probably because in mice (though not in humans, because of sequence variations), PC1/3 is involved in the processing of the growth hormone-releasing hormone (GHRH) precursor.[35] Other precursor proteins, such as pituitary POMC, pancreatic proinsulin and proglucagon, also undergo defective processing in tissues from this null mouse.[35] In 1997, the first human PC1/3 mutation was described;[10,20] this individual was shown to be a compound heterozygote for PC1/3, which resulted in a null phenotype. This phenotype was characterized by extreme obesity, intestinal dysfunction, and highly increased levels of circulating prohormones.[10] More recently, two other genetic abnormalities of PC1/3 have been described in humans: compound heterozygosity for PC1/3 mutations, including the G593R mutation which causes failure of maturation of the zymogen form of PC1/3 (proPC1/3) and its retention in the endoplasmic reticulum; and an A → C + 4 substitution in the donor splice site of intron 5, which results in exon skipping, frameshift, and introduction of a premature stop codon in the catalytic domain. These mutations result in defective absorption of monosaccharides and fat, indicating an important—but as yet, unclear—role for PC1/3 in intestinal function.[19] Another missense mutation, S370L, causes early-onset obesity and hyperphagia.[10] Strikingly, in mice, the N222D mutation is associated with obesity, hyperphagia, and increased metabolic efficiency in homozygotes;[22] the neighboring mutation N221D, which is associated with decreased PC1/3 activity, has also been reported to be linked to obesity.[4] Finally, in obese humans, common polymorphisms such as T690S and Q665E are associated with reduced postprandial fat oxidation; both of these polymorphisms are located in the C-terminal domain of PC1/3.[7] However, the identification of the specific PC1/3 substrates involved in the development of both obesity and intestinal dysfunction remains to be elucidated. Interestingly, an increasing number of genome wide association studies of PC1/3 show that changes in body weight, insulin sensitivity and processing, and blood glucose are associated with single nucleotide polymorphisms (SNPs) in PC1/3 in both European and Chinese populations.[10,20]

Peptidomic comparisons of PC1/3 substrates in PC1/3 null mouse and wild-type brains reveal few PC1/3 substrates involved in mouse development, but identify many peptides implicated in human obesity. Interestingly, a study of proSAAS knockout mice indicates that prenatal proSAAS expression is important in regulating prenatal processing of neuropeptides. By contrast, peptide levels seem normal in adult proSAAS knockout mice, suggesting that PC1/3 activity is not always affected by the absence of proSAAS.[25] Transgenic mice overexpressing proSAAS show an increase in body weight, but precursor processing by PC1/3 seems to be normal.[25]

Other important pathological conditions linked to PC1/3 expression include diabetes,[15] opportunistic diseases[8] and hypercholesterolemia, a high-risk condition for cardiovascular diseases.[2]

Owing to these clinical linkages, there is increasing interest in PC1/3 as a novel target for drug design. Such drugs will be of use not only for pathological intervention but also for biochemical studies to detail the role of PC1/3 in various peptidergic pathways. Indeed, a variety of convertase inhibitors (nearly all for furin) have been described during the past decade, representing proteins, peptides, and nonpeptide small molecules. Examples include the natural products of the andrographolide family and their succinoyl ester derivatives, certain metal complexes, dicoumarol and its derivatives (reviewed in Ref. 14) and 2,5-dideoxystreptamine derivatives. Because proteins or larger peptides are poorly permeable and often antigenic, small molecule inhibitors are more attractive as useful therapeutic targets; these often exhibit long-lasting metabolic and proteolytic stability, enhanced bioavailability, and easier syntheses.[3] However, only one report of a small molecule PC1/3 inhibitor has been published thus far, belonging to the andrographolide family.[3] Our ongoing work indicates that substituted dideoxystreptamine derivatives can function as low micromolar inhibitors (Vivoli et al., 2012, in *Mol Pharmacol*), though these first-generation inhibitors crossreact with furin to an unacceptable degree.

SUMMARY AND CONCLUSIONS

Both biochemical and *in vivo* studies have contributed immensely to our understanding of the physiological functions of PC1/3 and have shown that this enzyme is mostly localized within the Golgi apparatus and immature and dense core secretory granules of neural and endocrine cells. PC1/3 initiates the processing of many neuropeptide and peptide hormone precursors into their functional hormones, through proteolytic cleavage events occurring at pairs or single basic residues. More recent findings regarding the oligomerization and peptide activation of PC1/3 add to our knowledge of the regulation of PC1/3 activity, though additional biochemical characterization of regulatory events remains to be accomplished. The interesting phenotypes of the PC1/3 gene knockout and mutants in mice, and the discovery of increasing numbers of human patients with coding mutations in the PC1/3 gene both highlight the physiological importance of PC1/3. Indeed, humans with inactivating PC1/3 mutations exhibit high circulating levels of unprocessed prohormones, severe obesity, abnormal glucose homeostasis, and infertility of hypothalamic origin. However, more work remains to define the specific contribution of PC1/3 action to diseases such as obesity, endocrine dysfunction, and hypercholesterolemia. Efforts to obtain the crystal structure of PC1/3, made difficult by

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

its propensity to oligomerize, will contribute greatly to the eventual successful therapeutic manipulation of this enzyme by specific inhibitors.

Chapter 246

Prohormone Convertase 2

Mirella Vivoli and Iris Lindberg

ABSTRACT

The prohormone convertase PC2 plays an important role in the production of bioactive peptides. This calcium-dependent serine proteinase exhibits several unique features: a substitution in the oxyanion hole, and the requirement for a binding protein, 7B2, for blockade of unproductive zymogen aggregation. Knockout mouse experiments have shown that PC2 is involved in the synthesis of >100 different peptides, with possibly the widest substrate specificity of all of the convertases. Cell transfection experiments confirm that PC2 mostly participates in the later stages of precursor maturation. In at least one case, that is, glucagon synthesis, PC2 activity is regulated by levels of 7B2; other regulatory mechanisms consist of translational and transcriptional controls for both PC2 and 7B2. PC2 variants have been associated with only a few diseases as yet, and more will likely be discovered within the coming years. Future challenges include the creation of specific inhibitors and a crystal structure for this important enzyme.

DISCOVERY AND GENERAL FEATURES OF PC2

Prohormone convertase 2 (PC2) was one of the earliest eukaryotic convertases to be discovered. Hutton and colleagues first showed the presence of two calcium-dependent enzymes in insulinoma granule extracts prepared from transplantable rat islet cell tumors in 1988 (see the preceding chapter for references). However, another seven years passed before the protein corresponding to this enzymatic activity was finally identified as the second member of a new family of eukaryotic subtilases (reviewed in Ref. 28). It is a happy coincidence that both the Hutton and Steiner (and then Seidah) groups gave this enzyme the same number, though in the former case, it stood for "Type-II proinsulin converting endopeptidase," and in the latter two cases, the number became a part of the acronym for "prohormone convertase 2," or PC2. In this chapter, we present a general overview of the literature on this enzyme, focusing on recent work and referencing reviews wherever possible.

PC2 is initially synthesized as a 75 kDa glycosylated and sulfated proenzyme, which undergoes autocatalytic intramolecular maturation to a 64-kDa enzyme within regulated secretory granules.[20] Like other convertases, proPC2 contains a propeptide, a catalytic domain, a P domain, and a carboxy-terminal tail domain (Fig. 1). The propeptide functions as an intramolecular chaperone and has weak inhibitory activity against the active enzyme. The catalytic domain contains a serine proteinase catalytic triad in the subtilase configuration; however, one highly unusual feature of PC2 as a subtilase is the presence of an aspartate, as opposed to an asparagine, in the oxyanion hole which stabilizes the transition state. The adjoining P domain, also known as the Homo B or "middle" domain, is believed to contribute to enzyme stability and to calcium and pH dependence, and is integral to function.[2] Domain swap experiments show that PC2 requires its own propeptide and P domain for proper synthesis; corresponding domains from other convertases cannot be substituted.[2] Lipkind et al. proposed an eight-stranded β-barrel structure for the P domain, based on predicted secondary structure;[19] this structure was confirmed on crystallization of the homolog furin.[9] One group has shown that the carboxy-terminal domain of PC2 is capable of redirecting heterologous proteins to secretory granules; however, the role of the C-terminus of PC2 for sorting of the enzyme remains controversial.[30] Others have reported that the last 25 amino acids of PC2 form an amphipathic α-helix capable of interacting with raft-resident lipids.[1]

In humans, PC2 is encoded by the gene *PCSK2*, located on chromosome 20 p11.2 and consisting of 12 exons. In

mice, the gene is located on chromosome 2, which also harbors the 7B2 gene.

PC2 FUNCTION IN PEPTIDE BIOSYNTHESIS AND PROCESSING

Where PC1/3 is present, PC2 performs the later steps of peptide precursor processing on PC1/3-generated intermediates, as shown in the previous chapter (Fig. 1, Chapter 1).[2] However, many tissues express little or no PC1/3 and only PC2 (e.g. much of the brain), indicating that previous cleavage by PC1/3 is not a prerequisite for PC2 cleavage. This was confirmed on blockade of initial processing sites within proenkephalin which results in the efficient use of nearby sites.[2] PC2 cleavage has been implicated in the synthesis of at least 115 different peptides from 28 different precursors.[35] Although many of these precursors have been described in an earlier review,[2] the peptide precursors that have been added to this list in the last ten years (resulting in part from peptidomic analysis of the PC2 knockout mouse) include procholecystokinin, protachykinins A and B, secretogranin II, promelanin-concentrating hormone, pronociceptin/orphanin, prothyrotropin-releasing hormone, and VGF.[35] A critical role for the PC2 homolog *amontillado* (*amo*) in cleavage of signaling proteins in *Drosophila* was shown by gene knockout, which resulted in embryonic lethality, defective larval growth, and difficulty in hatching[24] (hence the name *amontillado*, from Poe's short story about an entombment, "The Cask of Amontillado"). Interestingly, worms seem to be less affected by mutation of their PC2 homolog *egl-3*; they do not die, but do exhibit pronounced egg laying and mechanosensory defects, probably caused by the failure to synthesize specific neuropeptides.[12]

PROPERTIES OF PC2

General Enzymatic Properties and Cell Biology

PC2 is a calcium-dependent serine proteinase with a pH optimum of 5.0s.[2] Enzymatic activity requires a low pH; lack of acidification, for example, by blockade of the vesicular proton pump[11] results in impaired substrate cleavage. PC2 is secreted from constitutively-secreting cells as a zymogen, proPC2; unless its obligate binding protein 7B2 (not a contraction; its name is derived from a fraction designation) is coexpressed, proPC2 is incapable of productive maturation to an active species[2,17] (Fig. 2). Within cells containing a regulated secretory pathway, proPC2 is exported to the Golgi after binding with 7B2, but does not undergo propeptide removal until after it reaches the secretory granule compartment. Activation is autocatalytic, intramolecular, requires a low pH, and is not calcium dependent;[2] this late, acidic compartment propeptide removal distinguishes

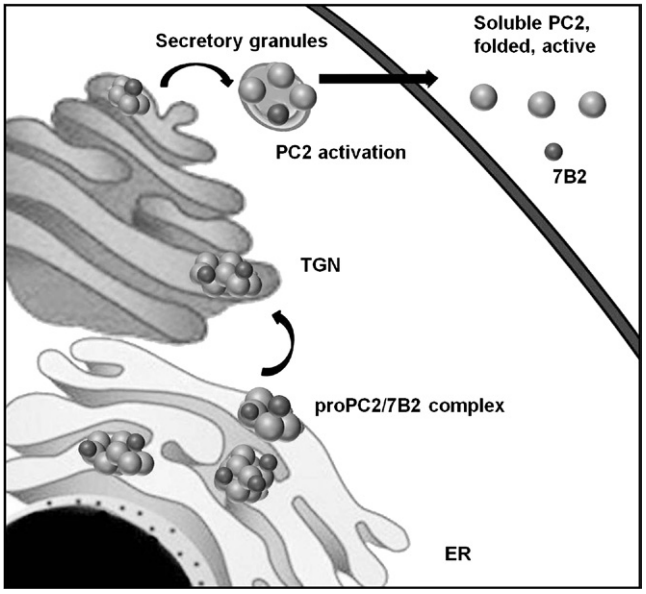

FIGURE 2 Maturation of proPC2 within the regulated secretory pathway. Following cotranslational cleavage of the signal peptide, slow folding of proPC2 occurs in the endoplasmic reticulum, which contains large quantities of this protein. The 27-kDa form of 7B2 binds to proPC2 in the endoplasmic reticulum, preventing oligomerization of the zymogen into inactivatable aggregates. In the Golgi apparatus, 7B2 is cleaved to its 21-kDa form by furin, decreasing its affinity for proPC2. Both proPC2 and 7B2 are then transferred to regulated secretory granules, where the low pH facilitates autocatalytic intramolecular maturation of proPC2 to PC2 (*note: 7B2 and PC2 are not drawn to scale*).

proPC2 activation from that of other convertases. After much work ruling out other mechanisms, it now seems that 7B2 functions mainly as a postfolding chaperone that blocks unproductive aggregation of proPC2 in various secretory compartments, thus preserving its ability to undergo activation.[17]

7B2, also known as secretogranin V and Sgne1 (secretory granule neuroendocrine protein 1), consists of two functional domains: an inhibitory C-terminal peptide and an N-terminal domain involved in proPC2 maturation; these are separated by a furin consensus cleavage site, as shown in Fig. 3.

In addition to the PC2 propeptide, two naturally occurring PC2 inhibitors are known, the 31 residue 7B2 carboxy-terminal peptide, which represents a nanomolar inhibitor of the enzyme *in vitro* (but see the discussion that follows); and the cystatin-related protein CRES,[3] present in testes (which however does not contain significant amounts of PC2). The enzyme is also inhibited by agents that chelate calcium, such as EDTA and EGTA, and by heavy metals such as zinc.[2] Synthetic inhibitors are just beginning to be developed; more recent results show that bicyclic guanidines and pyrrolidine bis-piperazines[14] and certain guanidinyl derivatives of dideoxystreptamine represent micromolar inhibitors of this enzyme (Vivoli et al., 2012, in *Mol Pharmacol*).

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

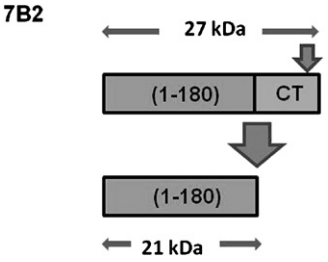

FIGURE 3 Schematic representation of 7B2: Cleavage at the furin site (indicated with a large arrow) results in the production of a 21-kDa domain, which is critical to proPC2 maturation; and a 31-residue "CT peptide," which represents a potent and highly specific inhibitor of active PC2. 7B2 inhibition is relieved by further cleavage within the CT peptide (indicated with small arrow) followed by CPE action.

Recombinant murine PC2, generated by dihydrofolate reductase-coupled overexpression in CHO cells, is about 80 times more active than PC1/3, with a specific activity of 30 μmol/h/mg protein.[2] Although this specific activity is comparable with that of the related enzyme furin, PC2 is much less active than the yeast enzyme kex2, which is itself orders of magnitude less active than trypsin. Because the residence time of peptide substrates with PC2 within secretory granules can be measured on the order of days, rapid enzyme action is not necessarily expected; however, pulse-chase studies in neuroendocrine cells and neuroendocrine cell lines indicate near-complete cleavage of peptide substrates within a matter of hours. Membrane tethering of PC2 with a portion of the peptidyl alpha-amidating enzyme results in alterations in several enzymatic properties, including increased activity,[2] possibly indicating constitutive inhibition by the carboxyl terminus similar to that observed for PC1/3 (see the preceding chapter).

Enzymatic activity for PC2 can be assayed in the laboratory in the extracts prepared from expressing tissues by blocking other, more active enzymes with a cocktail of protease inhibitors that do not affect PC2, such as pepstatin, TLCK, and E-64. Because the synthetic PC2 substrate pGlu-Arg-Thr-Lys-Arg-aminomethylcoumarin (AMC) is not specific for this (or any) convertase, PC2 activity must be given as the difference between activity found in the presence and the absence of micromolar concentrations of its specific inhibitor, the 7B2 carboxy-terminal peptide.[18]

Substrate Specificity

Catalysis by PC2 has been explored using a series of synthetic substrate analogs and by using internally quenched (IQ) peptides (reviewed in Cameron et al.[2]). Precursor processing has mostly been explored by transfection studies, though recombinant prohormones and chemically synthesized peptides have sometimes been used in *in vitro* experiments. The substitution of Ala in place of Pro at the position P1' (where the nomenclature of Schecter and Berger is used to denote positions prior to (P) and following (P') the scissile bond) in the dynorphin A 1-17 peptide enhanced cleavage by recombinant murine PC2, suggesting that Pro at this position hinders PC2 activity.[2] Moreover, the presence of charged residues such as Lys or Arg in the P2' position, again using dynorphin A 1-17 as a model substrate, hinders PC2 cleavage, whereas the presence of amino acids with aliphatic groups improved PC2 activity. Comparison of the various cleavage sites present in different prohormones and neuropeptide precursors suggests that sequences containing bulky groups such as Trp, Tyr, and/or Pro in the P1′ or P2′ positions are preferentially cleaved by PC2, and poorly if at all by other convertases.[35] The specificity of PC2 with regard to the P3 and P5 subsites has not been well defined; while a slight preference for an Arg or an acidic residue exists,[35] no clear preferences or restrictions have been shown as yet for these positions (see review in Cameron et al.[2]). Indeed, although it is clear that the substrate binding pocket of PC2 is more accepting than that of other convertases, further investigation is required to derive its precise binding specificity. Proghrelin, with a cleavage site of Leu-Asn-Pro-Arg-|Ala-Leu-Ala, is one of the few PC1/3 substrates that is completely resistant to cleavage by PC2.[22]

Regulation of Activity

The pH gradient within the secretory pathway is believed to regulate activation of the zymogen, contributing to the known late action of this enzyme within the secretory pathway, that is, in the mature secretory granule.[2] By contrast, PC1/3, with a higher pH optimum, is believed to initiate proteolytic action within the Golgi apparatus (see the previous chapter).

Like PC1/3, PC2 can be regulated by large quantities of catecholamines, such as those present within the adrenal chromaffin granule.[8] Whether this process also occurs in brain is not yet known. PC2 is also inhibited by its propeptide, though this inhibition is far weaker than the inhibition of other convertases by their propeptides (reviewed in Ref. 2). Other regulatory mechanisms for PC2 include translational[31] and transcriptional[21] controls.

Recent results strongly suggest that PC2 activity can be regulated by the small neuroendocrine protein 7B2 in at least some cases. As mentioned above, the carboxy-terminal 31 residues of this protein constitute a nanomolar inhibitor of this enzyme. When this peptide is overexpressed in neuroendocrine cells, it surprisingly does not reduce PC2-mediated cleavage;[6] therefore, the function of this carboxy-terminal peptide may instead be to prevent premature activity of PC2 within earlier portions of the secretory pathway.[6] However, 7B2 expression apparently can control PC2 activity via other means. For example, in strains of

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

mice exhibiting higher concentrations of endogenous 7B2 because of a polymorphism in the 5' region, the cleavage of glucagon from its precursor is enhanced.[29] Recent results from our laboratory confirm that reduction of 7B2 levels by antisense introduction reduces the production of glucagon, but not that of α-MSH; both are known PC2 products (Helwig et al., 2011, in *J Biol Chem*). The mechanism for this differential effect of 7B2 on precursor processing is not yet clear but may have to do with differential susceptibility of the two precursors to PC2 action. It will be interesting to learn whether cleavage of other precursors is affected by 7B2 modulation.

DISTRIBUTION/LOCALIZATION OF PC2

PC2 is widely distributed within neural and endocrine systems and is rich within the pancreas, the pituitary, and the adrenal gland. PC2 is widely expressed in the brain, but is especially concentrated in the hypothalamus. In the rodent, it is most concentrated in the neurointermediate lobe of the pituitary (reviewed in Ref. 28). Small quantities are also present in human dermal fibroblasts[26] and in the immune system.[15] Within neuroendocrine cells, PC2 is most concentrated in the endoplasmic reticulum as proPC2, which contains large amounts of immature carbohydrate chains, while the mature enzyme resides mainly within secretory granules.[2] The reasons for the large stores of endoplasmic reticulum zymogen are unclear but suggest potential dynamic control of activity, possibly by 7B2.

PATHOPHYSIOLOGICAL IMPLICATIONS OF PC2 AND 7B2 VARIANTS AND NULL ANIMALS

Only a few diseases have been associated with PC2 polymorphisms to date. These include increased risk of stroke and type-2 diabetes for four SNPs (single nucleotide polymorphisms) in an African-American population.[16] 7B2 variants have also been associated with alterations in glucose levels; interestingly, these polymorphisms occur in the 5′ untranslated region, an area known to exert considerable control over expression.[5,27] In certain strains of mice, increased levels of 7B2 are associated with a lean phenotype, while the adrenalectomized 7B2 knockout becomes obese in certain backgrounds[5] (see the discussion that follows on strain specificity).

The PC2 knockout mouse exhibits a surprisingly mild phenotype in most background strains (reviewed in Ref. 28). It is hypoglycemic due to the total absence of glucagon (because proglucagon processing is highly dependent on PC2 action),[33] and this knockout also exhibits depressed nociception[4] and delayed intestinal motility.[7] When the C57Bl/6 PC2 knockout is placed on the 7B2 null 129Sv background and back-bred for five generations or more, it phenocopies the lethal 7B2 null mouse (see below) and dies between 5 and 9 weeks of age.[23] The C57Bl/6 PC2 knockout mouse is available from Jackson Laboratories.

As discussed above, proPC2 requires a chaperone protein, 7B2, for the expression of enzymatic activity. The original 7B2 null mouse, generated in the Leder laboratory on the 129S6/SvEvJ background[34] exhibits a very interesting phenotype of extremely high circulating corticosterone, which results in death by 5–8 weeks of age. This high steroid level arises as a consequence of lack of PC2 processing of ACTH in the intermediate lobe of the pituitary, causing ACTH hypersecretion followed by excessive adrenocortical stimulation. These high corticosterone levels, coupled with a total lack of glucagon production, result in massive liver steatosis and necrosis coupled with chronic severe hypoglycemia, and lead to death between 5 and 8 weeks.[25] Interestingly, not all 129Sv substrains recapitulate this lethal phenotype; when bred onto the Jackson Laboratories 129Sv substrain, the 7B2 null does not show any particular abnormalities, either as received from Jackson Laboratories (the knockout is commercially available from this supplier), or after further back-breeding onto the Taconic 129Sv background (M. Helwig and I. Lindberg, unpublished observations). Thus, the lethal phenotype must represent a combination of both the lack of 7B2 and of specific modifier genes present within the original null 129S6/SvEvJ background. The identification of these modifier genes represents an interesting area for future study, which may be highly relevant to human Cushing's disease, a disease of excessive steroid production.

Interestingly, 7B2 expression is downregulated by epigenetic control in human medulloblastoma and in various gliomas,[32] suggesting that the ability to form colonies in soft agar is associated with lowered expression of 7B2. Most neural and endocrine cell lines express 7B2; there is apparently only one neuroendocrine cell line, which totally lacks 7B2 expression, the SK-N-MC neuroblastoma cell line. Introduction of 7B2 by transfection results in the manifestation of PC2 activity (reviewed in Refs. 17, 28).

PC2 may also play a role in tumor development and progression: increased expression of PC2 in neuroendocrine tumors over surrounding normal tissue occurs in various tumors, such as small-cell lung carcinoma, pituitary adenomas, medullary thyroid carcinoma, and lung and pancreatic cancer (reviewed in Ref. 13). Further investigation is required to elucidate the importance of this enzyme in cancer biology, with a view to a possible therapeutic intervention.

New work on PC2 is focused on identifying novel substrates,[35] inhibitor discovery,[14] and identifying additional diseases resulting from PC2 insufficiency. Detailed phenotypic characterization of the PC2 null reveals problems with intestinal transport,[7] and subtle behavioral anomalies, such as impaired nociception.[4]

SUMMARY AND CONCLUSIONS

The proprotein convertase PC2, one of the earliest convertases to evolve, plays an integral role in peptidergic signaling in organisms as diverse as flies and humans. More recent studies have elaborated the intricate interplay of PC2 and its binding protein 7B2 and suggest that there are unusual points of regulation for this enzyme in the production of active enzyme from zymogen via control of expression of its antiaggregant chaperone protein 7B2. These control mechanisms may differ from organism to organism, as the cell biology of PC2 is very different in insect cells than it is in higher organismss.[10] Unlike PC1/3 (see the previous chapter) few diseases associated with PC2 genetic variants have been identified as yet; whether this is a matter of experimental inattention, or whether PC2 represents a gene which is inherently more stable, remains to be established. A crystal structure for this enzyme, preferably in complex with 7B2, would provide much information on the molecular basis for its substrate specificity and the binding location of 7B2, as well as provide needed structural information for inhibitor design.

Chapter 247

Proprotein Convertase Furin and Proprotein Convertase PC5/6

Nabil G. Seidah

ABSTRACT

The secretory proprotein convertases furin and proprotein convertase 5/6 (PC5/6), while often exhibiting similar preference for polypeptide precursor cleavage at pairs or single basic amino acids motifs *in vitro*, also have unique functions *in vivo*, especially during embryonic development. Thus, although furin knockout mice exhibit a heart looping defect and die at embryonic day 10.5, mice lacking PC5/6 expression show multiple body axis defects and die at birth. Thus, although both proteinases are essential, they do so by the efficient cleavage of distinct precursors. Furin has a ubiquitous tissue expression and is implicated in the processing of a very wide panel of substrates throughout life. By contrast, PC5/6 is somewhat more restricted in its expression, and so far, its only specific substrate is growth-differentiating factor 11 (GDF11). Tissue-specific knockout of each convertase unraveled both redundant and specific functions emphasizing that unique *in vivo* substrates are yet to be identified for both enzymes.

DISCOVERY AND NOMENCLATURE

Activation via processing of a wide variety of in active secretory precursors by cleavage at specific single or pairs of basic amino acids (aa) was proposed since the mid-1960s, based on work on the model precursors of Insulin and Melanotropin-Stimulating Hormone (α- and β-MSH) (for reviews see Refs. 23, 28). Virologists also noted that to acquire fusiogenic activity, many infectious retroviruses required host cell proteases to process their cell surface glycoproteins at single or paired basic residues.[11] However, the identification of the cognate proprotein convertases (PCs) had to await the mid 1980s and really started in 1990. The major breakthrough was the elucidation of the primary structure of the yeast subtilisin-like serine protease Kex2p. The latter was genetically shown to be implicated in the processing of pro-α-mating factor and opened the way to the identification of mammalian homologs in 1990 (for reviews see Refs. 23, 28). The mammalian furin,[34] and the two regulated convertases PC1/3[24] (originally called PC1 or PC3) and PC2[24,27] were all discovered in 1989–1990. This initial wave of discoveries was soon followed by the identification of PC4, PC5/6 (originally called PC5 or PC6), PACE4 and PC7.[23,28] The human genes encoding these basic aa-specific Proprotein Convertases Subtilisin/Kexin-like were given the names of *PCSK1* to *PCSK7*. The furin-encoding *PCSK3* gene is often called *FUR* for FES/FPS Upstream Region. In this chapter, emphasis will only be on furin and PC5/6, its functionally closest PC-family member, both of which cleave precursors within constitutive secretory pathways at the RX(K/R)R↓ consensus motif. The *PCSK3 (FUR) and PCSK5* genes map to human and mouse chromosomes 15, 9 and 7, 19, respectively.

FUNCTIONS IN PEPTIDE BIOSYNTHESIS/ PROCESSING

Furin

Zymogen Activation and Cellular Trafficking

Like most secretory precursor proteins that undergo multiple posttranslational processing events before attaining their final bioactive form, the processing enzyme furin (Peptidase S8 family) is also subject to various modifications before becoming fully competent to cleave precursor proteins. The first event occurs during the translation of its mRNA in the endoplasmic reticulum (ER), whereby the type-1 transmembrane containing mouse preprofurin precursor (aa 1–793) loses its signal peptide (aa 1–24) by the action of the signal peptidase that is N-glycosylated at three sites $Asn_{387,440,553}$. Within the ER, the resulting profurin (aa 25–793) folds under the guidance of its prosegment (aa 25–107) and autocatalytically cleaves itself at site 1 (S1) within the recognition sequence $\underline{K}R\underline{R}A\underline{KR}_{107}$↓ DV, to generate a heterodimer of the inhibitory prosegment (pro; aa 25–107) and mature furin (aa 108–793) (Fig. 1). This pro≡furin complex is enzymatically inactive. However, cleavage at S1 allows the exit of pro≡furin from the ER toward the Golgi apparatus, whereby furin undergoes trimming and maturation of its *N*-glycosyl moieties and phosphorylation of its cytosolic tail at $Ser_{772,774}$

by the protein kinase CK2. On reaching the *trans* Golgi network (TGN), the mildly acidic pH and Ca^{2+} conditions are now favorable for a second autocatalytic processing of pro≡furin at an internal S2 site $_{69}$**HR**GVT**KR**$_{75}$↓, thereby eliminating the inhibitory prosegment and unmasking active furin, which is then capable of cleaving substrates *in trans*. Interestingly, His_{69} of the prosegment acts as a pH sensor allowing cleavage at S2 only under acidic conditions.[7] In agreement with the requirement of calcium for furin activity, the crystal structure of furin revealed that it binds two Ca^{2+} ions.[8] Furin is mostly concentrated in the TGN, a subcellular localization requiring phosphorylation of its cytosolic tail. However, furin can cycle from the TGN to the cell surface and back through the endosomal pathway. This traffic is regulated by the state of phosphorylation of its cytosolic tail and its interaction with the cytosolic phosphofurin acidic cluster sorting protein 1 (PACS-1) which mediates TGN localization and connection to clathrin adapters.[33] *In vivo*, furin exists as di, mono and nonphosphorylated forms, the latter being the preferred form at the cell surface.

In vivo Mouse Knockout Models

Furin is expressed at embryonic day e7.5 in the extraembryonic endoderm and mesoderm and at the late somite stages; it is also expressed in the cardiovascular system. Inactivation of the *fur* locus by homologous recombination in mouse causes embryonic death shortly after e10.5, due to hemodynamic insufficiency and cardiac ventral closure defects.[20] Although the specific physiological substrates of furin in the embryonic cardiovascular system have not yet been identified, the striking overlap in the distribution of furin mRNA coincides with that of several molecules reported to play critical cardiac-specific roles during this developmental stage. Among these molecules, members of the transforming growth factor (TGF) β family, such as TGFβ1,[3] and bone morphogenetic protein BMP10 (BMP10)[31] are efficiently processed by furin. This suggests that lack of processing of TGFβ-like precursors involved in the early cardiac development could be responsible for the defects observed in furin-null embryos.

In addition to these cardiovascular defects, the chorion of the furin-null embryos fails to fuse with the allantois that becomes highly vacuolated around e9.5. Similar absence of chorioallantoic fusion was previously observed in embryos lacking both BMP5 and BMP7, as well as vascular cell adhesion molecule (VCAM-1) and α4-integrin, two cell surface adhesion molecules that bind each other and are required for cell–cell adhesion. The most damaging deficiency in furin-null mutant embryos is their failure to undertake ventral closure to form a looping heart tube and a coherent primitive gut. So far, the exact mechanism behind these phenotypes and the cognate *in vivo* furin substrates, have yet to be identified unambiguously. However, the lack of suitable and sensitive antibodies to detect the

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

endogenous levels and forms of various substrates *in vivo* is hampering such an effort, and may be the use of quantitative mass spectrometry may help in this elucidation in the future.

An approach to reduce the complexity of the analysis *in vivo* furin functions is the use of tissue-specific knockout (KO) mice in which furin is inactivated only in a subset of tissues and cells. Such a strategy has indeed been very promising. A furin KO in liver and other tissues from adult mice, using the inducible Mx1-cre transgene, results in mice with no unusual phenotype, showing redundancy with other PCs, because typical furin substrates are still cleaved, albeit to a lesser extent.[19] By contrast, *in vivo* studies showed that in a spatiotemporal manner furin can uniquely process the Ac45 subunit of the vacuolar type H^+-ATPase in pancreatic β-cells.[13] Further, conditional deletion of furin in T cells allows for normal T-cell development but impairs the function of regulatory and effector T cells, which produce less TGFβ1.[18] Results obtained by furin deletion in salivary glands also suggest an important role for furin in enhancing the proto-oncogene PLAG1-induced salivary gland tumorigenesis in mice.[2] By using a hepatocyte-specific deletion of furin expression in liver, we showed that furin is the major PC implicated in the *in vivo* inactivation of the proprotein convertase PCSK9 by cleavage at the **R**FH**R**$_{218}$↓QA sequence.[5] In fact, primary hepatocytes derived from hepatocyte-specific furin KO mice[5] allowed us to unambiguously show that furin is the major processing enzyme of BMP10.[31] Finally, screening databases for potential furin-like substrates that exhibit a motif RxRR↓N similar to that of BMP10, reveal two new candidates, namely, the type II transmembrane growth factor ectodysplasin-A (*EDA*; **R**V**RR**$_{156}$↓**N**K), and the extracellular matrix collagen type V-alpha 1 (*Col5a1*; **R**T**RR**$_{1585}$↓**N**I), a minor component of collagen I fibrils. In e10.5 mice, *Col5a1* expression is found in the heart and dorsal aorta wall, and the *Col5a1* KO mice reveal that this protein is important in the development of functional connective tissues.

In vitro Properties of Soluble Furin and Information from Its Crystal Structure

A large body of data has been accumulated over the last 20 years on the *in vitro* enzymatic properties of soluble furin, a form lacking the transmembrane-cytosolic tail of the protease. The pH optimum of furin is approximately 7.0, but the enzyme is active at lower and higher pHs ranging from pH 6.0 to 8.5. Furin requires approximately 1 mM Ca^{2+} for optimal activity, the latter being completely inhibited by calcium chelators such as EDTA or EGTA. Heavy metal ions, such as Zn^{2+}, Hg^{2+}, and Cu^{2+} also inhibit furin activity, as well as the reducing agent DTT. Potent peptide-based furin inhibitors include those that contain the Arg-X-Lys/Arg-Arg-chloroalkanes, polyarginines, and the furin-prosegment. Several engineered inhibitors have been proposed such as the RXXR mutant of α1-antitrypsin (α1-PDX), and α1-proteinase inhibitor. However, so far nobody has found an endogenous secretory inhibitor specific for furin, except for the recently identified latent-TGFβ binding proteins (LTBPs), which albeit can also inhibit PC5/6 and PACE4.[30]

The consensus optimal recognition site for furin is Arg-X-Lys/Arg-Arg↓, containing a basic residue at P1, P2, and P4 positions. However, alternative motifs in which a P6 Arg can compensate for the absence of a basic residue at P4 or P2 have also been reported (**R**XX**R**↓ and **R**XXXX**R**↓). The residues at positions P1′, P2′, P3, and P5 and secondary structures such as β-turns also influence the efficacy of cleavage, in fact the **R**R**RR**↓EL sequence has been used to introduce optimal furin-like sites in specific regions of precursor proteins,[1] also exploiting the preference of furin for an acidic residue at P1′ and an aliphatic one at P2′.

The crystal structure of the soluble form of furin reveals a wide negatively charged catalytic pocket that is well suited to process secretory precursors at multibasic sites.[8] Homology modeling suggested a great similarity of this catalytic structure to that of the other basic aa-specific PCs that share >50% sequence identity.[9] The primary sequence and crystal structure of furin confirms it to be a type-I transmembrane subtilisin-like protease consisting of a signal peptide, a prosegment terminating at the autocatalytic Arg_{107} site (aa 25–107), a subtilisin-like catalytic domain containing the active sites Asp_{153}, His_{194}, and Ser_{368} and the oxyanion hole Asn_{295} (aa 108–445), a middle domain known as the P domain (aa 446–578), and a cysteine-rich domain (CRD; aa 556–705), followed by a C-terminal transmembrane anchor (aa 719–735) and cytosolic tail (aa 736–793) (Fig. 1). Furin is both *N*-glycosylated at $Asn_{387,440,553}$, and phosphorylated at $Ser_{772,774}$, resulting in an apparent mass on SDS-PAGE of approximately 100 kDa. The 2.6-Å crystal structure of soluble furin (lacking the CRD) and in complex with the inhibitor decanoyl-RVKR-chloromethane, revealed an 8-stranded jelly-roll P domain associated with the catalytic domain and compensating for the high negative field of the latter, thereby stabilizing the catalytic pocket.[8] Surface loops and highly negatively charged complementary substrate pockets are thought to explain the stringent requirement of furin for Arg at P1 and P4 and Lys at P2. However, the role of the CRD and its possible interaction with luminal or extracellular factor(s) that may regulate the function of furin are yet to be defined.

Furin Substrates: Activation or Inactivation?

Furin processes a very wide variety of precursors (Fig. 2) either in the TGN, cell surface or endosomes.[33] Although furin is mostly implicated in the processing of precursors secreted by constitutive pathway, such as growth factors and their receptors, adhesion molecules, blood coagulation

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

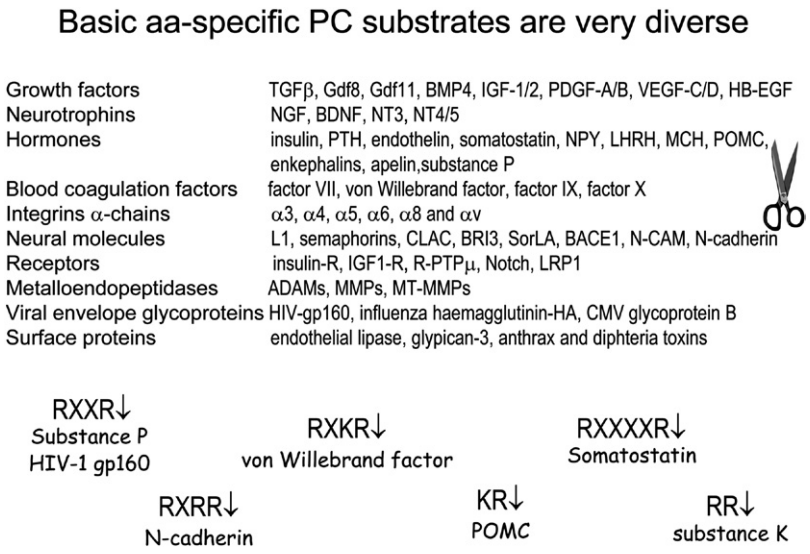

FIGURE 2 The types of precursor substrates of the basic aa convertases are shown, together with their functional annotations. The motifs recognized by these enzymes are emphasized.

factors, enzymes, and viral glycoproteins, it is also a major player in the processing of the regulated propeptide processing enzyme PC2, by cleavage of its chaperone 7B2 in the TGN.[17] The latter is needed for the productive zymogen activation of proPC2 into active PC2 in immature secretory granules. Further, furin not only has a pronounced effect on the regulated secretory pathway implicating dense-core granules, but also affects their acidification as it is critical in the *in vivo* activation of Ac45, an accessory subunit of the proton pump V-ATPase in pancreatic β-cells.[13]

In most situations, it was believed that furin would cleave precursor proteins at one or more sites resulting in active products. However, furin can also cleave certain precursors at strategic sites resulting in their inactivation. Although there are a number of such situations, we only present some of them. (i) Furin inactivates endothelial and lipoprotein lipases by cleavage at **R**N**KR**$_{330}$↓NS and **R**A**KR**$_{334}$↓SS, respectively. This results in an increase in circulating HDL.[10] (ii) The second example is the processing of PCSK9 by furin *in vivo* at the **R**FH**R**$_{218}$↓QA sequence, resulting in the loss of function of PCSK9 on the LDLR and increased levels of circulating LDL.[5] This is relevant physiologically, because a subset of patients suffering from hypercholesterolemia had an R218S mutation at the furin cleavage site, thus preventing its action and resulting in higher levels of active PCSK9 circulating. (iii) The liver peptide hepcidin is activated by low levels of furin by cleavage at a very favorable mutibasic R**RR**R**R**59↓DT site,[21] and inhibits iron absorption and recycling. Membrane HJV (m-HJV) acting as a coreceptor for BMPs has a key role in hepcidin regulation, and its inactivation causes severe iron overload. The shed form of m-HJV, known as soluble HJV (s-HJV) may down regulate hepcidin in a competitive way by interfering with BMP signaling. Furin is the convertase that generates s-HJV through the cleavage of m-HJV at a relatively less favorable site than hepcidin, that is, at **R**N**RR**335↓GA, resulting in the inactivation of HJV. Indeed, *in vivo* furin is upregulated by iron deficiency resulting in an increased level of s-HJV. Thus, while low levels of furin activate hepcidin to decrease iron uptake, on iron deficiency and hypoxia, the increased concentration of furin inactivates HJV to act as a counterbalance to increase iron absorption. (iv) Although furin activates a number of cell surface matrix metalloproteases, within the TGN it can also cleave the prodomain of proMMP-2 at **R**KP**R**72↓GA, leading to an inactive form of MMP-2. (v) Semaphorin-3B (sema3B) and semaphorin-3F (sema3F) are secreted tumor suppressors of lung cancer. Sema3F functions as an antiangiogenic factor that repels endothelial cells and compromises their proliferation/survival. However, sema3B is inactivated by furin-like PCs by cleavage at **R**F**RR**569↓QD, suggesting that upregulation of furin-like convertases in malignant cells may enable tumors to evade the antiangiogenic effects of sema3B.

Pathophysiological Implications

So far, no diseases have been found to implicate mutations in furin, possibly because of the lethality phenotype observed in KO mice. However, heterozygote mice are viable and show no overt phenotype(s), suggesting that only a small amount of furin is sufficient to perform its multiple functions. However, like PC1/3,[12] it is possible that the efficiency of cleavage of substrates that are weakly recognized by furin would be affected, especially in heterozygote mutants or in human mutants lacking one active furin allele. One example is the one caused by the natural SNP

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

causing a frame shift mutation due to the addition of a `C` nucleotide to the ACC codon coding for Thr_{381} and replacing it by CACC for His_{381} and hence replacing conserved wildtype sequence IIALL**T**LEANK by IIALL**H**LPGGQ (rs35998150). This is expected to result in a complete loss of function of furin. The other 29 SNPs reported for human furin that result in point mutations have yet to be carefully analyzed (http://www.ncbi.nlm.nih.gov/projects/SNP/snp_ref.cgi?geneId=5045).

Notwithstanding the effect of mutations in the furin coding sequence, furin is implicated in the processing of various growth factors and their receptors and furin upregulation may result in tumor growth and/or metastasis (for review see Ref. 22). Further, furin is implicated in the activation of cell surface viral glycoproteins resulting in enhanced viral infection and spread.[33] Therefore, a furin inhibitor may control these pathologies. The use of either an orally active nonpeptidic small molecule inhibitor or injectable biologics such as an antisense oligonucleotide, an antisense shRNA, or inhibitory monoclonal or single domain antibodies are but some of the available options.

Cancer patients are being recruited for treatment with an autologous vaccine that expresses rhGMCSF and bi-shRNAfurin (http://clinicaltrials.gov/ct2/show/NCT01061840). The GMCSF protein is a potent stimulator of the immune system, recruiting immune effectors to the site of intradermal injection and promoting antigen presentation. The furin bifunctional shRNA blocks furin production, resulting in a reduced processing of the proTGFβ1 and proTGFβ2 and by a feedback mechanism also decreases the levels of their mRNAs. The decrease in TGFβ1 and TGFβ2 proteins reduces their induced local immunosuppression and promotes tumor surface antigen and MHC protein display. We will have to await the results of such type of studies before drawing any conclusions.

However, the inhibition of furin may also cause problems, and could in some cases exacerbate the pathological condition. Thus, a targeted inhibitor to specific tissues may also be valuable. Finally, whether injection of active furin itself may be of value in some pathology is yet to be determined.

PC5/6

Zymogen Activation and Cellular Trafficking

After the discovery of the mammalian kexin/subtilisin-like convertases furin, PC1/3, PC2, and PC4, a new effort was made to detect other convertases in various tissues and cells. Using the PCR methodology as applied to mRNA isolated from rat and mouse testis, we were successful in isolating a novel convertase, which we termed proprotein convertase 5 (PC5).[14] At about the same time, another group led by K. Nakayama in Japan, also succeeded in isolating a similar cDNA from mouse brain and called it PC6. It turned out that PC5 and PC6 were identical, and the term PC5/6 is now mostly used. Alternative splicing of the mRNA from the single gene gives rise to two major forms of PC5/6, PC5/6-A and PC5/6-B, the former encodes the soluble protein of 915 aa that we isolated, and the latter a type-I membrane bound enzyme of 1877 aa.[25] This isoform, is generated from a single *PCSK5* gene presumably by alternative splicing of the PC5/6 heteronuclear RNA transcript.[15] Quantitative analysis of the tissue distribution of PC5/6 mRNA by qPCR revealed that the small intestine and kidney are the richest source of PC5/6-B, whereas all other tissues express mostly PC5/6-A, with the adrenal cortex especially rich in PC5/6-A transcripts.[4] Both transcripts share the first 20 exons encoding the signal peptide, prosegment, catalytic domain, P domain and the CRD. The 21st exon of PC5/6-A, coding for its last 38 residues, is replaced by 18 additional exons encoding the last 1000 residues for PC5/6-B.[16,26] Thus, the CRD of PC5/6-A contains 44 cysteine residues arranged in five tandem repeats of the consensus motif Cys-X_{2-3}-Cys-X_{3-4}-Cys-X_{2-7}-Cys-X_{5-10}-Cys-X_2-Cys-X_{9-13}-Cys-X_{3-5}-Cys-X_{7-16} (as it is also found in its closest homolog PACE4). The extended CRD of PC5/6-B contains 22 repeats of this cysteine-rich motif. The CRD binds both tissue inhibitors of metalloproteases (TIMPs) and heparin sulfate proteoglycans (HSPGs).[25]

PCs must go through an ordered process of autoactivation before they can cleave other protein substrates. After signal peptidase cleavage, human proPC5/6-A (aa 33–915) is *N*-glycosylated at 6 sites $Asn_{225,381,665,752,802,852}$ and proPC5/6-B (aa 33–1877) at 12 sites $Asn_{225,381,665,752,802,852,1014,1191,1290,1497,1985,1707}$. Both zymogens are then first cleaved at the S1 site **KK**R**T**K**R**$_{114}$↓DY in the ER, allowing them to exit this compartment as heterodimeric enzymatically inactive complexes pro≡PC5/6 and reach the TGN. Although furin is activated following a second autocatalytic cleavage of its prosegment leading to its dissociation from the catalytic subunit in the TGN,[7] the exact cellular location of PC5/6 activation, which also requires cleavage at an internal S2 site **R**TI**KR**$_{82}$↓SV of its prosegment is not so clear, as it may occur in both the TGN and at the cell surface. The complex pro≡PC5/6-A was detected bound to (HSPGs) at the cell surface.[25] These results indicated a novel pathway for PC5/6-A zymogen activation. Indeed, the loss of the prosegment coincides with the appearance of the PC5/6-A activity on various cell surface substrates (PCSK9, lefty, endothelial lipase and ADAMTS-4) was triggered after a 3-h cAMP treatment of cells by an as-yet undefined molecular mechanism. This mode of PC5/6-A activation is unique among the PCs and provides an additional level of cleavage regulation for cell surface substrates.

From the limited results available on the specificity of PC5/6 and its physiological substrates, it is expected that this convertase will have a major impact on cellular

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

proliferation and on sexual differentiation. The richness of PC5/6-B within the digestive system[4] also implies involvement in food metabolism. Interestingly, PC5/6-A and PC5/6-B are not expected to act on similar precursors, because this C-terminal variation causes the two isoforms to either remain within the constitutive secretory pathway (PC5/6-B) or could partially enter dense-core secretory vesicles (PC5/6-A) to process precursors destined to the regulated secretory pathway. Indeed, deletion of the unique C-terminal 38 amino acid segment in PC5/6-A leads to its secretion from the constitutive secretory pathway, suggesting that it contains a powerful signal for sorting toward the granules. The role of the CRD domain in PC5/6 is not yet understood, but it could well be implicated in protein–protein interactions either at the cell surface, intracellularly or in the extracellular matrix.

As for furin and PC7, PC5/6-B also has a transmembrane domain and a cytosolic tail, and cycles from the cell surface back to the TGN through endosomes.[35] This regulated transit into multiple compartments is controlled by several sorting signals in their cytosolic tails and their interactions with specific sorting adapters.

In vivo Mouse KO Models

PC5/6 exhibits a distinct distribution within the brain and it is expressed early during development.[4] The complete KO of PC5/6 causes embryonic death at birth, with mice exhibiting multiple morphogenic defects probably related to impaired homeotic transformations.[6,32] Thus, newborns exhibit major defects in the anteroposterior axis with extrathoraxic and lumbar vertebrates (18 and 8 instead of 13 and 6, respectively), and a lack of tail.[6] This phenotype had been reported for mice lacking the TGFβ-like factor, growth differentiation factor 11, GDF11, also known as BMP11. Both GDF11- and PC5/6-deficient mice lack kidneys, although the phenotype was more penetrant in PC5/6 KO mice (100% agenesis versus 86% lacking one or two kidneys). We showed that GDF11 is a favorite substrate of PC5/6, in part due to an Asn residue at P1′, the first position after the cleavage site **RSRR**$_{296}$↓NL.

Although PC5/6-deficiency perfectly mimics the GDF11 one, it also results in other phenotypes, suggesting the lack of processing of other substrates: *Pcsk5*$^{-/-}$ newborns die earlier, in the first 2 h versus first 2 days after birth for *Gdf11*$^{-/-}$ mice, probably by asphyxiation (lung alveoli were collapsed). They also exhibit smaller size than WT, retarded ossification, severe hindlimb hypoplasia, abdominal herniation, and superficial and tissular hemorrhages, suggesting vascular fragility.[6] Magnetic resonance imaging revealed severe phenotypes reminiscent of those observed in patients exhibiting VACTERL (vertebral, anorectal, cardiac, tracheoesophageal, renal, limb) malformations.[32] Finally, exon sequencing of control and VACTERL patients link mutations in the human PC5 gene (*PCSK5*) to this syndrome.[32] Thus, PC5/6, at least in part via GDF11, coordinately regulates caudal Hox paralogs, to control anteroposterior patterning, nephrogenesis, skeletal, and anorectal development.

The above studies suggest a role for PC5/6 in cardiovascular disease. Because lethality at birth of mice lacking PC5/6 precluded elucidation of its function in the adult, we generated mice in which the gene of PC5/6 (*Pcsk5*) is specifically inactivated in endothelial cells (ecKO), which are viable and do not exhibit overt abnormalities. To uncover the function of PC5/6 in the cardiovascular system, the effect of ecKO was studied in aging mice. In 16- to 18-month-old ecKO mice, the left ventricle (LV) mass, media cross-sectional area of aorta and coronary arteries, and media-to-lumen ratio of mesenteric arteries are decreased. The LV present decreased diastolic function, and mesenteric arteries show decreased stiffness. Collagen is decreased in the LV myocardial interstitium and perivascularly in coronary arteries and aorta. Cardiovascular hypotrophy probably develops with aging, because no significant changes are observed in 2-month-old ecKO mice. Fibroblasts, as a source of collagen in myocardium and vasculature, may play a role in the decrease in collagen deposition. Fibroblasts co-cultured with ecKO endothelial cells show decreased collagen production, decreased insulin-like growth factor (IGF)-1/Akt/mTOR signaling, and enhanced autophagic activation. PC5/6 inactivation in endothelial cells results in cardiovascular hypotrophy associated with decreased collagen deposition, decreased LV diastolic function, and vascular stiffness, suggesting a trophic role of endothelial PC5/6 in the cardiovascular system, probably mediated by IGF-1/Akt/mTOR signaling and control of autophagy. In conclusion, our results suggest that there is a specific role for endothelial cell-derived PC5/6 in fibroblast function. Although endothelial cells express 15- to 20-fold more furin than PC5/6 mRNA, furin exhibits similar ex vivo cleavage specificity to PC5/6, and cannot compensate *in vivo* for the loss of endothelial PC5/6. This indicates that a PC5/6-specific substrate(s) is responsible for the observed phenotypes. Inactivation of PC5/6 in endothelial cells results in a hypotrophic phenotype in mice that affects the cardiovascular system through its effects on fibroblasts. Autophagy plays a critical role in this process, mediated at least in part by decrease in the activity of the IGF/Akt/mTOR axis. These novel findings provide insights into potential new mechanisms, whereby PC5/6 in endothelial cells may participate in cardiovascular pathophysiology and may delineate new targets for cardiovascular therapy.

In vitro Properties of PC5/6

The convertase PC5/6[14,16] localizes to the cell surface via its C-terminal CRD, which binds TIMPs and HSPGs, and in many cases inactivate HSPG-bound proteins such as

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

endothelial and lipoprotein lipases,[10] and possibly adhesion molecules. The second cleavage of the prosegment, needed for zymogen activation, occurs at the cell surface, thereby limiting the functions of active PC5/6-A to the cell surface and/or extracellular matrix, thereby favoring substrates that are also bound to HSPGs. In the central nervous system, PC5/6-A can process the neural adhesion molecule L1 assisting in neuronal repair and migration. The specific physiological substrates of PC5/6 need to be unraveled *in vivo*, because in cellular experiments and *in vitro* many of the substrates processed by either enzyme were also cleaved by furin.

PC5/6-A has been prepared as a soluble 117-kDa product isolated from the medium of transfected cells with recombinant mouse or human PC5/6-A. A smaller, 69-kDa form of PC5/6 has also been detected on SDS-PAGE of a stable transfectant in AtT20 cells. Expression of PC5/6-A in baculovirus Sf9 cells or in Schneider 2 (S2) cells allowed its production at the level of 1 mg/l. The enzyme is most active at acidic pH 6.5 and is maximally activated by 5 mM Ca^{2+}. PC5/6 was able to cleave both monobasic and dibasic substrates without a strict requirement for a basic residue at P4. Although the PC5/6-B form of the convertase was predicted to be membrane bound like furin, soluble forms of both enzymes are released into the medium as a result of a cleavage at N-terminal to the transmembrane domain by an as yet unidentified "sheddase" or "secretase." The shed form of PC5/6-B exhibits an apparent mass on SDS-PAGE of approximately 170 kDa.

PC5/6 Substrates

PC5/6 is widely expressed in both endocrine and nonendocrine tissues, with high expression in the adrenal cortex, the gut, in testicular Sertoli cells[14] and in endothelial cells. These observations led to the analysis of the processing of human prorenin in the adrenals, pro-Mullerian inhibiting substance (proMIS) in Sertoli cells, and the receptor tyrosine phosphatase R-PTP-μ in endothelial cells. Interestingly, in both proMIS [**R**G**R**AG**R**↓S**K**] and R-PTP-μ [EE**RP**R**R**↓T**K**], the cleavage site contains a P2′ Lys, within the general sequence: **R**XX**R**↓S**K** or **R**XX**R**↓T**K**. PC5/6 is also responsible for the processing of a number of integrin α chains that exhibit a P1, P2 dibasic and an Ile at P4 but a His at P6, suggesting that this may also be a signature for PC5/6 processing. In addition, the TGFβ-like growth factor Lefty was also reported to be best processed by PC5/6-A, suggesting that PC5/6-A may have an important physiological role in the development of the heart and in endothelial cells. The human ortholog of the 915 amino acid PC5/6-A has been identified, and suggested to play a role in prorenin activation within the adrenal. However, KO studies revealed that PC5/6 is the major processing enzyme of proGDF11, cleaving at the distinguishing sequence **RSRR**$_{296}$↓NL, where Asn at the P1′ position is critical because if replaced by Asp, the site is now recognized by other convertases.[21] However, this motif may be specific to the GDF11 sequence, because other substrates with an Asn at P1′ are well cleaved by furin.[31]

Again, like the case of furin, PC5/6 may also be involved in the inactivation of substrates such as endothelial and lipoprotein lipases,[10] BMPs and adhesion molecules (Seidah et al., unpublished observations).

Pathophysiological Implications

We showed a downregulation of PC5/6 mRNA in human colon tumors at various stages.[29] Because PC5/6 is very rich in intestine, we evaluated its role in tumorigenesis by crosses with an $Apc^{Min/+}$ mouse model, which develops numerous adenocarcinomas along the small intestine and fewer in the colon. Because PC5/6-deficient mice die at birth, we generated mice lacking or not PC5/6-specifically in enterocytes (Villin-cre transgene) and analyzed the number and size of the tumors. The lack of PC5/6 in enterocytes results in a significantly higher tumor number in the duodenum, and a premature mortality of $Apc^{Min/+}$ mice, suggesting that intestinal PC5/6 is protective toward tumorigenesis, especially in mouse duodenum, and possibly in human colon.[29]

Increasing evidence suggests that extracellular accessory protein Vpr could contribute to HIV pathogenesis through its effect on bystander cells. Soluble forms of Vpr have been detected in the sera and cerebrospinal fluids of HIV-1-infected patients, and *in vitro* studies have implicated extracellular Vpr as an effector of cellular responses, including G2 arrest, apoptosis and induction of cytokines and chemokines production, presumably through its ability to transduce into multiple cell types. We provided evidence indicating that soluble forms of Vpr are present in the extracellular medium of HIV-1-producing cells. Release of Vpr in the extracellular medium is associated with HIV-1-mediated cytopathicity. Interestingly, Vprt undergoes proteolytic processing at a very well-conserved PC cleavage site, RQRR$_{88}$↓ located within the functionally important C-terminal Arg-rich domain of the protein. Vpr processing occurs extracellularly upon close contact to cells and most involve a cell surface-associated PC. Consistently, PC inhibitors suppress Vpr processing, while expression of extracellular matrix-associated PC5/6 and PACE4 enhances Vpr cleavage. PC-mediated processing of extracellular Vpr leads to the production of a truncated Vpr product that is defective in the induction of cell cycle arrest and apoptosis when expressed in human cells. Collectively, these results suggest that cell surface processing of extracellular Vpr by PC5/6 and/or PACE4 might regulate the levels of active soluble Vpr.

These results suggest that inhibition of PC5/6 may not be recommended, because in all the situations mentioned

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

above either during the development or in the adult, PC5/6 acts as a protective protease. However, preliminary evidence suggests that in some specialized situations, increased levels of PC5/6-A are associated with increased tumor metastasis (Seidah et al., unpublished observations). If PC5/6 inhibitors could be targeted to the tumor, this may then be useful in some therapy against cancer metastasis.

CONCLUSIONS

Although there is no doubt that furin and PC5/6 play major roles in various homeostatic processes within and outside the cell, they have both redundant and specific roles that are not interchangeable with other PCs. This is especially evident during embryonic development, as both enzymes are essential for life and the loss of their expression results in unique phenotypes. In mice, although the loss of furin expression leads to early developmental death at embryonic day 10.5 because of the lack of heart looping morphogenesis, the KO of *Pcsk5* results in lethality at birth with various body axis malformations and cardiovascular defects. The former may be related in part to the absence of BMP10 processing in the absence of furin,[31] the latter in part results from the lack of processing of proGDF11 by PC5/6.[6] However, this does not necessarily mean that the same substrates are important in the adult, and probably other unique substrates for each enzyme will be uncovered from tissue-specific mouse KO studies, or from human genetic mutations. The latter approach is still in its infancy, as only few mutations related to congenital heart disease have been related to PC5/6 function[32] resulting in either one of the congenital malformation syndromes: VACTERL (Vertebral, Anorectal, Cardiac, Tracheo-Esophageal, Renal, Limb malformations), CRS (Caudal Regression Syndrome), or CS (Currarino Syndrome; also known as Sacral Agenesis syndrome). We identified four patients with nonsynonymous variants in PC5/6-B (two with E1575K; one with E1256K, one with P1228S). In 13 patients with CRS, but with a VACTERL score <3, we identified one patient with a nonsynonymous change (heterozygous V1250I). E1256K, V1250I, and P1228S were not present in the relevant exons of ethnically matched controls, indicating that they are not common polymorphisms.[32] Before we could assign these mutations to a loss of function, we still need to carefully test these mutants for their effects on the ability of PC5/6-B to process proGDF11.[6] The future will surely tell whether the control of the activity of either furin or PC5/6 could find applications in the treatment of certain pathologies, including viral or pathogenic infections and cancer/metastasis. However, more probably we may find that the expression levels of these enzymes may be correlated with the progression of certain diseases and correlated with their predictive outcome.

ACKNOWLEDGMENTS

The author would like to acknowledge the tremendous help of all the past and present members of the laboratory who have actively participated in all phases of the work leading to this synopsis of the functions of furin and PC5/6. This work was supported by a CIHR Canada chair # 216684, a CIHR grant # MOP 44363, and a Strauss foundation grant.

Chapter 248

Proprotein Convertases PC4, PACE4, and PC7

Nabil G. Seidah

ABSTRACT

The unique secretory basic amino acid-specific proprotein convertases PC4, PACE4, and PC7 do not seem to have common substrates, and they have very different *in vivo* physiological functions. The loss of expression of either of these convertases is not essential, as all three knockout mice are viable. PC4 is exclusively expressed in male testis within germ cells and also in females within gonadotropin-activated macrophage-like ovarian cells. Male mice lacking PC4 are severely subfertile. PACE4 is widely expressed in many tissues, and in the adult brain, it is expressed in both neuronal and glial cells. In *Pcsk6* knockout mice, a proportion of embryos lacking this enzyme develop complex craniofacial malformations, establishing an important role for PACE4 in patterning the early mouse embryo. PC7 is mostly found at the cell surface and reaches this destination by both the conventional and unconventional secretory pathways. In cells, it indirectly induces the processing of proEGF, which is the only known physiological and specific target of PC7.

DISCOVERY AND NOMENCLATURE

The mammalian furin and the two regulated convertases PC1/3 and PC2 were all discovered in 1989–1990. This initial wave of discoveries was soon followed by the identification of PC4, PC5/6, PACE4, and PC7.[24] The human genes encoding the seven basic-aa specific Proprotein Convertases Subtilisin/Kexin-like were given the names of *PCSK1* to *PCSK7* (mouse *Pcsk1* to *Pcsk7*). In this review, emphasis will only be on PC4, PACE4, and PC7, each exhibiting unique physiological functions and cleaving very different substrates. The corresponding human and mouse genes map to chromosomes 19, 15, 11 and 10, 7, 9, respectively.

FUNCTIONS IN POLYPEPTIDE BIOSYNTHESIS/PROCESSING

PC4

In 1991, during our search by means of RT-PCR for other members of the PC-family in mRNA extracts of various tissues, we identified in rat testis three different approximately 600-bp cDNAs potentially coding for three different PCs, now known as PC4, PC5/6, and PACE4.[24] Shortly thereafter, an article appeared that reported the complete cDNA sequence of PACE4 from a human hepatoma HepG2 cell line and an osteosarcoma cDNA library.[12] We therefore first concentrated on the characterization of PC4.[27]

PC4 is expressed exclusively in male testicular germline pachytene spermatocytes and round spermatids, suggesting that it may play a specific physiological function in reproduction. In agreement, PC4 is detected in the acrosomal granules of round spermatids, in the acrosomal ridges of elongated spermatids, and on the sperm plasma membrane overlying the acrosome.[11] In female mice, PC4 is expressed in macrophage-like cells of the ovary, and its levels are downregulated in activated macrophages, such as in inflammation. PC4 is also expressed in human placenta. However, immunocytochemical results show that the PC4 protein is expressed at later stages of spermiogenesis and can even be detected in mature spermatozoa.

The structure of the catalytic domain of PC4 is closer to that of furin than that of any other proprotein convertase. Alignment of human, mouse, rat, and xenopus PC4 reveals that these are highly homologous except that each exhibits a specific C-terminal segment (from residue 593 onward). Interestingly, human and xenopus PC4 contains a single Cys-rich motif with six Cys within their unique C-terminal segment: Cys-X_2-Cys-X_3-Cys-X_2-Cys-X_7-Cys-X_2-Cys-X_{12}, similar to the ones found in furin, PC5/6, and PACE4.

Zymogen Activation and Cellular Trafficking

Results show that the bulk of PC4 remains as an intracellular zymogen (human aa 26–755), presumably trapped in the endoplasmic reticulum (ER), where it interacts with the general molecular chaperone glucose-regulated protein 78/Immunoglobulin heavy-chain binding protein (GRP78/BiP).[10] These results suggest that, unlike other members of the convertase family, proPC4 cannot efficiently self-activate in somatic

cells. These cells may lack the intracellular environment and the interacting molecules specific to testicular germ cells where this enzyme is normally expressed. Nevertheless, we have been able to isolate small amounts of recombinant, active PC4 after overexpression of its vaccinia virus recombinant in the constitutively secreting green monkey kidney epithelial BSC40 cells.[1] The zymogen human proPC4 is autocatalytically cleaved in the ER at the S1 site **R**RVKR$_{113}$↓SV. Different from most other convertases, no evident secondary S2 site is found. The usual autocatalytically cleavable S2 site found in furin ($_{69}$**H**RGVTKR$_{75}$↓SL), with the characteristic His$_{69}$ acting as a pH sensor, is replaced in PC4 by a PC-uncleavable sequence $_{75}$**H**RGVVQQ$_{81}$SL. This suggests that the prosegment (human aa 26–113) and the active enzyme separate early on in the secretory pathway may be without the need of a secondary S2 cleavage, as is the case of PC7.[22] Even though most of the PC4 remains intracellular, possibly resulting from the presence of a transmembrane domain (human aa 709–729), some are secreted as a soluble, Ca^{2+}-dependent enzyme exhibiting a neutral pH optimum, and can cleave *in vitro* fluorogenic substrates such as pGlu-Arg-Thr-Lys-Arg NHMec [XRTKR↓X]. The secreted enzyme consisted of two protein bands migrating at approximately 62, approximately 53 kDa on SDS-PAGE, which are attributed to C-terminal truncated PC4 forms. This enzyme displays strong protease activity toward fluorogenic Boc-RVRR-MCA and various intramolecularly quenched peptides derived from PC4 substrates.

In vivo Mouse Knockout (KO) Models

It took much effort from M. Mbikay to obtain during a sabbatical year at the Jackson laboratories mice that lacked PC4 expression.[16] This article that appeared on June 24, 1997, was the first report on any convertase KO mouse. The *in vivo* fertility of homozygous mutant males is severely impaired in these mice, without any evident spermatogenic abnormality.[16] *In vitro*, PC4 deficiency seems to cause reduced fertilization and early embryonic death.[16] A comparison of wild-type and *Pcsk4*-null sperm for their abilities in capacitation, acrosome reaction, and egg binding *in vitro* was undertaken.[11] The results reveal that *Pcsk4*-null sperm undergo capacitation at a faster rate; they are induced to acrosome react by lower concentrations of zona pellucida; and their egg-binding ability is only half that of wild-type sperm. These sperm physiologic anomalies probably contribute to the severe subfertility of *Pcsk4*-deficient male mice. Accordingly, these results strongly suggest that PC4 will play an important role in fertility and that functional redundancy mediated by any other PC is quite limited in the testis. PC4 thus seems to be a crucial enzyme for reproduction. Alterations of PC4 expression or activity could be the underlying cause of some unexplained cases of human infertility. Conversely, inactivation of this protease represents a potential strategy for nonhormonal contraception

PC4 Substrates

Many C-terminally[27] and N-terminally modified isoforms are predicted from the isolated cDNAs, probably arising from an alternative splicing of the gene. PC4 is a very special prohormone convertase whose C-terminus is species specific, with human and xenopus forms possibly being type-1 transmembrane containing proteins.[27] This may be necessary to ensure no crossspecies fertilization. PC4 has only been characterized in rat and mouse testis, and it is not known whether invertebrates express this enzyme.

So far, very little is known about the natural substrates of PC4. Vaccinia virus expression of PC4 allows the isolation of an active form of the enzyme of ~53 kDa. *In vitro* analysis using synthetic peptide substrates demonstrated a possible role of PC4 in the maturation of proIGF-1 and proIGF-2 and propituitary adenylate-cyclase-activating polypeptide (proPACAP). These results suggest that PC4 prefers to cleave sequences containing the motif **K**XX**R**↓ with a P4 Lys (where X denotes any other residue). Cellular coexpression studies confirm that PC4 is a genuine and sole proPACAP convertase in the testis and ovary of mice.[13] From the autocatalytic cleavage site required for zymogen activation of PC4, and by analogy to other convertases, it was predicted that PC4 will cleave precursors at the consensus sequence of (Lys/Arg)-Arg↓ [KR↓X; RR↓X] or (Arg/Lys)-(Xaa)$_n$-Arg↓, where $n = 2$, 4 or 6. *In vitro* studies with purified enzyme conclude that the most probable sequence motif for recognition by PC4 is KXKXXR↓ or KXXR↓, where X is any aa other than cysteine and that PC4 prefers a proline at P3, P5 and/or P2′ positions. PC4 is a good candidate processing enzyme for the growth factors IGF-1 and -2, and several ADAM (A Disintegrin And Metalloprotease) proteins such as ADAM-1, -2, -3, and -5.[2] Finally, potent PC4-inhibitory activity with K_i in low nanomolar range is observed with the tetrapeptide chloromethyl ketones, decanoyl-RVKR/K-chloromethyl ketone. Optimized PC4 inhibitors, possibly derived from those reported in flavonoids may one day serve as male contraceptives.

Pathophysiological Implications

Intrauterine fetal growth restriction is a leading cause of perinatal mortality. There is an unusual property of PC4 in the processing of proIGF-2, which is an important regulator of fetoplacental growth. Thus, PC4 cleaves proIGF-2 to generate the intermediate processed form, IGF-2$_{1–102}$ and, subsequently, mature IGF-2$_{1–67}$, thereby regulating fetoplacental growth.[21] In the future, SNPs variants PC4 that could affect its activity may explain some of the pathophysiology of fetoplacental growth restriction http://www.ncbi.nlm.nih.gov/projects/SNP/snp_ref.cgi?geneId=54760. Thus, although many of these coding variants are already known, they await biochemical confirmation of their effects,

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

especially for the mutants R202C (close to the active site His_{199}), G302S (close to the oxyanion hole Asn_{300}), C338Y, Y561C, and C649F, which are expected to result in a loss-of-function of PC4, probably resulting from misfolding of the zymogen and/or retention in the ER.

PACE4

The proprotein convertase PACE4 was discovered in 1991,[12] shortly after the identification of PC1/3, PC2, and furin. The convertases PACE4 and PC5/6 form a class of their own based on their primary structures and their ability to bind the cell surface via their C-terminal Cys-rich domains, which bind tissue inhibitors of metalloproteases (TIMPs) and heparin sulfate proteoglycans (HSPGs).[29] Quantitative real-time PCR (qPCR) analysis of mRNA expression revealed that PACE4 is expressed in many tissues, and in mouse, it is rich in liver, pituitary, adipose tissue, heart, pancreas, digestive system, and brain cerebellum, with very little expression in male reproductive organs such as testis but significantly expressed in female ovary (Fig. 1). The present results strongly suggest unique tissue-specific functions of PACE4.[8] Thus, in the brain, it is found in both neuronal and glial cells. However, in areas that are rich in neuropeptides such as cortex, hippocampus, and hypothalamus, mRNA levels of PACE4 are low or undetectable. In regions, such as the amygdaloid body and thalamus, there is a distinct distribution of PACE4 mRNAs. The medial habenular and cerebellar Purkinje cells express very high levels of PACE4 mRNA, as do anterior pituitary cells.[8] The specific physiological substrates of PACE4 need to be unraveled *in vivo*, because in cellular experiments and *in vitro* many of the substrates processed by PACE4 are also cleaved by Furin, PC5/6, and/or PC7.

Zymogen Activation and Cellular Trafficking

PCs must go through an ordered process of autoactivation before they can cleave other protein substrates. Following signal peptidase cleavage of the unusually long signal peptide of preproPACE4 (human 63 aa), proPACE4 (human aa 64–969) is N-glycosylated at three sites $Asn_{259,913,942}$. Like all PCs, the prosegment (human aa 64–149) acts as an intramolecular chaperone and inhibitor of PACE4. It is first autocatalytically cleaved in the ER at the S1 site $\underline{K}R\underline{R}V\underline{KR}_{149}$↓QV. This generates an enzymatically inactive heterodimer complex (pro≡PACE4) of the prosegment (aa 64–149) with mature PACE4 (aa 150–969), which can

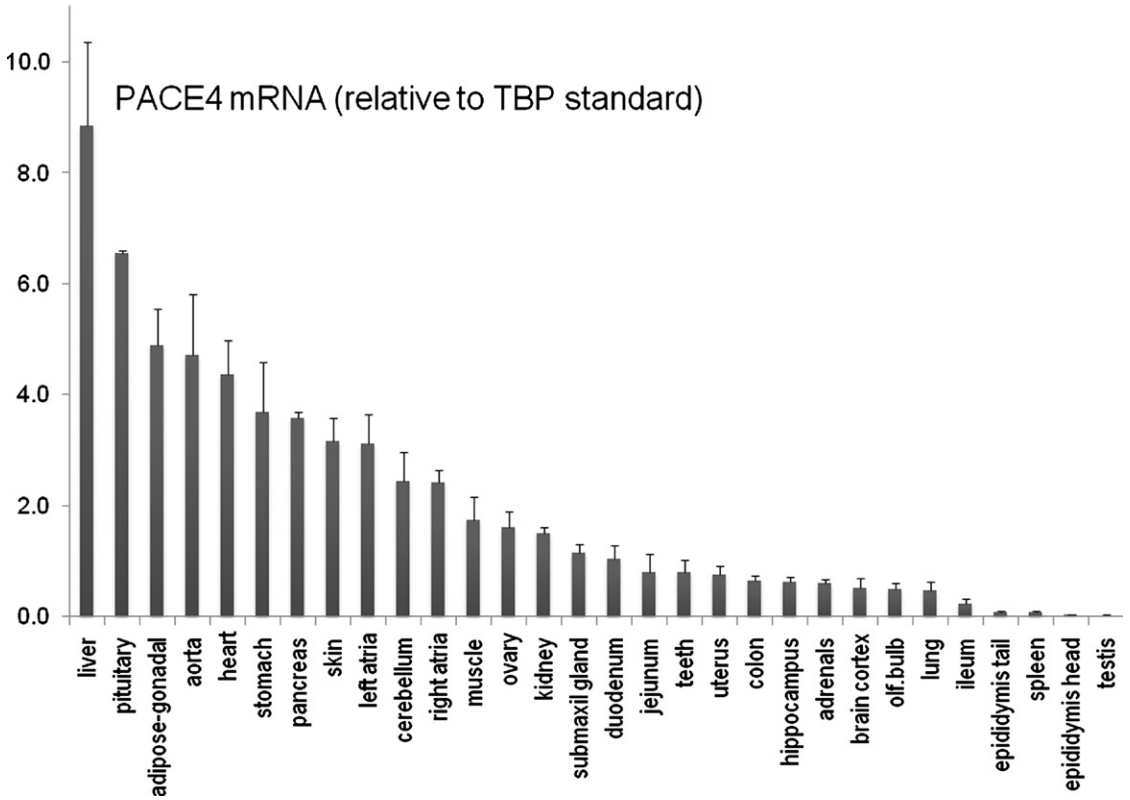

FIGURE 1 Quantitative reverse transcriptase PCR analysis of the mRNA expression of PACE4 in mouse tissues. Each measurement was done in triplicate, and the standard error from the mean is shown above each bar. The levels are normalized to the mRNA values of the housekeeping standard TATA-box binding protein (TBP).

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

then exit from the ER and reach the trans-Golgi network (TGN), undergoing trimming and remodeling of its sugar moieties along the way. The usual autocatalytically cleavable S2 site found in furin ($_{69}$**H**RGVTKR$_{75}$↓SL), with the characteristic His$_{69}$ acting as a pH sensor, is replaced by $_{111}$**H**SKTFKR$_{117}$↓ST in PACE4. However, where and when the secondary autocatalytic cleavage at the S2 site occurs is still not completely understood. The presence of the probable pH sensor His$_{111}$ suggests that it would occur in an acidic environment, where the His$_{111}$ would be protonated (e.g. TGN and/or recycling endosomes). Indeed, evidence has been presented that except for PC5/6, and different from the other convertases, PACE4 seems to be in large part activated at the cell surface while in contact with HSPGs.[15] This limits the functions of active PACE4 to the cell surface and/or extracellular matrix (ECM), thereby favoring substrates that are also bound to HSPGs. This is especially evident in the cellular processing of the TGFβ-like bone morphogenetic protein BMP10, which is completely inhibited by a noncell permeable hexa-Arg inhibitor.[31]

Within the catalytic domain, human, rat, and mouse sequences exhibit 98% sequence identity and contain the characteristic subtilisin-like serine proteases His*, Asp*, and Ser* catalytic triad and the oxyanion hole Asn. The catalytic domain (human aa 150–454) is then followed by a P-domain that seems to function as a stabilizer of the catalytic pocket via neutralization of its highly negatively charged environment, needed to attract positively charged substrates. The P-domain is followed by a cysteine-rich domain (CRD; aa 695–930) that contains 44 cysteine residues arranged in five tandem repeats of the consensus Cys-X$_{2-3}$-Cys-X$_{3-4}$-Cys-X$_{2-7}$-Cys-X$_{5-10}$-Cys-X$_2$-Cys-X$_{9-13}$-Cys-X$_{3-5}$-Cys-X$_{7-16}$ motif (as it is also found in its closest homolog PC5/6). The CRD binds both TIMPs and HSPGs[29] at the cell surface or in the ECM.[15] We showed that the extracellular activity of PACE4 is probably regulated by endogenous inhibitors known as latent-TGFβ binding proteins (LTBPs 2,3).[30]

In vivo Mouse Pcsk6 KO Models

In a mixed genetic background, the complete KO of the PACE4 gene *Pcsk6* in mice resulted in a 75% viable phenotype with bone morphogenesis defects.[6] About 25% of homozygous knockout embryos die prenatally and, at a later stage of development, between E13.5 and E15.5. However, the severity and penetrance of this phenotype may partly depend on the background of the KO mouse, as it seems less severe in C57BL/6 pure background mice (D. Constam, personal communication). Similar to furin KO mice (*fur*$^{-/-}$), and PC5 KO mice (*Pcsk5*$^{-/-}$)[9,32] the embryos have cardiac malformations that probably lead to death. Defects are also found in other internal organs including the liver, lungs, pancreas, spleen, and gut. These left/right axis defects are preceded at embryonic day 8.5 by an abnormal expression of the axis determining TGFβ-like growth factors Nodal and Lefty, which are both PC-substrates. These genes are normally asymmetrically expressed and involved in determining the left–right axis, but in *Pcsk6*$^{-/-}$ embryos expression can be absent or bilateral. Some embryos deficient in PACE4 show severe craniofacial defects such as cyclopism and truncation of the head, showing that PACE4 activity is necessary for anterior patterning. So far, in *Pcsk6*$^{-/-}$ mice, the identity of the substrate(s), which if left unprocessed would result in the observed complex craniofacial malformations, including cyclopia,[6] is/are yet to be defined.

In vitro Properties of PACE4

It is clear that the substrate specificity is more limited than that of furin. It can cleave substrates such as pGlu-Arg-Thr-Lys-Arg-MCA to release the fluorescent AMC close to neutral pHs. It does require 1 mM Ca^{2+} for optimal activity, and the latter is inhibited by EGTA. Aside from the ability of PACE4 to cleave substrates at pairs of basic residues within the consensus R-X-K/R–R↓SF (http://merops.sanger.ac.uk/cgi-bin/pepsum?id=S08.075;type=P; based on 17 peptide cleavages), PACE4 can also process precursors at monobasic residues that lack an Arg at P4. Thus, within the constitutive secretory pathway, PACE4 efficiently processes prosomatostatin at RLELQR↓SA (P1 and P6 Arg) generating somatostatin 28, or at APRERK↓AG (P1 Lys and P4 Arg) producing somatostatin 14.[5]

Ex vivo PACE4 Substrates

From the Merops database (http://merops.sanger.ac.uk/cgi-bin/substrates?id=S08.075), ex vivo some of the type of cellular precursors best cleaved by PACE4 include ADAM-TS4 (RAKR↓FA), aerolysin (RRAR↓SV), BMP4 (RAKR↓SP), Diphtheria toxin (RVRR↓SV), HIV gp160 (REKR↓AV), Insulin receptor (RKRR↓SL), endothelial lipase precursor (RNKR↓NS), angiopoietin-like 3 (RAPR↓TT), MMP11 (RNKR↓FV), neurotrophin-3 precursor (RRKR↓YA), LRP1 (RHRR↓QI), PDGF-B (RGRR↓SL), and von Willebrand factor (RSKR↓SL).

In the adult, PACE4 plays an important role in myogenic differentiation through its association with the IGF-2 pathway. Thus, although PC4 process proIGF-2 in testis, PACE4 seems to be its cognate convertase in muscle. It was also reported that PACE4 could process the TGFβ like substrate Nodal and that its intracellular traffic is dictated by the 18-kDa EGF-containing GPI-anchored proteoglycan Cripto that directs its traffic through an unconventional secretory pathway directly from the ER to the cell surface, and sorting to detergent resistant membrane microdomains.[4] Cripto is the first receptor that binds both a PC and its substrate (Nodal), thereby enhancing the processing step.

Pathophysiological Implications

PACE4 is a protective gene, because its specific absence results in a decreased extracellular inactivation of the HIV-1 accessory protein Vpr.[34] However, this does not exclude that under certain pathological conditions (e.g. metastatic cancer), overexpression of PACE4 may result in enhanced pathology. A similar type of situation may exist in osteoarthritis, where PACE4 is overexpressed, and its inactivation may relieve the associated pain symptoms. Indeed, proteolytic degradation of the major cartilage macromolecules, aggrecan and type II collagen, a key pathological event in osteoarthritis, is performed by ADAMTS-4,5, matrix metalloproteases that are proteolytically activated by PACE4 processing of their inhibitory prodomains in cartilage.[14,33]

More recently, it has been realized that PACE4 may play an important role in cancer development and possibly associated metastasis. For example, there is high expression of PACE4 in all different clinical stages of human prostate tumor tissues. Gene silencing studies targeting PACE4 in the DU145 prostate cancer cell line produced cells with slower proliferation rates, reduced clonogenic activity, and inability to grow as xenografts in nude mice. The direct role of PACE4 in prostate cancer is most probably through the upregulated processing of growth factors, or through the aberrant processing of growth factors, leading to sustained cancer progression, suggesting that PACE4 holds a central role in prostate cancer.[7] If PACE4 inhibitors or silencers could be targeted to the tumor, this may then be useful in some therapy against cancer and possibly its associated metastasis.

Finally, because PACE4 mRNA levels are consistently upregulated in prostate tumors and inhibition of PACE4 activity is associated with lower tumor growth, this suggests that this convertase could play an important role in either prostate tumorigenesis and/or its associated metastatis. It is therefore possible that PACE4 activity may be associated with enhanced tumorigenesis and conversely that loss-of-function mutations of PACE4 protease may be associated with a good long-term prognosis. In that context, we screened the publicly available missense or nonsense Single Nucleotide Polymorphism (SNP) data for the presence of SNPs (http://www.ncbi.nlm.nih.gov/projects/SNP/snp_ref.cgi?geneId=5046) associated with PACE4 exons. Accordingly, we found a limited number of natural coding mutations that are predicted as most damaging ones found in the PACE4 SNP database, two of which are rs45587040[Q569X, C-terminal aa 569–969 truncated; 48% prevalence] and rs75922759 [C845W, disrupts the CRD]. It would be interesting to search for such mutations in prostate cancer or osteoarthritis patients and to correlate these to the outcome or progression of the pathology.

PC7

Zymogen Activation and Cellular Trafficking

The type-I membrane-bound PC7 is the most ancestral member of the mammalian family, exhibiting the closest relationship to yeast kexin.[28] Biochemical and enzymatic characterization of the novel proprotein convertase rat PC7 (rPC7) was carried out using vaccinia virus recombinants overexpressed in mammalian BSC40 cells. ProPC7 is synthesized as a glycosylated proenzyme (101 kDa) and processed into mature rPC7 (89 kDa) in the ER which is then Cys-palmitoylated (Cys-palm) at the cytosolic tail Cys_{699} and Cys_{704} (Fig. 2A).[22,28] No endogenously produced, soluble forms of this membrane-anchored protein were detected, revealing that it is not shed into the medium.

The inhibitory prosegment of PC7[3,35] is primarily secreted alone as a noninhibitory protein via the conventional, Golgi-dependent, secretory pathway.[22] Mature PC7 is partially sulfated and thus reaches the cell surface via the conventional route. However, a fraction of PC7 reaches the cell surface through a brefeldin A- and COPII-independent unconventional secretory pathway. The latter trafficking may explain the rapid (<10 min) transit of a fraction of PC7 from the ER to the cell surface. Electron microscopy further confirmed the localization of PC7 to the cell surface of HEK293 cells. PC7 also localizes within subcellular compartments distal to the TGN and can be stored in undefined vesicular stacks close to the Golgi apparatus. Within the cytosolic tail, only two cysteines (Cys_{699} and Cys_{704}) are palmitoylated, but this modification does not affect the choice of trafficking pathway. Swapping the transmembrane-cytosolic tail (TMCT) sequences of the convertases Furin and PC7 revealed that the transmembrane domain of PC7 regulates the sorting of PC7 toward the unconventional secretory pathway. Thus, PC7 is distinct from other proprotein convertases in its zymogen activation, subcellular localization, and trafficking.[22]

Interestingly, although overexpression of the prosegments of Furin, PC5/6 and PC7 results in potent inhibitors of substrate cellular processing,[19,35] only the prosegment of PC7 is secreted into the medium.[35] Finally, the prosegment C-terminal $\underline{RAKR}_{140}$ motif of r-PC7 is critical for its convertase inhibitory activity.[3] Altogether, these results point out the particularities of PC7 in its zymogen activation and subcellular localization.

In vitro Properties of PC7

Because PC7 is membrane bound and never shed,[18] to isolate an active soluble form of PC7, we introduced a stop codon close to the beginning of transmembrane segment, herein called PC7sol.[18,28] Thus, the soluble, *in vitro* active form produced spans the segment ending at Gly-Tyr-Ser_{622}.[18,28] We thus obtained both vaccinia virus and baculovirus

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

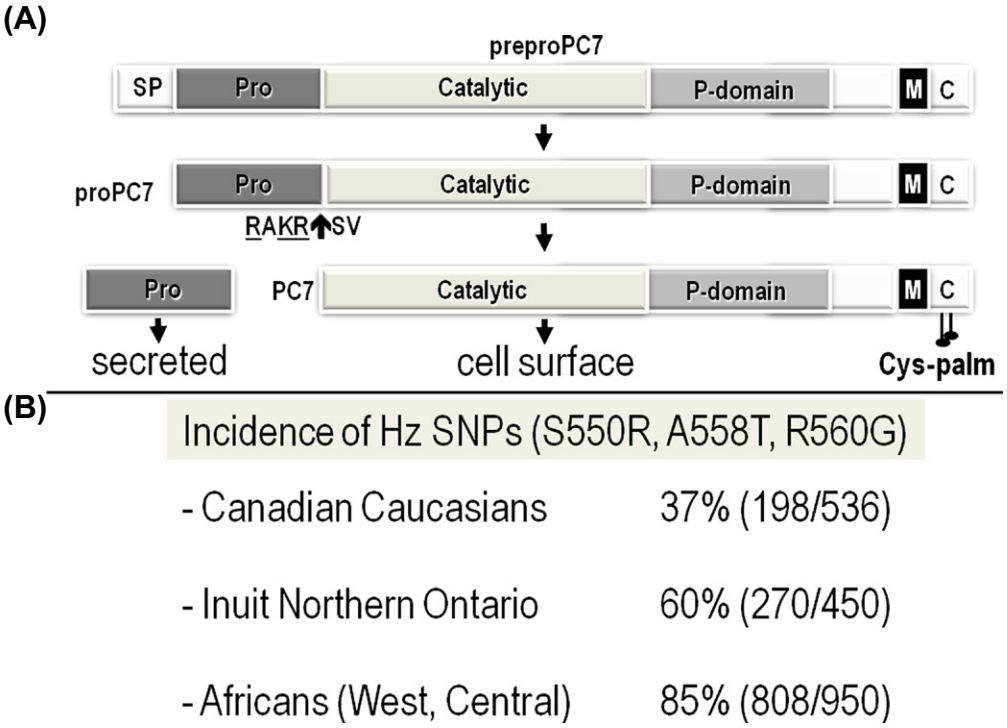

FIGURE 2 (A) Schematic representation of the autocatalytic processing of proPC7 into PC7 at **R**A**KR**$_{140}$↓SV and its posttranslational Cys-palmitoylation (at Cys_{699} and Cys_{704}; Cys-palm) in its cytosolic tail. The various domains are emphasized, including the signal peptide (SP), prosegment, catalytic and P-domains, the transmembrane domain (M) and the cytosolic tail (C). Although the cleaved prosegment is secreted alone, the active membrane-bound PC7 localizes to the cell surface. (B) incidence of heterozygote *PCSK7* coding SNPs (S550R, A558T, R560G) in three ethnic populations.

recombinants and showed that both systems yield active enzyme, in the range of 1–3 mg/l. Schneider 2 (S2) cells also produce active soluble human PC7. The activity is routinely measured using a fluorogenic substrate pyro-Glu-Arg-Thr-Lys-Arg-methyl-coumaryl-7-amide (pERTKR-MCA).

Enzymatic activity assays of PC7sol using fluorogenic substrates indicated that the enzyme exhibits a neutral pH optimum, and a Ca^{2+} dependence, and cleavage specificity largely similar to that of furin, with a general recognition sequence of either (K/R)-R↓ or (R/K)-$(X)_n$-R↓ where $n = 2$, 4 or 6.[25,26] However, with some substrates, cleavage specificity more closely resembles that of yeast kexin, suggesting a differential processing of proprotein substrates by this novel convertase. We examined the PC7sol- and human furin-mediated cleavage of synthetic peptides containing the processing sites of three proteins known to colocalize in situ with PC7. Although both enzymes correctly process the proparathyroid hormone tridecapeptide KSVKKR↓SVSEIQL and the heptadecapeptide YETLRRRVKR↓SLVVPTD of proPC4, neither enzyme cleaves *in vitro* a hexadecapeptide spanning the N-terminal cleavage site of proepidermal growth factor (proEGF): HLREDDHHYSVR-NSDS.

Several investigations aimed at defining the sequence recognition of PC7 and its redundancy with other convertases suggested that although less efficient than Furin, PC7 specifically cleaves overexpressed substrates at Arg↓ residues both *in vitro* and in cell lines. Thus, although Furin and PC7 have been proposed as the major gp160 processing convertases, rat liver microsomal gp160 processing activity is essentially different from Furin, and only partially overlaps with PC7. Density gradient studies reveal that PC7 resides in lighter subcellular fractions than Furin.

Ex vivo PC7 Substrates

Specific PC7 substrates are very difficult to find. We showed that only the full-length PC7, the most ancient and conserved basic amino acid-specific PC-family member, induces the processing of proEGF into an approximately115-kDa transmembrane form (EGF-115) at an unusual $VHPR_{290}$↓ motif.[23] Because site directed mutagenesis revealed that Arg_{290} is not critical, the generation of EGF-115 by PC7 is probably indirect. This was confirmed by testing a wide range of protease inhibitors, which revealed that the production of EGF-115 is most probably achieved via the activation by PC7 of a latent serine and/or cysteine protease(s). EGF-115 is more abundant at the cell surface than proEGF and is associated with a stronger EGF receptor (EGFR) activation, as evidenced by the higher levels of phosphorylated ERK1/2. This suggests that the generation of EGF-115 represents a regulatory mechanism of juxtacrine EGFR activation. Thus, PC7 is distinct from the other PCs in its ability to

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

enhance the activation of the cell surface EGFR. This is the first reported PC7-specific processing reaction.

Another possible PC7-specific processing reaction seems to be the shedding of the type-2 membrane-bound transferrin receptor (TfR) into a secreted soluble form TfRsol. Indeed, a recent Genome Wide Association Study (GWAS) revealed that a PC7-specific SNP (rs236918) was very positively genetically associated with lower levels of circulating human TfRsol.[20] These authors suggest that PC7 is probably the sheddase of the TfR, at least in human. This will need biochemical validation.

In vivo Models

So far, no report appeared on the phenotypic analysis of *Pcsk7*$^{-/-}$ mice, which are viable and healthy and live a normal life span. Our own preliminary data suggest that complete loss of PC7 expression leads to an anxiolytic phenotype implicating amygdala and/or hippocampus dysregulation within the central nervous system (CNS). We are in the process of identifying the underlying molecular causes of this subtle abnormality.

Northern blot analyses reveal a wide expression of PC7 mRNA in all rat tissues and cell lines analyzed.[28] Quantitative real time-PCR (qPCR) analysis of PC7 expression in adult mouse tissues shows that colon, kidney, duodenum, and heart are the richest sources of PC7 mRNA.[22] These results suggest that PC7 may have multiple physiological functions, some of which may be redundant with other convertases. It is thus interesting to note that the observed CNS phenotype in *Pcsk7*$^{-/-}$ mice would not have been predicted from the levels of expression of PC7 in various tissues, as amygdala and hippocampus are not the richest sources of this convertase in the adult animal.[22,28] It is therefore conceivable that the molecular foundation for the observed anxiolytic phenotype may be already in place during embryonic development and that in the adult PC7 may have other functions.

To identify mutations within the coding region of *PCSK7* in human, we analyzed the relevant SNPs database http://www.ncbi.nlm.nih.gov/projects/SNP/snp_ref.cgi?geneId=9159. To our surprise, we found 41 SNPs with aa changes. The predicted three most damaging, yet rare ones (<0.1% frequency), are: D188G (disrupts the conserved active site pocket around the active site Asp_{187}*), R316C (replaces the highly conserved Arg_{316} in all PCs by Cys, which may cause unfolding of the protein), L506P and frameshift afterward leading to a new 64 extra aa C-terminal domain followed by a stop codon (disrupts the P-domain and the whole C-terminus of PC7, likely causes unfolding of the protein).

Interestingly, we also found a more frequent damaging mutation R560G (often associated with A558(T/V) and/or S550R) in >1936 individuals of different ethnicity (Fig. 2B). The R560G mutation affects an absolutely conserved Arg_{560} in all convertases and the R560G mutant exhibits complete loss of activity, as confirmed biochemically in various cells using the proEGF target of PC7 (Seidah NG et al., in preparation). In this large cohort, we found that the heterozygote R560G mutation is very prevalent in Africans (85%), and its incidence diminishes in Aboriginal Inuits of Northern Ontario (60%) and Canadian Caucasians (37%). Amazingly, we never found any homozygote R560G mutation in any of the individuals analyzed. This curious result prompted us to look into more details at the PCSK7 gene. Indeed, multiple human genomic sequences revealed that exons 13–17 are inverted and duplicated in humans with the duplication residing 60 kb downstream to the complete gene of PCSK7, as originally reported for one *PCSK7* gene.[17] Deeper sequence analysis revealed that the R560G mutation is only found in the duplicated portion of *PCSK7* and not in the original complete gene. This explains the absence of homozygote mutation, because even if a homozygote R560G mutation was found, it will appear as heterozygote because the full gene is not mutated. Furthermore, analysis of the R560G mutation in other species revealed that it is found only in monkeys but not in any other species including rodents (Seidah NG, unpublished observations). This suggests that the R560G mutation probably occurred after exon 13–17 duplication and inversion. The fact that the incidence of the R560G mutation diminishes in ethnicities away from Africans, strongly supports the bottleneck effect that occurred approximately 100,000 years ago, when humanoids migrated out of Africa into the Middle East and Asia.

Pathophysiological Implications

So far, no pathology has been reported implicating PC7, except for its high expression in (https://www.oncomine.org/resource/login.html;jsessionid=EDAC840EAC27B5867C651747898FE3D1) hepatocellular carcinoma, colon adenocarcinoma, and B-cell lymphoma, and much reduced mRNA levels in many other types of cancers, for example, those originating in bladder, brain, breast, kidney, lung, prostate, and uterus.

CONCLUSIONS

Although PC4, PACE4, and PC7 are basic-aa specific proprotein convertases, they exhibit a widely different repertoire of substrates, and phenotypes observed in mice lacking these proteinases. The future development of specific inhibitors against each of these convertases will likely be used as male contraceptives, reduction of pain in osteoarthritis, and as novel anxiolytics, respectively.

Chapter 249

Proprotein Convertases SKI-1/S1P and PCSK9

Nabil G. Seidah

ABSTRACT

SKI-1/S1P and PCSK9 are the last members of the proprotein convertase family. The former localizes to the *cis/medial* Golgi and is implicated in the processing of several membrane-bound transcription factors, e.g. SREBPs that regulate cholesterol and fatty acid synthesis and metabolism, ATF6 that affects the endoplasmic reticulum stress response, and other CREB-like proteins. Other substrates include proBDNF, prosomatostatin, the RGMa that regulates axonal connections, and the α/β-subunit precursor of GlcNAc-1-Ptase needed to phosphorylate mannose residues for protein export to lysosomes. It is also needed for infectivity of arenaviruses via the activation of their cell-surface glycoproteins. Mice lacking SKI-1/S1P die during very early stages of embryogenesis. PCSK9 only cleaves itself and then acts as a receptor binding protein. It is implicated in the induced intracellular degradation of the LDLR, VLDLR, and ApoER2 via its ability to bind these receptors and drag them to endosomes/lysosomes. Mice and humans lacking PCSK9 live and exhibit a hypocholesterolemia phenotype.

DISCOVERY AND NOMENCLATURE

The generation of bioactive proteins and peptides by limited proteolysis of inactive precursors is an evolutionarily ancient mechanism determining the level and duration of specific bioactivities. It was realized since the early 1970s that limited cellular processing of precursors occurs at single or pairs of basic amino acids (aa) and also at sites that are not occupied by basic residues. The search for the enzyme(s) responsible for such cleavages led to the identification of a novel pyrolysin-like homolog of subtilisin (in peptidase subfamily S8A) known either as subtilisin kexin-isozyme-1 (SKI-1),[30,31] or site-1 protease (S1P).[9] These studies revealed that SKI-1/S1P is a major processing enzyme of the endoplasmic reticulum/Golgi (ER/Golgi) lumen that acts on sterol regulatory element-binding proteins (SREBPs), and thereby regulates cholesterol and fatty acid biosynthesis. It is also critical for the N-terminal processing of probrain derived neurotrophic factor (proBDNF)[30] and prosomatostatin, resulting in products that are sorted to the regulated secretory pathway of endocrine and neural cells. Homology searches reveal that SKI-1/S1P is an enzyme highly conserved in vertebrate and invertebrate organisms.

FUNCTIONS IN POLYPEPTIDE BIOSYNTHESIS/PROCESSING

SKI-1/S1P

Zymogen Activation and Cellular Trafficking

Biosynthetic analysis of full-length SKI-1/S1P (gene *MBTPS1*) shows that proSKI-1/S1P (~150 kDa) is a membrane-bound zymogen that is progressively autocatalytically processed at three N-terminal prosegment sites (RKVF$_{133}$↓RSLK$_{137}$↓YA followed by RRLL$_{186}$↓RA) within the ER/*cis*-Golgi to finally generate the membrane-bound active SKI-1/S1P (98 kDa; aa 187–1052). The full-length prosegment (14 kDa; human aa 18–186) is both a chaperone and an inhibitor of the enzyme, which is autocatalytically cleaved into inactive 10- and 8-kDa fragments.[8] The mature protein has five N-glycosylation sites at Asn$_{236,305,515,728,939}$. These glycosylation sites are critical for the function of the enzyme and if N-glycosylation is inhibited by 5-thiomannose-containing disaccharides, it blocks the intracellular activity of SKI-1/S1P on SREBPs.[35]

Subcellular localization studies revealed that SKI-1/S1P can be found in the *cis/medial* Golgi and in endosomes/lysosomes, but not at the cell surface.[23] Thus, different from furin, proprotein convertase 7 (PC7) and PC5/6-B, which cycle from the cell surface to the trans Golgi network (TGN), SKI-1/S1P does not reach the cell surface, and probably transits directly from the TGN to endosomes/lysosomes.[23] In addition, careful analysis of the intracellular forms of SKI-1/S1P revealed a much shorter (~8.5 kDa) alternate translation product that may act as a dominant negative form of the enzyme.[23]

SKI-1/S1P Substrates In Vitro

Because SKI-1/S1P is membrane bound, to obtain sufficient amounts of an active secreted enzyme, we engineered a soluble form called BTMD-SKI-1/S1P (before transmembrane domain), by placing a stop codon upstream of the C-terminal transmembrane segment. Thus, the soluble, *in vitro* active approximately 98-kDa form produced spans the segment ending either at $YNQE_{996}$ or at the shed site $QKLL_{953}$.[8] We thus obtained both a vaccinia virus recombinant and stable transfectants in CHO or HEK293 cells and showed that both systems yield an approximately 98-kDa active enzyme, in the concentration range of 100 μg/l. A larger milligram/liter quantity of active soluble SKI-1/S1P was also isolated from a baculovirus recombinant in insect cells.

Biochemical and enzymatic characterization of SKI-1/S1P reveal it to be a serine protease, because mutation of the active-site Ser abolished its autoactivation and its exit from the ER.[8,9,30] Further, *in vitro* assays with peptides mimicking either the SKI-1/S1P prosegment cleavage sites or that of the Lassa virus (LAV) glycoprotein reveal it to be maximally active around neutral pH.[2,30] The best *in vitro* SKI-1/S1P substrate is that which mimics the processing of the LAV glycoprotein precursor (GP0) to form the proteins GP1 and GP2 that are responsible for viral fusion with the host cell membrane. The favored quenched fluorogenic RRLL-containing substrate is Abz-Asp-Ile-Tyr-Ile-Ser-Arg-Arg-Leu-Leu↓Gly-Thr-Phe-Thr-(3-nitro)Tyr-Ala-$CONH_2$.[2] The 4-, 7- and 8-mer fluorogenic substrates RRLL-MCA, YISRRLL-MCA and IYISRRLL-MCA are also very efficiently cleaved by SKI-1/S1P.[20]

Potent inhibitors of SKI-1/S1P include the cell permeable decanoyl-RRLL-chloromethyl ketone,[20] a transfectable cDNA coding for the N-terminal prosegment R134E mutant of SKI-1/S1P,[24] or an α1-antitrypsin variant containing the RRVL sequence in the reactive site loop,[24] and a Pfizer pharmaceuticals nonpeptidyl small molecule aminopyrrolidine-amide inhibitor known as PF-429242.[12] The latter inhibits LAV glycoprotein processing.[33] The general serine protease inhibitor 4-(2-aminoethyl)benzenesulfonyl fluoride (AEBSF) or decanoyl-RRLL-chloromethyl ketone also blocks the activity of SKI-1/S1P in cells and during primary bone mineralization.[11]

The compilation of all the known SKI-1/S1P-substrates suggests that the major recognition motif of SKI-1/S1P is: **R**-X-(**hydrophobic**)-Z↓,[20] with the basic P4 and hydrophobic P2 positions being the most critical ones (Fig. 1). Based on this conclusion, our results show that we could inhibit the cellular SKI-1/S1P activity using either an overexpression of an R134E P4 mutant of the prosegment of SKI-1/S1P, or alpha-1 antitrypsin variants such as those containing either an RRVL or RRYL sequences at the reactive center loop of this serpin.[24] The crystal structure of SKI-1/S1P is not yet defined, as it would really improve our understanding of the structure of this critical protease.

SKI-1/S1P Substrates Ex Vivo

In general, SKI-1/S1P processes precursors containing basic and hydrophobic/aliphatic residues at P4 and P2, respectively, with a relatively relaxed acceptance of amino acids at P1 and P3 (Fig. 1). SKI-1/S1P shows a preference for cleavage at luminal sites of membrane-bound transcription factors spanning the membrane either once (ATF6, Luman, Oasis, CREB-H, CREB-4) or twice (SREBP-1 and -2). The cleavage of these transcription factors is usually followed by a second cleavage by site-2 protease (S2P), a metalloprotease in the *medial* Golgi, to release a cytosolic fragment that translocates into the nucleus and activates the transcription of multiple mRNAs to produce proteins/enzymes that regulate many processes in the cell such as cholesterol and fatty acid biosynthesis (SREBPs), the tissue-specific ER stress response regulation (ATF6, CREB3, CREB3L1, CREB4, and CREB-H) (Fig. 1). Amazingly, SKI-1/S1P also regulates the sorting of proteins to lyosomes from the Golgi via the cleavage activation of the α/β-subunit precursor of the GlcNAc-1-phosphotransferase (GlcNAc-1-Ptase)[16] (Fig. 1). However, novel unsuspected functions of SKI-1/S1P are yet to be discovered, as this protease is also responsible for the generation of the N-terminal prosomatostatin peptide Antrin ($prosomatostatin_{1-10}$ fragment), and for the processing of the prodomain of proBDNF.[30] Sortilin binds to numerous ligands and plays a major role in mannose 6-phosphate receptor-independent transport of lysosomal hydrolases using motifs in intracellular luminal domains that mediate trafficking from the Golgi and late endosomes. Thus, the cleavage of prodomain of proBDNF

by SKI-1/S1P may modify its subcellular sorting and degradation in lysosomes that depends on sortilin binding to the prodomain. Finally, both SKI-1 and furin are involved in axonal growth, via cleavage of the repulsive guidance molecule (RGMa), which is essential for neogenin-mediated outgrowth inhibition.[32]

In Vivo Mouse Knockout Models (For Review see Ref. 31)

In situ hybridization data obtained in a day 2 postnatal rat also provide evidence of a widespread if not ubiquitous distribution of SKI-1/S1P mRNA.[30] Thus, SKI-1/S1P mRNA is detected in liver, the anterior and intermediate lobes of the pituitary as well as in the pituicytes of the pars nervosa, developing skin, striated muscles, cardiac muscles, bones and teeth, brain, and many internal organs. Strong hybridization signals are detected in the retina, cerebellum, pituitary, submaxillary, thyroid and adrenal glands, molars, thymus, kidney, and intestine. In the central nervous system, SKI-1/S1P mRNA labeling is mostly confined to neurons.

The gene name for SKI-1/S1P derives from an acronym to membrane-bound transcription factor site-1 protease (human *MBTPS1*, mouse *Mbtps1*) precursor, sometimes called *PCSK8*. The gene coding for SKI-1/S1P maps to human and mouse chromosomes 16q24 and 8, respectively. Complete gene deletion in mouse leads to death at the blastocyst stage (embryonic day 3.5) with the absence of inner cell mass formation. Complete knockdown of SKI-1/S1P mRNA in zebrafish is also lethal, revealing a disorganization of chondrocytes and showing that SKI-1/S1P is critical in cartilage formation.

The importance of SKI-1/S1P in the processing of SREBPs and in turn in the regulation of cholesterol and fatty acid metabolism was confirmed using conditional knockout studies using the Mx1-cre transgene. Thus, although a complete silencing of SKI-1/S1P results in an embryonic lethal phenotype, the elimination of approximately 70–90% of SKI-1/S1P protein expression in liver (but only ~50% of the active enzyme) results in a drop of about 50% in the level of circulating cholesterol and triglycerides. In addition, very low levels of nuclear SREBPs and reduced mRNA of their target genes are observed. In these mice, the liver biosynthesis of cholesterol and fatty acids declines by approximately 75%. Low-density lipoprotein (LDL) receptor mRNA declines by 50%, as does the clearance of LDL from plasma, but plasma cholesterol falls, suggesting that LDL production is reduced. In addition, tissue-specific knockout of the SKI-1/S1P gene in cartilage reveals that this protease is also essential for endochondral bone formation in mice.

A study of the mRNAs affected by overexpression of the R134E-prosegment inhibitor of SKI-1/S1P in HepG2 cells,[6] or the small-molecule inhibitor PF-429242[12] using μ-array analyses reveals that SKI-1/S1P inhibition reduces lipogenic enzyme gene expression and lipid synthesis in cultured cells and experimental animals. These results raise the possibility that SKI-1/S1P inhibitors, such as the non-peptidyl PF-429242,[12] might be effective lipid-lowering agents, but careful monitoring is advised for any side effects implicating other pathways affected by lowering the SKI-1/S1P activity.

Pathophysiological Implications

SKI-1/S1P plays a major role in the processing of surface GP0 of infectious arenaviruses such as LAV (Fig. 1), which is endemic in West Africa and is estimated to affect some 100,000 people annually. Other GP0s of arenaviruses activated by SKI-1/S1P include crimean Congo hemorrhagic fever virus (CCHFV), and lymphocytic choriomeningitis virus (LCMV) (Fig. 1). The present results suggest that arenavirus GP0s evolved to mimic SKI-1/S1P autoprocessing sites, probably ensuring efficient cleavage and perhaps avoiding competition with SKI-1/S1P's cellular substrates, which are less efficiently cleaved. No vaccines or antivirals are available against such deadly viruses, emphasizing the need for a potent SKI-1/S1P inhibitor to fight such deadly infections.

Mucolipidosis II is a severe lysosomal storage disorder caused by defects in the α and β subunits of the hexameric GlcNAc-1-Ptase complex essential for the formation of the mannose 6-phosphate targeting signal on lysosomal enzymes. The observation that SKI-1/S1P activates the α/β-subunit precursor of the GlcNAc-1-Ptase is physiologically pertinent in the biogenesis of lysosomes. In fact, loss of SKI-1/S1P expression, or by extension its inhibition, may result in lysosomal dysfunction, because instead of sorting via the mannose-6-phosphate receptor to lysosomes, proteins lacking mannose 6-phosphate will then be secreted into the extracellular matrix.[16]

Analysis of the SNPs associated with the human gene coding for SKI-1/S1P revealed many heterozygote mutations (http://www.ncbi.nlm.nih.gov/projects/SNP/snp_ref.cgi?geneId=8720). Of these, 10 SNPs are deemed deleterious, including C38S, Y54C, S71X, R130Q (eliminates B' autocatalytic site), R191C, G220E (eliminates Gly_{220} important for active-site Asp* in the conserved DTG_{220} sequence in all subtilases), T413I (disrupts the Thr_{413} important for the active-site Ser* in the conserved $GT_{413}S$* sequence in all subtilases), S724C, S954C, T1049-frame shift (will extend the cytosolic tail from VHPPKT-PSV_{1052}-stop to VVPPKT-$LRCDRQPG_{1057}$-stop). However, the frequencies of these mutations are rather rare, and thus, their correlation with a specific phenotype in human will be difficult. Further, based on the liver-specific knockout of SKI-1/S1P, it is clear that a reduction of >80% of the activity of SKI-1/S1P is needed to observe a phenotype, suggesting that a heterozygote loss-of-function (LOF) SNP may seem to be a silent mutation.

PCSK9

Complications resulting from cardiovascular disorders are the main cause of death worldwide. Elevated plasma cholesterol levels result in excess cholesterol deposition in arterial vessel walls and are a major risk factor for atherosclerosis and premature death by coronary artery disease. In the blood, cholesterol is transported in lipoprotein particles, approximately 70% of which in human are LDL. LDL is constantly cleared by internalization into cells by the LDL receptor (LDLR), which binds and internalizes LDL via its unique apolipoprotein B (apoB) protein. Mutations in LDLR or APOB genes are major causes for the frequent autosomal dominant genetic disorder known as familial hypercholesterolemia. Although hypercholesterolemia affects 1 in 20 subjects, inherited autosomal dominant hypercholesterolemia (ADH; OMIM #143890), which results in even higher levels of cholesterol, only occurs at a frequency of 1 in 500. To date, it has been linked to heterozygous dominant mutations occurring in the genes encoding the LDLR (67%), apoB (14%) or PCSK9 (~2%).[31] However, approximately 17% of ADH-affected patients have no mutations in these three genes, indicating that other genes remain to be identified. Thus, the rare occurrence of dominant heterozygote mutations in *PCSK9* is approximately 1 in 25,000 (2% of 1:500). Patients affected by this type of familial hypercholesterolemia are typically characterized by plasma LDL-cholesterol (LDLc) greater than the 95th percentile, and the presence of tendon xanthomas and premature atherosclerosis.

Originally named NARC-1 for "neural apoptosis-regulated convertase," PCSK9 was first discovered and characterized in my laboratory.[28] In collaboration with C. Boileau and M. Abifadel in Paris, we established the association between single-point mutations in the *PCSK9* gene and autosomal dominant hypercholesterolemia in two French families.[1] Thus, *PCSK9* is the third gene associated with familial hypercholesterolemia,[1,31] with *LDLR* and *APOB* as the other two. Later, Cohen et al. showed that nonsense PCSK9 mutations are associated with hypocholesterolemia in approximately 2% of black subjects.[4] Up to approximately 7% of black Africans living around the equator exhibit the loss of one allele of PCSK9. In summary, point mutations in PCSK9[31] are associated with either familial hypercholesterolemia (gain-of-function (GOF) of PCSK9) or hypocholesterolemia (LOF of PCSK9). Two women lacking functional PCSK9 exhibited an approximately 85% reduction in circulating LDLc. *Pcsk9*$^{-/-}$ mice are also viable and exhibit an approximately 80% drop in circulating LDLc,[34] emphasizing the therapeutic potential of a PCSK9 inhibitor/silencer.

Zymogen Activation and Cellular Trafficking

The discovery of PCSK9, the 9th member of the PC family[28,31] as a third protagonist in ADH shed light on the unsuspected regulation of the LDLR levels by this protein. PCSK9 is mostly expressed in hepatocytes and small intestinal enterocytes.[28] By an as yet unknown mechanism(s), and independent of its enzymic activity,[14] PCSK9 enhances the degradation of cell-surface LDLR in endosomes/lysosomes, resulting in increased circulating LDLc. Surprisingly, although PCSK9 undergoes an autocatalytic cleavage of its N-terminal prosegment that remains associated with PCSK9 and keeps it in an inhibited state, it has no other substrates but itself. Statins, the best cholesterol-lowering drugs, reduce cholesterol synthesis by inhibiting the rate-limiting HMG-CoA reductase. The resulting cellular cholesterol depletion leads to transcription of genes involved in cholesterol metabolism, including those of PCSK9 and LDLR. While upregulation of LDLR reduces circulating LDLc, that of PCSK9 counterbalances it through degradation of the LDLR. PCSK9 inhibition is thus a promising complement to statin therapy to lower LDLc.

PCSK9 (692 aa in human) comprises a signal peptide (aa 1–30) followed by a prosegment (Pro; aa 31–152), catalytic (aa 153–407), hinge region (HR; aa 408–452), and C-terminal Cys-His-rich domain (CHRD; aa 453–692) segments. After translocation into the ER, the prosegment is autocatalytically cleaved at the $VFAQ_{152}$↓SIP site.[3] In all the other PCs, the prosegment is an essential intramolecular chaperone and inhibitor, which is usually removed intracellularly to yield a fully active protease.[29] Different from other PCs, PCSK9 is secreted as a stable, enzymatically inactive, noncovalent complex [Pro≡PCSK9].[3,28,31] In accordance, enhanced degradation of the LDLR[3,17,19] induced by PCSK9 does not require its catalytic activity.[14] In human and mouse plasma, both full-length PCSK9 (aa 152–692) and a truncated form PCSK9-ΔN_{218} (aa 219–692) can be detected. The latter, which has no activity on LDLR, is probably generated by Furin, because it efficiently cleaves PCSK9 ex vivo at $RFHR_{218}$↓ and mice lacking furin in hepatocytes no longer exhibit the presence of this cleaved form in plasma.[10] Interestingly, the human GOF R218S, F216L and R215H mutations associated with hypercholesterolemia, prevent such a cleavage and presumably result in increased levels of active PCSK9. To optimize PCSK9 inactivation by Furin, we designed a PCSK9-$RRRR_{218}$EL mutant, which results in the secretion of only the inactive PCSK9-ΔN_{218}. We also contributed to the set-up of an ELISA assay of circulating human PCSK9, revealing a good correlation between the levels of PCSK9 and LDLc in human plasma.[7] Sequencing of *PCSK9* exons from individuals at the extremes of the PCSK9 distribution provides a database of PCSK9 mutations resulting in valuable tools in structure–function analyses. Indeed, we have identified a novel LOF variant, R434W, associated with low levels of circulating PCSK9 and LDLc.[7] This mutation, which occurs in an exposed loop of the hinge region, does not prevent LDLR binding, but drastically reduces the

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

ability of PCSK9 to enhance the degradation of the LDLR.[7] A database of all PCSK9 mutations is online (http://www.ucl.ac.uk/ldlr/LOVDv.1.1.0/index.php?select_db=PCSK9).

The crystal structure of PCSK9 reveals three separate domains: the prosegment and catalytic domain in tight complex, and the spatially separated CHRD.[5] In all three crystal structures, aa 31–60 of the prosegment and portions of the CHRD are unresolved, indicating their unstructured nature. Biochemical and cocrystal structure studies reveal that aa 153–156 and 367–381 directly interact with the EGF-A domain of the LDLR. The most severe mutation associated with hypercholesterolemia, D374Y, is within aa 367–381 and results in an approximately 25-fold higher affinity of PCSK9 toward LDLR.[5] The shallow binding surface on PCSK9 is distant from its catalytic site, and the EGF-A domain of LDLR makes no contact with either the prosegment or the CHRD.

The Prosegment of PCSK9

Even though the prosegment does not bind the EGF-A domain of LDLR, it negatively regulates this interaction. The removal of its N-terminal acidic stretch (aa 31–53), which exhibits Tyr_{38} sulfation[28] and Ser_{47} phosphorylation, enhances the binding of PCSK9 to LDLR by up to approximately 7-fold. Whether this unstructured acidic stretch,[5] binds another domain of PCSK9 and/or interacts with another protein is yet to be defined.

The HR-CHRD of PCSK9

The HR is an exposed loop structure connecting the catalytic domain and the CHRD.[7] The latter is composed of a six β-strand structure repeated 3-times and hence forming 3-subdomain modules M1, M2, and M3.[5] In the reported crystal structures, disordered segments include aa 573–584 (in M2), 660–667 (in M3), and the C-terminal aa 683–692 exhibiting Ser_{688} phosphorylation. Many GOF (R469W, E482G, R496W, F515L, and H553R) and LOF (Q554E and the new one R434W)[7] mutations within the HR-CHRD were identified, but their underlying mechanisms are unknown.

The Cellular Biology of PCSK9 (For Review see Ref. 27)

PCSK9 Targets

More than 20 years' experience with PCs led us to predict that PCSK9 should have more than one target. We thus first tested PCSK9 ex vivo activity on other members of the LDLR-like protein family. The closest members to LDLR, i.e. very LDLR (VLDLR) and ApoER2, are degraded faster in the presence of PCSK9, in a cell-type dependent fashion.[21] This was confirmed *in vivo*, as circulating PCSK9 enhances the degradation of the VLDLR in adipose tissues.[26] We also showed that PCSK9 enhances the degradation of the major hepatitis C virus (HCV) receptor, the tetraspanin protein CD81.[15]

PCSK9-Enhanced Degradation of the LDLR

The cell-surface localization of PCSK9 is dependent on the presence of the LDLR. The two proteins also colocalize in early and late endosomes. We previously developed an approach in which the fusion of a secretory protein of interest with the transmembrane domain and cytosolic tail (TM-CT) of the lysosomal protein Lamp1 results in an efficient degradation of its partners. This strategy was applied to PCSK9 to better target its partners, including the LDLR, to degradative compartments. Thus, fusion of PCSK9 to the TM-CT of Lamp-1 (PCSK9-Lamp1) results in superactive forms of PCSK9 capable of depleting cells from its targets[21] including LDLR, VLDLR, and ApoER2.[21]

Extracellular versus Intracellular Pathways

The extracellular pathway is defined by the ability of extracellular PCSK9 to target the LDLR. Indeed, incubation of cells with PCSK9, but not PCSK9-ΔCHRD, enhances the degradation of cell-surface LDLR in endosomes/lysosomes. Because the PCSK9-ΔCHRD still interacts with the LDLR and is internalized, the CHRD is probably essential for the trafficking of [PCSK9≡LDLR] to endosomes/lysosomes. Internalization of cell-surface LDLR requires the adaptor protein ARH that binds its cytosolic tail on the cytoplasmic side of clathrin heavy chain-coated vesicles. In accordance, many pharmaceutical companies developed clinically relevant monoclonal antibodies that inhibit the PCSK9 interaction with LDLR. These mAbs are now in clinical trials (Fig. 2). However, we more recently showed the existence of an intracellular pathway. First, PCSK9 can degrade the LDLR *in vivo* and ex vivo in the absence of ARH. Second, siRNAs knockdown of both a and b chains of clathrin light chains, which exclusively blocks the intracellular pathway by preventing the trafficking from the TGN to lysosomes, resulted in a drastically decreased LDLR degradation.[22]

HR-CHRD Binding Proteins

In view of the critical importance of the HR-CHRD for targeting [PCSK9≡LDLR] to lysosomes, we hypothesized that it binds directly or indirectly a membrane-associated protein that would sort the complex to lysosomes. Accordingly, a Far-Western screen of endogenous interactors of PCSK9 revealed that annexin A2 (AnxA2) binds the HR-CHRD, and inhibits the ability of PCSK9 to enhance the degradation of the LDLR. AnxA2 lacks a signal peptide but is found at the cell surface of endothelia, keratinocytes, epithelial and tumor cells. The N-terminal repeat domains (R1-R7) of the LDLR itself can bind the CHRD, especially

at acidic pHs, suggesting that at neutral pHs, and via its catalytic domain, PCSK9 first binds the EGF-A domain of the cell-surface LDLR, and then once the complex is internalized in acidic endosomes, the CHRD can then bind the repeat domains of the LDLR. However, how does this process lead to sorting of endosomes to lysosomes is still a mystery, especially because ex vivo PCSK9 can degrade an LDLR lacking a cytosolic tail,[13] which normally would bind cytosolic motor proteins implicated in subcellular movement of organelles.

In Vivo Mouse Pcsk9 Knockout Models

Knockout (KO; *Pcsk9*$^{-/-}$) mice exhibit higher levels of LDLR protein in liver and 42% less circulating total cholesterol, with an approximately 80% drop in LDLc.[25,34] By contrast, transgenic mice overexpressing PCSK9 exhibit 5- to 15-fold higher levels of LDLc.[34] We also developed mice carrying conditional floxed alleles, in which the proximal promoter and exon 1 of *Pcsk9* are flanked by *loxP* sites (*Pcsk9*$^{f/f}$). In mice expressing the Cre recombinase under the control of the albumin promoter, *Pcsk9* was specifically inactivated in hepatocytes by *loxP* sites recombination (*Pcsk9*$^{f/f}$ *Alb-cre*). Total KO and liver-specific KO (LivKO) mice exhibited 42% and 27% less circulating total cholesterol, respectively, indicating that hepatic PCSK9 is responsible for approximately two-thirds of the phenotype. This suggests that the role of PCSK9 in cholesterol homeostasis is primarily mediated by its activity on LDLR, because the liver accounts for approximately 70% of the body LDLc clearance. Analysis of [*Pcsk9*$^{f/f}$ *Alb-cre*] livers shows that PCSK9 expression is restricted to hepatocytes, from where circulating PCSK9 mostly originates. We generated double KO mice lacking both PCSK9 and the LDLR (dKO; *Pcsk9*$^{-/-}$ *Ldlr*$^{-/-}$) and showed that their plasma lipid profile is identical to that of *Ldlr*$^{-/-}$ mice, confirming that PCSK9 activity on LDLR mediates most of its role in cholesterol homeostasis. PCSK9 also binds VLDLR and apoER2[21] closely related to LDLR. Indeed, VLDLR proteins accumulate in adipose tissue of PCSK9 KO mice, resulting in marked adipocyte hypertrophy.[26] PCSK9 is thus pivotal in fat metabolism: it maintains high circulating cholesterol levels via hepatic LDLR degradation, but it also limits visceral adipogenesis likely via adipose VLDLR regulation.

Pathophysiological Implications

Circulating PCSK9

Human plasma contains approximately 100–200 ng/ml of PCSK9.[7] Its physiological role remains undefined, as well as that of its truncated form PCSK9-ΔN_{218} that represents approximately 50% of the PCSK9 species in mouse plasma. The analysis of transgenic lines that overexpress low or high levels of mouse PCSK9 in the liver indicates that only supraphysiological levels of circulating PCSK9 (~30-fold higher) increase circulating cholesterol (+60%); a 3-fold increase has no significant impact on circulating cholesterol. Moreover, results from transgenic mice expressing very high levels of human PCSK9 in kidney or liver, or continuous infusions of recipient wildtype (WT) mice with recombinant human PCSK9 indicated that micrograms per milliliter amounts of circulating PCSK9 are required to significantly affect liver LDLR protein levels. Transgenic expression in kidney (32-fold the endogenous liver levels) leads to 100% loss of LDLR protein in liver, but only 50% loss in kidney. Thus, even at high levels, circulating PCSK9 reduces primarily liver LDLR with little effect on extrahepatic tissues, e.g. adrenals. By contrast, our genetic models show that at physiological levels circulating PCSK9 is responsible for the downregulation of VLDLR protein levels in mouse adipose tissues, and its absence gives an adipocyte hypertrophy phenotype.[26]

Partial Hepatectomy (PHx)

To better understand the role of PCSK9 in the liver, its major site of expression, we challenged this tissue by performing

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

sham or PHx operations in WT and KO mice. Hepatectomized KO, but not WT, mice develop lesions, still visible 10 days after the liver had recovered its original mass. In addition, the proliferation of KO hepatocytes is delayed.[34] Critically low levels of cholesterol may impede efficient liver regeneration. Indeed, HMG-CoA reductase mRNA levels are increased in KO regenerating livers only (2.5-fold at 72 h post-PHx). Also, when fed a high cholesterol diet one week before PHx, *Pcsk9*$^{-/-}$ mice no longer exhibit necrotic lesions.

Total Lack of PCSK9 May Affect β-cell Function and Predispose to Diabetes

It was originally observed that the pancreatic insulin-producing β-TC3 cells express high levels of PCSK9.[28] LDLR is also highly expressed in insulin-producing pancreatic islet β-cells, possibly affecting the function of these cells. We showed that compared with control mice, PCSK9-null male mice over 4 months of age carry more LDLR and less insulin in their pancreas; they were hypoinsulinemic, hyperglycemic, and glucose-intolerant; their islets exhibit signs of malformation, apoptosis, and inflammation. Collectively, these observations suggest that PCSK9 may be necessary for the normal function of pancreatic islets.[18]

Ongoing Clinical Trials Using PCSK9 Inhibitors/Silencers

In the USA alone, some 63 million individuals have elevated levels of LDLc. Of these, 12 million patients do not reach target LDLc levels with the available medications. Clearly, an alternative therapy is urgently needed. Many polyclonal antibodies against PCSK9 have been reported. Some of these are produced from a fragment of PCSK9 produced in bacteria, and others used the whole protein produced in HEK293 cells, or even via injection of a plasmid coding for human PCSK9. Further, some monoclonal antibodies against PCSK9 block its extracellular activity on LDLR by either interfering with the PCSK9 direct interaction with the EGF-A domain of the LDLR or by modifying the conformation of the CHRD. Another approach to inhibit the function of PCSK9 is to reduce its mRNA levels by injecting antisense oligonucleotides, e.g. as therapeutic RNAi, or 13-mer locked nucleic acids (Fig. 2). So far, no small molecule has been found to inhibit the function of PCSK9. The use of monoclonal antibodies and antisense oligonucleotides as injectable compounds has now entered in phase I and II clinical trials (Fig. 2). Preliminary Phase II trial results for REGN727—a human anti-PCSK9 monoclonal antibody codeveloped by Regeneron and Sanofi—indicate that it effectively and safely reduces the levels of low-density lipoprotein-cholesterol (LDLc) in patients with hypercholesterolemia undergoing statin therapy. Inhibiting PCSK9 function is expected to be specific and to have lower side effects than statins, which have a more extended repertoire of consequences, aside from only reducing LDLc production and increasing its uptake by liver. Accordingly, a combination therapy consisting of a statin and a PCSK9 inhibitor may be beneficial, as it would reduce the effective dose of the former. We will have to await clinical efficacy and side effects before we can assess the tolerability of this promising approach to silence the function of PCSK9.

CONCLUSIONS

Since 1999 when SKI-1/S1P was discovered, it became evident that some of the proprotein convertases would be implicated in lipid and sterol metabolism. However, little did we know that aside from these functions, SKI-1/S1P is also implicated in a wide variety of other cellular pathways that regulate ER-stress, chondrocyte differentiation, bone mineralization, brain development, and neuronal queuing, and lysosomal function. Highly infectious and deadly arenaviruses also exploit the host cell's ability to activate their surface glycoproteins. Whether inhibitors of SKI-1/S1P will one day reach the clinic to treat specific disorders is yet to be proven for this versatile and highly conserved PC.

It is amazing that PCSK9, the last member of the PC family, only needs its enzymatic activity to autocatalytically process its prosegment in ER, which remains tightly associated with the catalytic subunit, resulting in an inactive protease. The absence of enzymatic activity may well explain the dominant pathological consequences of the lack or excess of PCSK9, which may result from modified stoichiometric levels of protein–receptor complexes, such as PCSK9-LDLR. The development of specific inhibitors/modulators of PCSK9 may find future applications in the control of some pathology, e.g. hypercholesterolemia and associated metabolic syndrome including type-2 diabetes and atheroscleorosis. The difficult, but possible, identification of an orally active PCSK9 inhibitor may one day be the next future statin-equivalent drug.

ACKNOWLEDGMENTS

The author wishes to acknowledge the tremendous help of all the past and present members of the laboratory who have actively participated in all phases of the work leading to this synopsis of the functions of SKI-1/S1P and PCSK9. This work was supported by a CIHR Canada chair # 216684; CIHR grants # MOP 93792, 102741; and a Strauss foundation grant.

Chapter 250

Tyrosylprotein Sulfotransferases

Jens R. Bundgaard and Jens F. Rehfeld

ABSTRACT

A tyrosylprotein sulfotransferase (TPST) catalyzes the transfer of a sulfonyl group from the cosubstrate 3′-phosphoadenosine-5′phosphosulfate (PAPS) to a tyrosyl residue of a protein or peptide. This O-sulfation is a common irreversible posttranslational modification of proteins traversing the *trans* Golgi network during biosynthesis. It affects up to 1% of tyrosyl residues in proteins of secretory cells. Two isoforms of TPST are present in all animal cells and a single one in lower eukaryotes and plants. In mammals both the isoforms seem to be ubiquitously expressed although the levels vary between tissues. Tyrosyl O-sulfation substantially alters the properties of the side chain from a hydrophobic to a more hydrophilic form. Accordingly, tyrosine sulfate typically affects protein–protein interactions. This has been shown in for instance receptor–ligand and enzyme–substrate interactions. The biological significance is underlined by the observation that mice lacking both isoforms die shortly after birth and deficiency in single isoforms display specific phenotypes.

The sulfotransferases include a variety of enzymes belonging to several classes, and they perform different cellular functions. The soluble sulfotransferases catalyze sulfation of molecules such as estrogens, phenols, and other small molecules, and they are expressed mainly in the liver. Another class is membrane anchored sulfotransferases that catalyzes the sulfation of carbohydrates and tyrosyl residues of larger proteins or peptides. They are ubiquitously expressed in accordance with their diversity of substrates. The latter class of enzymes, denoted as the tyrosylprotein sulfotransferases (TPST, EC 2.8.2.20), are the subject of this chapter.

Tyrosine sulfation was first recognized as a modification of fibrinopeptide B in the 1950s and was long considered to be an exceptional posttranslational modification. With the structural identification of the two gastrointestinal hormones gastrin and cholecystokinin (CCK) in the 1960s and the demonstration of tyrosine sulfate in both peptide hormones,[9,10,24] interest in the modification grew. In the 1980s, the regulatory role of tyrosine phosphorylation was unfolded and this spurred the interest in tyrosine sulfate as a posttranslational modification regulated in a corresponding way to that of tyrosine phosphate by kinases and phosphatases. However, because tyrosine sulfate turned out to be an irreversible posttranslational modification, interest declined, and it was not until the late 1980s that it was recognized that tyrosine sulfation is a widespread modification of not only secretory proteins but also of some lysosomal proteins.[11,12] It was then estimated, that up to 1% of all tyrosyl residues in the eukaryotic proteome of secretory cells are tyrosine sulfated. Nevertheless, the number of mammalian proteins that were proven targets of tyrosine sulfation remained less than a hundred, and today, it is still expected that tyrosine sulfation has escaped identification in a number of proteins. In the late 1980s, purification of the enzymes was initiated, and *in vitro* assays of tyrosine sulfation were established using enriched enzymatic activity obtained from purified Golgi membrane fractions, suggesting that the tyrosylprotein sulfotransferase was a membrane bound protein. These studies revealed the first characteristics of TPST in terms of substrate specificities and enzymatic properties. Moreover, pulse-chase labeling experiments suggested that tyrosine sulfation occurred as a late event in protein secretion, advocating that TPST activity was localized to the *trans* Golgi Network. Purification of the enzyme activity proved to be difficult, but in 1998, Moore et al. managed to purify a rat liver TPST and, based on deduced amino acid sequences, to clone a cDNAs encoding the human TPST-1.[26] The identification of a human isoenzyme, TPST-2, rapidly followed.[1,27] This increased the insight into enzyme structures and properties significantly. Both TPST genes are now known to be widely expressed in tissues, suggesting that early studies on enzyme activities were performed in a mixed pool of enzymes. Subsequent identification of TPST genes showed that the TPSTs are present also in fruit fly, zebra fish, and worms, although only a single form of TPST is present in lower eukaryotes. There is also a TPST in the plant *Arabidopsis*,[18] and thus TPST

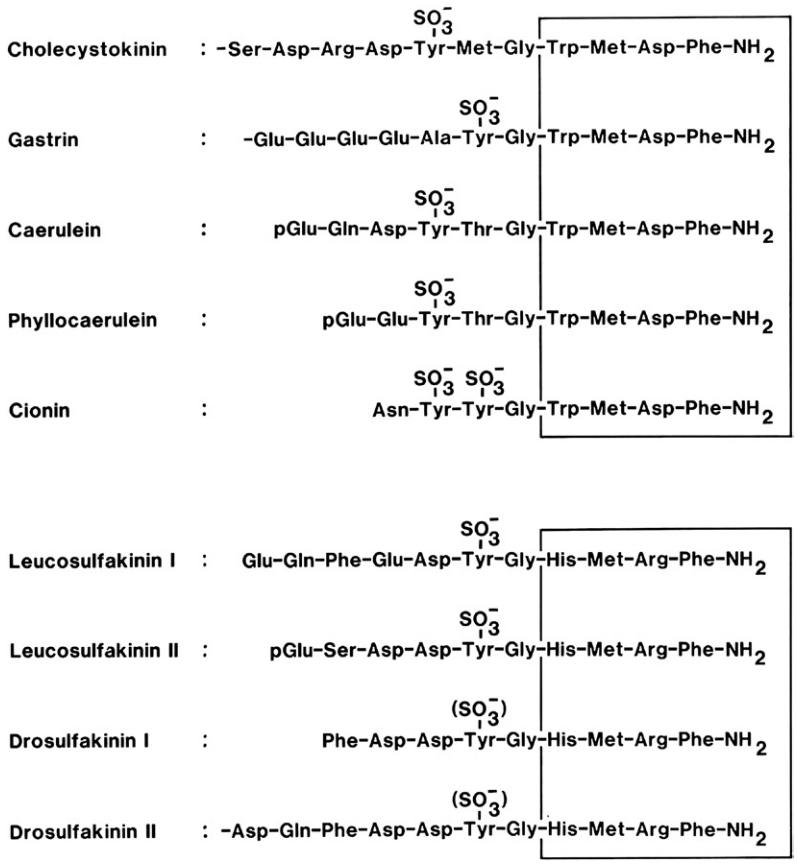

FIGURE 1 A comparison of the individual structures of the bioactive sites of members of the gastrin/CCK peptide hormone family (upper half) and the sulfakinins (lower half) showing the sulfated tyrosyl residues.

might be present in most, if not all multicellular organisms. *Arabidopsis* TPST is structurally very different from the known TPSTs and forms a new class of TPST that must have evolved independently from the mammalian TPSTs.

FUNCTION IN CELLULAR SYNTHESIS AND PROCESSING OF PEPTIDES

Tyrosine sulfation is a posttranslational modification that occurs in the vertebrate and protochordate bioactive peptides CCK, gastrin, cionin, caerulein, leucosulfakinin, and drosulfakinin. It has also been reported in several members of the granin family, for instance secretogranin II and chromogranin B, which are important factors in propeptide expression. Some enzymes that are active in propeptides activation are also targets of tyrosine sulfation, among these are the prohormone convertases 1/3 (PC1/3), PC2, and peptidylglycine alpha-amidating monooxygenase (PAM) described in separate chapters in this section of the book. Tyrosine sulfation also occurs in membrane receptors, particularly among chemokine receptors and endocrine receptors like the TSH receptor. Tyrosine sulfation is a physiologically irreversible posttranslational modification that introduces a charged hydrophilic moiety to an otherwise hydrophobic residue. The reported number of tyrosine-sulfated proteins and peptides is limited, and the reported functional effects even more so, although an increasing number of studies suggest a functional significance of the modification. One of the earliest descriptions of the biological functions of tyrosine sulfation concerned CCK that requires tyrosine sulfation to exert its defining cholecystokinetic, that is, gallbladder emptying effect. In peptide biosynthesis, the role of tyrosine sulfation has been intensively studied in the family of gastrin/CCK peptides (Fig. 1). Tyrosine sulfation affects many aspects of the biology and pathology of gastrin/CCK peptides, from the biosynthesis to the receptor activation. It has a pronounced influence on the accuracy of gastrin and CCK measurements by immunoassays in diagnostics. Gastrin and CCK share a C-terminal, carboxyamidated pentapeptide sequence that mediates a common affinity to the CCK-2 receptor. The sulfated tyrosyl residues are located in neighboring positions on the amino terminal side of the active site and the distance of the site defines the ability to bind to the CCK-1 receptor.

The tyrosine sulfate in CCK-8 is necessary for interactions with the CCK-1 receptor but not the CCK-2 receptor. CCK and gastrin both bind to the CCK-2 receptor, whereas only sulfated CCK is a ligand for the CCK-1 receptor. Thus, tyrosine sulfation governs the specific actions of CCK. Although nonsulfated proCCK products have been reported, the majority of CCK peptides are sulfated. The homologous peptide gastrin displays a more complex sulfation pattern. Thus, progastrin-derived peptides vary grossly in stoichiometry of sulfation, depending on the site of expression. The majority of gastrin peptides are produced in the antral G-cells and is here partially sulfated, depending on the species. In man, half of the antral gastrins are tyrosine sulfated. Although the interaction with the CCK-2 receptor may be enhanced by sulfation, the modification is not decisive for gastrin activity. Other possible roles of gastrin sulfation have been reported. Sulfation of progastrin seems to increase the proteolytical cleavage the Lys–Lys residues,[3] an endoproteolytical cleavage by PC2, which processes gastrin-34 to gastrin-17. The stoichiometry of tyrosine sulfation varies with the different processing intermediates of human progastrin according to the mode of secretion. Thus, incompletely processed peptides that are secreted via a constitutive-like secretory pathway are more sulfated than the corresponding completely processed forms secreted via the regulated pathway.[2] This suggests that TPST activity might continue in an intracellular compartment of the secretory pathway later than the *trans* Golgi network.

ENZYME PROPERTIES

The mammalian TPSTs are type II integral membrane proteins of about 54 kDa that contain a small N-terminal cytoplasmic domain and a larger catalytic domain that is glycosylated and contains several disulfide bridges (Fig. 2). They catalyze the transfer of a sulfonate group from the universal sulfate donor molecule 3′-phosphoadenosine-5′phosphosulfate (PAPS) to the hydroxyl group of the target tyrosine. In accordance with their intracellular localization in the *trans* Golgi network, both TPST-1 and TPST-1 have optimal activities at slight acidic pHs of 6.5 and 6.0, respectively.[22] It has been suggested that TPSTs might form dimers or oligomers, but this is unclear, and it is not known whether the enzymes might form heterodimers of TPST-1 and TPST-2.[8] Several studies on the enzymatic properties of TPST have been performed. However, the early studies were performed using membrane fractions enriched in activity of both isoforms, and the individual properties were not revealed, because both isomers are almost ubiquitously present in all cells and tissues. Both isoenzymes are stimulated by Mn^{2+} ions, inhibited by Ca^{2+} ions and the substrate affinities are in the orders of micromolar to millimolar. The affinity of TPSTs toward the cosubstrate PAPS is in the micromolar range and was recently determined to be 8,4 micromolar for TPST-2. A major difference between the isoforms is that TPST-2 is stimulated by Mg^{2+} ions, whereas TPST-1 is not.

An intriguing question in TPST biochemistry concerns the substrate specificities of the isoenzymes. The presence of specific phenotypes in mice deficient in either TPST isoforms suggests that there are different targets of the isoenzymes, although it could be result of difference in expression of the isoforms. Because the number of known tyrosine-sulfated proteins is low compared with the relatively high abundance of sulfated tyrosyl residues in secretory cells, much attention has been given to the identification of new tyrosine sulfation substrates. Based on the known sulfation sites, Huttner et al. suggested a consensus sequence for the prediction of sulfation targets.[16] This consensus sequence emphasizes the presence of acidic residues on the N-terminal side of the tyrosyl residue, in particular in the −1 position. Thus, most known substrates, have an aspartate or a glutamate in this position. This is also the case in plants, although the homology between plant TPST and mammalian TPST is limited. In the case of the gastrin/CCK peptide family, CCK has an aspartate in the −1 position and is completely sulfated, whereas gastrin has an alanine in the −1 position, and is only partially sulfated (Fig. 1). But then, gastrin has a stretch of five glutamates in positions −2 to −6, which is believed to compensate for the lack of an acidic residue in the −1 position. However, gastrin and its precursors are expressed in various tissues under normal and pathological conditions and display large variations in the stoichiometry of sulfation. When the neutral alanine in the −1 position of gastrin is substituted for an aspartyl residue by mutagenesis and expressed in cell lines, the resulting peptides are completely sulfated, suggesting that an acidic residue in this position is important for sulfation.[3] Nevertheless, other substitutions in the acidic stretch N-terminally of the tyrosine displayed smaller influence on sulfation, even when basic residues were introduced.[4] Gastrin sulfation has been examined in both TPST-1 and TPST-2 deficient mice, and in both cases, about half of the gastrin expressed in the antrum is sulfated, which corresponds to the level in normal mice (unpublished results). Thus, both isoenzymes potentially sulfate gastrin and it is generally believed that TPST-1 and TPST-2 have overlapping substrate specificities.

Although the presence of acidic residues around the sulfation site seems to be the single most important determinant of tyrosine sulfation, it is also indicated there should be no structures that could introduce steric hindrance around the sulfation site, that is, glycosylation sites, disulfide bridges, or tertiary structures. Based on the structures of known sulfation sites, several computer algorithms have been proposed for prediction of protein sulfation with varying success and these have not until now been used for a general search of sulfated proteins.[23,34]

Plant TPST is a type I membrane integral protein of 62 kDa that has no significant homology to the mammalian TPSTs (Fig. 2). Like the mammalian TPSTs, it is localized to the Golgi network of *Arabidopsis* cells. There have been no reports on the enzymatic properties of the plant TPST so far.

DISTRIBUTION

All higher eukaryote genomes examined contain two TPST genes, with the only exception of the fruit fly. When expressed sequence tags (ESTs) are examined, both the TPST-1 and TPST-2 genes appear to be widely expressed in all tissues. Nevertheless, there is a striking variation in EST counts between different tissues suggesting a variation in expression levels. This has been confirmed by TPST-1 and TPST-2 mRNA quantification in human tissues.[22] TPST-1 is expressed at higher levels than TPST-2 in neuronal tissue such as the cerebellum and in the reproductive organs. In contrast, TPST-2 is expressed at higher levels in particularly the liver and salivary glands. Thus, TPST seems to be ubiquitously expressed in all examined tissue in man and in all cells of higher eukaryotes.

PATOPHYSIOLOGICAL IMPLICATIONS

Over the years, a variety of important biological functions of tyrosine sulfated have been reported in several different species, some of which have been clarified on a molecular level. The first examples were that tyrosine sulfation is a prerequisite for CCK binding to the CCK-1 receptor and that the leech anticoagulant protein inhibitor, hirudin, depends on tyrosine sulfation to interact with human thrombin.[6] In fact, tyrosine sulfation plays a role in several coagulation factors, including Factor VIII, which depends on tyrosine sulfation in its interaction with von Willebrand factor.[20] Since then, many similar important functions involving direct protein–protein interactions have been reported. For instance, the chemokine receptor 5 (CCR5) is tyrosine sulfated, and sulfation is necessary for HIV-1 entry of cells by CCR5 and CD4.[7] Another example involves the cell adhesion molecule, p-selectin glycoprotein ligand-1, PSGL-1, which is a surface protein of the leukocytes that binds in a tyrosine sulfation dependent interaction to p- and s-selectin in an inflammatory response.[28] Tyrosine sulfation of PSGL-1 was also recently reported necessary for entry and replication of Enterovirus 71 in the leukocyte.[25]

After the cloning of the two mice TPSTs, generation of TPST-deficient mice gave distinct clues to important physiological functions. First, despite there being a considerable overlap in substrate specificity of TPST-1 and TPST-2, both TPST knockout mouse strains display phenotypes of reduced growth. A possible explanation of this could be a reduction of tyrosine sulfation of a TSH receptor leading to impaired responsiveness to TSH, a situation reported in the *grt* mice, a natural mouse strain having a mutation in the TPST-2 gene.[15] In addition, detailed studies have shown that the TPST-2 knockout mouse displays primary hypothyroidism,[32] but in addition, homozygous males also turn out to be infertile. This may be caused by the loss of ADAM6 and ADAM3 on epididymal sperm.[21] Alternatively, or in addition to this, Mfge8 is a protein present on mouse sperm cells that is specifically sulfated by TPST-2 and which is involved in fertilization.[14] Mice with disrupted Mfge8 gene have reduced fertility.

Similarly, tyrosine sulfation modulates the interactions between p-selectin and PSGL-1. Generation of TPST-deficient mice also allows for elaborate studies of the role of PSGL-1 sulfation on leukocyte rolling *in vivo* using transplanted hematopoietic progenitors from TPST-deficient animals. Experiments performed in *Ldlr* deficient mice result in a decrease of atherosclerosis in these mice, showing a direct link between tyrosine sulfation and atherosclerosis.[33]

Studies resulting from the breeding of a mouse strain lacking both the TPST-1 and TPST-2 genes underline the general biological importance of tyrosine sulfation. Thus, most of the pups die within the first two days of birth

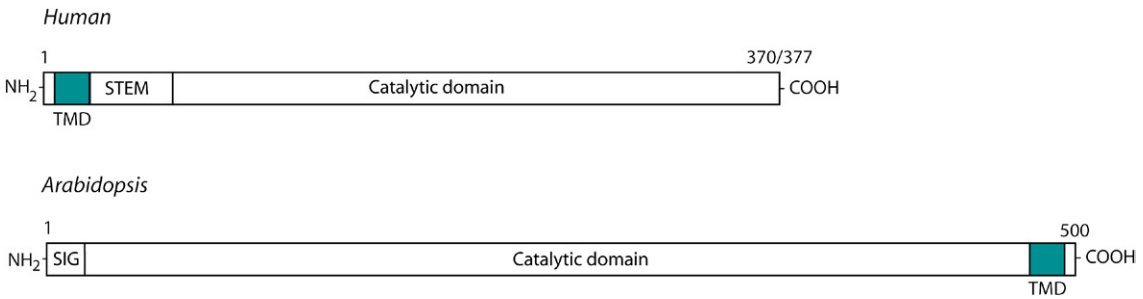

FIGURE 2 Structures of the two different types of TPSTs. The human TPST represents the two isoforms found in animals whereas *Arabidopsis* TPST represents the TPST found in plants. Note the fundamental differences in the types of the enzymes, which have very little homology in primary structure. Animal TPSTs are type II integral membrane proteins in contrast to the plant enzyme, which is of type I. Numbers refer to amino acid numbers, TMD denotes the transmembrane domain and SIG the signal peptide.

because of failure of lung expansion leading to asphyxiation.[32] In the same mouse strain, tyrosine sulfation plays important functions in morphogenesis of outer segments of the retina, as well as synaptic function by an unknown mechanism.[31]

Implications of tyrosine sulfation have been most intensively investigated in mammalian biological systems. However, there have been notable important functions reported in other species. In the frog *Xenopus laevis*, tyrosine sulfation plays an important role during development. Here, the Wnt11 and Wnt5a proteins form complexes that are dependent on sulfated tyrosyl residues, and the complex formation is required for formation of the dorsal axis during development.[5] In *Caenorhabditis elegans*, tyrosine sulfation affects the formation of cuticles by regulating the secretion of a collagen protein called ROL-6. In plants, tyrosine sulfation also plays a pivotal role on plant development. In *Arabidopsis,* a group of proteins denoted root meristem growth factors (RGF) are targets of tyrosine sulfation, and these proteins play important roles in the formation and maintenance of the root stem cell niche.[35] Thus, deficiency in TPST activity in *Arabidopsis* leads to severe impairment of root growth and general developmental defects.

IMMUNOCHEMICAL AND DIAGNOSTIC IMPLICATIONS

In studies of tyrosine sulfation, biochemical as well as pathophysiological, an antibody specific for sulfated tyrosyl residues would be helpful, much in the same way as antibodies for phosphorylated tyrosine have proven its value.[17] For unknown reasons, it has, however, with a single exception been impossible to raise such antibodies.[13,19] This is a paradox because tyrosine sulfation as such profoundly influences the antibody binding of peptides. Hence, a study of seventeen different antisera raised against nonsulfated gastrin showed that tyrosine sulfation induced a hundredfold variation in the binding to these gastrin antibodies.[29]

Immunoassays are decisive tools for plasma measurement of secretory proteins and peptides in several endocrinological and cancer diseases. Because of the above-described influence of tyrosine sulfation on antibody binding, it is essential to know the extent to which an actual diagnostic immunoassay will measure sulfated peptides or proteins. The significance is revealed in a comparison of diagnostic gastrin immunoassays (ELISA (enzyme-linked immunosorbent assays) and RIA (radioimmunoassays)). The study shows that more than half of the commercially available diagnostic gastrin kits are inaccurate, often because tyrosine sulfation results in falsely high plasma concentrations in patients suspected of harboring gastrin-producing carcinomas.[30]

ADDITIONAL FINDINGS

Two reports on tyrosine sulfation may have important implications on the future studies of TPST activity. One is the discovery of another TPST enzyme in plants, which has limited similarity to both the animal TPSTs and the animal soluble sulfotransferases that catalyze sulfate conjugation to steroid hormones, bile salts, and other molecules. This has obvious implications in plant studies, because lack of plant enzymes displays altered phenotypes even though only two protein substrates are known. But having three variations of enzymes catalyzing similar chemical reactions, it might also be possible to refine our knowledge of the function of these enzymes in general and contribute to our insight into the phylogenetic evolution. The other finding concerns one of the major questions about tyrosine sulfation that remains to be answered: how many proteins are substrates of the animal TPSTs? It has always been expected that tyrosine sulfate in many more proteins awaited discovery. Consequently, much effort has been made to improve analytical methods and the provision of tools to predict the presence of the modifications. Several computer prediction models have been reported over the years, which have been more or less successful and with the report of an improved algorithm it will be interesting to examine possible new sulfation substrates.[34] To assist identification of new tyrosine-sulfated proteins, a monoclonal antibody that is specific for sulfotyrosine already has proved valuable for this purpose. Because tyrosine sulfate mediates protein–protein interactions, proteins acting as receptors or ligands will be of particular interest. Inhibitors of TPSTs are already available, although delivery across the cellular membrane poses a challenge, but maybe one day, tyrosine sulfation and the TPSTs might become a therapeutic target.

Chapter 251

Classical Neurotransmitters and Neuropeptides

Tomas Hökfelt, Sven Ove Ögren and Zhi-Qing David Xu

ABSTRACT

Neuropeptides as transmitters in the nervous system have been seriously considered for approximately four decades. Starting at a modest level, their number has steadily increased, now encompassing >100 in mammals. In parallel, an equally rich occurrence has been seen in other species. A correspondingly large number of receptors have been discovered, almost always of the 7-transmembrane, G protein-coupled type. The diversity of the neuropeptide system is impressive, and neuropeptides quantitatively outnumber classic (and all other) transmitters such as monoamines and amino acids. It has been recognized that other classes of chemicals, such as large proteins (neurotrophins), small fatty acids (prostaglandins), and "gases" (nitric oxide), also act as neuronal messengers. These different molecules may be produced in, and released from, the same neuron–transmitter coexistence. This insight has provided a new perspective on signaling in the nervous system in health and disease as being complex, but perhaps also offering new openings for understanding and treating disease.

SOME HISTORICAL NOTES ON NEUROTRANSMITTERS

It was around 60 years ago that the first neurotransmitter was identified in the central nervous system—acetylcholine (ACh). Working on the spinal cord Eccles et al.[7] provided "strong evidence … indicating that at the synapses formed by the collaterals of motor axons on the interneurones transmission is mediated by acetylcholine." In a 38-page landmark article, the authors showed that activation of the Renshaw cells occurs via the release of ACh from collaterals of motor axons. Eccles et al.[7] in their summary wrote "In conformity with Dale's principle[6] that the same chemical transmitter is released from all the synaptic terminals of a neurone, pharmacological investigation has indicated that acetylcholine mediates the excitation of Renshaw cells by impulses in the collaterals of motor axons just as it mediates the excitation of muscle fibers at the peripheral terminals of the same axons." This is a sentence that has been much discussed more recently in relation to transmitter coexistence and corelease, not at least with regard to the large group of neuropeptide transmitters. Interestingly, it was Sir John Eccles who provided the first evidence for chemical transmission in the central nervous system, despite the fact that he had been a strong advocate for electrical communication.

Having been involved in neuroscience research for some 50 years, it is remarkable to have witnessed how new, proposed transmitter candidates regularly were met with skepticism, often been subject to strong criticism. In some cases, I felt sorry for the colleagues who had to take tough flak, especially because, eventually, they turned out to be correct. Not only in the beginning but also later,[2] there was doubt about peptides – and some of this may still persist. After one of my early lectures on neuropeptides, a leading enzyme biochemists voiced the view that all these small peptides were just breakdown products of a larger protein(s), without a specific function. I was pleased to see that a year later that particular laboratory was busy studying exactly those peptides. But that is science, I guess.

Chemical transmission, nonsynaptic or synaptic, is a fundamental process in normal nervous system function. However, there is also increased interest in the synapse in pathology. For example, in both autism and Rett's syndrome[35] as well as Alzheimer's disease and schizophrenia,[33] there is today increasing emphasis on the involvement of deranged synaptic transmission. As we now know, many molecules of different types are involved in neuronal (and glial) signaling (Table 1). At this point, it may not be relevant to discuss in depth, if they should be called, and meet stringent criteria for, a neurotransmitter. Other names have also been used: messenger molecule, signaling/transmitter substance, modulator, and more. The distinction between these molecules has become difficult, because they in addition to propagating the message across the synaptic cleft/nonsynaptic space, also can exert other functions, for example, acting as growth factors—even glutamate can

TABLE 1 Different Categories of "Transmitter Substances"

Amino acids (GABA, glutamate, glycine)
Biogenic monoamines [dopamine. noradrenaline, adrenaline, serotonin (5-hydroxytryptamine), histamine]
Acetylcholine (first central transmitter)
Neuropeptides (substance P, cholecystokinin, LHRH, TRH, enkephalins, NPY, orexins/hypocretins, and many more)
"Gaseous" molecules (nitric oxide, carbon monoxide) ("on demand")
Others [arachidonoyl ethanolamide (AEA, anandamide), 2-arachoidonoyl glycerol (2-AG), ATP, adenosine, eicosanoids, leukotrienes, neurotrophic factors]

have trophic effects. Moreover, a messenger may have different functions during development and adult life; in some cases, they are highly expressed in the fetal nervous system followed by postnatal downregulation, and then reactivation can occur under certain conditions, for example, nerve injury.

NEUROPEPTIDE RESEARCH—THE BEGINNINGS

Early in the 1970s, an intense research on neuropeptides took off, fueled by many seminal discoveries including (i) most of the hypothalamic releasing and inhibiting hormones are peptides (Roger Guillemin, Andrew Schally, and coworkers). This was in good agreement with preceding studies by Vincent du Vigneaud, showing that vasopressin and oxytocin are nonapeptides, and extensive analyses on neurosecretory systems, for example, the magnocellular hypothalamic neurons, by Ernst and Berta Scharrer, Wolfgang Bargmann, and many others; (ii) substance P, discovered in 1931 (Ulf von Euler and John Gaddum), was chemically identified as an 11 amino acid peptide by Susan Leeman and coworkers; (iii) the first endogenous ligands for the morphine receptors are pentapeptides, leucine- and methionine-enkephalin, reported by John Hughes, Hans Kosterlitz and coworkers; (iv) the gut peptide cholecystokinin (CCK) (Erik Jorpes and Viktor Mutt) and the vasodilatory peptide, vasoactive intestinal polypeptide (VIP) (Sami Said and Viktor Mutt) were found in the brain, as shown for CCK-8 by Graham Dockray and Jens Rehfeld's groups and for VIP by Larsson, Rehfeld, and associates; (v) the exciting behavioral work carried out by David de Wied and colleagues and Abba Kastin and associates, showing interesting central effects of peripherally administered peptides such as vasopressin, oxytocin, and alpha-melanocyte-stimulating hormone, a field that today goes through an astounding revival;[12] and last but not least (vi) the isolation of dozens of peptides from frog skin by Vittorio Erspamer and his team. The rate of discovery of neuropeptides accelerated, and still during the first decade of this millennium new members of the family have been added. Thus, we now face at least a hundred different neuropeptides, many of them belonging to chemically, or functionally, distinct families—clearly the largest group of messenger molecules, in both the central and peripheral nervous systems.[3]

NEUROPEPTIDES AT KAROLINSKA

After Ulf von Euler, working with Sir John Gaddum in the U.K., had discovered substance P in 1931, and his student Bengt Pernow had written his thesis on this peptide in the early 1950s, it took another 20 years until this peptide was revived at Karolinska Institutet, together with discoveries of new peptides in other laboratories. Thus, the first half of the 1980s was a remarkable period in the group of Viktor Mutt, Professor in the Department of Biochemistry at Karolinska Institutet. Within a couple of years, Viktor and his Japanese graduate student Kazuhiko Tatemoto isolated/discovered, based on a novel principle, four important peptides [Peptide Histidine Isoleucine (PHI), Peptide Tyrosine Tyrosine (PYY), Neuropeptide Tyrosine (NPY), and galanin (see below)], which were the basis of Kazuhiko's PhD Thesis in 1982, and which were going to keep many laboratories around the world busy until this day and for days to come. As indicated above, Viktor had realized the danger of giving peptides a "functional name," so these peptides were named after their peptide content, for example, NPY [neuropeptide with C- and N-terminal tyrosine (Y), plus more Ys] and galanin (N-terminal glycine and C-terminal alanine). Also Abba Kastin and collaborators wrote about "the danger of constricted nomenclature."

NEUROTRANSMITTER STORAGE—SYNAPTIC VERSUS DENSE CORE VESICLES

Early electron microscopic studies showed the presence of at least two types of storage vesicles in neurons/nerve endings [see Ref. 14]: (i) synaptic vesicles (SVs) (diameter ~500 Å) and (ii) large dense core vesicles (LDCVs) (diameter ~1000 Å) (Fig. 1).

The synaptic vesicles were always believed to harbor classical transmitters such as ACh. Neuropeptides are, as shown with immunohistochemistry, exclusively stored in large dense core vesicles (LDCVs),[30] a view supported by subcellular fractionation studies.[9] The peptide folliculin-like 1 in SV-like vesicles seems to represent the first exception to this rule.[23] Histochemical analysis using $KMnO_4$ fixation provided evidence that some classic transmitters such as noradrenaline (NA) and 5-hydroxytryptamine (5-HT) could

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

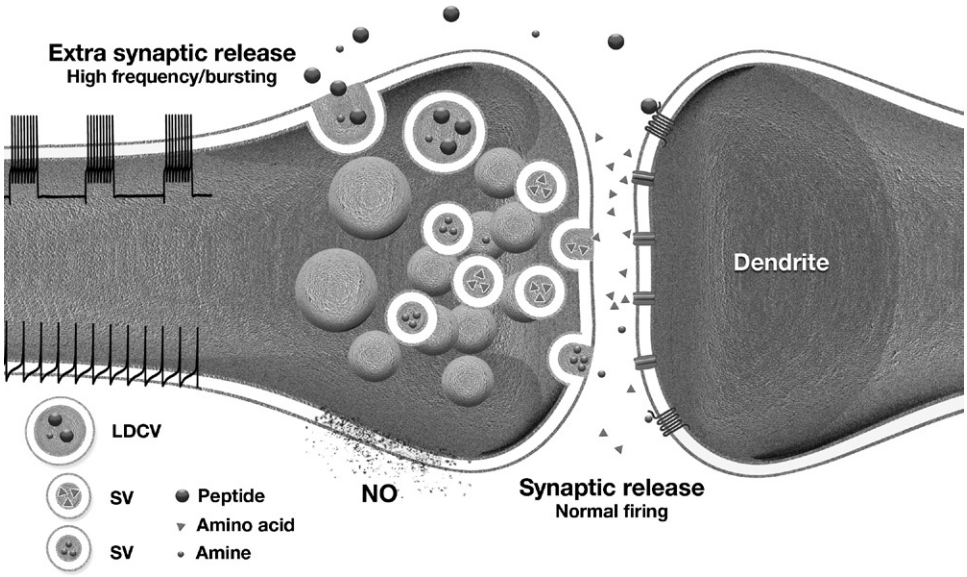

FIGURE 1 Schematic drawing of a synapse. A presynaptic nerve terminal (left) harbors different types of vesicles: Small synaptic vesicles (SVs) storing either an amino acid or, for example, an amine like serotonin. Large dense core vesicles (LDCVs) mainly store neuropeptides, but in some cases, a monoamine may also be present. Release from SVs occurs at low, normal firing rate, whereas exocytosis from LDCVs may occur in response to burst or high frequency firing. This release is extrasynaptic. Nitric oxide (NO) is not stored but synthesized and released on demand. Postsynaptic receptors on the dendrite are of two types, ligand gated channels and seven TM GPCRs. Receptors for neuropeptides are mostly extrasynaptic. (Drawing by Mattias Karlén).

be stored not only in SVs (then often called small dense core vesicles) but also in LDCVs.[19] Whether or not amino acid transmitters such as glutamate in addition are present in LDCVs is still unclear.[30]

NEUROTRANSMITTER COEXISTENCE

In 1976, Geoffrey Burnstock[4] wrote an influential review article suggesting reexamination of the "one-neuron-one-transmitter" concept, pointing in particular to the wide distribution of neuropeptides in the nervous system. This was in line with early evidence for multiple transmitters in isolated (large) invertebrate neurons.[22,31] Moreover, results from mononeuron cultures[10] showed a developmental switch in autonomic neurons from a noradrenergic to a cholinergic phenotype with a transient synthesis and release both NA and ACh. A further type of transmission was termed NANC (nonadrenergic, noncholinergic), the prime transmitter candidate being ATP, so called purinergic transmission with corelease of NA [see Ref. 5]. The first direct evidence for presence of a peptide and a classic transmitter in the same neuron was then observed in guinea pig sympathetic ganglia, where the tridecapeptide somatostatin was found in noradrenergic neurons,[21] histochemical findings that were rapidly followed by functional explorations,[25,26] and led to some further discussion on the "one-neuron-one-transmitter" hypothesis (see above).

A further modification, and in fact distinctly opposite to Dale's statement, were findings in Aplysia, showing that two different peptides can to be directed into different processes of a neuron,[34] thus not having the same transmission mechanism, in any case not the same transmitter, at all processes. Another interesting concept that has emerged is that peptides (and classic transmitters) can be released from soma and dendrites, and that dendrites and nerve endings of a neuron can operate separately and independently in releasing a messenger substance [see Ref. 24].

More recent work has shown many examples of coexistence of classic transmitters, including GABA with dopamine or 5-HT, glutamate with dopamine, NA or 5-HT and even two amino acids, excitatory glutamate with inhibitory GABA.[16] Here, the discovery of the vesicular glutamate transporters (VGLUTs) [see Refs 8, 28] has played an important role by providing tools to unequivocally identify glutamatergic neurons in the microscope.

PLASTICITY IN NEUROPEPTIDE EXPRESSION

Of particular interest, the expression of genes for peptides and sometimes also for peptide receptors is highly dynamic, for example, in response to stimuli such as nerve injury, electrical stimulation, seizure activity, or pharmacological manipulations. This reflects that each neuropeptide molecule released has to be replaced by ribosomal protein synthesis, which is preceded by a rapid increase in transcript levels. Thus, by monitoring transcript levels, one can indirectly get information of degree of activity of neurons and peptide release. The newly synthesized peptide has

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

then to be centrifugally transported to the site of release from nerve terminals, dendrites, or cell soma. However, induction, even de novo synthesis of neuropeptides, may also occur in response, for example, to nerve injury. This elaborate mechanism for transmitter replacement may seem highly uneconomic but could reflect that peptide signaling probably has an ancient origin, in fact is present in organisms harboring the most primitive nervous system, such as coelenterates (Fig. 2).[15] This distinctly contrasts the complex machinery for fast transmission existing in the mammalian nervous system.

NEUROPEPTIDE RECEPTORS

Until Nakanishi and collaborators cloned the first neuropeptide receptor from the gut, a substance K receptor,[29] it was somewhat uncertain how neuropeptides exert their actions in the nervous system. The substance K receptor turned out to be a 7-transmemembrane (7-TM), G-protein-coupled receptor (GPCR), and subsequent work has shown that virtually all other, several hundreds or so, neuropeptide receptors are of that type. An exception: the peptide Phe-Met-Arg-Phe-NH_2 (FMRFamide) induces a fast excitatory depolarizing response via direct activation of an amiloride-sensitive sodium channel.[13] Several peptide receptors are expressed at low levels. Thus it is probable that neither in situ hybridization nor immunohistochemistry can visualize such low abundancy transcripts/proteins, even if powerful antibodies can produce impressive stainings. This view is strongly underlined by studies on hypothalamic, warm-sensitive neurons reporting hundreds of receptor transcripts in a single cell, in several cases evidencing functionality by electrophysiological analysis.[1] These results should be taken in consideration when discussing, for example, neurotransmitter–receptor mismatch[17] and volume transmission.[11]

NEUROPEPTIDE RECEPTORS AND DRUG DEVELOPMENT

More than half of all drugs prescribed today are acting via seven transmembrane GPCRs, which also are targets for neuropeptides. The large number of receptors, their wide distribution in discrete systems, many directly associated with diseases, have provided a basis for drug development.[20] New drugs seem highly needed in view of the immense costs of, for example, mental disorders. Table 2 shows many candidate neuropeptide ligands that have been considered as potential antidepressants.[32] In our laboratory, focus has been on the 29 amino acid peptide galanin, and Fig. 3 illustrates a possible scenario how a galanin antagonist could exert an antidepressant action via locus coeruleus neurons costoring NA and galanin.[27]

An important aspect is that neuropeptide systems are prone to species variations.[2] Thus, results from animal experiments have to be validated through studies on human tissue to be a solid basis for developing drugs for treatment of disease. Also, the concept of cotransmission is associated with both advantages and problems, as indicated below:

1. Neuropeptides are comparatively large molecules and have difficulties in passing through the blood–brain barrier (BBB), reaching receptors in the brain and spinal cord only to a limited extent. Thus, small, BBB-penetrating, nonpeptide molecules are needed for systemic treatment of brain diseases. Many drugs have shown efficacy in animal experiments, but clinical tests have then not rarely failed, due to serious side effects.
2. If several transmitters are released from the same nerve ending, it may not be sufficient to block one receptor to obtain the expected effect. For example, even if animal work clearly indicated that substance P antagonists would be analgesic, this was not achieved in clinical trials.[18] It is possible that excitatory transmitters, such as glutamate, CGRP and others, coreleased from central sensory nerve endings, conveyed the pain message, even if NK1 receptors were blocked.
3. Intervention with antagonists may be preferred, since
   - **(i)** peptide transmission is mostly silent under normal conditions, and antagonists will therefore only affect deranged (upregulated) systems. This should result in fewer side effects;
   - **(ii)** agonists, acting on receptors in the entire body, should have more side effects. This is the case with morphine, which in addition to its well established and unsurpassed antinociception can produce serious side effects.

CONCLUDING REMARKS

In summary, the following features seem to characterize neuropeptide systems:

1. Neuropeptides are ribosomally synthesized as large precursor molecules (MW ~ 25,000) in soma/dendrites and stored in LDCVs. The bioactive molecule is cut out by enzymes, convertases. By contrast, classic transmitters are mainly stored in SVs, although amines such as noradrenaline and serotonin can also be present in LDCVs.
2. Neuropeptides are believed to be extrasynaptically released, from nerve endings and soma/dendrites. By diffusion, they can reach distant receptors, so called volume transmission,[11] probably one explanation for "mismatch" between distribution of ligand and receptor.[17] Termination of action occurs via degradation by extracellular peptidases and "dilution."

TABLE 2 Brain Neuropeptide Receptors and Antidepressant-like Effects: Nonpeptide Ligands

Peptide	Type of drug	Drugs developed
MCH	MCH_1 antagonists	ATC0175; SNAP-7941
Substance P	NK_1 – antagonists	MK0869 (Aprepitant)
CRF	CRF antagonists	DMP696; R121919
NPY	Y1 agonists	Not available
	Y2 antagonist(?)	Not available
Galanin	GalR3 antagonists	SNAP37899
		SNAP398299
	GalR2 agonist	Not available
Nociceptin/orphanin FQ	NOP antagonist	J-113997

Modified from Ref. 32.

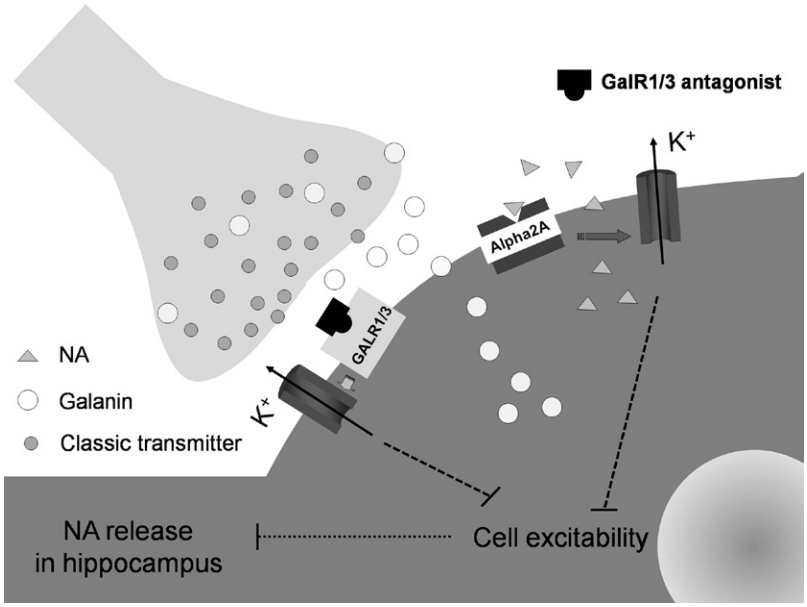

FIGURE 3 Schematic drawing of a noradrenergic neuron in the locus coeruleus costoring galanin and an adjacent nerve ending with a classic transmitter and galanin. LC neuron has both alpha2A receptors and galanin R1/3 receptors. It is well known that noradrenaline, presumably released from soma and dendrites can activate alpha2A receptors causing potassium outflow, hyperpolarization and decreased cell excitability. Galanin, released from soma/dendrites and possible nerve endings, can activate galanin R1/3 receptors similarly, causing potassium outflow and hyperpolarization. This signaling can be blocked by a galanin R1/3 antagonist, attenuating hyperpolarization and hypothetically preventing decrease in excitability and resulting in increased noradrenaline release in the forebrain and an antidepressant effect.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

3. Released molecules have to be replaced by new synthesis preceded by increase in transcript followed by intraaxonal transport to nerve endings, and/or to dendrites. Contrasting classic transmitters, there is no reuptake mechanism at the cell membrane or at the membrane of the storage vesicles.
4. Neuropeptides coexist with other molecules, classic transmitters (e.g. ACh, dopamine, noradrenaline, adrenaline, GABA, glutamate), nitric oxide and others. It has been shown that at least some neurons have a combination of several of them (e.g. serotonin + glutamate + substance P + nitric oxide). Neuropeptides are thus not the main messengers but have auxiliary, often modulating functions.
5. Neuropeptides act at very low concentrations, in the nanomolar range, and they virtually always, as many classic transmitters, act via seven TM, GPCRs.
6. The multiplicity of receptors offers unique and important openings for the development of specific agonists and antagonists as potential candidates for treatment of various diseases. Clinical trials of drugs targeting neuropeptide mechanisms have been initiated and, even if not yet reaching prescription drugs, there are many promising candidates that very well may take the decisive step into the clinic in a not too distant future. Close contenders are a calcitonin-gene-related peptide antagonist for treatment of migraine, and orexin/hypocretin antagonists as sleeping pills.

Chapter 252

Evolution in Action: Skin Peptides

J. Michael Conlon

ABSTRACT

Peptides with antibacterial and antifungal properties are present in skin secretions of nonmammalian vertebrates that include Agnatha (hagfish and lampreys), Elasmobranchii (sharks and rays), Teleostei (bony fish), and Amphibia and constitute a component of the organism's system of innate immunity. Host-defense peptides produce cell death either by disrupting the integrity of the cell membrane or by translocating across the membrane without producing lysis and binding to intracellular targets. In the first category, there has been little or no evolutionary pressure to conserve amino-acid sequences that define antimicrobial activity but, in the great majority of cases, the peptides are cationic, contain a relatively high proportion of hydrophobic amino acids, and one or more domains with the ability to adopt an amphipathic α-helical conformation on binding to the cell membrane. The second category, of particular importance in the host-defense systems of teleost fish, includes strongly cationic peptides derived from the proteolytic cleavage of histones, particularly histones H1, 2A, and 2B, and ribosomal proteins.

INTRODUCTION

Peptides with potent antibacterial and antifungal activities play an important role in the system of innate immunity that predates adaptive immunity and constitutes the first-line defense against invading pathogens for all classes of vertebrate species. As might be expected, the major sites of synthesis of these peptides are those tissues that interface directly with the environment, such as skin, intestine, and lung/gill. A comparison of amino-acid sequences reveals evolutionary pressure to conserve the primary structures of the antimicrobial peptides has been extremely weak, and it is not possible to identify invariant domains that are associated with biological activity. This observation is consistent with the mechanisms by which the peptides produce cell death, which most commonly involve a nonspecific interaction with the bacterial cell membrane or with intracellular targets rather than binding to a specific receptor (see Cationic Antimicrobial Peptides chapter in the Bacterial/Antibiotic Peptide section of the book).

However, vertebrate host-defense peptides are associated with certain common physicochemical features. The majority of known antimicrobial peptides are cationic due to the presence of multiple arginine and lysine residues. Of the antimicrobial peptides listed in the http://aps.unmc.edu/AP/main.php database, approximately 90% are cationic with an average net charge of +4.4. Although there is no single mechanism by which cationic antimicrobial peptides produce bacterial cell death, the initial interaction of the peptide with the cell membrane involves binding of the polar residues in the peptide to the negatively charged phospholipid head groups in the lipid bilayer. Several structure–activity studies involving both naturally occurring antimicrobial peptides and synthetic model peptides show that increasing cationicity increases antimicrobial potency until a certain optimal molecular charge is reached. The peptides that act by membrane disruption generally have an overall hydrophobic content >40%, but effects of hydrophobicity on antimicrobial activity are less pronounced as electrostatic interactions of the peptide with the charged bacterial cell membrane predominate. Peptides with a very high proportion of hydrophobic amino acids are usually cytotoxic to mammalian cells such as human erythrocytes.[10]

Although the β-strand structural motif is found in several vertebrate antimicrobial peptides such as the defensins (see the Defensins chapter in the Bacterial/Antibiotic Peptides section of the book), the conformational feature that predominates among the host-defense peptides found in epidermal secretions is the amphipathic α-helix in which there is segregation of the polar residues on one face of the helix and the hydrophobic residues on the opposite face. The example of pseudin-2 from the paradoxical frog *Pseudis paradoxa* (Hylidae) is presented in Fig. 1 as a Schiffer–Edmundson helical wheel. The charged residues (Lys^6, Lys^7, Glu^{14}, and Lys^{17}) are located on one face of the helix and the hydrophobic residues (Leu^2, Leu^5, Val^8, Phe^9, and Ile^{16}) on the opposite face. The peptides generally exist in a random coil conformation in aqueous solution but adopt the helical conformation on

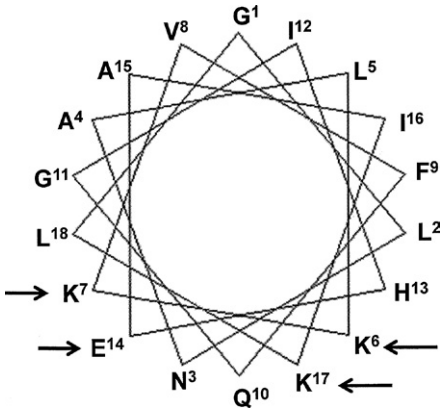

FIGURE 1 A Schiffer–Edmundson wheel representation of the N-terminal domain (residues 1–18) of pseudin-2 illustrating the amphipathic nature of the α-helical conformation. The polar residues are indicated by the arrows.

binding to the bacterial cell membrane. Structure–activity studies show that both helicity and amphipathicity correlate directly with hemolytic activity and small increases in the hydrophobic moment (a semiquantitative measure of the amphipathicity of a α-helical peptide) may produce major changes in activity.[10] Because they are readily incorporated into a helix, leucine, alanine, and lysine frequently occur in skin antimicrobial peptides but many contain an essential proline residue that produces a kink or bend in the molecule that facilitates membrane penetration.

Histones and peptides derived from histones by proteolytic cleavage constitute a second category of host-defense peptides found in epidermal secretions. Traditionally, post-translationally modified histones are known as major components of the nucleosome structure in eukaryotic cells that regulates of gene transcription. However, unmodified or minimally modified histones are also present in mitochondria and cytosolic granules. These proteins display biological activities different from those associated with chromatin and "extranuclear" histones play important roles in host defense, particularly in teleost fish. Their mechanism of action has not been elucidated but involves ATP-dependent translocation across the bacterial cell membrane without producing lysis and inhibiting cellular function by binding to intracellular DNA and/or RNA targets.[20]

The major antimicrobial peptides present in skin secretions and/or skin extracts of species belonging to the Agnatha (hagfish and lampreys), Elasmobranchii (sharks, rays, and skates), Teleostei (bony fish), and Anura (frogs and toads) are shown in Tables 1–3. Although many peptides with antimicrobial activity, such as the β-defensin-like crotamines and cathelicidin-related peptides, have been identified in the venoms of snakes (see Snake Peptides chapter in Venom Peptides section of the book), host-defense peptides in the skin secretions of reptiles and birds have not yet been described.

AGNATHA

The Agnatha, or jawless fishes, represent the first vertebrate stock whose line of evolution diverged from that leading to gnathostomes at least 550 million years ago. The fossil record indicates that agnathans were numerous during the late Silurian/early Devonian (390–420 million years ago) but only the lampreys (Petromyzontiformes) and hagfishes (Myxinoformes) have survived until the present day. The system of adaptive immunity that characterizes the higher vertebrates is not fully developed in the Agnatha so that host-defense peptides of the innate immune system are of particular importance.

Three potent, broad-spectrum antimicrobial peptides (HFIAP-1, -2, and -3), identified as ancient orthologs of the mammalian cathelicidin family, are present in hagfish intestinal tissue but, as yet, there is no evidence for their occurrence in skin secretions. However, a 12-amino-acid peptide, termed myxinidin, is present in the voluminous epidermal mucus produced by the Atlantic hagfish *Myxine glutinosa*.[35] The peptide shows potent growth-inhibitory activity against a wide range of bacteria and yeast pathogens. The microbicidal activity of myxinidin is retained in the presence of sodium chloride at concentrations up to 0.3 M and the peptide shows no hemolytic activity against mammalian red blood cells at concentrations up to 500 μg/ml.

An arginine/cysteine-rich peptide, termed lamprey corticostatin-related peptide (LCRP), is present in extracts of the skin and brain of the sea lamprey *Petromyzon marinus*.[11] A structurally similar peptide is present in the brain of the river lamprey *Lampetra fluviatilis* (J.M. Conlon unpublished data). The presence of six cysteine residues in LCRP indicates limited structural similarity to mammalian corticostatins and defensins (see the Defensins chapter in the Bacterial/Antibiotic Peptides section). In particular, the peptides contain a polyarginine sequence at the N-terminus of the molecule that is believed to be important in mediating both the antimicrobial actions and the inhibitory effect on ACTH-stimulated steroidogenesis of the corticostatins. The peptide from *P. marinus* shows potent growth-inhibitory activity against the Gram-negative bacterium *Escherichia coli* [Minimum Inhibitory Concentration (MIC) = 10 μM] but was less active against Gram-positive species.

ELASMOBRANCHII

The Elasmobranchii, represented in the present day by sharks, rays, and skates, diverged from the line of evolution leading to mammals at least 500 million years ago. The innate immune system of elasmobranchs is best known for hepatic production of the broad-spectrum antibacterial aminosterol, squalamine that is also active against fungi and protozoa. However, extracts of the skin of the fermented

TABLE 3 Skin Antimicrobial Peptides from Frogs of the Neobatrachia

Anuran family	Representative genera	Peptide family
Myobatrachidae	*Uperoleia*	Uperin
	Crinia	Signiferin
		Riparin
Hylidae: Phyllomedusinae	*Agalychnis*	Dermaseptin, Dermatoxin
	Phasmahyla	Hyposin, Phylloseptin, Phylloxin, Plasticin
	Phyllomedusa	
Hylidae: Pelodryadinae	*Litoria*	Aurein, Caerin
		Citropin, Dahlein
		Fallaxidin, Maculatin
Hylidae: Hylinae	*Pseudis*	Pseudin
	Hyla	Hylaseptin
	Hypsiboas	Raniseptin
Leptodactylidae	*Leptodactylus*	Ocellatin
		Plasticin
Hyperoliidae	*Kassina*	Kassinatuerin-1
Dicroglossidae	*Hoplobatrachus*	Tigerinin
Ranidae	*Amolops*	Brevinin-1, Brevinin-2
	Glandirana	Esculentin-1, Esculentin-2
	Hylarana	Ranatuerin-1, Ranatuerin-2
	Lithobates	Temporin, Palustrin-2
	Odorrana	Japonicin-1, Japonicin-2
	Pelophylax	Nigrocin-2, Ranacyclin
	Rana	

skate *Raja kenojei* contain a 28-amino-acid antimicrobial peptide, termed kenojeinin I, whose primary structure shows no significant similarity with any other known antimicrobial peptide. This strongly cationic peptide (molecular charge +9) shows potent growth activity against *E. coli*, and against the Gram-positive bacterium *Bacillus subtilis* and the yeast *Saccharomyces cerevisiae*.[4]

TELEOSTEI

The bony fish represent a particular successful branch of the vertebrate family tree with in excess of 20,000 species. It is speculated that the explosive radiation of present-day teleost fish is a consequence of whole genome duplication that occurred in the ancestral fish lineage immediately before the emergence of this vertebrate class (320–350 million years ago). The last decade has seen a marked increase in the number of antimicrobial peptides isolated from skin mucus and/or skin extracts from teleost fish and the peptides have excited interest for their therapeutic and commercial potential.

Piscidins are linear, amphipathic, antimicrobial peptides that were first identified in mast cells of the hybrid striped bass (*Morone chrysops* female x *M. saxatilis* male) but have a wide distribution in teleost fish species from the superorder Acanthopterygii.[32] Piscidins 1–3 are 22 amino acids long, whereas piscidin 4 comprises 44 residues and may contain a hydroxylated tryptophan at position 20.[25] The piscidins show potent, broad-spectrum, antibacterial activity against many fish and human pathogens and markedly reduce the infectivity of channel catfish virus.[3] Piscidin 1 adopts a α-helical structure from Phe^2 to Thr^{21} in the presence of SDS micelles.[23] The piscidin prepropeptide consists of three domains: a signal peptide (22 amino acids), a mature peptide (22 amino acids), and a C-terminal prodomain (35

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

amino acids). The piscidin gene consists of three introns and four exons with a TATA box and several consensus-binding motifs for transcription factors found in the region 5′ to the transcriptional start site. The gene encoding a 21-amino-acid piscidin 1-related peptide, termed epinecidin-1, is present in the genome of the grouper *Epinephelus coioides*.[27] Like the piscidins, epinecidin-1 has the propensity to adopt an α-helical conformation and shows potent broad-spectrum antibacterial activity and cytotoxic activity against tumor cells. RT-PCR reveals high concentrations of epinecidin-1 mRNA in skin as well as intestine and head kidney. Epinecidin-1 treatment is effective in promoting fish survival after the injection of the pathogen *Vibrio vulnificus* in tilapia (*Oreochromis mossambicus*) and grouper.

Pardaxin, a 33-amino-acid pore-forming polypeptide isolated from defensive secretions of the Red Sea Moses sole *Pardachirus marmoratus*[26] is one of most intensively studied fish antimicrobial peptides because of its ionophore neurotoxin properties and its potential as a shark repellant. The peptide adopts the helix-hinge-helix structure that is a common structural motif found both in antibacterial peptides that can act selectively on bacterial membranes (e.g., cecropin), and in cytotoxic peptides that can lyse both mammalian and bacterial cells (e.g., melittin). Pardaxin possesses potent, broad-spectrum antibacterial activity (comparable to magainin, cecropins, and dermaseptins) by a mechanism that involves total disruption of the bacterial cell wall, but a significantly reduced hemolytic activity toward human red blood cells compared with melittin.[26]

A 25-residue linear broad-spectrum antimicrobial peptide, termed pleurocidin is present in the skin mucous secretions of the winter flounder *Pleuronectes americanus*.[7] The peptide has the propensity to adopt an amphipathic α-helical conformation, and there is some structural similarity with members of the dermaseptin family from the skins of phyllomedusid frogs (see the chapter on Dermaseptins in the Amphibian Peptides section of the book). The pleurocidin gene comprises four exons. Its upstream region demonstrates consensus-binding sequences for transcription factors found in host-defense genes in mammals, including sequences identical to the NF-IL6 and α- and γ-interferon response elements.[6] Subsequently, four genomic sequences encoding pleurocidin-related peptides have been identified in the genomes of the winter flounder and other flatfish species.[12] Northern and RT-PCR analyses of RNA from multiple tissues show that two of the pleurocidin genes are expressed predominantly in the skin whereas two other genes are expressed mainly in the intestine. RT-PCR assays of total RNA from larvae of different ages indicate that the pleurocidin gene is first expressed at 13 days posthatch in winter flounder. The 20-amino-acid peptide pelteobagrin is present in the skin mucus of the yellow catfish *Pelteobagrus fulvidraco* and shows broad-spectrum antibacterial and antifungal activity but low hemolytic activity.[33] This peptide shows little structural similarity to other vertebrate antimicrobial peptides.

Traditionally, histones are known as major components of the nucleosome structure in eukaryotic cells and are functionally classified into two groups: linker histones (histone H1) and core histones (histone H2A, H2B, H3, and H4). Posttranslationally unmodified, or minimally modified, histones and fragments derived from histones with antimicrobial properties are present in the epidermal mucus of a range of teleost species and their concentration increases after bacterial challenge.

A 30-amino-acid N-terminally acetylated peptide derived from the N-terminal part of histone H1 is the dominant antimicrobial peptide in skin mucus from Atlantic salmon (*Salmo salar*).[24] The peptide, termed salmon antimicrobial peptide (SAMP H1) is active against both Gram-negative and Gram-positive bacteria. The N-terminal acetyl group is not necessary for activity but the peptide exists in an inactive form that can be converted to the active form by treatment with peptidyl-proline cis–trans-isomerase, indicating that conformation of the proline peptide bonds are an important determinant of activity. Comparison of the active and inactive forms by CD spectroscopy suggests that the active form is more condensed and rigid than the inactive form which has a more nonstructured conformation. Intact histone H1 and a 26-amino-acid N-terminally acetylated peptide representing the (1–26) fragment of histone H1, termed histone-derived fragment 1 (HSDF-1), are present in the mucus of bacterial lipopolysaccharide-challenged coho salmon *Oncorhynchus mykiss*.[30] Although inactive itself against the salmon pathogens *Vibrio anguillarum* and *Aeromonas salmonicidia*, HSDF-1 potentiates the antimicrobial action of pleurocidin and lysozyme. A 69-amino-acid C-terminal fragment of histone H1, termed oncorhyncin II, is present in epidermal mucus of the rainbow trout *Oncorhynchus mykiss*.[15] With a molecular charge of +30, oncorhyncin II is the most cationic antimicrobial peptide identified to date. The peptide has MIC values in the submicromolar range against both Gram-positive and Gram-negative bacteria and it does not display significant hemolytic activity toward trout erythrocytes.

A potent broad-spectrum antimicrobial peptide, termed hipposin, is present in skin mucus of Atlantic halibut *Hippoglossus hippoglossus*. The 51-amino-acid peptide is N-terminally acetylated and represents the N-terminal domain of histone H2A.[2] CD analysis reveals that hipposin is nonstructured in aqueous solution but adopts an amphipathic, α-helical conformation in the presence of dodecylphosphocholine micelles and negatively charged liposomes. A smaller 19-amino-acid antimicrobial peptide, termed parasin I, also derived from histone H2A is present in the skin mucus of the catfish *Parasilurus asotus* after induction by epidermal injury.[28] Parasin I shows strong antimicrobial activity, about 12–100 times more potent than magainin-2,

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

against a wide spectrum of microorganisms without any hemolytic activity. The peptide is generated by the action of cathepsin D activated by a matrix metalloproteinase 2. This activated form of cathepsin D then cleaves the Ser19–Arg20 bond of histone H2A to produce parasin I. Immunohistochemical analysis reveals that unacetylated histone H2A, the precursor of parasin I, and procathepsin D are present in the cytoplasm of epithelial mucous cells and that parasin I is produced on the mucosal surface after epidermal injury. Parasin I forms an amphipathic α-helical structure (residues 9–17) flanked by two random coil regions (residues 1–8 and 18–19) in helix-promoting environments. Structure–activity studies show that a basic residue at the N-terminus of the peptide is essential for membrane-binding activity and the α-helical structure is necessary for membrane-permeabilizing activity.[22]

Skin exudates of the rainbow trout *Oncorhynchus mykiss* contain a potent antimicrobial protein that was identified as intact histone H2A, acetylated at the N-terminus.[14] The protein exhibits rapid (loss of viability after 30 min) antibacterial activity against Gram-positive species with MIC values in the submicromolar range. Histone 2A has no hemolytic activity toward trout erythrocytes at concentrations <0.3 μM and its antibacterial activity probably does not involve the formation of transmembrane pores. Trout skin secretions also contain a 6.7-kDa peptide, termed oncorhyncin III, which is a cleavage product of the nonhistone chromosomal protein H6 (residues 1–66) that probably contains two methylated residues or one double methylation.[16] The purified peptide exhibits potent growth-inhibitory activity against both Gram-positive and Gram-negative bacteria, with MIC values in the submicromolar range. Scanning electron microscopy reveals that oncorhyncin III does not cause direct disruption of bacterial cells, suggesting that its mechanism of action involves translocation across the cell membrane and binding to intracellular targets.

Histone H2B, together with ribosomal protein L40, ribosomal protein L36A and ribosomal protein L35, contribute to the observed antibacterial and antifungal activities present in an extract of epidermal mucus of the Atlantic cod *Gadus morhua*.[1] Histone H2B is also present in acid extracts of channel catfish *Ictalurus punctatus* skin and is inhibitory to *Aeromonas hydrophila* and *Saprolegnia* spp., which are important bacterial and fungal pathogens of fish.[31] The 40S ribosomal protein S30 is present in skin secretions and epithelial cells of the rainbow trout *Oncorhynchus mykiss*.[17] The peptide is active at submicromolar concentrations against the marine bacterium *Planococcus citreus* suggesting that, in addition to its conventional function in the ribosomal complex, it may play a role in protection against intracellular or extracellular pathogens.

AMPHIBIA

For at least part of their life cycle, anurans are of necessity confined to a warm and moist environment that is conducive to the growth of potentially harmful bacteria and fungi. It is not surprising, therefore, that these animals have developed over the course of evolution a system of host defense that will protect the skin of the organism from invasion by pathogenic microorganisms. The extent to which the synthesis of dermal antimicrobial peptides is necessary to the frog's survival strategy or confers an evolutionary advantage to the species is unclear. The distribution of dermal antimicrobial peptides among anuran families is sporadic, and it is a common misconception that all frogs synthesize and release these peptides into their skin secretions. Among the phylogenetically more ancient Archaeobatrachia, peptides with the ability to inhibit growth of bacteria and fungi have been identified in species belonging to the families Leiopelmatidae, Alytidae, Bombinatoridae, and Pipidae. In contrast, such antimicrobial peptides have not been detected in those species examined to date that belong to the families Pelobatidae and Scaphiopodidae.[8] Among the more highly derived Neobatrachia, antimicrobial peptides have been identified in the skins of species belonging to the families Dicroglossidae, Hylidae, Hyperoliidae, Leptodactylidae, Myobatrachidae, and Ranidae. Such peptides have not been detected in those species examined to date that belong to the families Bufonidae, Ceratophyridae, Eleutherodactylidae, Microhylidae, and Pyxicephalidae.[8]

The frog skin antimicrobial peptides may be grouped together in peptide families on the basis of limited similarities in amino-acid sequence. Skin secretions from a single species frequently contain several members of a particular family that are presumed to have arisen from multiple duplications of an ancestral gene. The molecular heterogeneity of the peptides within a particular family is considerable with a peptide from one species rarely being found with an identical amino-acid sequence in another, even when those species are quite closely related phylogenetically. This variation in primary structure is reflected in a wide variation in antimicrobial potencies and specificities for different microorganisms. This multiplicity may provide a broader spectrum of defense against the range of pathogenic microorganisms encountered in the environment but firm evidence to support this claim is lacking. The distribution of antimicrobial peptides among genera classified in the Archaeobatrachia is shown in Table 2 and the distribution in genera classified in the Neobatrachia is shown in Table 3. Peptides belonging to the bombinin, dermaseptin, and temporin families and peptides from Australian frogs are reviewed in detail in the Amphibian Peptides section of the book.

With very few exceptions, the frog skin antimicrobial peptides are cationic, generally with a molecular charge between +1 and +4. The peptides exist in a random coil

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

conformation in aqueous solution but adopt an amphipathic α-helical conformation in a membrane-mimetic solvent such as 50% trifluoroethanol (TFE)–water or in the environment of a phospholipid or sodium dodecylsulfate vesicle.[8] Detailed tertiary structures have been established by NMR for a wide range of frog skin antimicrobial peptides from different families that include magainin-2, PGLa, peptide XT-7 (Pipidae); alyteserin-1c (Alytidae); bombinin H2, maximin-4 (Bombinatoridae); caerin 1.1, citropin 1.1, dermaseptin B2 and S9, fallaxidin 4.1a, frenatin 3, maculatin 1.1, uperin 3.6 (Hylidae); brevinin-2, nigrocin-2, ranalexin, ranatuerin-2CSa, temporin-SH (Ranidae). All peptides contain either a single α-helical domain spanning most of the molecule, for example, peptide XT-7 from *Silurana tropicalis*,[34] two α-helical domains joined a flexible loop region, for example, brevinin-2 from *Glandirana emeljanovi*,[29] or three α-helical domains, for example, esculentin-1from *Rana esculenta* (reclassified as a hybrid between *Pelophylax lessonae and P. ridibundus*).[18] Ascaphin-8 from the N. American tailed frog *Ascaphus truei* (Leiopelmatidae), the most primitive extant anuran that is sister-group to the clade of all other living frogs, adopts an amphipathic α-helical conformation in 50% TFE water demonstrating that this structural feature arose early in anuran evolution.[10] Although amphipathicity characterizes the α-helical domain in most cases, this feature is not essential for antimicrobial activity, particularly against Gram-negative bacteria. For example, dermaseptin S9 shows broad-spectrum antibacterial activity despite the fact that spatial segregation of hydrophobic and hydrophilic/charged residues on opposing faces along the long axis of a helix is lacking (see the chapter on Dermaseptins in the Amphibian Peptides section of the book).

The plasticins are a group of glycine-leucine-rich antimicrobial peptides first identified in the skin secretions of frogs belonging to the genera *Agalychnis* and *Phyllomedusa* in the subfamily Phyllomedusinae[13] and subsequently in frogs of the genus *Leptodactylus* (Leptodactylidae).[9] The plasticins contain multiple copies of the motif GXXXG where X is any amino acid. This structural feature (or the related GXXXA/S and A/SXXXG) occurs in the bombinins and temporins and in PGLa peptides from frogs belonging to the Xenopodinae. The plasticins show greater conformational flexibility than most frog skin antimicrobial peptides. Plasticin-DA1 from *Agalychnis dacnicolor*, for example, adopts a predominantly helical conformation when bound to anionic 1,2-dimyristoylphosphatidyl glycerol phospholipid vesicles but a β-sheet structure when bound to zwitterionic dimyristoylphosphatidylcholine vesicles.[13] CD spectroscopy has shown that plasticin-L1 from *Leptodactylus laticeps* behaves in a similar fashion adopting a disordered or random coil conformation in water but a well-defined β-sheet structure in methanol and a helical structure in 50% TFE water.[9]

As with teleost fish, "extranuclear" histones and fragments of histones play a role in the system of host defense of some frogs. The best characterized amphibian histone-derived peptides are the potent antimicrobial peptides buforin 1, comprising residues (1–39) of histone H2A, and buforin 2 comprising residues (16–36) of buforin 1. These amphipathic α-helical peptides are present in an extract of stomach tissue of the toad *Bufo bufo gargarizans* but are probably not released into skin secretions in high concentrations.[21] Those Afro-Asian treefrogs belonging to the family Rhacophoridae examined to date do not produce cationic α-helical antimicrobial peptides in their skin secretions, but intact histone H2B with growth-inhibitory properties against *E. coli* is present in skin secretions of Schlegel's green tree frog *Rhacophorus schlegelii*.[20] Like the buforins, the mechanism of action does not involve lysis of the bacterial cell membrane but may involve generation of an N-terminal histone H2B fragment by outer membrane proteinase T (OmpT) that penetrates the cell membrane with subsequent inhibition of cell functions by binding to DNA or RNA targets. Similarly, cationic α-helical antimicrobial peptides are also not detected in an extract of the skin of the Japanese tree frog *Hyla japonica*, but an antibacterial post-translationally modified form of histone H4 is present that is strongly hemolytic against human erythrocytes.[19]

CONCLUSIONS

The emergence in all regions of the world of strains of pathogenic bacteria and fungi with resistance to commonly used antibiotics constitutes a potentially serious threat to public health and has necessitated a search for novel types of antimicrobial agent, with appropriate pharmacokinetic and toxicological properties, to which the microorganisms have not been exposed. The http://aps.unmc.edu/AP/main.php antimicrobial peptide database lists well over ten times as many amphibian peptides than those isolated from fish so that marine organisms represent an underexploited resource for discovery of novel peptides with the potential for development into therapeutically valuable anti-infective agents. The Acipenseriformes (sturgeons and paddlefish), Polypteriformes (bichirs and reedfish), and Dipnoi (lungfish) are yet to be examined as a source of antimicrobial peptides. Similarly, after 100,000 years of human history, mankind is finally obliged to replace the "hunter gatherer" phase of exploitation of marine resources as a food source by aquaculture. In such facilities, fish are more prone to infection by pathogenic microorganisms and the development disease-resistant transgenic fish expressing antimicrobial peptide genes, such as the pleurocidin and cecropin genes, is underway.

Chapter 253

Peptide Chronomics

Franz Halberg, Weihong Pan, Earl E. Bakken and Germaine Cornélissen

ABSTRACT

Chronomics is the mapping of broad time structures (chronomes) in us and around us. It consists of endpoints of rhythms, trends, and deterministic chaos, and any residual variation. Trends, rhythms, and deterministic chaos are resolvable as a function of the length and density of a time series. Peptide chronomics is complicated by persistent biological effects after the original peptide has been degraded, and some of the secondary effects could be dissimilar or opposite to the native peptide. In regard to production and blood/tissue concentrations, 8-h rhythms are detected for endothelin, substance P, and neuropeptide Y, whereas circadian rhythms are seen for vasoactive intestinal peptide and leptin and most other variables. Chronomics mapping has been performed for gastrin and prolactin, among others. Exogenous peptides show differential effects at different circadian times of administration. Assessing circadian and other rhythms is more informative than analyses of means from single spot checks. A better understanding and use of peptide chronomics should improve current clinical practice.

PREAMBLE

In seemingly rigorous tests comparing two concomitantly sampled groups at some convenient time, we obtained, in our own replications, some very contradictory results. Many of the discrepancies may have originated from the fact that random sampling does not reflect general changes encompassed by chronomics. This is summarized in an extensive review of examples collected since the early 1950s.[9] Intergroup difference in phase has resulted in erroneous inferences from spot checks of caloric restriction effects on the incidence of breast cancer; this probably involves the rhythmicity of the hypothalamic–pituitary (ACTH)–adrenocortical network. The importance of rhythms lies in the assessment of intervention effects, notably in relation to stress or allergy. Another source of confusion is explained by an intergroup difference in the period of rhythms in blinded mice as compared with controls that led to the concept of free-running rhythms. In each case, information on time structure is the indispensable control information.

The goal of sampling across time span and cosinor analysis is to avoid such blunders while getting a usually better average. In addition to the mean, some dynamic parameters are included in the analysis. This includes the period (τ), an amplitude (A), acrophase (ϕ) at each τ, and a waveform [the (A,ϕ) pairs of harmonics of the fundamental τ] (Fig. 1). By quantifying these parameters, we attempt to find potentially useful new facts beyond the limited information available from spot check measurements of peptides.

INTRODUCTION

Peptides exert circadian time-dependent biological functions. However, the interpretation and statistical analysis of data in most studies do not usually take account of broad chronomes. Peptide chronomics addresses the production, distribution, actions, and turnover of peptides. Our goal is to use chronomics to characterize peptide production and actions in a way that better reflects the multitude interactions and complexity of the biological system.

Chronomes are broad time structures, whereas chronomics is the mapping of chronomes that involves description of rhythms, trends, and chaos. These parameters are resolved as a function of the length and density of a time series. Fig. 2 shows the three major components of the time structure: (1) multifrequency rhythms; (2) trends, when the data are long enough; and (3) probabilistic or other chaos, when the data are dense enough.[9] The analysis of chronomics contrasts with purely static interpretations of measurements. It has immediate clinical implications pertinent to human health. A single "snapshot," interpreted without any temporal reference, may not suffice for a medical diagnosis, notably of wellness. It has long been known that the values vary greatly along several time scales in health and disease, with age, geography, and/or lifestyle. However, even today, physicians typically rely on measurements at one or very few arbitrary time points for diagnosing gross clinical–chemical pathology based on spot checks at an unspecified time. This approach is time honored but ignores timing. Chronomics has the advantage of offering more accurate diagnoses and treatment.[3]

Here, we address the relationships of chronomic (time structural) components among several biological variables involving peptides. We propose that statistical analysis should

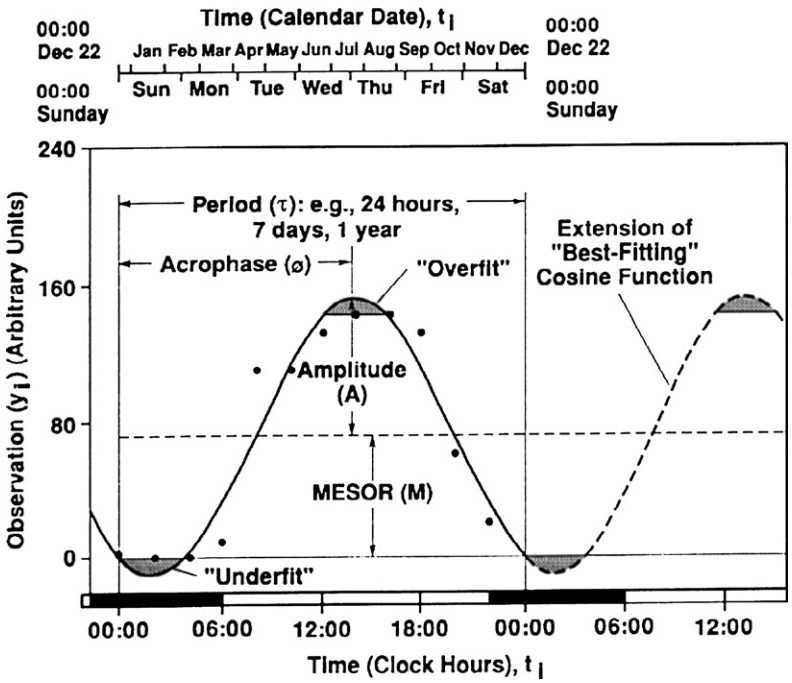

FIGURE 1 Estimation of parameters M, A, and ϕ by least-squares fit of cosine model with fixed period. $Y_i = M + A\cos(\omega t_i + \phi) + e_i$; where $\omega = 2\pi/\tau$, t_i=time; Y_i=observation at t_i and e_i=error at t_i; assumed as a first approximation to have the same independent normal distribution with mean zero and unknown variance σ^2, regardless of time; F statistic from zero-amplitude test compares sum of squares (SS) accounted for by fitted model either with the residual SS (original or pooled cosinor) or with the SS due to pure error, uncontaminated by lack of fit (unpooled cosinor).

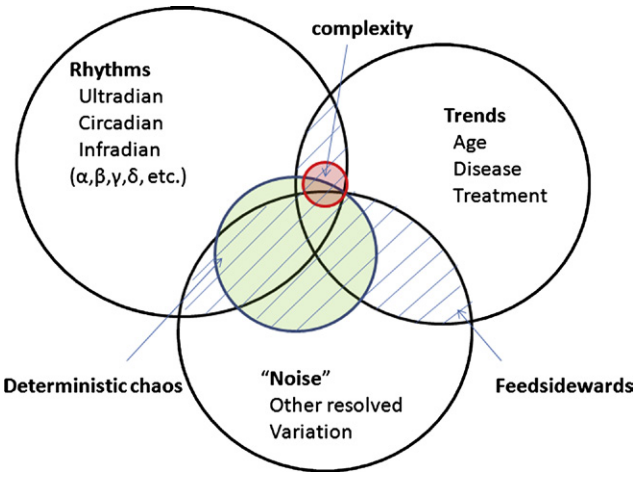

FIGURE 2 Measurable time structure (chronome) of a variable. The chronome (derived from *chronos*, *time*, *and nomos*, *rule)* represents quantitatively the measurable time structure of any variable, biological or environmental. In biology only, the ending "-ome" can also stand for "chromosome," to convey the genetic basis of (habitat and broader cosmos influenced) multifrequency rhythms, which are the major elements of chronomes, along with developmental and other age trends, and chaos, all interacting as feedsideward among different frequencies in us and in our environment. Modified from Ref. 9.

consider as many time-dependent issues as possible. We will summarize methods used to explore chronomics in the past few decades.[2,7] Peptide transcriptome analyses involving clock gene regulations are described elsewhere.[5,28]

AVOIDING BLUNDERS

The usual understanding of normal range does not take into account any rules of variation within this range. This is further complicated by free-running schedules without circadian cues, such as the erratic patterns of sleep and core body temperature in unsighted individuals. Two circadian rhythms or any other rhythms with the same frequency may happen to be out of phase, or may differ in frequency, and these observations are frequently overlooked. Blunders of interpretation are then unavoidable but are readily corrected by abandoning the misleading concept of homeostasis and by estimating parameters of the underlying rhythms. The solution of these puzzles in Minnesota led to chronobiology as a *sine qua non* to avoid a mistaken interpretation. Unrecognized differences in frequency can also play havoc, yielding faulty interpretations until resolved. By contrast, when the rhythms are recognized, a new rule (nomos) of behavior in time (chronos) may emerge as chronomics.[13]

CHRONOMICS SPAWNED BY CHRONOBIOLOGY MAPS DYNAMICS

Chronobiology is the study of mechanisms underlying chronomes, structures in time, found in organisms, in populations, and in the environment. The development of chronomics from chronobiology can be compared with that of genomics from genetics. Genetic focus on factors underlying

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

inter-organismic diversity in space needs the complementary chronobiologic realization of intra-individual and intra-population diversity in time. Genetics led to genomics, the mapping of genomes; chronobiology led to chronomics, the mapping of chronomes that were found to be near matches of environmental chronomes near and far.[10]

ENDPOINTS

Computer-based chronomics provides, by cosine fitting, the probability of the occurrence of a cycle with a given anticipated τ length and of its uncertainties, and inferential statistical estimations of the parameters. The parameters include 95% confidence intervals for each, the τ (if there are replications of a cycle in the data analyzed), the A, a measure of extent of change; the acrophase, ϕ, a measure of timing, and the waveform given by the (A,ϕ) pairs of the harmonics of a given τ. Chronomics also assesses trends, for example, by the coefficients of polynomials fitted to the data. When time series are dense, with observations numerous enough, nonlinearity and endpoints such as an approximate entropy or a correlation dimension can also be determined, preferably analyzed further by curve fitting.[20] Trends are often superposed on cycles, and if the data are long enough, whether in a population or in the individual, they may turn out to be just parts of rhythms with a period, τ, longer than the data span.[14] Circadecadal cycles characterize individuals (whose vital functions are monitored for up to three or more decades). In populations, rhythms, again including circadecadals, are found in endpoints that are unique for the individual such as birth or death.

SUSCEPTIBILITY RHYTHMS

For a few variables, chronomics has already mapped a very broad spectrum of rhythms with τ covering cycles, for example, in a second, in fractions of a minute, a day, a year, and a decade or still longer spans in populations. There is a cycle stage-dependent set of responses in each of these rhythms. Not all serial data to be collected can be sampled over many multifrequency cycles; usually, the data cannot be collected densely enough to document all aspects of the stage dependence of effects of stimuli on the cycles involved. Single experiments performed along a system time, such as a day, reveal a dependence of responses, as shown for the case of ACTH[6] and TSH. This applies to peptide drugs. A promising molecule may be discarded because it is tested at the wrong time. Testing for timing should precede the regular three phases of drug testing and has hence been called a phase-zero design.[8]

ATLAS

Insufficient sampling may lead to bioaliasing. Thus, there is a need for an atlas of maps for international use. This will help to gain a proper time horizon, so that the whole mapped spectrum can be consulted instead of repeating the work of mapping in each study. Results can then consider the context of a much broader time horizon. This will include other cycles already mapped for the same variable and the rhythm investigated. In dense and long time series, chaos and/or trends that are organized by rhythms may also be resolved.[20]

BEGINNINGS OF OPPORTUNISTIC MAPPING ALONG THE SCALE OF YEARS

Chronomics may find associations of certain circannual rhythmic patterns of a peptide. We will first summarize the ultradian and infradian rhythms of endothelin-1 (ET-1, Fig. 3) and ACTH (Fig. 4). ET-1 has an 8-h and a 3.5-day cycle in human blood,[15,25,26] with eight-hourly components in other circulating peptides such as substance P and neuropeptide Y.[19] Extracircadian rhythms of ET-1 are also found in the population densities of endotheliocytes, the cells producing ET-1.[17]

These findings in blood and pinnal ear tissue contrast with earlier findings of circadians in circulating ET-1.[1] Indeed, some circadian rhythms may undergo changes with solar cycle stage in frequency to the point that the same variable a few years apart, can be primarily circadian[1] vs. primarily

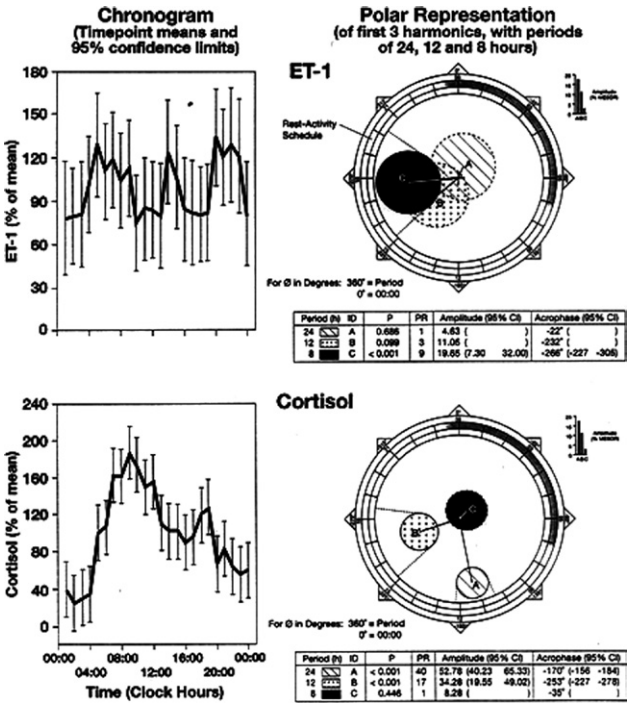

FIGURE 3 Circaoctohoran endothelin-1 (ET-1) vs. circadian cortisol in clinically healthy students, showing coexisting 8- and 24-h patterns in the same circulation. Data were obtained from two women and seven men, 22–27 years of age. Note that 8-h component is most significant for ET-1 ($p<0.001$), but it is not detected for cortisol ($p>0.4$).

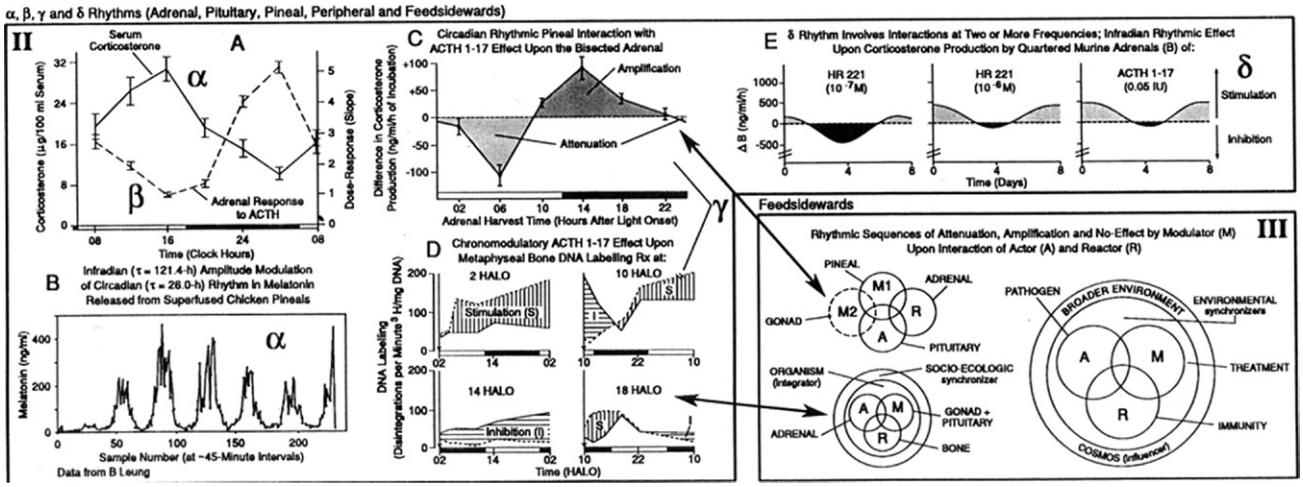

FIGURE 4 Endogenous time structure (chronome) shown by spontaneous (α), reactive (β), and modulatory (γ, δ) rhythms. The components of the chronome are internally coordinated through feedsideward in a network of spontaneous (α), reactive (β), and modulatory (γ, δ) rhythms. A: Serum corticosterone has a spontaneous rhythm (α) that is in antiphase with a reactive rhythm (β). B: Melatonin release has a spontaneous rhythm. C–E: Examples of ACTH and corticosterone rhythms in different *in vitro* studies. Reproducible sequences of attenuation, no-effect, and amplification, the time-qualified feedsidewards, may replace time unqualified feedbacks and feedforwards. Modified from Ref. 9.

extracircadian.[13,15,17,25,26] In view of the ubiquity of circadians, which is now widely accepted, a line of thought that allows for their disappearance seems unreasonable, just as half a century ago the opposite, namely, the possibility of a circadian rhythmic RNA and DNA synthesis, seemed unreasonable since nucleic acids were then regarded as the most constant material in the organism. Ascertaining stable vs. transient features of the maps here presented is also a task for the future.

In young healthy adults, there is a morning cortisol peak, but the circadian variation of ET-1 does not necessarily present itself as a circadian rhythm. Rather, the 8-h ultradian rhythm is most pronounced.[15] This circaoctohoran rather than a circadian variation also contrasts with a circadian rhythm of vasoactive intestinal peptide (VIP). The circadian rhythm of VIP shows a nocturnal peak about 8 h before the acrophase of cortisol. Like ET-1, substance P (SP) and neuropeptide Y (NPY) can have a circaoctohoran variation. Overall, the results indicate that maps of circadian and extracircadian patterns provide a broader picture of true variations, which may guide screening, diagnosis, and a better understanding of mechanisms underlying the etiology of various diseases.[19]

When the circadian rhythm of circulating concentrations of atrial natriuretic peptide (ANP) is determined after a week of synchronization with the environmental lighting schedule, a mean circadian acrophase of ANP is seen around 4 am. The ANP rhythm is in antiphase with those of blood pressure (BP) and heart rate, and seems to be anticipatory in its circadian periodic rise to awakening. This is more than what could be accounted for by postural changes.[22] It is known that ANP can affect BP by several mechanisms, including modification of renal function and vascular tone, counteraction of the renin–angiotensin–aldosterone system, and action on brain regulatory sites. The antiphase relationship between the circadian rhythms of ANP and BP is seen not only in health but also in essential hypertension. The loss in the nocturnal decrease of BP is accompanied by a comparable loss in the nocturnal surge of ANP in hypertensive renal failure and hypotensive heart failure. In the latter condition, BP and ANP variabilities correlate significantly both before and after therapy-induced functional recovery, independently of the mean BP. Overall, ANP is a modulator of the circadian rhythm of BP.[23]

In another study of ANP, VIP, and beta-endorphin in young and aged healthy subjects on controlled diets and structured sleep time (recumbency), ANP is higher in the elderly, whereas VIP, beta-endorphins, and cortisol are lower. The results indicate an age-dependent change in the secretion of these peptides.[4]

Circadian (daily) rhythms are present in almost all plants and animals. In mammals, a brain clock located in the hypothalamic suprachiasmatic nuclei maintains synchrony between environmental light/dark cycles and physiology and behavior. This has been greatly modified by modern living in the past century, by electric lighting, around-the-clock lifestyle, transmeridian air travel, and so on. Conceivably, environmental factors not only induce acute circadian disruption of physiology and behavior but also lead to chronic changes of circadian cellular mechanisms that impact on mental and physical health. In a mouse study with shortened light/dark cycle to 20-h, there is an accelerated weight gain and obesity, concurrent with changes in metabolic hormones. Circadian-disrupted mice have shorter dendritic length and decreased complexity of neurons in the prelimbic prefrontal

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

cortex, a brain region important in executive function and emotional control. Changes in brain architecture coincide with decreased cognitive flexibility and changes in emotionality.[16] The findings are profound and strongly support the necessity to characterize peptide chronomics.

Leptin is a hormone mainly secreted by adipose tissue and has pleiotropic effects on many organ systems. Leptin concentration has a circadian rhythm with a nadir preceding the active dark phase in mice.[21] Circadian dependence of leptin effects on food intake, locomotor activity, glycemia, and plasma cortisol levels has been studied in goldfish (Carassius auratus). When leptin is injected intraperitoneally at the time of photophase feeding (10:00), there is a reduction in food intake and locomotor activity and an increase in glycemia. Leptin injected at the scotophase (22:00) or in fish maintained at constant lighting does not have an effect irrespective of the feeding schedule. The results suggest that leptin actions could be dependent on the feeding time and light/dark cycle as synchronizers.[27] The results are highly pertinent to human obesity, which has a higher prevalence in shift workers and in patients with nocturnal eating disorders.

As yet, there are no densely longitudinally sampled and replicated rhythms of about 10, about 20 and about 50-years mapped for peptides, but a circadecadal is seen for a steroidal metabolic variable coordinated by the peptide ACTH.[14] These rhythms are tentative not only because of the sparsity of sampling but also because each inferentially statistically validated cycle, however ample its underlying sampling, is first mapped as a candidate rhythm and needs a separate confirmation. About 30-day cycles, primarily in women, are complemented by data on circatrigintans in men. Then, there are half-yearly cycles, some changing with geographic (geomagnetic) latitude. A circannual rhythm characterizes the (peptide) vasopressin-containing nuclei in the hypothalamus.[24]

There is no single peptide variable in which we can quantify, with uncertainties of parameters, ultradians with a τ in the second, minute, or a few-hour domain and approximately 10-year rhythms, as can be done for heart rate and in the infradian as well as circadian range for 17-ketosteroid excretion. The need for mapping is introduced today to show that we should seek proper reference values for tomorrow. Chronomics, the systematic mapping of chronomes (time structures) based on long and dense serial peptide data, is undoubtedly complementary to genomics and proteomics.

CHRONOMICS IN MEN

One set of maps on peptide chronomics stems from clinically healthy and/or symptom-free men studied around-the-clock for 24 h on five occasions (always in May) at 5- to 10-year intervals over a 29-year span (1969–1998). This was part of a study of biological rhythms in more than 140 variables, in checking vital signs, blood and urine. The number of subjects and age range per study were as follows: Study 1: $n=13$, ages 22–27 years; Study 2: $n=14$, ages 23–51 years; Study 3: $n=11$, ages 41–60 years; Study 4: $n=11$, ages 46–72 years; Study 5: $n=10$, ages 52–77 years. Four of the original subjects participated in each of the 5 studies. During the study, participants were free to move about during the day without napping, with bed rest between 23:00 and 07:00, being briefly awakened for the 01:00 and 04:00 samplings. Meals were served at 16:30, 07:30, and 13:30. No food or liquids, except for water, were allowed between meals.

Measurements were obtained at 3-h intervals beginning at 19:00, with subsequent sampling beginning at 22:00, 01:00, 04:00 07:00, 10:00, 13:00, and 16:00 (and at 19:00 in Study 2). At each test time, the subjects voided their bladder for a urine sample, followed by measurement of vital signs before drawing of blood samples. Since variables were added or eliminated from the study over the years, not every variable was measured in each study or from each subject. Therefore, as few as 10 and up to 46 time series for some of the variables are available for analyses, yielding the candidate rhythms (Table 2 in Ref. 11). Changes with age notwithstanding, we are making a transition from candidate to replicated rhythms. This was actually first shown by the simple but very useful data transformation as percentage of series mean.[12] The original data are averaged and expressed as percentages of the series mean to obtain relative values. After these time-macroscopic steps, an approach by cosinor follows, which yields parameters with their uncertainties. Maps such as those of Fig. 5 are desirable for many peptides not analyzed in this figure and for many frequencies beyond the circadian. An example of gastrin chronomics is shown in Fig. 5.

A good example of the application of peptide chronomics occurs with prostate cancer risk assessment. As prostatic cancer shows geographic differences in morbidity and mortality, the extent of circannual variation also changes as a function of risk and/or cancer. In blood sampled with serial independence as to subjects in the morning at different times of the year, a prominent circannual rhythm in thyroid-stimulating hormone (TSH) of healthy subjects at low risk of prostatic cancer is lost in prostatic cancer, and even in men at high risk of prostatic cancer (Table 3 in Ref. 11). For prolactin, a circannual rhythm becomes demonstrable in the case of prostatic cancer, while it is not demonstrable with serially independent sampling in healthy men of low or high prostatic cancer risk (Table 4 in Ref. 11).

CHRONOMICS IN WOMEN

Another illustrative example of the application of chronomics is shown in a study of women. The Kyushu–Minnesota study involved sampling of three age groups of women in Minnesota, each group consisting of two subgroups, one at high, the other at low familial risk of developing breast

FIGURE 5 Gastrin was measured around the clock for 24 h in 11–13 men, followed-up longitudinally in three studies in 1979, 1988, and 1993. The large variability (A) can be reduced by expressing the data as a percentage of the 24h mean (B). Averaging across studies at each circadian stage is associated with large error bars obscuring the circadian variation (C). This is corrected by averaging the relative values at each circadian stage (D). From studies by E. Kanabrocki.

cancer, and of three age groups of women at low risk in Japan. Two dozen, mostly endocrine variables were sampled around the clock, at four stages of the menstrual cycle in the two menstruating groups, in four seasons. From this international study, circulating prolactin was analyzed as three-hourly means of determinations at 20-min intervals. Geographic, ethnic and/or other differences were taken into consideration. A prolaction peak >50 ng/ml was seen in Japanese women at night; this was hardly more than half that value in Minnesotans. There was also a very marked within-day variation, overwhelming all other sources of variability. With harmonic interpolation, a second peak in the late afternoon could also be found for the Japanese subjects and has been discussed in the context of the literature. We emphasize that the smooth curves only describe results from a given season. But first, let us point out the errors that can occur if such rhythms are ignored.

This dense (20-min) sampling suggests both a larger circadian amplitude and a higher rhythm-, or rather chronome-adjusted mean or MESOR of the circadian rhythm in blood plasma prolactin in Japanese as compared with North American women ($P<0.002$ from Hotelling T^2 test). Judged on the basis only of daytime samples, erroneous conclusions may be drawn. Circadian acrophases of plasma prolactin of adolescent, young adult, and postmenopausal women from Japan and Minnesota in each of the four seasons show a relatively high degree of synchronization. The vectorial cosinor summary achieves at a glance, objectively and quantitatively, what a display of all original data cannot readily convey.

The difference of plasma prolactin between clinically healthy Japanese and Minnesotan women is seen again in a replication of part of the study in March 1978 (15 whites of mixed ethnic background [18–24 years old] in Minnesota and 20 Japanese [~20 years old] in Kyushu, Japan). Time-macroscopy by a chronogram is complemented by time-microscopy in a cosinor. The 95% error ellipses do not overlap the pole. The circadian amplitude (in nanograms per milliliter) is 5.4 (1.2–9.6) for Minnesotans and 19.3 (12.1–26.6) for Japanese.

We then applied circannual chronopathology to breast cancer risk assessment. An obliteration of the circannual but not of the circadian rhythm in prolactin is seen by an overlap of the pole by the 95% error ellipse for data on fibrocystic mastopathy as compared with clinical health for women sampled in Florence, Italy. Although the circadian amplitude (expressed in nanograms per milliliter or as percentage of MESOR) is not affected in the presence of benign breast disease, the circannual amplitude is drastically reduced. The alteration of a circannual prolactin rhythm may be a harbinger of increased breast cancer risk in Europe as in the USA.

A negative correlation between the total relative breast cancer risk evaluated from epidemiologic criteria and the circannual prolactin amplitude seems to corroborate the finding that an elevation of breast cancer risk is associated with a decrease in circannual amplitude (based on the least-squares fit of 365.25-day cosine curve to circadian MESORs assessed in each of the four seasons). There is positive correlation between epidemiologically assessed breast cancer risk and the circannual amplitude of TSH. Clinical hypothyroidism has empirically been associated with breast cancer risk. The circannual stage dependence of the correlation seems pertinent and may prove to be useful for treating an elevated cancer risk rather than the disease, to the extent that the interaction of rhythms with different frequencies can be untangled.

Thus, TSH and prolactin show opposite behavior along the 1-year scale in cancers of both breast and prostate rather than responding in the same fashion as occurs after acute stimulation with the hypothalamic tripeptide TSH-releasing hormone (TRH). It is also noteworthy that the circannual relations of plasma TSH and prolactin to the risk of breast cancer are opposite to those with respect to prostatic cancer (and as noted, opposite to each other in each cancer).

DISCUSSION

The new finding of spectral components longer than a year deserves emphasis.

Such components are the transyears, some, the near-transyears, exceeding the 1-year length by only a few weeks; others, far-transyears, exceeding the year length by a few months. Both transyear and far-transyear patterns are found in 17-ketosteroid excretion, a variable influenced by peptides, among other variables, but are not yet mapped for peptides. A chaotic regime has been proposed in accounting for a modulation by neuropeptides of information processing at the level of a single neuron;[18] apart from modeling, the use of algorithms for the analysis of probabilistic chaos in time series collected with appropriate density and length will constitute another challenge for students of peptide dynamics.

Alchemy seemed to be less complex than chemistry; nonetheless, we are now in an age of clinical and other chemistry and automation runs smoothly. We successfully diagnose gross deviations from a normal range of peptide values with time-unspecified samples! These spot checks are the routine of our day for sampling blood for peptides in the clinic and in research. The task of budding chronodesms, time-specified tolerance, and prediction intervals, not only for interpreting single values but also for time-structural characteristics, still lies ahead for peptides. But biological variability has to be known not only to reduce the width of the reference interval for single samples beyond that achieved by reducing the sources of technical variation, and not only because what may be acceptable at one time can be unacceptable at another, but also to avoid blunders and, equally importantly, to make new discoveries.

A great opportunity for applications of peptide chronomics lies in the pharmaceutical industry. A peptide drug may act at one time but not at another, and testing across different circadian times allows the fit of a cosine curve and the detection of optimal timing. It is important to remember that peptides in organisms are not constants; they are variables. Indeed, the alternative to a putative homeostasis is to study the dynamics in the normal range and thus eventually to treat risk elevation, rather than waiting for actual disease to occur, whether we are dealing with severe vascular disease, cancer, or the basic science of our relation to our cosmos.

Chapter 254

Peptides and Behavior

Susan Rotzinger

ABSTRACT

The role of peptides in modulating a wide range of behaviors has been recognized for many years. It is increasingly apparent that peptides influence behavior in unique ways that are state dependent, coordinated, and redundant. In addition, peptides show unique dose–response characteristics and can have long-lasting effects on behavior. Peptides modulate behavior as part of a concerted and coordinated effect on physiology, neuroendocrine, and behavioral output to facilitate goal-directed behavior and support homeostasis. Peptides modulate behavior through their interactions with other peptides and neurotransmitter systems in the brain and represent a promising new class of therapeutics for neuropsychiatric disorders. This chapter reviews some general features of peptide modulation of behavior.

INTRODUCTION

With >100 different neuropeptides in the mammalian brain,[18] it is not surprising that peptides play a role in a large number of behavioral, emotional, and cognitive processes. It is also to be expected that with such a number of peptides, there will be many different peptides that modulate the same types of behaviors and that many individual peptides will modulate more than one type of behavior. Peptides can exert both peripheral and central effects. Peptides act through the hypothalamic–pituitary axes to initiate endocrine responses throughout the periphery. Most peptides and their receptors are also found in the brain at extrahypothalamic sites where they can exert effects on cognition, emotion, social, and motivational processes.

Many reviews of peptides and behavior have previously been published.[35] An exhaustive review of all peptides and behavioral effects is beyond the scope of this chapter. Instead, the focus will be on general concepts relating to the effects of peptides on behavior. The second section will cover the current understanding of some of the major peptide systems that impinge on a few of the most important behavioral processes. The third section will provide a brief discussion of the potential therapeutic aspects of peptide-based compounds.

GENERAL FEATURES OF PEPTIDE MODULATION OF BEHAVIOR

Peptides Are Modulatory

In examining the large body of data concerning the behavioral effects of peptides, one principle that emerges is that the influence of a peptide on behavior is dependent on the current physiological, neuroendocrine, and behavioral state of the organism, as well as the environmental conditions. In animal models of anxiety, for example, the effects of a peptide or peptide receptor ligand often depend on the animal in which they are tested. For example, the V1b antagonist SSR149415 shows antidepressant-like effects, but only in the genetically selected Flinders Sensitive Line, but not in Flinders Resistant Line.[23] Similarly, CRH_1 receptor antagonists have anxiolytic effects but often only in rats selectively bred for high anxiety behavior.[28] Intracerebroventricular (icv) infusions of oxytocin decreases anxiety in female rats selectively bred for high anxiety but not in their male counterparts.[31] Conversely, oxytocin increases anxiety in the female rats bred for low anxiety but again had no effect in the males. Thus, oxytocin increases anxiety in low anxiety rats, but it decreases it in high anxiety rats. The peptide teneurin C-terminal associated peptide (TCAP) has also shown differential effects on anxiety in the acoustic startle test depending on the baseline anxiety of the animal.[28]

In experimental models, test conditions will also affect the behavioral outcome of peptide manipulation. SSR149415 shows modest anxiolytic-like effects in classical tests of anxiety such as the elevated plus maze and light–dark test but shows more clear-cut anxiolytic actions in more traumatic models such as the social defeat test.[8] Cholecystokinin (CCK) ligands also show this property. For example, the CCK2 antagonist L-365,260 does not affect baseline acoustic startle responses, but does attenuate fear-potentiated acoustic startle.[29] Many examples of this principle can be found in which paradigms that involve more intense stress are required to observe a behavioral effect.[28]

Peptides can also have sexually dimorphic effects on behavior. Intranasal arginine vasopressin (AVP) differentially affects social communication processes in men and women.[32] Men and women were administered intranasal AVP and then were shown pictures of same-sex models expressing various facial expressions and asked to rate the approachability/friendliness of the faces. AVP promotes agonistic responses in men, and affiliative responses in women, although both the groups reported an increase in anxiety on a self-report measure.

Environmental stimuli can also play an important role in the modulatory effects of peptides on behavior. Galanin is an orexigenic peptide, but its effects on feeding are dependent on the fat and carbohydrate content of the diet.[20]

These studies emphasize the modulatory role that neuropeptides play in behavior, particularly under challenging conditions of stress.[12]

Peptides Have Coordinated Effects on Behavioral and Physiological Processes

Peptides modulate behavior in a concerted and coordinated way, modulating several parallel behavioral processes in addition to the neuroendocrine and physiological properties required to support the ongoing behavior. Corticotropin releasing hormone (CRH) is the classic example of a peptide that activates a concert of neuroendocrine, autonomic, and behavioral responses to stress. Hypothalamic CRH activates adrenocorticotropin (ACTH) release from the pituitary and subsequently corticosteroid release from the adrenal cortex. In addition to these hypothalamic–pituitary adrenal (HPA) axis functions, CRH and its receptors are distributed throughout many limbic brain regions that modulate behavioral processes. CRH activates behavioral processes that would facilitate responding to a stressor, such as increasing locomotion, anxiety, arousal, and suppressing feeding. CRH has also been implicated in learning and memory processes, cognition, and addictions.

AVP also has both HPA and extrahypothalamic effects on behavior and physiology and works in a coordinated fashion with CRH. AVP plays a critical role in regulating blood pressure and water balance. However, it also modulates emotional and social behavior. In an interesting examination of the coordinated effects of stress on physiology and behavior, rats were rendered hypernatremic and exposed to a psychogenic stress.[15] Hypernatremic rats had decreased HPA and cardiovascular responses to stress, as well as increased circulating oxytocin levels, and decreased anxiety behavior in the social interaction test. The authors suggest that hypernatremia could initiate a coordinated set of behaviors to support engaging in drinking behavior, which for animals may necessitate increased social interaction and decreased anxiety behavior, such as would be required to approach a watering hole in the wild.

Oxytocin has peripheral effects on uterine contractions during childbirth and facilitates ejection of milk. Not surprisingly, oxytocin also plays a role in maternal behaviors, which in rats include nest building, and pup grooming, licking, and retrieval. Oxytocin also facilitates social behavior and reduces aggression. Its uses range clinically from induction of labor, to potential roles in social anxiety disorder and autism.

Neuropeptide Y (NPY) also affects a broad range of behaviors, most notably feeding and water consumption. However, consistent with this proconsummatory action, NPY also plays a role in many other behaviors that can be considered important to supporting this role, such as locomotor behavior, circadian rhythms, temperature regulation, cardiopulmonary function, learning and memory, pain perception, and anxiety. NPY also interacts with central reward pathways to increase the rewarding properties of food, and may play a role in addiction.

Peptides Have Unique Dose–Response Relationships

Peptides and peptide receptor antagonists often show nonlinear dose–response relationships, commonly an inverse-U shaped function.[3,13] Many examples of this can be found in the behavioral literature. For example, 1 μg of alpha-helical $CRH_{9\text{-}41}$ is effective in antagonizing stress-induced reductions in exploration in the elevated plus maze in rats, whereas higher doses of 5 and 25 μg have no effect.[11] Similarly, NPY shows an anxiolytic profile in the elevated plus maze at 700 pmol, but at 7 pmol is anxiogenic.[21] This is probably attributed to the differential activation of NPY receptors at different doses, having an anxiogenic effect via Y2 receptors, and anxiolytic via Y1.

The Tyr-MIF-1 family of peptides also shows unique dose–response characteristics, with low doses being more effective than high doses in the rat forced swim test.[14] In clinical trials, low doses (60–75 mg) of MIF-1 but not higher doses (150–750 mg) are associated with improvement in depressive symptoms.[25]

Unique dose–response relationships for peptides may also result from transport across the blood brain barrier. For example, low leptin levels trigger an increase in feeding, but high circulating leptin in obese individuals does not suppress feeding and high leptin levels aggravate weight gain.[7] However, this phenomenon can largely be explained by saturation of the transport system for leptin.[13]

Peptides May Have Long-Lasting Effects on Behavior

The half-life of a peptide in the blood does not necessarily correlate with the duration of its effect in the body.[13] This may result from a number of factors, including transport

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

mechanisms. However, the action of neuropeptides also involves longer-term changes in gene expression and function of local circuits. Peptides can act on G protein-coupled receptors, neighboring cells, and over circuits through effects on gene expression and synaptogenesis. They can also prime activity-dependent release.[18] "Priming" makes vesicles more ready for release, thus enhancing the capacity for local interactions. Peptide-mediated reprogramming of a neuronal system could be the substrate for prolonged behavioral effects.

NPY injected into the basolateral amygdala (BLA) has an anxiolytic effect in the social interaction test which persists for 8 weeks after the end of a series of five NPY injections.[30] Nemifitide, a peptide analog of MIF-1 shows antidepressant effects in the rat forced swim test that continues for 5 days after the completion of a 14-day treatment regimen, an effect that is not seen with tricyclic antidepressants.[24] Repeated TCAP administration shows long-lasting effects on the acoustic startle response in rats.[28]

Consistent with the long-term reorganization of circuits associated with the effects of neuropeptides on behavior is the finding that repeated dosing with neuropeptides is often required to observe a behavioral effect. For example, acute injections of the V1b antagonist SSR149415 are inactive in the rodent forced swim and tail suspension tests, whereas repeated injections show an effect.[23] Repeated injections of oxytocin for 8–10 days show an enhanced antidepressant effect over acute dosing in preclinical models.[1] An acute icv dose of oxytocin has no effect on anxiety-like behavior, but 6 days of treatment results in a decrease in anxiety in female, but not male rats bred for high anxiety behavior.[31]

PEPTIDE MODULATION OF SPECIFIC BEHAVIORS

Peptides play a role in modulating virtually every behavioral process, and integrating behavior with neuroendocrine responses. It is not possible to cover all behaviors in detail in this chapter, and therefore the focus will be on the three most extensively studied classes of peptide-mediated behavior, namely, social, consummatory, and mood related behaviors.

Social Behavior

Social behavior, including parental and reproductive behavior, is critical to the ability to successfully interact with members of one's species, obtain food and mates, and avoid predation.[22] It is therefore not surprising that many different peptides influence social behavior. Oxytocin and vasopressin have been the most extensively studied peptides in this area, are highly conserved and modulate social and reproductive behavior across many species. Many excellent reviews of their role in social behavior are available.[27] Expression of oxytocin and vasopressin receptors outside of the hypothalamus is both sex and species specific, and is believed to be important in defining differences in behavioral effects across species. AVP has a more important role in male behavior and aggression, whereas oxytocin is more closely linked to female behavior. Oxytocin is a key peptide for maternal behavior, and both oxytocin and AVP are important in pair bonding, mate preference, and social recognition memory. In preclinical models, oxytocin generally has positive effects on social behavior, and can restore stress-suppressed social behavior.[28] AVP and oxytocin modulate social behavior in opposite directions and have been suggested to be part of a circuit modulating anxiety especially in response to social defeat in rodents.[17] Modulation of oxytocin and vasopressin systems are targets for intervention in a number of disorders involving social cognition such as schizophrenia, autism, social anxiety disorder, and depression.[4,9]

Social behavior is also facilitated to a large degree by peptide interactions with central reward pathways, such as the mesolimbic dopamine system. AVP facilitates social attachment through interactions with nucleus accumbens dopamine systems. Intranucleus accumbens injections of morphine increase social play in rats, suggesting that mu opioid receptors may be important for the rewarding aspects of social behavior.[33] Many other opiate peptides also play a role in social behavior.[2]

Peptides that decrease anxiety also facilitate social behavior in the social interaction test in rodents. NPY, CRH_1 antagonists, galanin antagonists, and NK-1 antagonists all decrease anxiety in the social interaction test in rodents, and facilitate social interaction.[28]

CONSUMMATORY BEHAVIOR

Feeding behavior is normally tightly controlled by central nervous system mechanisms that balance nutrient and energy requirements of the organism. Many different peptides play a central role in these processes, such as adiposity signals such as leptin and insulin that detect the status of energy reserves, and other peptides that are activated by these signals to increase or decrease the feeding behavior and corresponding alterations in energy expenditures.

Leptin is an adiposity signal and its levels generally correlate directly with body fat. Leptin regulates melanocortin signaling in the hypothalamus through distinct populations of neurons to increase or decrease food intake.

CCK is a satiation factor produced by the intestinal cells in response to meal ingestion. CCK reduces meal size, and CCK-1 antagonists can increase meal size. Other gut peptides that reduce meal size are gastrin releasing peptide, neuromedin B, enterostatin, somatostatin, glucagons-like peptide-1, apolipoprotein A-IV, and peptide YY. Ghrelin is

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

a gut peptide that stimulates food intake whether peripherally or centrally administered.

Urocortin inhibits food intake, increases anxiety, and improves performance on some learning and memory tasks. Urocortin interacts extensively with leptin, NPY, orexins, and CRH in its modulation of feeding behavior.

Galanin is an orexigenic peptide, and injection into the hypothalamus stimulates feeding without affecting other feeding-related behaviors such as drinking, locomotion, or grooming.[20] It plays a role in diverse physiological functions such as nociception, arousal/sleep, cognition, feeding, energy balance, thermoregulations, osmotic and water balance, and reproduction.

NPY is involved in a wide range of behaviors, including food intake, anxiety and depression, reward, pain, circadian rhythms, as well as neuroendocrine and cardiorespiratory behaviors. Central injections of NPY stimulate feeding and water intake.

In addition to caloric and nutritional value, feeding behavior is intertwined with the rewarding and emotional aspects of food intake, especially in humans.[34] The reward system plays an important role in feeding behavior, and dopaminergic cells in the VTA have receptors for many peptides involved in feeding such as NPY, leptin, ghrelin, insulin, orexin, and CRH.[34] Similarly, melanocortins regulate feeding and other rewarding and addictive behaviors through interactions with mesolimbic neurons.[5] Orexigenic peptides may also play a role in addiction that the consumption of drugs of abuse and of palatable foods is stimulated by similar mechanisms. Opiates also affect feeding behavior, probably through mu opiate interactions with central reward pathways.[2] Not surprisingly, opiates play a role in the rewarding effects of drugs of abuse of all classes. Opiates also interact with other peptides and neurotransmitters to modulate sexual behavior. Central CCK function has also been implicated in sexual behavior and other reward processes,[29] and effects on feeding may also be influenced by central reward pathways.

Anxiety and Depression

Many different peptides have the potential to influence mood, and indeed, the list of peptides that have shown effectiveness in animal models of anxiety and depression is extensive.[28] There is abundant evidence for the role of HPA dysregulation in mood disorders, and in many psychiatric disorders. Prolonged stress and anxiety are closely linked to mental illness. Therefore, it is probable that any peptide that is involved in the modulation of stress responses could have potential to influence the mood. Most peptides that have anxiogenic properties also show prodepressant effects in animal models, whereas those with anxiolytic effects generally show antidepressant-like effects. The effects of neuropeptide receptor manipulation on anxiety and depression have been reviewed[28] and are briefly summarized here.

The CRH family of peptides in humans consists of CRH, urocortin, urocortin 2 and urocortin 3. Antidepressant and anxiolytic effects of CRH1 antagonists have been noted in behavioral tests that involve either rats selectively bred for high depression or anxiety-like behavior, or under enhanced stress conditions during testing.[28] Urocortin acts on a broad range of behaviors from anxiety, learning and memory to food intake.[26] CRH_1 antagonists, and urocortin (Ucn) 2 and 3 show antidepressant activity in preclinical models of depression. Ucn1 is anxiogenic, whereas Ucn2 and 3 can show both anxiolytic and anxiogenic properties.

NPY is highly implicated in mood regulation. NPY immunoreactivity is expressed throughout cortical and subcortical regions of the rat brain and in key behavioral centers such as the hippocampus, nucleus accumbens, amygdale, and the bed nucleus of the stria terminalis. Preclinical models have shown an antidepressant-like profile after central NPY administration, as well as an anxiety-reducing effect. The anxiety regulating effects of NPY are thought to depend on activity in the amygdala. NPY itself is anxiolytic, whereas blockade of NPY receptors has an anxiogenic effect.[28] NPY compounds have therapeutic potential for obesity, depression, anxiety, addiction, and posttraumatic stress disorder (PTSD).

Clinical trials with MIF-1 have shown rapid antidepressant effects at low doses with good tolerability. MIF-1 has an antidepressant effect that has been shown in several small clinical trials, including a double-blind, placebo-controlled, crossover study in which depressed individuals receiving 10 mg/day of subcutaneous MIF-1 showed remission of symptoms after 5 days.[6]

Arginine vasopressin (AVP) acts peripherally to regulate water balance but has many central neuropeptide effects on behavior mediated through V1a and V1b receptors that are distributed in brain regions associated with regulation of mood and emotion, such as the lateral septum, amygdala, bed nucleus of the stria terminalis (BNST), hippocampal formation, and cortical regions.[17] Vasopressin is also highly implicated in anxiety related behavior, and AVP receptor antagonists are anxiolytic and antidepressant. V1b antagonists have shown antidepressant potential in the rat forced swim test.[8,23]

Similarly, oxytocin receptor agonists are anxiolytic and show antidepressant effects in some models. Intraperitoneal injections of oxytocin can have antidepressant-like effects in the forced swim test.[1] Intranasal oxytocin also has antidepressant potential in humans and shows promise in social anxiety disorder.[10]

Substance P is the preferred ligand for the NK-1 receptor, which is abundantly expressed in limbic regions. Although Substance P was originally implicated in pain and nociception, it is also clear that it plays a role in stress

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

and mood regulation. Substance P is anxiogenic and has pro-depressant properties, whereas NK1 receptor antagonists have been tested extensively in animal models of depression, and NK1 antagonists are currently in clinical trials for their antidepressant potential, as well as a possible role in PTSD.

Galanin and Gal3 antagonists have anxiolytic effects in rodent models. Galanin shows prodepressant effects in the forced swim test, probably through GalR1 and GalR3 receptors, whereas galanin antagonists show an antidepressant effect. In rat models of depression, galanin administration seems to enhance depression-like behavior. Central administration of galanin increased immobility in the rat forced swim test.[16] However, the depressive-like effect seems to be specific to the GAL1 and GAL3 subtypes, whereas GAL2 stimulation results in an antidepressant profile. The effects of galanin on anxiety-like behavior seem to depend heavily on the specific test conditions and administration conditions. It seems that galanin has a more modulatory role in anxiety and not a directionally specific anxioltyic or anxiogenic property.

CCK is abundant in the brain and is distributed throughout limbic brain regions and cortex. CCK has well-characterized effects on anxiety and panic behavior in both animals and humans.[29] CCK is anxiogenic, which has been mostly attributed to the CCK2 receptor. CCK2 antagonists are generally anxiolytic, whereas CCK peptides and CCK2 agonists are anxiogenic. CCK2 antagonists have shown efficacy in animal models of depression.

PEPTIDE THERAPEUTICS

Neuropsychiatric disorders represent an area of great potential for peptide-based therapeutics. Their coordinated effects on multiple behavioral and physiological systems provide distributed control over affected networks and may bring more integrated modulation of dysregulated systems for complex disorders such as mood and anxiety disorders in which multiple physiological systems are affected. For example, in depression, in addition to mood dysregulation, there are abnormalities in motivation, reward processes, circadian rhythms, feeding behavior, sexual behavior, and cognitive processes. CRH, SP, NPY, AVP, oxytocin have all been implicated in the disorders of social behavior, mood, and feeding. Thus, peptide modulation is poised to represent a truly novel therapeutic option for future drug development which may more effectively target core symptoms in addition to other related dysfunctional systems.

The development of peptide-based therapeutics for CNS diseases has been hampered by issues relating to poor bioavailability, low stability, and difficulties in crossing the blood brain barrier. However, new research is addressing these issues.[19] Oral delivery of peptides is problematic because of poor absorption and high enzymatic degradation, but many alternative routes of administration exist and are in development such as across nasal, buccal, and other mucosa. Improvements in bioavailability and uptake can be achieved through the inhibition of enzymatic degradation, or chemical modification to improve uptake so that peptide therapeutics can be delivered to the brain and exert their multiple effects. Other methods of facilitating peptide delivery to the CNS are in development.

Peptides have unique properties, including their unique dose–response characteristics, and their modulatory, coordinated effects on multiple systems. Individual differences in behavior and physiology may be a key factor influencing the outcome of peptide therapeutics. The move toward personalized medicine in psychiatry and other CNS therapeutic areas has grown in popularity as a result of the difficulty in matching the correct treatment to the correct patient, and because of the heterogeneity of clinical presentation. As flexible modulators of neurotransmitters, immune function, and neurotrophic factors, peptide therapeutics stand to provide new avenues for therapeutic development.

CONCLUSION

Peptides represent a fascinating class of compounds that modulate behavior in concert with the appropriate physiological and neuroendocrine support. Social behavior, consummatory behavior, and stress modulation are three key areas for survival and are thus modulated by many different peptides. The unique properties of peptides should not be a deterrent to peptide-based therapeutics but rather should be exploited for the unique opportunities associated with peptides.

Chapter 255

Peptides and Sleep

A. Steiger

ABSTRACT

A bidirectional interaction exists between the electrophysiological activity of sleep as recorded by sleep electroencephalogram (EEG) and nocturnal hormone secretion. Various neuropeptides participate in sleep regulation. A reciprocal interaction of growth hormone-releasing hormone (GHRH) and corticotropin-releasing hormone (CRH) plays a key role in sleep regulation. GHRH promotes sleep and growth hormone and inhibits cortisol, whereas CRH exerts opposite effects. Age and gender seem to modulate these effects. Also ghrelin and galanin promote sleep, whereas somatostatin impairs sleep. Neuropeptide Y regulates sleep onset. VIP is involved in the temporal organization of sleep. Pituitary adenylate cyclase-activating polypeptide modulates sleep homeostasis. Orexin/hypocretin is an important sleep-regulating factor. Its lack results in narcolepsy.

INTRODUCTION

Human sleep is characterized by the cyclic occurrence of periods of non-rapid eye movement (non-REM) sleep and rapid eye movement (REM) sleep and by distinct patterns of hormone secretion. During the first non-REM sleep period, the major portion of slow wave sleep (SWS) and in electroencephalogram (EEG) spectral analysis the major portion of slow wave activity (SWA) occur. During the first half of the night, the growth hormone (GH) surge preponderates, whereas corticotropin (ACTH) and cortisol levels are low. It is vice versa during the second half of the night; ACTH and cortisol concentrations are high, whereas GH release is low. This pattern points to (1) a reciprocal interaction of the hypothalamic–pituitary–somatotropic (HPS) and the hypothalamic–pituitary–adrenocortical (HPA) systems and (2) the existence of common regulators of the sleep EEG and the nocturnal hormone secretion. As described in detail below, a reciprocal interaction of the key hormones of the HPS and HPA systems, GH-releasing hormone (GHRH) and corticotropin-releasing hormone (CRH) seem to play a major role in sleep regulation.

HYPOTHALAMIC–PITUITARY–SOMATOTROPIC (HPS) SYSTEM

Basic Activity

In humans, the major GH peak is found closer to sleep onset. This GH surge is associated with the first SWS period. The GH surge is widely sleep-dependent and is suppressed during sleep deprivation, whereas there is a weak circadian component in the regulation of GH release.[30] As early as during the third decade of our life span, parallel decrease in SWS, SWA, and GH secretion begin.[3]

Hypothalamic GHRH mRNA depends on a circadian rhythm. In rats, its highest concentration occurs at the onset of the light period when sleep propensity reaches its maximum. Hypothalamic GHRH has sleep-related variations with low levels in the morning, increases in the afternoon, and decreases at night.[18] In patients with isolated GH deficiency, SWS is lower than in normal controls. Excessive GH levels are found in patients with acromegaly. One year after tumor removal, REM sleep and SWS time increase in these patients.[1]

Growth Hormone-Releasing Hormone

GHRH is an important endogenous sleep-promoting substance. In mice, the GHRH gene is found in the region linked to SWA. Intracerebroventricular (icv) GHRH increases SWS in rats and rabbits. The same effect occurs after the injection of GHRH into the medial preoptic area in rats or after iv administration to rats.[18,27]

Similarly, after repetitive hourly iv injections of GHRH around sleep, onset SWS and GH increase whereas cortisol is blunted in young men. Mimicking of the pulsatile endogenous release seems to be crucial because sleep remains unchanged after GHRH infusion. Sleep promotion in young males resumes after GHRH by iv and intranasal administration. The effects of GHRH on human sleep were examined in three states with a change of the GHRH/CRH ratio in favor of CRH. (1) After repetitive iv GHRH between 04:00 and 07:00 h, sleep is not affected. Only a weak

Copyright Elsevier 2024

sleep-promoting effect of GHRH occurs in the elderly. (2) The effect of iv GHRH in drug-free depressed patients of both sexes (19–76 years) and in matched controls shows a sexual dimorphism in the response to GHRH. In male patients and control subjects, GHRH decreases ACTH and cortisol, whereas these hormones are enhanced in normal and depressed females. Similarly, non-REM sleep increases and wakefulness decreases in males, whereas sleep-impairing effects occur in women.[27] These results point to a reciprocal antagonism of GHRH and CRH in men, whereas a synergism of GHRH and CRH is suggested in women. In rats, non-REM sleep decreases and sleep latency increases after GHRH receptor antagonists. Non-REM sleep is reduced after administration of antibodies to GHRH.[18]

In the rat preoptic hypothalamus, GABAergic neurons in the median preoptic nucleus and the ventrolateral preoptic nucleus (VLPO) are potential targets of the sleep-regulatory actions of GHRH.[20] Multilateral application of low doses of GHRH to the surface of the somatosensory cortex of rats diminishes SWA ipsilaterally, whereas after higher dosages SWA increases. Multilateral application of a GHRH antagonist onto the somatosensory cortex surface of rats decreases SWA ipsilaterally. Similarly injection of GHRH receptors small interfering RNA is followed by the suppression of SWA for up to 24 h.[13]

Sleep deprivation is a powerful stimulus for sleep. GHRH seems to mediate this effect. It is antagonized by GHRH antibodies in rats and by microinjections of a GHRH antagonist into the area preoptica of rats. After sleep deprivation, a depletion of hypothalamic GHRH and low hypothalamic GHRH contents occur, whereas hypothalamic GHRH mRNA increases in rats. This high rate of release is thought to stimulate transcription. The increase in hypothalamic GHRH mRNA concentration is associated with decreases in hypothalamic somatostatin. GHRH receptor mRNA and GHRH binding decline in the rat hypothalamus after sleep deprivation, whereas pituitary GHRH receptors remain unchanged.[18]

The effect of GHRH on recovery sleep after sleep deprivation was tested in a sample of healthy volunteers of a wide age range and of both sexes. The increase of non-REM and the decrease of wakefulness after sleep deprivation are augmented by GHRH. Interestingly this effect is shared by CRH.[25]

In mice, viral infections enhance non-REM sleep. After influenza A infection, non-REM sleep increases in wild-type mice. However, in the GHRH-receptor-deficient *lit/lit* mice, non-REM sleep and SWA decrease after influenza inoculation. Non-REM sleep decreases after negative feedback inhibition of GHRH by GH in humans, cats, and rats or after higher dosages of icv insulin-like growth factor-(1 IGF-1). However, GH antagonism impairs sleep.[18,27] In sum, non-REM sleep is promoted by high GHRH activity at least in male humans and animals, whereas non-REM sleep declines when GHRH activity is reduced.

Somatostatin

Selective increases of REM sleep have been reported in rats after icv somatostatin. Systemic and icv administration of the somatostatin analog octreotide in rats decreases non-REM sleep and GH.[2] Similarly, SWS declines, and wakefulness increases in young men after subcutaneous octreotide administration. Octreotide is long acting and more potent than somatostatin is. This explains why repetitive iv somatostatin impairs sleep in normal elderly subjects, but not in young men.[27] A reciprocal interaction of GHRH and somatostatin in sleep regulation similar to their opposite effects on GH release is probable.

Ghrelin

Similar to GHRH, repetitive iv ghrelin enhances SWS and GH in young men. In contrast to GHRH, which blunts cortisol release in young men, ACTH and cortisol increase after ghrelin administration. Also in mice, ghrelin promotes non-REM sleep. An intact GHRH receptor is the prerequisite for this effect, because ghrelin does not modulate sleep in mice with nonfunctional GHRH receptors.

In addition to its stimulating effect on GH and cortisol, ghrelin elevates the nocturnal release of prolactin in young healthy male volunteers. Furthermore, in healthy young men receiving ghrelin, the concentrations of luteinizing hormone (LH) and testosterone decrease during the early hours of the night. After ghrelin administration, both a delay and a suppression of the amplitude of LH pulses occur. After ghrelin administration in young healthy female and male volunteers, nocturnal thyroxine (T_4) concentrations are elevated followed by marked decline of thyroid-stimulating hormone (TSH). These findings suggest that ghrelin suppresses the hypothalamus–pituitary–thyroid (HPT) axis in humans which counteracts its energy-saving effects.

In a series of human studies, the role of the time of administration, sex, and age on the effects of ghrelin on sleep were studied. Sleep EEG is not changed after pulsatile administration of ghrelin during the early morning hours. In young healthy female volunteers, pulsatile ghrelin injections around sleep onset do not affect sleep EEG, whereas the changes of cortisol and GH are similar to those in young men. This sexual dimorphism is also found in older healthy women and men. Although sleep is promoted in healthy male volunteers who are ≥60 years, sleep EEG remains unaffected in women of the same age range.

A bolus injection of 100 μg of ghrelin at 22:00 h prompted distinct hunger in a single healthy volunteer. This effect differs from sleep promotion after 4 × 50 μg of ghrelin

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

starting at the same time. The development of hunger after ghrelin administration may explain the contrasting findings of a series of studies of Szentirmai and colleagues, in the rat. Wakefulness and food intake increase after intracerebroventricular and intrahypothalamic ghrelin administration. In some of these experiments, the feeding period is followed by increases of SWA. This change may mirror a delayed sleep-promoting action of ghrelin. Similarly ghrelin knockout mice sleep less than the wild type do. Also, this finding is compatible with the sleep-promoting effect of ghrelin.

The relationships among plasma ghrelin and hypothalamic ghrelin content and sleep and feeding were investigated in rats. There is a major influence of feeding on the diurnal rhythm of ghrelin. Variations in hypothalamic ghrelin suggest an association with the sleep–wake activity. One study examined interactions of sleep and ghrelin levels in young men who were semirecumbent during 24 h. When they were allowed to sleep, ghrelin increased by sleep onset. This is followed by a decline throughout the night. The nocturnal rise is blunted during sleep deprivation. Ghrelin levels were determined between 20:00 and 07:00 h in normal female and male control subjects who were active during daytime. In males, ghrelin increases continuously between 20:00 and 23:00 h. In females, however, ghrelin levels at 20:00 h are already in the same range as they are during the sleeping period. In a sample of >1000 subjects, short sleep-time is associated with higher ghrelin levels. Similarly, the comparison between extended (12 h) and restricted (4 h) sleep time during 2 days each shows increases in ghrelin after sleep restriction at daytime.[28]

GH Secretagogs

Before the discovery of ghrelin, synthetic GH secretagogs were available. Several studies investigated the effects of these substances on human sleep. Oral administration of the GH secretagog MK-677 for 1 week prompts a distinct sleep-promoting effect in healthy young male volunteers, whereas a weak effect is observed in elderly subjects. This study shows that oral administration of a peptide is capable of promoting sleep. After repetitive intravenous administration of GH-releasing peptide 6 (GHRP-6), non-REM sleep stage 2 increases. Similar to the effects of ghrelin in male subjects GH, ACTH, and cortisol are elevated. In a set of studies, the intranasal, oral, and sublingual administration of GHRP-6 was tested. By these routes of administration the effects of the peptide on the sleep EEG and on hormone secretion are less distinct and partly different from those after intravenous injection. In contrast to the sleep-promoting effects of GHRP-6 and ghrelin, hexarelin prompts a decrease of SWS, whereas the pattern of endocrine effects after hexarelin resemble the endocrine changes after ghrelin and GHRP-6 in that there is a marked stimulation of GH. The decrease of SWS after hexarelin may be related to negative feedback inhibition of endogenous GHRH. After a single dose of GHRP-2 during the third period of REM sleep, sleep remains unchanged. The lack of effects in this study may be related to the method that uses only a single injection of the substance.[28]

Animal Models of HPS System Changes

In the giant transgenic mice, GH is permanently elevated. During the light period, non-REM sleep is higher and REM sleep is almost doubled in these mice. After sleep deprivation, these mice sleep more than normal mice do. In dwarf rats, with deficits in the central GHRHergic transmission and reduced hypothalamic GHRH, non-REM sleep is reduced compared with that in the wild type. In dwarf homozygous *(lit/lit)* mice with a nonfunctional GHRH receptor, non-REM sleep and REM sleep are lower than that in control mice. Chronic infusion of GH leads to normalization of REM sleep but not of non-REM sleep. Ghrelin, GHRH, and octreotide exert no effect on sleep EEG in dwarf mice. These results suggest that (1) GHRH deficiency is linked with decreases in non-REM sleep; (2) decreases in GH lead to decreases in REM sleep; (3) the actions of GHRH, ghrelin, and octreotide on sleep EEG require intact GHRH receptor signaling.[18]

HYPOTHALAMIC PITUITARY ADRENOCORTICAL SYSTEM

Basic Activity

In rats, CRH gene transcription levels increase during the dark period, when the animals are active, and decrease throughout the light period. In humans, both the nadir and the major portion of the secretion of ACTH and cortisol occur during sleep. Between 02:00 and 03:00 h, the first pulse of cortisol occurs. It is followed by further pulses until awakening.[32] Although ACTH is the prime regulator of nocturnal cortisol secretion in humans, the secretion of ACTH and cortisol may dissociate[4] [for reviews, see Ref. 27].

Sleep in Disorders with Pathological Changes of HPA Activity

Characteristic sleep-EEG findings in depressed patients are disturbed sleep continuity, a decrease of non-REM sleep, and REM sleep disinhibition. Well documented endocrine changes include signs of (1) HPA overactivity and (2) HPS dysfunction. Most sleep-endocrine studies in depressed patients report elevated cortisol and ACTH, in comparison with normal controls. GH is blunted in most but not in all studies.[27]

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

These findings suggest a causal relationship between shallow sleep, low GH, and HPA hyperactivity in depression. Further, there are similarities in the sleep-endocrine changes during depression and during normal aging. Linkowski et al.[15] compared HPA hormones longitudinally between acute depression and recovery. These authors reported a decrease of ACTH and cortisol 24 h after recovery. Furthermore, Linkowski et al. reported a normalization of REM sleep after recovery. Because some of the patients received antidepressants, which suppress REM sleep, it is difficult to differentiate between the effects of drugs and of remission. In another study, an intraindividual comparison was performed in depressed patients who were drug-free at least 14 days before each examination. This study confirmed a decrease of cortisol after recovery. However, the sleep-EEG changes and low GH concentrations persist in the recovered patients.[27] Similar to the findings in depression, 24-hour ACTH and cortisol are higher in young insomniacs than in controls.[31]

Effects of Changes of Sleep–Wake Behavior on HPA Hormones

In rats, after 72 h of sleep deprivation, CRH levels increase in the striatum, limbic areas, and pituitary, whereas hypothalamic CRH decreases. CRH binding decreases in the striatum and in the pituitary. When rats are sleep deprived, during intervals up to 92 h, ACTH and corticosterone plasma levels increase from 24 h of sleep deprivation and decrease during the recovery period. The expectation of waking up at a certain time induces a marked increase in ACTH before the end of sleep. The anticipatory increase in ACTH may facilitate spontaneous waking.[27]

Corticotropin-Releasing Hormone

After icv CRH, SWS decreases in rats[8] and rabbits.[19] Even after 72 h of sleep deprivation, CRH reduces SWS in rats. Further, sleep latency and REM sleep increase. Similarly after repetitive iv CRH around sleep onset in young men SWS and REM sleep decrease. Furthermore, GH is blunted and cortisol increases. A dose of CRH that does not affect sleep in young men, impairs sleep in middle-aged men.[27] Obviously, the vulnerability of sleep to CRH increases during aging.

After two different CRH antagonists, α-helical CRH and astressin, wakefulness declines. By contrast, another study reported an effect of α-helical CRH only in stressed animals. In these rats, REM sleep increases and decreases to values of the nonstressed condition after the substance. In sleep-deprived rats, α-helical CRH diminishes the REM sleep rebound during recovery sleep. Stress acting via CRH is believed to induce the REM sleep rebound after sleep deprivation. In the rat, amygdala kindling at light onset decreases SWS and REM sleep and enhances corticosterone. Icv astressin or alpha-helical CRH antagonizes the decrease of SWS after kindling. After a 4-week trial with a CRH receptor-1-antagonist, the characteristic sleep-EEG changes in patients with depression are counteracted. The number of awakenings and REM sleep density decreases and SWS increases. These results suggest that CRH is involved in the pathophysiology of sleep-EEG changes during depression and that CRH-1-receptor antagonism helps to treat symptoms of depression including impaired sleep.[27]

Vasopressin

Icv vasopressin increases wakefulness in rats. After acute infusion of the peptide to humans, stage 2 sleep increases and REM sleep decreases. Chronic intranasal vasopressin for 3 months improves sleep in elderly subjects.[27]

CORTICOTROPIN

Infusions of ACTH suppress REM sleep in normal subjects, whereas cortisol and GH increase. The synthetic ACTH (4–9) analog ebiratide shares several behavioral effects of ACTH whereas it has no influence on peripheral hormone secretion. Accordingly, after repetitive iv ebiratide administration, GH and cortisol remain unchanged in young men. A set of sleep-EEG changes is found after ebiratide corresponding to a general central nervous system (CNS) activation.[27]

Animal Models of HPA System Changes

In the Lewis rat, the synthesis and the release of CRH is reduced in comparison with other rat strains. Lewis rats spend more time in SWS and less time awake than the intact strains. After icv CRH, waking increases similarly in Lewis and Sprague–Dawley rats. A role of CRH in the maintenance of wakefulness and sleep-disturbing effects of CRH is confirmed by this study. Similarly, spontaneous wakefulness of rats decreases after CRH antisense.[27]

Sleep of conditional mouse mutants overexpressing CRH in the total CNS or selectively in the forebrain including limbic structures was investigated in comparison to sleep in control animals. In both strains of homozygous CRH-overexpressing mice, elevated REM sleep occurs constantly during 24 h. A weak decrease of non-REM sleep during the night is observed only in the strain overexpressing CRH in the entire CNS. REM sleep increases after 6 h of sleep deprivation during recovery sleep and also in heterozygous CRH-overexpressing mice. This effect is reversed in heterozygous and homozygous CRH-overexpressing mice as well by treatment with a CRH-1 receptor antagonist. No

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

change of peripheral HPA hormones occurs at baseline or after sleep deprivation. Because the peripheral HPA axis is not modulated in these animals, the sleep-EEG changes, particularly the elevation of REM sleep, probably results from elevated forebrain CRH through activation of CRH-1 receptors.[12]

HYPOTHALAMIC–PITUITARY–THYROID SYSTEM

The release of TSH follows a circadian rhythm. The lowest TSH levels are found during daytime. TSH increases during the night and reaches its maximum by midnight. Pulsatile iv thyrotrophin-releasing hormone (TRH) prompts decreases of sleep efficiency and earlier occurrence of the cortisol morning increase in young male subjects.[27]

OTHER PEPTIDES

After icv cortistatin, non-REM sleep increases in rats distinctly.[6]

Delta-Sleep Inducing Peptide (DSIP)

Delta-sleep inducing peptide (DSIP) was first detected in the cerebral venous blood of rabbits that had been subjected to sleep by electric stimulation of the intralaminal thalamic area. Promotion of SWS after DSIP was reported in several species, although not all preclinical studies reproduced these effects. Only one study has investigated the effects of DSIP on sleep EEG in normal men and found only minor effects. Studies on the efficiency of DSIP in the treatment of insomnia produced conflicting results. DSIP-like immunoreactivity was compared in young men between baseline sleep, sleep deprivation, and recovery sleep. Plasma DSIP-like immunoreactivity decreased at the transition from wakefulness to sleep in both evening sleep and morning recovery sleep. These results suggest that DSIP is induced by mechanisms that are involved in the initiation of sleep.[27]

Galanin

Sleep in rats remains unchanged after icv galanin, whereas REM sleep deprivation induces galanin gene expression. After repetitive iv galanin in young men, SWS and REM sleep periods increase.[27] A cluster of GABAergic and galaninergic neurons was identified in the ventrolateral preoptic area, which may stimulate non-REM sleep.[23] Iv galanin or placebo were given to patients with depression during a steady state of antidepressive therapy with trimipramine. After galanin administration, REM sleep latency increases and the severity of depression decreases.[27]

Neuropeptide S

Neuropeptide S (NPS) is believed to elevate wakefulness and to participate in the regulation of anxiety. NPS acts via the NPS receptor. NPS mRNA is widely localized in the brain including the amygdala and the midline thalamic nuclei. Central administration of NPS to rats increases wakefulness and decreases SWS and REM sleep in a dose-dependent fashion.[21]

Neuropeptide Y (NPY)

After icv neuropeptide Y (NPY), EEG spectral activity changes in rats similarly to the effects of benzodiazepines.[9] The prolongation of sleep latency by CRH is antagonized dose dependently by NPY in rats.[10] Although these findings point to a sleep-promoting effect of NPY, intracerebroventricular and lateral hypothalamic administration of NPY to rats suppressed non-REM sleep and REM sleep during the first hour after the injection.[29] However, also human studies suggest sleep-promoting effects of NPY. In young men, repetitive iv administration of NPY decreases sleep latency, the first REM sleep period and cortisol and ACTH levels, and increases stage 2 sleep and sleep period time. In depressed patients of both sexes, with a wide age range and age-matched controls, the sleep latency decreases and prolactin increases after NPY administration, whereas cortisol and ACTH levels and the first REM sleep period remain unchanged.[27] These results suggest that NPY participates in sleep regulation, particularly in the timing of sleep onset as an antagonist of CRH acting via the $GABA_A$ receptor.

Pituitary Adenylate Cyclase Activating Polypeptide (PACAP)

Icv pituitary adenylate cyclase-activating polypeptide (PACAP) enhances REM sleep in rats.[11] Repetitive iv injections of PACAP to young male healthy volunteers prompt a significant decrease in the theta frequency range during the first 4-h interval and in the spindle frequency range during the second 4 h interval. The decline of the time constant τ (tau) of the physiological delta power increases during the night. This observation suggests a decrease of the dynamics of homeostatic sleep regulation. Furthermore, nocturnal prolactin secretion tends to decrease trend during the first four hours of the night.[16]

Substance P

Microinjection of substance P into the ventrolateral preoptic area of rats enhances SWS. This effect is blocked by a phospholipase C inhibitor and by 3-mercaptopropionic acid, an

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

inhibitor of GABA synthesis and release.[33] In young men, repetitive iv substance P increases wakefulness and REM sleep latency.[14]

Vasoactive Intestinal Polypeptide (VIP)

Icv vasoactive intestinal polypeptide (VIP) enhances REM sleep. VIP given to rats during the dark period enhances non-REM sleep and REM sleep. Also, VIP microinjections into the pontine reticular tegmentum enhance REM sleep in rats. Immunoneutralization of prolactin inhibits the REM sleep promotion by systemic VIP in rats. Stimulation of prolactin seems to be involved in the promotion of REM sleep after VIP. In young men, two doses of iv VIP prompt different effects. After the lower dose prolactin decreases, sleep EEG remains unchanged. By contrast, after the administration of a higher dose of VIP, prolactin increases. Further, the non-REM sleep – REM sleep cycles are decelerated. Each of the non-REM sleep and REM sleep periods is prolonged, the cortisol nadir seems advanced and the GH surge is blunted. It is believed that VIP exerts a specific effect on the temporal organization of the sleep cycles and the sleep-related hormone secretion. VIP seems to affect the circadian clock, resulting in longer sleep cycles and the early occurrence of the cortisol nadir. The blunted GH surge may arise from the advanced elevated HPA activity.[27]

OREXINS/HYPOCRETINS

In 1998, two groups discovered a pair of neuropeptides in the lateral hypothalamus, which they named orexins[22] or hypocretins.[7] Animal models showed that a lack of orexins or their receptors causes symptoms of narcolepsy. In narcolepsy, several abnormalities of the sleep–wake organization and the sleep structure occur. This includes cataplexy, a sudden and transient episode of loss of muscle tone, triggered by emotions, excessive daytime sleepiness, and in the sleep EEG sleep onset REM periods. The latter means the occurrence of REM sleep during the first 10 min after sleep onset. A cataplexy-like behavior occurs in knockout mice, which do not produce orexins. A genetic form of narcolepsy was found in dogs related to mutation of the gene for the orexin-B receptor. Only few orexin neurons are found in the brains of patients with narcolepsy.[17] Orexin A levels are low in patients with narcolepsy, whereas plasma concentrations are in the normal range.[5] Saper et al.[24] suggest that the role of the orexins is to stabilize the sleep–wake pattern. This occurs by preventing unwanted transitions between sleep and wake stages. In patients with narcolepsy, a lack of orexins or orexin receptors leads to many unintended transitions between the vigilance states and to the intrusion of fragments of REM sleep into wakefulness. Siegel[26] hypothesized that orexin facilitates "motor activity tonically and physically in association with motivated behaviors and to coordinate their facilitation with the activation of attention and sensory systems." After orexin A administration, cataplexy is reduced, and the sleep–wake pattern is normalized in a dog model of narcolepsy.[23]

CONCLUSIONS

The results reviewed in this chapter show that various neuropeptides exert specific effects on the sleep EEG in several species including humans. Figure 1 provides a model of peptidergic sleep regulation in humans.

It is well documented that a reciprocal interaction of the neuropeptides GHRH and CRH plays a key role in sleep regulation. GHRH promotes sleep, at least in males, and stimulates GH, whereas CRH enhances vigilance and the secretion of ACTH and cortisol and impairs sleep. Changes in the CRH:GHRH ratio in favor of CRH contribute to shallow sleep, elevated cortisol, and blunted GH during depression and aging. GHRH participates in sleep promotion after sleep deprivation. There may be CRH-like effects of GHRH in women. Several findings, particularly the effects of CRH-1 receptor antagonism in patients with depression, suggest that CRH promotes REM sleep, whereas other studies do not support this view. NPY is another endogenous antagonist of CRH. Its major role seems to be the timing of sleep onset. Besides CRH, somatostatin is a sleep-impairing peptide. At least in males' GHRH and somatostatin exert opposite actions on GH and on sleep. Besides GHRH, galanin, and ghrelin promote SWS. Intact GHRH receptors are the prerequisite for sleep promotion by ghrelin. In contrast to GHRH, ghrelin stimulates HPA hormones in males and may act as an interface between the HPA and HPS systems. Galanin is colocalized with GABA in the ventrolateral preoptic nucleus. Many hypothalamic GHRH responsive neurons are GABAergic. Galanin, ghrelin, and GHRH may either act in a synergistic fashion, or these peptides may be part of a cascade resulting in the promotion of non-REM sleep. GABAergic neurons probably mediate the effects of these peptides. In young normal men, after administering VIP, the non-REM sleep/REM sleep cycle is decelerated, probably by action on the suprachiasmatic nucleus. PACAP seems to be involved in the regulation of sleep homeostasis. Orexins/hypocretins are important factors of sleep–wake regulation. They lack results in narcolepsy.

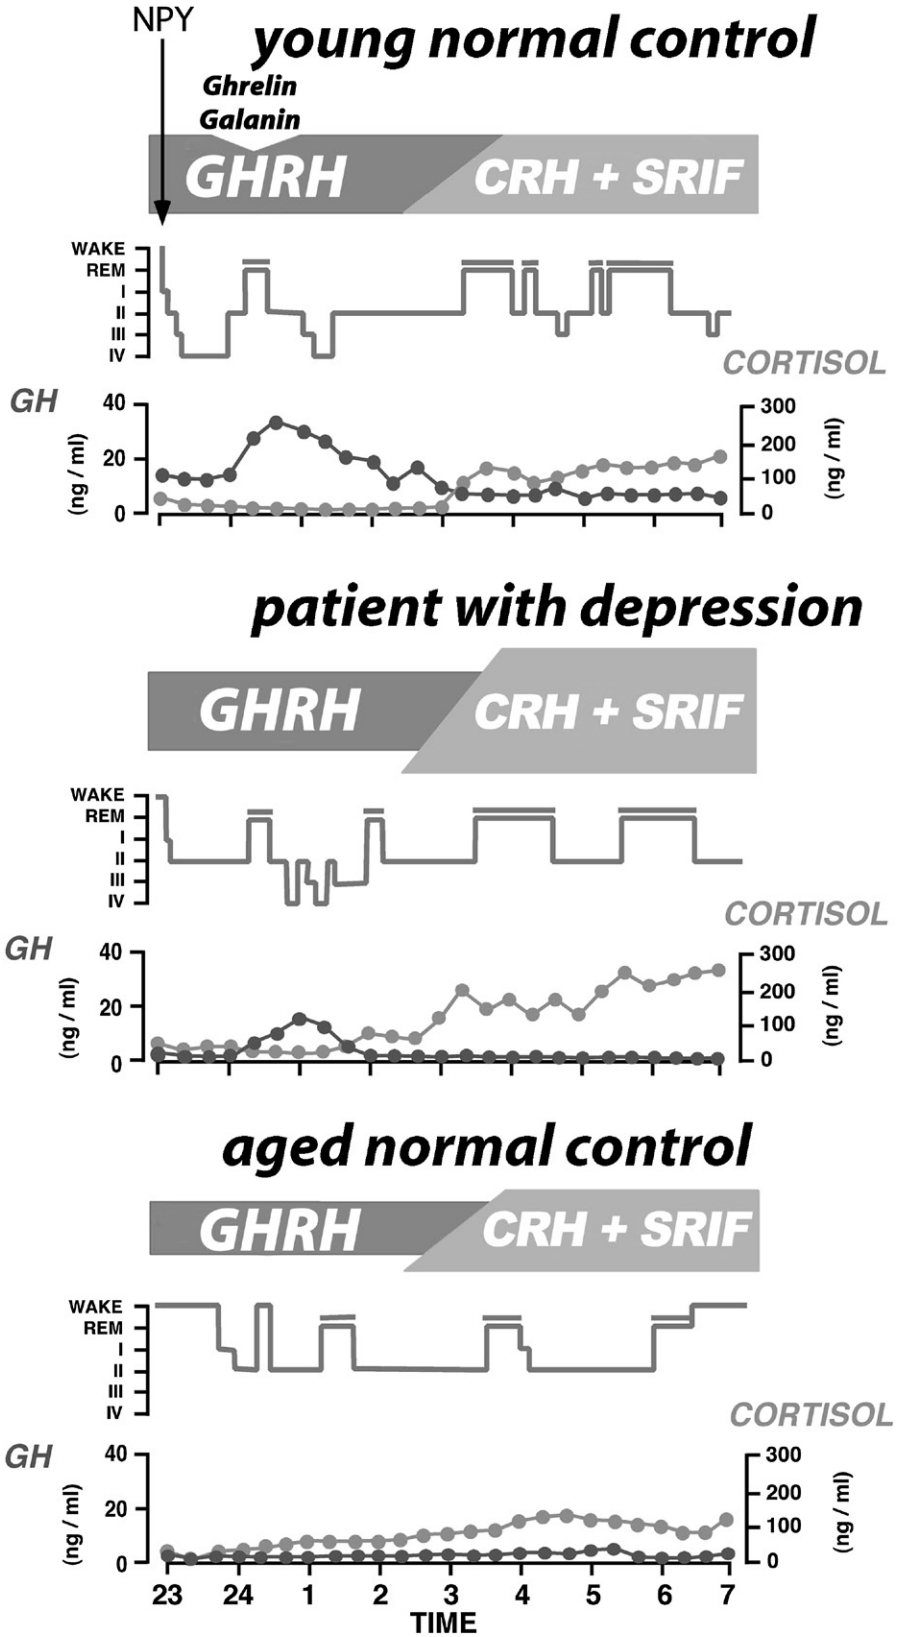

FIGURE 1 Model of peptidergic sleep regulation, CRH, corticotrophin-releasing hormone; GHRH, growth hormone-releasing hormone; NPY, neuropeptide Y; SRIF, somatostatin. Characteristic hypnograms and patterns of cortisol and GH secretion are shown in a young and in an elderly control subject and in a depressed patient. It is believed that GHRH is released during the first half of the night, whereas CRH preponderates during the second half of the night. GHRH contributes to the high amounts of GH and SWS after sleep onset, whereas CRH is linked with cortisol release und REM sleep in the morning hours. Neuropeptide Y (NPY) is a signal for sleep onset. In addition to GHRH, galanin and ghrelin are sleep-promoting factors, whereas somatostatin is a sleep-impairing factor. During depression (CRH overactivity) and during normal aging, similar changes of sleep-endocrine activity occur. It is believed that changes in the GHRH/CRH balance in favor of CRH play a key role in these alterations. Chapter 256

Peptides and Stress

Annika Thorsell

ABSTRACT

Many disorders prevalent today stem from chronic activation of our stress response system, a system biologically intended to be used in acute, short-lasting, stress exposure. The regulation of the general stress response, the hypothalamic–pituitary–adrenal axis and sympathetic nervous system activation, is well known. However, many neuropeptides participate in the central regulation of other components of the behavioral and endocrine stress response. The chapter will focus on how the neuropeptides regulate stress-related phenomena (behavioral and endocrine responses), as well as on how the neuropeptides themselves are regulated (expression pattern, activity and actions) by the individual's exposure to stress. The most commonly known neuropeptide involved in centrally mediated stress regulation is corticotropin-releasing hormone (CRH), an endogenous anxiogenic neuropeptide. The most common anxiolytic neuropeptide is neuropeptide Y (NPY). In this chapter, only their involvement in central stress- and anxiety-related events will be covered. In addition, the following neuropeptides will be discussed: the urocortins, substance P, neuropeptide S, and vasopressin.

INTRODUCTION

Neuropeptides are involved in central regulation and mediation of numerous behaviors. Their relative abundance and regional expression patterns, as well as their structural and functional diversity, may indicate an involvement in the fine tuning of centrally regulated behaviors and responses. Neuropeptides tend to exert a long-lasting modulatory effect on the small-molecule neurotransmitters with which they colocalize, by regulating the response times of second messenger and intracellular signaling systems. Thus, neuropeptides are important for adaptation of the nervous system to changes in physiological conditions. To understand the place for neuropeptides in the regulation of complex mechanisms such as stress and stress-related events, a background on the concepts involved in the general stress response as well as the endocrine mechanisms will be presented here. After that, a short, summarized description of each neuropeptide is given and the role of the neuropeptide in stress-related events described.

THE "STRESS" CONCEPT

A "stress" or "stressor" can be defined as "anything that disrupts the optimal balance of the body." In turn, the stress response is defined as the responses made by the body to restore this optimal, or homeostatic, balance. Stress as a term refers to processes involving perception, appraisal, and response to threatening, challenging and/or possibly harmful stimuli. There exists a division of stressful stimuli into emotional, or psychological, stimuli and physiological stimuli. Examples of stimuli that are considered emotional/psychological include social interactions/conflicts, inescapable situations, death of a loved one and so forth. Physiological stimuli can be hypo/hyperthermia, an immune challenge, starvation, and also drug withdrawal.

Under acute conditions, stress invokes a response that may be beneficial for survival, for example, fleeing a dangerous situation, and the systems activated then are necessary to provide the means to avoid being attacked (or ending up as someone's dinner). However, when activated chronically, stress responses can cause damage and be the basis for, as well as accelerate, disease conditions. This is because of the issue of chronically activating endocrine factors and central neurotransmitter systems that are not evolutionary intended to be switched "on" continuously. The changed balance induced by the internal stress response can be related by the term "allostasis," and this refers to the process of reestablishing homeostasis in response to a challenge. As mentioned above, homeostasis refers to the consistency of internal parameters within a normal/optimal range, while allostasis describes the body's way to keep stable outside the normal range by changing internal systems to match external demands. Allostasis links the brain with the endocrine system and our immune system to coordinate appropriate responses to an (external) stressor.

Cannon (1927) pioneered the concept of a specific site regulating emotional responses. Later work by Papez (1937) and Klüver and Bucy (1937) confirmed a role for, among other regions, the amygdala in emotional regulation. Studies in human subjects, and in animals, have since shown that activation of the amygdala is crucial for the mediation of

behavioral and emotional responses associated with anxiety. Lesioning of the amygdala in turn leads to decreased levels of experimental anxiety and decreased sensitivity to stress. A role has been proposed for the amygdala to integrate inputs from the varying brain regions to produce a coherent behavioral response to fear and anxiety. Many of the neuropeptides described in this chapter exercise their anxiety-related (be it either anxiogenic or anxiolytic) properties through actions within the amygdala complex. However, other anatomical targets are also involved and these include, for example, the hypothalamus, the parabrachial nucleus, the hippocampus, and other limbic structures.

The endocrine response to stress consists mainly of the hypothalamic–pituitary–adrenal (HPA) axis. The paraventricular nucleus (PVN) of the hypothalamus contains neuroendocrine neurons that synthesize and secrete vasopressin and corticotropin-releasing hormone (CRH). CRH and vasopressin are released from neurosecretory nerve terminals at the median eminence. CRH is transported to the anterior pituitary through the portal blood vessel system of the pituitary stalk and vasopressin is transported by axonal transport to the posterior pituitary. There, CRH and vasopressin act synergistically to stimulate the secretion of stored adrenocorticotropic hormone (ACTH) from corticotroph cells. CRH released from the hypothalamus acts to release ACTH (corticotropin) from the anterior lobe of the pituitary. ACTH in turn activates the release of glucocorticoids (cortisol in humans; corticosterone in rodents) from the adrenal gland cortices. Glucocorticoids in turn act back on the hypothalamus and pituitary (to suppress CRH and ACTH production) in a negative feedback cycle. The HPA axis is controlled by complex regulatory mechanisms. Numerous factors such as CRH, vasopressin, oxytocin, angiotensin II, and conceivably other peptidergic hormones may stimulate the release of the stress hormone ACTH. On the other hand, glucocorticoids inhibit the secretion of ACTH by acting at the hypothalamic and/or pituitary level. The release of ACTH is therefore the final outcome of the interactions between the hypothalamus, the adrenal gland, and possibly other organs. The multimolecular nature of the factors responsible for the control of the pituitary–adrenal axis gives rise to the speculation that various factors could have specific roles in various stress situations. They provide a highly sensitive mechanism regulating very finely the stress hormone in response to a whole variety of endogenous and exogenous stimuli. Depending on the type of stress, they may therefore singly or in combination affect the amount and duration of ACTH and steroid secretion. The released glucocorticoids may then produce their numerous downstream effects.

The clinical implications of a dysregulated stress response are many. Together with genetic predisposing factors, the chronic activation and dysregulation of the stress response may underlie some of the pathophysiology of anxiety- and stress-related disorders, as well as depressive illnesses. Anxious individuals emotionally anticipate an aversive situation. Approximately one in four individuals will experience an anxiety-related disorder during their lifetime. This together with well-known issues such as side effects and limited efficacy for existing anxiolytics makes the need for new treatments urgent. Neuropeptide systems may offer opportunities for such treatment development. Neuropeptides have been suggested to only be released if the firing of a neuron exceeds a certain level, i.e. frequency-dependent release. Furthermore, neuropeptides, when compared with classical neurotransmitters, can act over longer distances and may thus be used to recruit large neuronal populations to produce a concerted physiological effect. Additionally, the accessibility of neuropeptides is higher because of limited reuptake mechanisms as compared with that of classical neurotransmitters.

Neuropeptides such as neuropeptide Y (NPY) and CRH have been implicated not only in the acute regulation of stress/anxiety-related behaviors but adaptations and changes in these neuropeptide systems may also participate in the regulation of behavior and endocrine responses during chronic stress. NPY is an endogenous anxiolytic neuropeptide, whereas CRH has anxiogenic properties on central administration. Changes in these neuropeptide systems may contribute to disease states and give us indications for putative treatment targets for stress/anxiety disorders and alcohol/drug dependence. In this review, we briefly present these two systems and review their involvement in mediating the responses to acute and chronic stressors, as well as their possible roles in the development and progression of stress/anxiety disorders. In addition other neuropeptide systems involved in the central regulation of stress-related responses and behaviors will be presented, including the urocortins, substance P (SP), neuropeptide S, and (arginine) vasopressin/oxytocin. The urocortins are peptides activating the CRH-R1 and CRH-R2 receptors, while SP may be considered as "CRH light" in the sense that many of its actions and effects are similar to the effects of CRH. Vasopressin coexists and coregulates the effects of CRH on the HPA axis, and has stress effects of its own.

CRH

CRH is the major neurohormone regulating the vertebrate endocrine stress response. CRH is a 41 amino acid peptide that is part of a peptide family also including urocortin, urocortin II and urocortin III. The human and rat CRH-peptide sequence are identical and only differ from the ovine in seven positions, indicating an overall conservation of peptide sequence and structure between species. The effects of these peptides are mediated via two G protein (Gs)-coupled receptors: CRH-R1 and CRH-R2. Agonist activation of these receptors leads to increased intracellular concentrations of

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

cyclic AMP (cAMP). CRH-R1 is the primary receptor for CRH and participates in mediation of the behavioral stress response.

The distribution of CRH within and beyond the hypothalamus provides an anatomical context for the observation that CRH can simultaneously activate and coordinate metabolic, circulatory, and behavioral responses that are adaptive in "stressful" situations. CRH not only stimulates the HPA axis, but it also influences several aspects of CNS function which may be of relevance to psychiatric illnesses. Within the hypothalamus CRH is primarily found within the PVN. Other regions with predominant CRH-containing neurons are the lateral bed nucleus of the stria terminalis and the central division of the central nucleus of the amygdala. To a smaller degree, there are CRH cells in the lateral hypothalamus, prefrontal, and cingulate cortex. In brainstem regions, CRH cells are clustered near the locus coeruleus (Barrington's nucleus), the parabrachial region, and regions of the solitary nucleus. The regions mentioned are involved in behavioral stress responses and regulation of autonomic function.

CRH participates in the mediation of the autonomic, neuroendocrine, and behavioral responses to stress. The action of CRH can be potentiated by vasopressin, oxytocin, epinephrine, norepinephrine, VIP, and angiotensin II. Intracerebroventricular administration of CRH in the rat produces prolonged elevations of plasma epinephrine, norepinephrine, it elevates mean arterial pressure and heart rate, increases locomotor activity and decreases feeding and sexual behavior.

On central administration, CRH induces anxiogenic (i.e. it increases anxiety levels and anxiety-related behavioral measures) responses in several animal behavioral tests such as the novel open-field, acoustic startle, and operant conflict tests. Transgenic mice overexpressing CRH show increased anxiety-like behaviors, and these behaviors may be reversed by administration of CRH-R1 receptor antagonists. CRH is released within the amygdala during periods of stress exposure and increases in anxiety-like responses after restraint stress are dependent on the activation of CRH-R1 receptors within the amygdala. Many stressors induce CRH release and CRH mRNA expression within the amygdala, for example, drug withdrawal, restraint stress, and neonatal stress exposure.

Whether the centrally mediated, anxiogenic behavioral effects of CRH are dependent on the HPA axis, or completely independent thereof requires further discussion. Lesions of the central nucleus of the amygdala, but not of the hypothalamic PVN, disrupt CRH-potentiated fear responses, and peripheral blockade of ACTH/glucocorticoids does not affect the behavioral response. Central administration of CRH in dexamethasone-treated rats still elicits an anxiogenic effect. However, adrenalectomy abolishes the locomotor activity-inducing effects of central CRH administration. Further, in nonhuman primate models of early adverse events chronic elevation of cerebrospinal fluid (CSF) CRH is seen, and patients with posttraumatic stress disorder (PTSD) have significant elevation of CSF CRH, indicating significant activation of the extrahypothalamic CRH system in these conditions.

Given the above studies, the administration of CRH-R1 receptor antagonists may offer an effective treatment for stress-induced anxiety disorders. Indeed, treatment with CRH-R1 receptor antagonists does result in decreased levels of experimental anxiety in rats with a "high anxiety" phenotype, in mice after exposure to a chronic mild stress paradigm, as well as in human subjects diagnosed with major depression or PTSD. Further, a CRH-R1 antagonist was effective in blocking alcohol withdrawal-induced anxiety on the elevated plus-maze as well as stress-induced reinstatement of alcohol seeking. Similar to other potent stressors, acute alcohol withdrawal induces anxiety-like responses that are correlated with increased CRH levels in the central nucleus of the amygdala and in the bed nucleus of the stria terminalis, sites mediating the behavioral responses to stress. Accordingly, anxiogenic effects of alcohol withdrawal are reversed by CRH-R1 antagonism. It should be noted that limited to no effect of CRH-R1 antagonists on administration to naive/unstressed animals was seen, suggesting that the CRH system may have limited tone under baseline (nonchallenged) conditions.

NEUROPEPTIDE Y

Neuropeptide Y is a 36 amino acid peptide abundantly expressed throughout the mammalian central nervous system, with high levels in regions regulating stress- and anxiety-related behaviors. The mature NPY peptide is derived from a protein precursor that also contains a signal peptide and a C-terminal flanking peptide, CPON. The signal peptide is cleaved on entry of the NPY prepropeptide into the lumen of the endoplasmatic reticulum. The generated NPY propeptide migrates into specific large dense core vesicles which are present in dendrites, cell bodies, and axons. Phylogenetic studies have revealed NPY to be well conserved during evolution implying important functional roles of the peptide. Consequently, there is very high between-species homology, and, for example, the peptide sequence between human and rat NPY is identical.

In the CNS of rats, high levels are found in brain regions such as the hypothalamus, in particular the arcuate and the PVN, nucleus accumbens, the periaqueductal gray, and septum. Moderate expression levels are detected in the amygdala, the hippocampal formation, the thalamus, and the basal ganglia. Although tissue concentrations of the peptide correlate well with fiber density and terminal networks, this is not true for cell-body density. NPY is expressed both in interneurons and long projection neurons.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

To date, all NPY receptors cloned belong to the superfamily of G protein-coupled receptors, but differ in their ligand affinity profiles. NPY receptors are coupled via Gi/o proteins to several downstream signaling pathways, including inhibition of adenylyl cyclase, activation of mitogen-activated protein kinase, regulation of intracellular calcium (Ca^{2+}) concentrations and activation of G protein-coupled, inwardly rectifying potassium (K^+) channels. Currently, there are four subtypes of NPY receptors known to mediate biological responses: Y1, Y2, Y4, and Y5. The predominantly postsynaptic Y1 receptor requires the intact NPY sequence for recognition and activation and has been proposed as the subtype mediating the antianxiety actions of NPY. The presynaptic Y2 receptor subtype is in addition activated by C-terminal fragments of NPY, such as NPY13–36 and NPY3–36. The Y4 receptor has low affinity for NPY and is primarily the target for pancreatic polypeptide (PP), another member of the PP family of peptides. The Y5 receptor was initially believed to be the receptor regulating the effect of NPY on feeding behavior and Y5 receptor antagonists have been evaluated for putative obesity treatment, possibly in combination with compounds aimed at other NPY receptors such as the Y1.

After its isolation, NPY has been extensively studied with particular attention to anxiety/stress-related behavior and feeding. Already in the late 1980s, mounting evidence was presented to indicate anxiolytic/sedative properties of NPY. These studies included the synchronization of electroencephalographic activity, the prevention of stress-induced ulcers, and suppression of locomotor activity. It has since been repeatedly shown that central administration of exogenous NPY produces an anxiolytic phenotype in numerous animal models of experimental anxiety. Antianxiety effects of NPY are dependent on the activation of Y1 receptors, proposedly within the amygdala. Intracerebroventricular injections of NPY or Y1 receptor agonists, but not Y2 receptor agonists, are anxiolytic in behavioral models of experimental anxiety.

In agreement with antianxiety effects observed after the central administration of exogenous NPY, a role for endogenous NPY in the control of stress- and anxiety-related behaviors is suggested by several findings. Acute physical restraint, which promotes experimental anxiety, suppresses NPY mRNA and peptide levels within the amygdala and cortex. By contrast, repeated exposure to the same stressor once daily for 10 days leads to a complete behavioral and endocrine habituation, accompanied by an upregulation of amygdala NPY expression. Further, chronic overexpression of NPY generates a stress-insensitive and "anxiolytic" phenotype. Genetic variations in human NPY expression affect stress response and emotion. We have therefore proposed that an upregulation of NPY expression may contribute to the behavioral adaptation to stress. This extends a proposed hypothesis that endogenous NPY may act to "buffer" behavioral effects of stress-promoting signals within the central nervous system. In the periphery, it would seem the opposite is valid with NPY exacerbating the cardiovascular and metabolic adverse effects of chronic stress exposure.

EVIDENCE FOR INTERACTIONS BETWEEN CRH AND NPY SYSTEMS

NPY and CRH are present in many regions of the brain that are relevant for the behavioral and emotional response to stressful stimuli and/or fear/anxiety-producing events. In 1994, Heilig et al. proposed opposing roles for NPY and CRH within the amygdala to maintain emotional balance after stress exposure. NPY was suggested to be released subsequently to increases in amygdalar CRH producing an opposing action on the stress system, facilitating return to a homeostatic (or allostatic) balance.

Numerous studies have indicated anxiolytic and anxiogenic effects of NPY and CRH, respectively, on administration into the CNS. In addition, studies have revealed overlapping biological substrates, primarily within the amygdala, for these effects. Both CRH and NPY receptors are found within the amygdala. The basolateral nucleus (BLA) is of particular interest because CRH, as well as urocortin I, elicit long-term anxiety-like responses on administration into the BLA. However, the opposite behavioral response is seen on BLA administration of NPY. Furthermore, pretreatment with NPY into the BLA before administration of urocortin blocks the anxiogenic effect of the CRH-R1/2 receptor activation on anxiety-related behavior. This indicates a direct interaction of CRH and NPY systems within the BLA to modify anxiety-related behavior. The molecular mechanism for this interaction has been proposed to be differential regulation of cAMP levels. In addition, at the level of the hypothalamus, dose-dependent increases in NPY overflow from the PVN were observed after the administration of CRH. Further investigation into the clinical implications for these interactions is needed.

The opposing roles of CRH and NPY in the regulation of stress/anxiety-related behaviors and responses may open the way for putative combination treatments aimed at targets within these systems.

UROCORTINS

As previously noted, there are additional members to the CRH family of peptides, the urocortins. Urocortin-1 was introduced in 1995 as the mammalian ortholog of urotensin. Because urocortin-1 exhibited greater affinity for and activation of CRH-R2 receptors than did CRH, it was hypothesized to be a natural CRH-R2 receptor ligand. Genomic sequence mining revealed the presence of another lineage of peptides, urocortin-2 and urocortin-3 in 2001, and they were recognized for their structural relation to both CRH

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

and urocortin-1 preproteins. They were named "urocortins" because of the predominant affinity of predicted mature peptides for the CRH-R2 receptor.

The urocortin peptides are phylogenetically distinct, although they share moderate sequence identity with one another and with CRH. The CRH/urocortin peptide family resulted from multiple gene duplication events during evolution before the divergence of modern vertebrate fish from tetrapods. In addition, each peptide has a unique anatomical distribution under the control of different genes. Consequently, despite a structural family resemblance, the natural functions of urocortins and CRH in stress responses *in vivo* may differ significantly.

In the mammalian brain, the most abundant expression of urocortin-1 has been reported in neurons located in the midbrain in the Edinger–Westphal (EW) nucleus. The EW is compact, cholinergic, preganglionic parasympathetic brain structure primarily involved in oculomotor adaptation; however, the EW is much more complex and the existence of distinct neuron populations within the EW has been postulated. Certain acute, stressful stimuli (e.g. lipopolysaccharide administration and restraint) will activate the EW urocrtin-1 system, whereas chronic stress may result in a partial habituation of urocortin-1 mRNA responses to stress. The possibility of a long-term, inverse relation between CRH and EW urocortin-1 systems in homeostatic stress responses has been proposed because CRH-activating events seemingly decrease the urcortin-1 system activity and vice versa. The urocortin-1 EW sends ascending projections to the lateral septum and to the bed nucleus of the stria terminalis, the globus pallidus, the hypothalamus, thalamus, and periaqueductal gray. Descending urocortin-1-projections go to, among other regions, the substantia nigra, the dorsal raphe nucleus, and the parabrachial nucleus.

Urocortin-2 mRNA is localized in the suproptical nucleus and magnocellular subdivision of the PVN as well as in brainstem motor neurons and the spinal cord. Urocortin-2 also has marked expression in the arcuate nucleus of the hypothalamus and the locus coeruleus.

Urocortin-3 is synthesized in among other regions of the median preoptic nucleus of the hypothalamus and the dorsomedial amygdala. In addition, urocortin-3-like immunoreactive fibers of unknown origin project heavily to the ventromedial hypothalamus and the arcuate nucleus, and medial amygdala urocortin-3 neurons project to the ventral premammillary nucleus.

One of the most prominent physiological functions of CRH is activation of the HPA axis. For the urocortins, peripheral administration of urocortin-2 or urocortin-3 does not increase corticosterone secretion, consistent with the relative absence of their preferred CRH-R2 receptor on ACTH-secreting pituitary corticotroph cells. However, both central and peripheral administration of urocortin-1 activates the HPA axis, supposedly via a CRH-R1-dependent mechanism. However, urocortin-1-deficient mice exhibit normal basal and stress-induced HPA hormone levels indicating that urocortin-1 is not a physiological regulator of the HPA axis. Female mice lacking urocortin-2 or the CRH-R2 receptors exhibit greater peak corticosterone and ACTH concentrations at the circadian light/dark phase transition. In addition, urocortin-2 and urocortin-3 mRNA is increased in the parvocellular PVN after restraint stress, and hypothalamic urocortin-2 expression is increased by the administration of glucocorticoids. Arginine vasopressin (AVP) expression within the hypothalamus is increased in urocortin-2 knockout, which is known to augment ACTH secretion. Thus, urocortin-2 may via CRH-R2 receptors modulate basal HPA axis circadian amplitude via an AVP-dependent mechanism.

The anxiogenic-like properties of central urocortin-1 infusion, mediated at least partly by CRH-R1 receptors, have been shown in several animal models of anxiety-like behavior, including the open field, elevated plus-maze, light-dark box, and social interaction. Quite unlike CRH-R1 receptor agonists, central administration of urocortin-2/3 does not consistently have anxiogenic-like effects in rats. On the contrary, central administration of urocortin-3 acutely produced and anxiolytic-like phenotype in the elevated plus-maze as well as the light/dark box test. Central administration of urocortin-2 also lacks anxiogenic-like effects in the rat open field and elevated plus-maze.. Rather, urocortin-2 has a delayed, anxiolytic-like effect under high baseline anxiety conditions in the plus-maze and counteracts the anxiogenic-like and locomotor activating effects of CRH in the open field.

In summary, although CRH-R1 receptor activation has known anxiogenic-like effects, conclusions regarding anxiety-related effects of central urocortin administration are not yet possible and may be brain site-specific. Moreover, the endogenous anxiety-related roles of urocortins remain similarly unclear as shown by the differential anxiety-like behavior in different lines of urocortin-1 knockout mice. In addition, urocortin-2 deficient mice also do not exhibit altered anxiety-like behavior in the plus-maze, light/dark box, or conditioned fear tests. Whether these results result from compensatory mechanisms commonly seen in constitutive knockouts, or other factors, remains to be seen.

SUBSTANCE P

Substance P (SP) was originally discovered in 1931 by Ulf von Euler and John H. Gaddum as a tissue extract that caused intestinal contraction *in vitro*. It is one of the most abundant neuropeptides in the brain and was one of the earliest to be purified and sequenced. The tachykinins are bioactive peptides defined by a common carboxy-terminal amino acid sequence. SP and a second tackykinin, neurokinin A, are both encoded by the preprotackykinin A gene. The preprotachykinin A gene has four different splice variants, all

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

of which encode SP but only two also encode neurokinin A. The third tackykinin, neurokinin B, is encoded by a separate gene preprotackykinin B. These three peptides act on three receptor subtypes, NK-1, -2, and -3. The preferential, although perhaps not exclusive, receptor for SP is NK-1, for neurokinin A is the NK-2, and for neurokinin B the NK-3 receptor subtype (Regoli et al., 1994). However, it is important to keep in mind that there is a notable crosstalk among the three receptor subtypes because of the limited selectivity of the neurokinins. Binding of SP to NK-1 results in internalization by a clathrin-dependent mechanism to acidified endosomes where the SP/NK-1 complex disassociates. SP is subsequently degraded and the NK-1 receptor is reexpressed on the cell surface. As a neuropeptide, SP coexists with other fast neurotransmitters within axons including glutamate, GABA, serotonin, and acetylcholine depending on its location in the brain. Further, SP may be found in neurons containing norepinephrine and serotonergic neurons express the NK-1 receptor. Indeed, SP regulates both enkephalin and serotonin neurotransmission in regions important for mood and pain such as the periaqueductal gray and the dorsal raphe nucleus. In the human brain, about ½ of the serotonin-containing neurons in the dorsal raphe nucleus coexpress SP. However, the extracellular efflux of serotonin in the cerebral cortex has been shown to be not affected by the increased firing rate of dorsal raphe nucleus neurons resulting from genetic deletion or pharmacological blockade of NK-1 receptors. Blockade of an inhibitory SP pathway such as the one originating in the habenula may instead be responsible for this.

The NK-1 and NK-3 receptor subtypes are widely expressed in the brain, while the NK-2 subtype is only observed in areas such as the prefrontal cortex, hippocampus, thalamus, and septum. For the SP peptide, high levels have been detected in areas such as the cingulate cortex, caudate putamen, nucleus accumbens, hippocampus, septum, amygdala, periaqueductal gray, parabrachial nucleus, locus coeruleus, and in the dorsal raphe, among others. Many of these areas are involved in the modulation and regulation of stress responses and anxiety-related behaviors. In general, there is good overlap between the expression of SP and the NK-1 receptor, with the exception of the substantia nigra.

There is much evidence indicating a role of the SP-NK-1 system in stress-related behaviors. For example, the SP concentrations are altered in regions relevant to stress-related behavior after aversive or stressful stimuli; exposure to foot shock increases SP levels in the septum and dentate gyrus, restraint stress induces SP expression in the periaqueductal gray, and so does isolation stress. After maternal separation in guinea pigs internalization of the NK-1 receptor is seen in the amygdala indicating previous SP release and receptor binding, and subsequent receptor/peptide complex internalization. Furthermore, central administration of SP is anxiogenic in a number of animal models of anxiety, and induces behaviors and a cardiovascular response similar to that seen after exposure to stressful stimuli.

Genetic deletion or pharmacological blockade of NK-1 receptors may lead to an attenuated behavioral stress response. Deletion or inactivation of the NK-1 gene leads to an anxiolytic-like and antidepressant-like behavioral phenotype in mice neurokinin. Neonatal stress responses, such as vocalizations, are inhibited in two independent lines of NK-1 knockout mice after separation stress. In addition, a less aggressive phenotype occurs in NK-1 knockout mice as well as an antidepressant-like phenotype in the forced swim test.

Pharmacological blockade of the NK-1 receptor has been made possible in the last decade through the development of highly selective NK-1 antagonists. With the high-affinity human NK-1 receptor antagonist L-760735 neonatal stress responses, such as vocalizations, are inhibited dose-dependently and enantioselectively, mimicking the results seen after genetic deletion. The L-760735 compound also causes a dose-related inhibition of aggressive behavior in a hamster resident-intruder test. And the depressant effect of pharmacological blockade of the NK-1 receptor has been shown both in experimental preclinical studies and in clinical studies using patients with major depression and high anxiety.

Regional specificity in the behavioral responses to SP has been shown through direct local administration of SP into regions such as the amygdala. The amygdala is a crucial component in the mediation of extrahypothalamic behavioral stress responses. Injection of SP into the medial amygdala produces an anxiogenic behavioral profile in the elevated plus-maze test, and this can be blocked by pretreatment with an NK-1 receptor antagonist. Administration of the antagonist alone in addition blocks the anxiogenic effect of an immobilization stress but does not by itself affect behavioral measures in the elevated plus-maze. Although the amygdala seemingly mediates only the anxiogenic effect of SP, the lateral septum may be involved in the mediation of both anxiety-related and depression-like behaviors. This was indicated by a significant antidepressant-like effect of an NK-1 receptor antagonist, L-822,429, as well as an anxiolytic-like effect after administration into the lateral septum.

There is very limited evidence for the effect of anxiolytic or antidepressant treatments on SP and/or NK-1 expression levels or activity. In rats, a single dose of diazepam, a benzodiazepine anxiolytic, reduces SP levels in the hippocampus and the periaqueductal gray while the level was increased in the substantia nigra. Results with antidepressant treatments are ambiguous and have yielded mixed and contradictory results.

There is growing evidence that SP is involved in the regulation of the HPA axis through actions in the hypothalamus and the adrenal glands. SP-containing fibers heavily innervate the PVN of the hypothalamus, and there are also NK-1 receptors present within this structure. Presumably, SP stimulates

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

the secretion of cortisol/corticosterone during stress exposure or when the HPA axis is disturbed. During normal conditions however, SP acts as a preventive agent for any excess secretion of glucocorticoids. Endogenous SP does not inhibit the initial magnitude of the stress response but reduces the duration of the response, proposedly through a central action on NK-1 receptors. This suggests that SP may be an important central agent controlling the transition between acute and chronic stress. In addition, an intraglandular modulatory role of SP has been suggested, and SP mRNA and SP immunoreactivity have been detected in the anterior pituitary as well as the adrenal glands of several mammalian species. Immunocytochemistry shows the presence of both cell and nerve fibers containing SP immunoreactivity in the anterior pituitary. Further, SP-positive nerve terminals are distributed around parenchymal cells and blood vessels of the adenohypophysis of monkeys, dogs, guinea pigs, and rats. SP immunoreactivity has been shown by RIA in the adrenal glands, both in nerve fibers and medullary chromaffin cells, of several mammalian species, including human, cow, dog, guinea pig, rabbit, mouse, and rat. The SP-containing nerve fibers penetrate the capsule and the cortex to innervate the medulla in both human and rat adrenal. The evidence suggests that the role of tachykinins, and especially of SP, could become very relevant under paraphysiological (e.g. physical or inflammatory stresses) or pathological conditions (e.g. ACTH-secreting pituitary tumors), when an excess of steroid-hormone production has to be counteracted. Stress-induced expression of c-fos is lower in NK-1 knockout mice than their wildtype controls, indicating an involvement of the SP/NK-1 system in hypothalamic activation in response to stress exposure.

NEUROPEPTIDE S

Neuropeptide S, a 20 amino acid peptide named after its highly conserved N-terminal serine, is a recently identified neuropeptide with anxiolytic and activity-promoting properties. It was revealed through reverse pharmacology to be the ligand for a former orphan G protein-coupled receptor (PGR14; GPR154; VRR1). Activation of the NPS receptor induces elevation of intracellular Ca^{2+} and cAMP, implying coupling of the NPS receptor to both Gq and Gs proteins and a resulting increased cellular excitability. Human NPSR1 mRNA encodes eight splice variants only two of which, hNPSR1-A and hNPSR1-B, are functional receptors. In rodents, only one single NPSR exists and it shows high similarity with hNPSR1-A.

As with many other neuropeptides, NPS has strong sequence conservation across species and is evolutionarily old. The N-terminal amino acid in all animal species is a serine, and the N-terminal sequence Ser-Phe-Arg-Asn-Gly-Val-Gly is identical in all species, possibly indicating a representation of the peptides bioactive core. The NPS peptide precursor (ppNPS; 89 amino acids) contains a hydrophobic signal peptide and a pair of basic residues in addition to the mature NPS sequence. Although the mRNAs for NPS and its receptor are expressed in many tissues, including the thyroid gland and brain, in the brain, NPS expression is mainly limited to three brainstem nuclei – and area adjacent to the locus coeruleus, the lateral parabrachial nucleus, and the principle trigeminal nucleus. Additionally, a few scattered NPS-expressing neurons have been detected in the medial amygdala and dorsomedial hypothalamus. Most of the NPS-expressing cells in the area adjacent to the locus coeruleus and the principle trigeminal nucleus are glutamatergic neurons. Within the area adjacent to the locus coeruleus there is also expression of NPS in cholinergic neurons. In the lateral parabrachial nucleus NPS is coexpressed with CRH.

In contrast to ppNPS, the NPS receptor is widely expressed in the central nervous system. High levels of NPSR mRNA expression can be detected in the thalamus, hypothalamus, cortex, olfactory nuclei, amygdala, and subiculum. The expression pattern for the NPS receptor is indicative of the confirmed role for the NPS/NPSR system in arousal, anxiety, and regulation of food intake. Central administration of NPS increases locomotor activity in both naive and habituated mice. Furthermore, it was shown in multiple behavioral models of anxiety-related behavior that central administration of NPS is anxiolytic. Additional evidence for a role of NPS in the regulation of stress-related behaviors and measures come from a study indicating that central administration of NPS significantly reduces the hyperthermic response induced by stress. On the contrary, NPS does not seem to have an antidepressant-like effect, as measured in the mouse tail suspension test.

With regards to interactions with other neuropeptide systems, central NPS administration activates c-fos expression in hypocretin-1/orexin-A (Hcrt-1/Ox-A) immunoreactive neurons in the lateral hypothalamus and in the perifornical area. In addition, NPS is colocalized with CRH in the parabrachial nucleus. CRH acts within the dorsal aspect of the brachium and the locus subcoeruleus to increase plasma ACTH and AVP through actions within the medial parabrachial nucleus. Intracerebroventricular administration of NPS stimulates the HPA axis activity and leads to increased plasma levels of ACTH and corticosterone in rats. Neither icv nor iPVN administration of NPS stimulated the release of either LH or TSH, suggesting a direct and specific effect of NPS on the HPA axis. In addition, treatment of pituitary segments with NPS did not alter ACTH release, suggesting that NPS does not have a direct effect on the pituitary gland. It is therefore probable that the effects of NPS on the HPA axis are mediated via the hypothalamus through the release of CRH and AVP.

Also of interest is that NPS induces not only locomotor activity but also anxiety-like behavior, as measured in the light-dark box test, and cocaine-seeking behavior (reinstatement) through a mechanism dependent on the CRH-1 receptor. Thus, NPS on one hand is anxiolytic and

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

on the other hand it is activity-inducing, activates the HPA axis, and induces reinstatement of drug-seeking, probably through a CRH-dependent mechanism.

ARGININE VASOPRESSIN

Vasopressin is reviewed here because of its prominent effects on the HPA axis. Already in the 1890s scientists showed that the extracts of pituitary when administered altered blood pressure. However, isolation and identification of the peptides/hormones vasopressin and oxytocin would take almost half a century. In the 1950s, amino acid sequences, structures, and synthesis of the peptides were elucidated. Both vasopressin and oxytocin are nine amino acid peptides, nonapeptides. Oxytocin and vasopressin are ancient neuropeptides that are highly conserved between species. Additionally, vasopressin is evolutionarily well conserved as even the primitive organism hydra expresses a vasopressin-like peptide and, vasotocin, the evolutionary progenitor of the vertebrate vasopressin can be found in birds and reptiles.

As for most neuropeptide receptors, the vasopressin receptors, V1 (with subtypes V1a and V1b, central nervous system expression) and V2 (predominantly peripherally expressed in liver and kidney), are seven transmembrane G protein-coupled receptors. Activation of V2 increases cAMP, and this mediates the classical diuretic effect of vasopressin. V1a and V1b activate phospholipase C activity.

The majority of vasopressin within the CNS is located within the magnocellular neurons of the supraoptic nucleus and the PVN. There are projections from the PVN to primarily the brainstem and spinal cord, but there is scant evidence for any extrahypothalamic projections from the supraoptic nucleus. Vasopressin fibers innervate the hippocampus and subiculum, the locus coeruleus, the solitary tract nucleus, and the spinal cord, among other regions. Further, vasopressin is expressed in the bed nucleus of the stria terminalis, in parvocellular neurons of the suprachiasmatic nucleus, and the medial amygdala.

Vasopressin is primarily known for its role in fluid metabolism; however, vasopressin also regulates the HPA axis and stress-related behaviors. In response to a stressor, vasopressin is released from the median eminence into the pituitary portal circulation, thereby potentiating the effect of CRH on ACTH release. The relative contributions of CRH, vasopressin, as well as oxytocin, to the control of ACTH secretion seemingly varies with different types of stress. In general, vasopressin stimulates ACTH secretion in all species studied. Oxytocin also stimulates ACTH release in rats but is inhibitory in primates. The involvement of AVP and OT in the control of ACTH secretion may have important implications for physiological and pathological conditions associated with activation of the HPA axis.

In response to acute and chronic stress, release of vasopressin in the PVN increases. Stress exposure can also increase V1b in the pituitary. Antagonism of the V1b-receptor reduces ACTH secretion and V1b knockout mice have significantly lower ACTH and corticosterone levels compared with that of wildtype mice after certain stress exposures.

High densities of vasopressinergic fibers and V1a-receptors are found within the septum and septal infusion of antisense oligodeoxynucleotide to the V1a-receptor mRNA, as well as with a V1a-receptor antagonist, d(Ch2)5Tyr(Me)AVP, significantly reduces anxiety-related behavior, as measured on the elevated plus-maze. Additionally, overexpression of the V1a-receptor gene in the lateral septum significantly increases anxiety-related behavior and V1a-receptor knockout males display significantly less anxiety-related behavior than wildtype males on a variety of tasks, further implicating V1a in controlling the anxiety response V1a. Differences in strain background and technique may account for these differences. Interestingly, V1a knockout females do not display anxiolytic behaviors. Also, contradictory results have been presented indicating an anxiolytic-like effect of central and peripheral administration of vasopressin.

Oral administration of SSR149415, a V1b-receptor antagonist, prevents the vasopressin-induced rise in plasma ACTH levels. Additionally, peripheral administration of SSR149415 is anxiolytic in various classical and atypical models of anxiety. Local infusion of SSR149415 into the basolateral amygdala, but not central or medial nuclei, produces anxiolytic-like effects in performance on the elevated plus-maze.

CONCLUDING REMARKS

There are many more stress-related peptides than those mentioned here. For example, galanin, ghrelin, nociception/orphanin Q, the orexins, melanin-concentrating hormone, are some of the ones not included in this chapter. As with all the peptides discussed in this chapter, other chapters in the book discuss these peptides.

In conclusion, this review briefly discusses the importance of neuropeptide systems in the regulation of stress- and anxiety-related behaviors and responses. The "dominant players," CRH and NPY, have been well characterized with regards to their individual and overlapping contribution to stress/anxiety-related behaviors and responses. The other members of the CRH family, the urocortins, are still being studied and evaluated. SP is predominantly known for its effects on nociception but is emerging as a possible future dominant player in stress- and anxiety-related behaviors and disorders. In general, it seems neuropeptide systems may offer more attractive treatment targets than the classical neurotransmitter systems because of the limited tonic activity of neuropeptide systems. Lack of tonic activity may generate treatments that have efficacy only during times of specific neuronal activity and may thus lead to state-specific treatments as well as a reduction in the appearance of side effects.

Chapter 257

Peptides and Temperature

Miklós Székely, Márta Balaskó and Erika Pétervári

ABSTRACT

The body's overall energy balance includes thermal balance and involves regulatory peptides representing the actual feeding status (hunger/satiety) or the nutritional status (body weight/composition). Acting directly or through vagal afferents, peripheral peptides (e.g. leptin, cholecystokinin, ghrelin, glucagon-like peptide-1) modify the expression/action of peptides in hypothalamic or brainstem nuclei (melanocortins, cocaine-amphetamine-regulated transcript, corticotropin-releasing factor, neuropeptide-Y, orexins, melanin-concentrating hormone, etc.), and influence the function of brain peptidergic systems. Catabolic peptide interactions suppress food intake, enhance metabolic rate, and eventually body temperature; these may be adaptive changes to acute/chronic calorie excess (postprandial hyperthermia, particularly in overfeeding). To retain calories in acute/chronic fasting, anabolic peptide activities result in hunger, hypometabolism, and (especially at subthermoneutral environments) in temperature decline. Apart from securing energy balance, body weight, and the adaptation to caloric availability, actions of these and other peptides participate in thermal adaptation, fever, and stress responses, and they influence nonexercise activity.

INTRODUCTION

Metabolic rate, on the one hand, is in equilibrium with food intake to maintain stability of body weight, while on the other hand, it has to be in equilibrium with heat loss to secure homeothermy. Each component of the overall energy balance has relative independence, allowing for alterations in body weight or body temperature. An increasing number of results show that besides the role of monoamines that have been widely accepted as regulators of individual components of energy balance for over half a century, regulatory peptides may also make an outstanding contribution to the regulation of the overall balance and can also influence body temperature. Depending on the mechanism of action, this influence and the physiological importance of various peptides may be different.

BODY TEMPERATURE AND ITS REGULATION

In homeothermic species, core temperature is regulated at different levels, and with varying accuracy, depending on the species. The regulatory arch consists of (1) thermosensors, (2) regulatory nuclei of the central nervous system (CNS, mainly hypothalamic and brainstem nuclei), which influence (3) thermoeffectors for heat production, heat loss, and thermoregulatory behavior. Heat production (metabolic rate) provides the link between regulations of body weight and body temperature. Each component of the arch of thermoregulation can be influenced by nonthermal factors, e.g. thermosensors by local anesthetics, effectors by the state and amount of heat producing tissues/organs (muscle, brown adipose tissue) and substrate availability, and the central regulation by many hormones, neurotransmitters, and neuromodulators, including regulatory peptides.

In humans and in experimental rodents, body temperature may be altered passively, when the exogenous/endogenous thermal load (e.g. extreme cold/heat, exhausting exercise, postprandial state) cannot be completely counterbalanced by the thermoregulatory effectors, or it may be altered actively in a centrally regulated process (e.g. fever). Skin vasodilatory substances may induce passive hypothermia (e.g. in cold environments alcohol acts partly this way), while other effects (e.g. generalized convulsions) may elevate body temperature passively. Peptides may also contribute to such passive changes in body temperature by acting directly on the effector systems (e.g. skin vessels, brown fat). In the past decades, however, more and more important roles were found for peripheral and central peptides that influence functions at higher CNS levels (brainstem, hypothalamus, etc.) and participate in many processes affecting metabolic and thermal balance in centrally regulated ways. Many relevant studies on the regulation of the overall energy balance were analyzed in a recent review.[29] This chapter deals with the thermoregulatory effects of some of the most important peptides in this field.

PARTICIPANTS OF ENERGY BALANCE REGULATION

Decerebrate rats with a functional brainstem are capable of regulating short-term ingestive behavior and satiety.[4] The nucleus of the solitary tract (NTS) with the area postrema

Copyright Elsevier 2024

serves as a portal for assessing and integrating visceral afferent signals (vagal signals, nutrients), and the dorsal motor nucleus of the dorsal vagal complex (DVC) provides outbound signals toward the neurons of the rostral medullary raphe to influence efferent responses. However, although this system can adapt to the actual feeding status (satiety/hunger), it cannot coordinate long-term adaptation (e.g. adaptation to starvation, to high-fat diet, or to changes in nutritional status) to maintain standard body weight. Cognitive, rewarding, aversive, and emotional responses are also absent in these rats. In addition to the indispensable hindbrain, the hypothalamus, and higher regulatory centers may modify the activities of the brainstem.

Similar mechanisms are involved in the regulation of body temperature.[3] Although the circadian rhythm of body temperature may also be maintained at the brainstem level,[14] the brainstem may not be sufficient for normal adaptation to alterations of environmental temperature or to nutritional status, to emotional status, etc. These necessitate the contribution of higher centers. Neurons of the dorsomedial hypothalamus, paraventricular nucleus (PVN), the ventrolateral medulla, and NTS convey information to the inhibitory rostral raphe pallidus in the brainstem; disinhibition leads to enhanced brown fat thermogenesis, skin vasoconstriction, and temperature elevation. Peptides are involved at several levels of this complex regulatory system and help adaptation to various situations. Thus, peripheral peptides, e.g. cholecystokinin (CCK), can influence NTS activity, and leptin can bind to its receptors on neurons of the arcuate nucleus (ARC), PVN, and the retrochiasmatic area. The ARC contains neurons expressing proopiomelanocortin (POMC), cocaine-amphetamine-regulated transcript (CART), neuropeptide-Y (NPY), and agouti-related peptide (AgRP), whereas the second-order neurons of the lateral hypothalamus contain melanin-concentrating hormone (MCH), orexins, and those of the PVN contain corticotropin-releasing hormone (CRH). Neurons of the PVN and elsewhere project to the DVC and further to the brown adipose tissue (BAT); they influence sympathetic tone and modify the expression and function of uncoupling protein-1 (UCP-1). It has not been clarified as to how the central influences alter the expression of other UCP-s in other tissues (e.g. UCP-2 and UCP-3 in muscles).

Peptides vs. Temperature: Acute/Chronic Exposure to Various Environmental Temperatures

A cold environment-induced heat loss should be compensated by increased metabolic rate and/or tendency to reduce further loss of heat in order to maintain stability of core temperature. At thermoneutrality, the metabolic rate is minimal (basal/resting metabolic rate: BMR), and no heat loss mechanism is activated. In a warm environment, heat loss should be increased and the metabolic rate reduced to or near BMR level. Results are scarce regarding peptidergic regulation of changes in heat loss, but results are abundant regarding the role of peptides in regulation of metabolic rate (role of brown fat,[6] nonshivering, and activity-related thermogenesis). Hypothermic effects of any peptide can only be observed at subthermoneutral or cold ambient temperatures (only toxic effects suppress metabolism below BMR; therefore, only these can cause temperature decrease at relatively warm environments), whereas peptide-induced temperature elevations may develop more easily at any environment (except in extreme cold).

Leptin, Insulin

Leptin primarily represents the nutritional status (adiposity), and it influences both food intake and energy expenditure. The peptide is derived mainly from white adipose tissue. By a receptor-mediated saturable transport system, it can enter the CNS and bind to its receptors in the ARC (similarly to insulin), with projections to the PVN,[5] the lateral hypothalamic area, the median preoptic area, and also to the DVC and spinal cord. It normally activates those neurons of the ARC, which produce anorexigenic peptides of the POMC and CART systems. It also binds to and suppresses the ARC cells producing orexigenic NPY and AgRP, with projections to the perifornical, paraventricular, dorsomedial, ventromedial, lateral hypothalamic, and median preoptic nuclei. The POMC-melanocortin system acts to stimulate, whereas the NPY system acts to minimize the sympathetic drive to BAT, thereby influencing thermogenesis in this tissue.[29] Intracerebroventricular (icv) infusion of leptin to young rats results in temperature elevation, particularly during the nadirs of the circadian rhythm.[25] Both the absence of leptin (ob/ob mice) and abnormalities of the peptide (Zucker fa/fa rats) or its receptors (db/db mice, Koletsky f/f rats) are accompanied with defective metabolic response and hypothermia on exposure to a subthermoneutral environment.[27] In ob/ob mice, leptin repletion elevates the low body temperature. With aging and in diet-induced obesity, leptin resistance develops,[22] and the thermal response to exogenous leptin becomes attenuated both in old rats (Fig. 1) and in diet-induced obese 6-month-old ones.[25] In contrast to lean controls, in severely obese (leptin resistant) subjects, cold exposure does not easily enhance metabolic rate. Rather, it promotes vasoconstriction in the insulating fat layer. In acute cold exposure or during cold adaptation, plasma leptin concentrations decrease in normal rats and mice, allowing for an increase in food intake; the simultaneous increase in heat production must be independent of leptin.

Direct administration of leptin to the hindbrain also induces hyperthermia, in a cooperative interaction with thyrotropin-releasing hormone (TRH) and by activation of

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

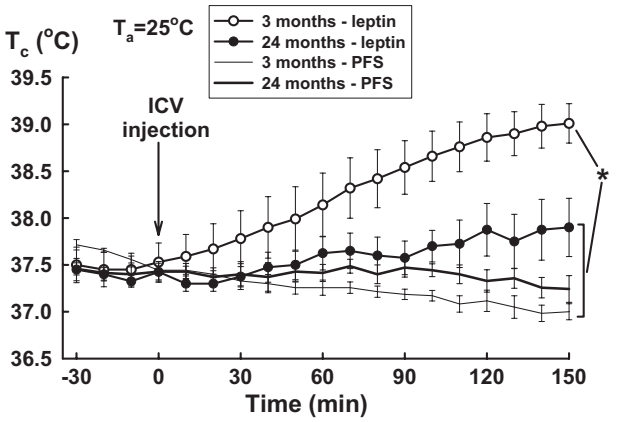

FIGURE 1 The effect of icv injection of leptin (4 μg) vs. pyrogen-free saline on core temperature in 3-month-old (○ vs. thin line) and 24-month-old (● vs. thick line) male Wistar rats at 25 °C environmental temperature (unpublished data of the authors).

the hindbrain melanocortin system. Normally, the forebrain actions of leptin (mainly by projections from the PVN) are superimposed on and regulate the integrative functions at hindbrain level;[15] melanocortin production in the brainstem increases, and this can excite the locally dense melanocortin receptors. Leptin also has effects on peripheral white adipose tissue, but this is only indirectly related to the thermoregulatory changes evoked by the peptide.

Apparently, the activity of leptin is influenced mainly by nutritional status (adiposity), which develops in a long-term process, and the peptide acts as a peripheral catabolic substance in the first line of defense for maintaining energy balance also on the long run. This includes the stability of body temperature, but the effects are not directed primarily to the regulation of body temperature. In physiological amounts, leptin-induced metabolic effects do not necessarily lead to temperature changes (resulting from the simultaneous rise in heat loss). Not all of the leptin effects are exerted directly; the activity of a number of other regulatory peptides is influenced by but not fully dependent on leptin.

In the regulation of energy balance, insulin has a similar role has as leptin; it provides information about the general status of energy availability in the body. Hypothalamic insulin receptors exhibit similar localization and roles as leptin,[5,19] and they are also present in the preoptic area. Preoptic injection of insulin-like growth factor-1 elicits dose-dependent hyperthermia, except in transgenic mice lacking neuronal insulin receptors. In humans, intranasal insulin enhances postprandial hyperthermia.

Melanocortins, AgRP

On leptin's binding to its receptors or as a local effect of nutrients, the appropriate cells of the ARC enhance the production of POMC and its derivatives, mainly alpha-melanocyte stimulating hormone (alpha-MSH) as an endogenous agonist of the melanocortin system. On similar stimuli, melanocortins are also produced in the brainstem, where their receptors are particularly numerous. In the NTS, CCK can also activate POMC neurons. In the absence of melanocortin-3 and -4 receptors (MC3R and MC4R), leptin cannot exert its activities, while leptin-deficient animals are capable of responding to melanocortin agonists, indicating that melanocortins act downstream to the point of leptin actions. Leptin-independent mechanisms (driven mainly by nutrients and their metabolites) may contribute to the activation of melanocortins. Melanocortins act as catabolic peptides at their receptors (mainly MC4R) on the second-order neurons in the PVN and other nuclei: They suppress food intake and enhance energy expenditure. The icv administration of melanocortin agonists enhances metabolic rate and leads to hyperthermia. The hyperthermic effect depends on the initial body temperature,[2] and because it is not accompanied by skin vasoconstriction, it cannot be regarded as a regulated hyperthermia or fever. In rats, a melanocortin antagonist (SHU9119) given icv reduces core body temperature.[1] Either insufficient activation of the melanocortin system (e.g. resulting from a defective leptin effect), or the absence of MC4R (in knockout mice) leads to failure of upregulation of UCP-1 and heat production of BAT on cold exposure[33] leading to a decline in core temperature, while at the usual (not cold) laboratory temperatures in such animals, the ingested energy accumulates and obesity develops. The leptin-melanocortin circuitry is presumed to play an essential role in cold adaptation[33] by its influence on BAT function. However, the role of melanocortins may be even more essential in the short-term adaptive changes of metabolism in response to feeding status (central effects of nutrients, CCK, glucagon-like peptide) and in indirect metabolic reactions to the nutritional status (conveying central leptin, insulin actions). Melanocortins also participate in the mediation of the effects of other peptides in the adaptation process, and they influence peripheral substrate use.

The endogenous melanocortin antagonist (inverse agonist) AgRP and several exogenous antagonists of the system decrease the resting metabolic rate in rats and diminish the cachexia-related elevation of metabolism in tumor-bearing mice. AgRP also suppresses the elevation of metabolic rate and body temperature induced by beta-3 agonist stimulation of BAT thermogenesis. As compared with wild-type mice, AgRP deficient mice exhibit higher metabolic rate and body temperature together with an age-related lean phenotype.[34]

In sum, the melanocortin system is probably the principal central catabolic system in the short-term (partly in the long-term) regulation of overall energy balance. It acts in a complex relationship with its endogenous antagonist, the AgRP peptide, as well as other peptides of the regulation of energy balance. The system plays an important role in metabolic adaptations to the actual feeding

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

status, to the nutritional status, and to the predominant nutrients.

CART

Cocaine-amphetamine regulated transcript (CART) is a CNS peptide that was originally described as an anorexigenic peptide causing anorexia and high-energy expenditure, resembling the effects of melanocortins. In line with this idea, the peptide was shown to be coexpressed mainly with POMC in cells of the ARC and retrochiasmatic area. Its production is activated by leptin, and it contributes not only to anorexia but also to stimulation of the sympathetic system and BAT thermogenesis.[7] Results obtained later suggest a somewhat different role for CART. The absence of MC4R prevents leptin's ability to increase UCP-1 in BAT and white adipose tissue (but not its effect to suppress food intake). The absence of MC3R prevents leptin-induced anorexia (but not its effect to increase UCP-1 in BAT and fat deposition in white adipose tissue), while the absence of CART has no influence on either effect of leptin. Moreover, a 7-day long treatment of rats with CART injections into the ARC enhances food intake and also enhances UCP-1 mRNA expression in BAT and the thermogenic responses to a beta-3 agonist.[10] The finding that on food deprivation CART overexpressing rats lost more weight than the controls did also indicates that CART has a hypermetabolic effect. Chronic overexpression of CART (by recombinant adenoassociated virus technique) in rats enhances food intake and increases body weight. The hypermetabolic and hyperphagic dual effect suggests a role for CART in special physiological situations, e.g. in cold adaptation.[10] Indeed, after chronic cold exposure, hypothalamic CART mRNA expression is elevated. Acute cold exposure also increases CART mRNA levels in the PVN.[21]

However, in contrast to the effects of direct intrahypothalamic injections, hindbrain (fourth cerebral ventricle) injections of CART have hypophagic and hypothermic effects; decerebration or GLP-1 receptor antagonist prevents the hypothermia. These indicate a role for extrahypothalamic sites of CART action.[24] Such CART actions were suggested to be distinct from coordinated regulatory patterns of energy balance, but they are believed to show a role for CART either in other processes mediated by GLP-1, or a role in hypothermic neuroprotection.

TRH

Apart from regulating thyroid function, TRH has a direct impact on energy balance. Production of the peptide in the PVN is influenced by melanocortins and CART from the ARC. TRH acts also on the thermosensitive cells of the preoptic/anterior hypothalamic region, the activation of which leads to an increase in core temperature.[11]

CRH, Urocortins

CRH-containing cells of the CNS are located mainly in the PVN and the ventromedial nucleus. The CRHR1 and CRHR2 receptors are sensitive not only to CRH but also to various urocortins and other ligands (e.g. sauvagine). Urocortin is produced mainly in the neurons of the Edinger–Westphal nucleus and in midbrain sympathetic neurons adjacent to it, but the brainstem, hypothalamus (supraoptic and lateral nuclei), and substantia nigra also contain this peptide. CRH is a regulator of the hypothalamus–pituitary–adrenal axis; it is important in stress reactions, in anxiety (mainly via CRHR1), and it also has various neurotransmitter or modulator roles. Cold exposure may represent a special form of stress: in cold-adapted rats CRH elicits an enhanced ACTH response, and it has metabolic actions. Cold exposure increases the hypothalamic mRNA expression of both CRH and CRHR2, but not CRHR1. Although CRH may participate in stress-induced hyperthermia (conjointly with orexin), many metabolic and thermoregulatory effects of CRH or urocortins seem to be independent of stress.[17] CRH suppresses food intake, increases oxygen consumption, and elevates body temperature in rodents, although urocortin-1 is a more potent ligand. These actions of the peptides are similar as those of melanocortins, but in MC4R knockout obese mice CRH and urocortin-1 still attenuate food intake, indicating that the CRH action is downstream to the point of action of melanocortins. Minute amounts of intraperitoneal urocortin also cause satiety.

The mediation of hyperthermia is complex. Urocortin-1-induced hyperthermia (via BAT activation) seems to be mediated by CRHR2. Urocortin-2 and -3 (and partly CRH) are less potent, but they also elevate body temperature by acting at CRHR2 in a fever-like fashion by increasing BAT thermogenesis and by causing skin vasoconstriction. Urocortins have been suggested to play a role in the response to cold; the thermogenic response is smaller in urocortin-1 knockout mice. In CRHR2-deficient mice, high-fat feeding or repeated cold stress results in high calorie intake and hypermetabolism with a lean body, presumably resulting from the relative hyperactivity of CRHR1; unfortunately, skin vasomotor change or other form of heat loss was not analyzed. The issue of the role of CRH is further complicated by some reports on a hypothermia-inducing effect of the peptide.

NPY

Peripherally produced NPY, although it acts synergistically with the sympathetic fibers, influences mainly the vasomotor system and no results are known regarding its effects on thermoregulation. In the CNS, NPY production is under the feedback regulation of leptin and ghrelin; leptin inhibits while ghrelin activates the NPY-producing neurons of

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

the ARC.[8] The NPY thus produced acts at receptors of the second-order neurons in the PVN and perifornical hypothalamus.[5] Early experiments showed that, when applied into these nuclei or administered icv to rats, this peptide induces food intake at the same time it blocks BAT activity and metabolic rate, and induces hypothermia (without concurrent rise in skin temperature) at subthermoneutral environments, e.g. at usual laboratory temperatures. However, it may elevate core temperature at suprathermoneutral environments. An icv injection of an NPY Y1-receptor agonist induces and its antagonist prevents torpor-like hypothermia in Siberian hamsters. Similar application of an agonist of the Y5-receptor also causes dose-dependent hypothermia, whereas a Y5-receptor antagonist increases energy expenditure. Centrally injected NPY Y1-receptor antisense elicits hyperthermia. NPY knockout mice have higher oxygen consumption and UCP-1 expression during fasting than the wild-type controls. This indicates that the thermoregulatory/metabolic effects of NPY have an adaptive role during fasting. The orexigenic and hypometabolic effects of the peptide are not interconnected; perifornical NPY injections elicit food intake only, but not the thermal effects. Apparently, the effect of this peptide on food intake may be more important than its influence on body temperature; the metabolic effects have an importance in the course of adaptation to low food intake.

In acute cold exposure, the NPY content in the arcuate and dorsomedial nuclei decreases. Chronic cold exposure presents a controversial issue: to adapt to the cold, the orexigenic but not the hypothermia-inducing effects of NPY should be enhanced. According to experimental results, during cold adaptation the hypothalamic NPY level does not change, although the orexigenic responsiveness to NPY and the spontaneous food intake increases. In cold-adapted animals, the basal core temperature is somewhat lower, and the responsiveness to acute cold exposure may increase significantly.[31]

Orexin-A

In addition to the first recognized effects of orexins, i.e. their role in increasing the arousal state, orexin-A has also been described as a peptide that contributes to the regulation of feeding behavior and energy balance. Orexins are produced mainly by neurons of the lateral/posterior hypothalamic and perifornical areas. Its type-1 and type-2 receptors can be found in many areas of the CNS. Peripheral metabolic factors (glucose). leptin, CCK, and ghrelin may influence the production/activity of orexin neurons via vagal afferents and the NTS (hypoglycemia is stimulatory). On central administration, orexin-A was reported to elicit short-lasting food intake, increase spontaneous activity and elevate core temperature. However, the results on the influence on core temperature are controversial. According to various reports, the orexin-A-dependent increased arousal status is coupled with higher body temperature.[35] This is suggested to be connected with increased sympathetic tone. Orexins activate CRH-containing neurons, and they are important in the stress-induced increase in metabolic rate, but orexins may be more important in non-exercise activity-induced thermogenesis. By contrast, other reports have shown that icv orexin-A may induce a short-lasting fall in core temperature in semirestrained animals, which is later followed by an increase. The hypothermia was prevented by NPY antiserum.[29] In orexin knockout mice, resting body temperature (nadirs of circadian rhythm during sleep) is elevated.[13] In rats, the orexin-A receptor antagonist SB-334867-A increases BAT thermogenesis.[32]

MCH

In the CNS, the expression of MCH is most abundant in the neurons of the lateral hypothalamus, where it is mostly coexpressed with orexin. These neurons project to the DVC and have interaction with afferent impulses reaching the NTS. Strong hyperphagia and a fall in core temperature develop after MCH administration into the fourth or the lateral cerebral ventricle: metabolic rate and UCP-1 expression in the BAT decreases.[23] Chronic treatment elicits obesity and hypothermia in mice. MCH or MCH-receptor knockout mice are lean, hypophagic, hyperactive, hypermetabolic, and have high body temperature. An icv infusion of the MCH antagonist SNAP-7941 increases brown fat thermogenesis in rats.[32] Also, in rats, MCH expression increases on acute cold exposure, probably as part of an adaptive metabolic change. On refeeding (after a short-term fasting) or after CCK treatment, the expression of MCH and its receptor in the afferent vagus is downregulated. The high hypothalamic MCH content of ob/ob mice[23] contributes to their tendency for hypothermia.

CCK

Although the so far analyzed peptides are connected mainly with nutritional status, the activity of CCK and other peptides of the gastrointestinal tract is influenced mainly (though not exclusively) by the actual feeding status.

As hormones of gastrointestinal regulation, CCK peptides have been known for a century. The recognition that CCK is present also in the brain and may have a principal role in satiety, and that it is important in energy balance dates back for only three decades, but our knowledge in this field is still growing. It is clear that energy balance and body temperature can be influenced by either peripheral or central actions of CCK.[30] The CCK-1 (CCK-A) receptors of the peptide are located mainly in the periphery, mainly on the afferent vagus, some in the CNS (hippocampus, NTS, hypothalamus, etc.), while the CCK-2 type (CCK-B) receptors are present throughout the CNS. In subthermoneutral environments, peripherally applied fragments of the peptide induce hypothermia through action on the afferent vagus; capsaicin-induced desensitization of the vagus prevents

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

CCK-hypothermia.[26] This indicates that the hypothermia develops on the basis of a reflex and not on local action of the peptide. CCK-1 receptor defective OLETF (Otsuka Long Evans Tokushima Fatty) rats do not respond to CCK administration, their circadian core temperature rhythm is similar to controls; the only difference they have is that their responses to changes in environmental temperature are slow. Although most of the peripheral CCK binds to receptors on the afferent vagus in complex interaction with other peptides that also bind at this site, some CCK binds to the ARC and nuclei of the brainstem (NTS) or other parts of the CNS (e.g. supraoptic nucleus, PVN). In OLETF rats, CCK cannot inhibit the anabolic activities of the ARC, and thus, the hypothalamic NPY content is higher than in controls, contributing to their obesity. Centrally applied CCK also exerts anorexigenic effects, but it elevates body temperature[30] in a way corresponding to fever (increase in metabolic rate together with skin vasoconstriction). This idea will be dealt with in the section on fever. The central effects of CCK better represent a catabolic-type activity.

Ghrelin

This orexigenic peptide originates predominantly from the stomach. Its production is enhanced by fasting, weight loss, and hypoglycemia, and it is inhibited by feeding or hyperglycemia. Apart from its growth-hormone secretagog function, ghrelin activates the receptors of NPY/AgRP producing neurons of the ARC (which inhibit the POMC-producing neurons), and also activates receptors of the PVN where NPY/AgRP are released, thereby increasing food intake.[5] CCK-1 and ghrelin receptors are colocalized on vagal afferent neurons where they are in antagonistic interaction. The effect of ghrelin on ARC is also attenuated by CCK pretreatment. Apart from enhancing NPY activity and the indirect (NPY-dependent) ways to induce hypothermia, ghrelin binding axonal terminals are located in the vicinity of thermosensitive neurons in the median preoptic area of the hypothalamus, and this provides an anatomical basis for direct thermoregulatory effects of the peptide. The sympathetic activity and BAT function are suppressed and hypothermia is induced by icv infusion of ghrelin. By contrast, in transgenic rats in which the ghrelin receptor is suppressed, BAT function is activated.[12] Deletion of ghrelin and its receptor is followed by increased energy expenditure.[12] In mice fasting in a cool environment a torpor-like hypothermia can be induced which is deepened by peripheral ghrelin (via NPY-associated pathways).

GLP-1

On food ingestion, GLP-1 is produced in the gut. It causes satiety and temperature elevation, and in animals, it acts even after decerebration or subdiaphragmatic vagotomy, indicating that the hormone acts directly in the lower brainstem. Intravenous or icv administration of GLP-1 increases metabolic rate and body temperature. Accordingly, a role for GLP-1 in postprandial hypermetabolism is suggested. However, in other experiments fourth cerebroventricular injections of GLP-1 receptor agonist or antagonist[20] have been reported to induce hypothermia or hyperthermia, respectively.

Miscellaneous Peptides

In addition to its known endocrine functions in salt/water balance, the *renin–angiotensin* system (RAS) participates in the regulation of energy balance. In a transgenic mouse model, the brain RAS activity induces a marked increase in energy expenditure and body temperature, which exceeds the simultaneously increased calorie intake and results in a lean body. Both food intake and energy expenditure increases in transgenic rats overexpressing the human renin gene, but the ratio changes in the opposite way, and obesity develops.

Vasopressin causes hypothermia by acting at V1 receptors.

An icv injection of *neurotensin* decreases food intake and also induces hypothermia in mice and rats. Neurotensin 1-receptor knockout mice are hyperthermic and slightly heavier than the controls.

Amylin injected icv causes dose-dependent hyperthermia. Similar results have been reported for *substance P*.

Brain-derived neurotrophic factor (BDNF) suppresses food intake and increases body temperature. The effects are prevented by a CRH antagonist, indicating that BDNF acts via the activation of the CRH system.

Infused icv, *ciliary neurotrophic factor* (CNTF) suppresses food intake and elevates body temperature even in high-fat diet-induced obese mice.

Nociceptin/orphanin FQ infusion icv leads to obesity resulting from high food intake and low energy expenditure, with low body temperature.

The *RF amide peptide QRFP* is an endogenous ligand of the orphan G protein-coupled receptor GPR103. An icv infusion of QRFP43, an active sequence of the peptide, causes hyperphagia, weight gain (particularly in mice kept on a high-fat diet), and a decrease in the UCP-1 of BAT with a decrease in body temperature.

The newly discovered *C-type natriuretic peptide* (CNP) possibly contributes to the regulation of energy balance: CNP-knockout mice are of smaller size, consume less food, and have a higher metabolic rate and hyperthermia.

An icv injection of a stable (not receptor-specific) *somatostatin* analog modulates the action of several transmitters, all together increasing food intake and elevating body temperature.

Fever and Hypothermia in Systemic Inflammation, Peptides

The role of some peptides can be seen not only in basic responses to thermal challenges but also in experimental fevers as fever-promoting or -antagonizing substances.

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Because of leptin-induced hyperthermia, the question repeatedly arises: "Does leptin participate in febrigenesis?" Leptin's action is presumably mediated by interleukins that do participate also in febrigenesis. Still, in obese Zucker or OLETF rats, the febrile response to lipopolysaccharide (LPS) is similar to that in controls, and in diet-induced obesity (presumably coupled with leptin resistance), the fever is even more pronounced. Accordingly, leptin may have a different role in the LPS-response: after hypothermia induced by large LPS doses the recovery is faster in control than in leptin-receptor-deficient Koletsky rats.[27]

Although peripherally applied CCK causes hypothermia, icv administration is followed by fever-like coordinated (high heat production, low heat loss) temperature elevation, which is not sensitive to antagonists of prostaglandin synthesis. A centrally applied CCK-2 receptor antagonist partially inhibits LPS-induced fever.[30] The LPS fever is also diminished in CCK-2 receptor knockout mice. Administration of a GLP-1 antagonist enhances the LPS-induced fever.[20]

Fasting attenuates LPS-induced fever. This may be connected with fasting-induced changes in peptide activities. In starving rats, the attenuated fever can be at least partly normalized by leptin. The fasting-induced elevation in ghrelin levels possibly contributes to the suppression of experimental fevers. In interleukin-1-induced fever, hypothalamic NPY release decreases, probably contributing to both the febrile anorexia and the elevation of body temperature. By contrast, during fasting high NPY levels may contribute to attenuation of the febrile response.

After 1980, many peptide hormones, including melanocortins, vasopressin, and CRH, were regarded as endogenous antipyretics.[9] Interestingly, not all of them caused only hypothermia. Several studies investigated the role of melanocortins in LPS fever. Although this peptide itself elevates metabolic rate and core temperature, it also increases heat loss, and the latter action possibly explains the antipyretic effect.[2] Vasopressin-induced antipyresis has been confirmed several times, without clarifying the precise mechanism of action. Similarly, the role of CRH has not been clarified.

Peptides and Adaptation to Food Restriction vs. Feeding

Food restriction is usually accompanied by a decrease in temperature, which eventually may be severe (particularly in cold), whereas food consumption is followed by a postprandial increase in body temperature (unless a high simultaneous heat loss can prevent it, e.g. in a very cold environment). Several mechanisms are believed to participate in these changes.

Fasting tends to suppress core temperature in humans and experimental animals. This is not simply a result of substrate deficiency. In fasting cold-adapted rats, the core temperature is lower than in the fed counterparts, but an icv injection of prostaglandin E elevates the temperature to the same level (the increase is relatively greater in the fasting group). On acute cold exposure, fasting rats can still elevate metabolic rate, although only for a shorter period. During complete fasting, in rodents, the nadirs but not the acrophases of the circadian temperature rhythm decrease until the very end. Accordingly, regulatory changes are responsible for the suppression of temperature during fasting. Regulatory peptides may have a role in this process. In food-deprived or calorie-restricted animals, the plasma leptin concentration decreases, hypothalamic melanocortin expression decreases, too, whereas NPY/AgRP expression increases. Suppressed CCK- and enhanced ghrelin-secretion are characteristic for the fasting state. All these changes are factors that indicate the presence of adaptive energy saving mechanisms and help in lowering the resting body temperature.

In leptin-deficient ob/ob mice that fasted at a room temperature of 22 °C, even torpor develops with a core temperature of 24 °C, and this can be reversed by leptin treatment. Similarly, in db/db mice, the hypothermia induced by fasting or cold exposure is prevented by BDNF via activating the sympathetic system and inducing UCP-1 gene expression in BAT. Because of results showing leptin-dependent reversal of large dose LPS-induced hypothermia, leptin has been suggested to counteract other conditions of negative energy balance, like fasting-induced hypothermia.[28] Indeed, in 6-month-old calorie-restricted rats icv leptin infusion induces much greater hyperthermia than in controls or obese ones of the same age.[25]

After food intake (postprandial state), the heat production and resting body temperature rise, especially after previous fasting. In a cold environment, this heat is used as part of the thermoregulatory excess heat production and the increase in core temperature may be missing. The normal elevation partly results from the caloric content of the food or the specific dynamic action of the nutrients. However, after previous fasting, even calorie-free feeding can evoke a temperature increase, that is, the increase has regulatory components originating from stretching of the gastrointestinal system. Gastric stretch evokes a rise in CCK and a fall in ghrelin-secretion via the vagal afferents that can influence the function of the brainstem and the hypothalamus, including peptidergic regulation (e.g. activation of the melanocortin system, inhibition of NPY). Perivagal capsaicin desensitization can block some forms of the postprandial hyperthermia (e.g.the form evoked by calorie-free food).[18] The nutrients (glucose, fatty acids) may act directly at the area postrema and/or the ARC, and they also modify peptidergic functions.

Peripheral nutrients and metabolites can also influence the energetic effects of peptides. Urocortin crosses the

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

blood–brain barrier (BBB) more easily in mice pretreated with either peripheral glucose or insulin, and this contributes to the development of satiety. Urocortin also enhances the influx of leptin through the BBB.[17] Glucose-transporter type-2 (Glut-2) of the ARC leads to the enhancement of leptin sensitivity in POMC and NPY neurons; the Glut-2 defective mice become hypothermic in a cold environment, and in their circadian rhythm the temperature nadirs are extremely low.[16]

In rats of high-fat diet-induced obesity, leptin resistance develops and icv or peripheral injection of leptin does not induce hyperthermia. Diet-induced obesity leads also to ghrelin resistance in NPY/AgRP neurons,[5] and the fasting-induced hyperphagia is attenuated as well as the cold responsiveness. Hindbrain leptin injections remain effective and cause hyperthermia even in diet-induced obese animals. In the hindbrain leptin acts via the local melanocortins and melanocortin sensitivity is maintained despite obesity. In these rats, the melanocortin antagonist SHU9119 can prevent the leptin-induced hyperthermia.[24] POMC defective mice do not decrease food intake even if maintained on a high-fat diet, and, unlike control mice, they do not increase either physical activity or energy expenditure. In obesity resistant mice a high-fat diet enhances spontaneous activity and muscle thermogenesis: this is how obesity is prevented.

Chapter 258

Pheromone Peptides

Miriam Altstein

ABSTRACT

Pheromones are chemical messages known to elicit changes in behavioral reactions that are followed by physiological alterations in conspecific receiver organisms. Pheromones comprise a wide range of compounds, of varied chemical nature, that range from small-molecule volatile compounds to high-molecular-weight, water-soluble, nonvolatile peptides and proteins. Although volatile pheromone molecules have been studied extensively, much less is known about the chemical nature of the equivalent nonvolatile water-soluble cues. In this chapter, we summarize the state of our knowledge of pheromone peptides and a few proteins, in a variety of species belonging to various phyla and classes.

INTRODUCTION

Pheromones are chemical messages that are secreted from an individual and that elicit a behavioral reaction or an endocrine change in another individual of the same species. In the receiving organism, pheromones can elicit an immediate behavioral reaction, such as alarm, defense, aggregation, attraction, kin and colony recognition, marking of territories and egg-deposition sites, mating behavior, recruitment, and thermoregulation. They also can induce complex behavioral and physiological alterations—such as development of a particular caste, or sexual maturation—via long-term endocrine changes.

Chemical communication among organisms is a highly sophisticated procedure that involves the regulation of many genes in the donor, and initiation of complex processes in the recipient, in which interpretation of the individual chemical constituents or "signals" depends on the particular combination, ratios, concentrations, and order of presentation of signal molecules, and also on the physiological state of the receiver. It is believed that, during the course of evolution, pheromones of different organisms have become very distinctive, to avoid ambiguity and to ensure that the channels of communication through which they exert their activity do not overlap, which causes even greater complexity.

Chemically, pheromones range from small-molecule volatile compounds to high-molecular-weight, water-soluble, nonvolatile peptides and proteins. Usually, small molecules are used for communication, which requires rapid dispersal of the signal, whereas the larger molecules of less volatile compounds tend to function in attraction and stimulation, for which prolonged exposure is necessary. Although airborne signal molecules have been identified and studied extensively, and are being applied commercially to disrupt mating and to monitor insect pests, much less is known about the chemical nature of the equivalent water-borne cues.

Pheromone peptides are widely distributed throughout the prokaryotic and eukaryotic organisms; they serve to mediate a variety of functions in Gram-positive and Gram-negative bacteria, fungi, ciliates, and in many different animals that belong to the mollusk, annelid, arthropod, and vertebrate (amphibians and mammals) phyla. The very extensive distribution of this means of signaling, among so many, widely diverse organisms, hints at the evolutionary importance of this mode of communication.

Pheromone peptides have been studied for many years, and in several systems, the nature of the peptides, their origins, and their modes of action are quite well understood. In other systems, however, our understanding is still very nascent, and the chemical, molecular, physiological, and biological aspects remain to be explored. Interestingly, in the few years that have passed since the publication of this chapter in the 1st edition of this book, >30 review articles have been published on pheromone peptides in organisms belonging to the bacterial, fungal, and animal kingdoms (most of them on bacterial and mammalian peptide pheromones). A vast amount of knowledge has accumulated on some of these signaling molecules, covering aspects such as: identification of the chemical nature of these peptides; discovery of new peptide pheromones and identification of their biosynthetic pathways, their molecular cloning and their structure/activity relationship (SAR); their inter-molecular interactions; their mechanisms of production and reception, as well as their modes of action at the cellular level; signal transduction pathways that follow peptide pheromone binding to the receptor; intracellular communication at the genome level; and the neural circuitry leading to specific pheromonal outputs and physiological effects. These "signal transduction" and "intracellular communication" studies attracted most

attention from many research groups, and thus emerged as the most studied topic across the various phyla, leaving an overall impression that the field had made immense progress and had moved from "preliminary-discovery" studies that merely documented the involvement of peptide pheromones in conspecific species to studies that focused on in-depth understanding of the molecular and cellular mechanisms that underlie peptide pheromone reception and activity. This chapter presents a short summary of the state of our knowledge on pheromone peptides and a few proteins, in a variety of species. The limited scope of the chapter does not enable a detailed description of each system, and the reader is referred to the references (mostly recent review articles) in each section, for further information. A summary of the peptides mentioned in this chapter is presented in Table 1.

BACTERIAL PHEROMONE PEPTIDES

One of the most complex and diverse systems of pheromone peptides is found in bacteria. Both unicellular organisms and individual cells of metazoans have evolved complex signaling mechanisms by which they respond to the environment and communicate with one another. These mechanisms involve short peptides that can be secreted as unmodified structures or as posttranslationally modified peptides. These peptides are sensed by target organisms via cognate sensors, with each signal molecule initiating a complex multilevel response pathway. There are two basic types of bacterial communication systems: those in which the signal is detected solely by organisms other than the emitter, and those in which the signal is sensed by the emitting organism as well.

TABLE 1 Major Pheromone Peptides or Protein Families in Bacteria, Fungi and the Animal Kingdom

Pheromone Peptide or Protein Family	Organism or Group Studied: (Order/Genus/Species)	Function	Ref.
Bacterial Pheromone Peptides			
Mating pheromones			
cCF10, cAD1, cPD1, cAM373, cOB1	*Enterococcus faecalis*	Cellular aggregation and plasmid transfer	Dunny and Johnson[13], Thoendel and Horswill[29], Wardal, Sadowy, and Hryniewicz[31]
Quorum-sensing peptides			
Gram-positive peptides			
Autoinducing peptide (AIP)	*Staphylococcus aureus*	Virulence peptides	Thoendel and Horswill[29]
Autoinducing peptide (AIP)	*Lactobacillus plantarum*	Virulence peptides	Thoendel and Horswill[29]
Gelatinase biosynthesis activating pheromone (GBAP)	*Enterococcus faecalis*	Virulence peptides	Thoendel and Horswill[29]
PapR	*Bacillus cereus*	Virulence peptides	Thoendel and Horswill[29]
Cytolysin subunit ($CylL_s''$)	*Enterococcus faecalis*	Virulence peptides	Shankar et al.[26]
Competence-stimulating peptides (CSP-1, CSP-2)	*Streptococcus pneumoniae*	Genetic competence	Thoendel and Horswill[29]
Competence-stimulating factor (CSF, PhrC)	*Bacillus subtilis*	Genetic competence	Thoendel and Horswill[29]
Competence factor ComX	*Bacillus subtilis*	Genetic competence	Thoendel and Horswill[29]
Nisin	*Lactococcus lactis*	Production of bacteriocins	Kleerebezem et al.[18]
Subtilin	*Bacillus subtilis*	Production of bacteriocins	Kleerebezem et al.[18]
Plantaricin A (PlnA) peptides	*Lactobacillus plantarum*	Production of bacteriocins	Diep et al.[11]
BlpC (also termed SpiP) peptides	*Streptococcus pneumoniae*	Production of bacteriocins	Lyon and Novick[23]
Gram-negative peptides			
Double Gly (G-G) containing peptides	Various bacterial spp.	Quorum sensing	Thoendel and Horswill[29]

TABLE 1 Major Pheromone Peptides or Protein Families in Bacteria, Fungi and the Animal Kingdom—*Cont'd*

Pheromone Peptide or Protein Family	Organism or Group Studied: (Order/Genus/Species)	Function	Ref.
Vertebrate Pheromone Peptides			
Amphibian peptides			
Sodefrin	*Cynops pyrrhogaster*; *Triturus carnifex*	Female attraction	Woodley[32]
Silefrin	*Cynops ensicauda*	Female attraction	Woodley[32]
Aonirin	*Cynops pyrrhogaster*	Female attraction	Woodley[32]
Splendipherin	*Litoria splendida*	Female attraction	Woodley[32]
Courtship pheromones (PRF, PMF, SPLF)	*Plethodon jordani*	Shortening of courtship process	Woodley[32]
Leptodactylus aggression-stimulating peptide (LASP)	*Leptodactylus fallax*	Stimulation of male aggression	King et al.[17]
Mammalian peptides			
Aphrodisin	Rodents	Induction of copulatory behavior	Briand, Trotier, and Pernollet[5]
Major urinary proteins (MUPs)	Rodents	Communication of individual identity and ownership via scent marks	Touhara[30]
Major histocompatibility complex, (MHC,) class I peptides	Rodents	Communicate individual identity and mediate pregnancy blockage or spontaneous abortion	Touhara[30]
Tear exocrine-gland-secreting peptide 1 (ESP1)	Rodents	Communication of individual identity and ownership via scent marks	Touhara[30]
Vasopressin and oxytocin	Rodents and sheep	Assistance in processing of pheromonal cues associated with social discrimination	Bielsky and Young,[4] Higashida et al.[16]

The first type is typified by the mating pheromones of the enterococcal bacteria, e.g. *Enterococcus faecalis*: cCF10 and cAD1, which are hepta- and octapeptides with sequences LVTLVFV and LFSLVLAG, respectively. Among these bacteria, a potential recipient releases a small peptide that is taken up by a potential donor, in which it elicits a plasmid-coded response that leads to cellular aggregation and transfer of the plasmid from donor to recipient. Production of the mating-pheromonal peptide in the donor is dependent on the close proximity of recipient cells. The enterococcal pheromone is processed from a chromosomally encoded lipoprotein precursor. Most strains produce multiple pheromones with mutually differing spectra of activities, but each plasmid responds specifically to its cognate pheromone with extremely high specificity and sensitivity. Details on the synthesis of the enterococcal mating pheromone molecules, the components of the regulatory machinery that interact specifically with the peptides, the molecular basis for their exquisite sensitivity and specificity, and the regulatory circuits controlling the multiple levels of regulation of intracellular communication have been reviewed recently.[13,29,31]

The second group of bacterial pheromone peptides comprises the autoinduction or quorum-sensing (QS) systems, which are widespread among bacteria, in which they elicit population-wide responses (cell-cell or cell-environment responses) to low-molecular-weight signaling molecules, depending on cell-population density. The structures of the signaling molecules differ between Gram-negative and

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Gram-positive bacteria: in the latter, the mating pheromones and most QS signals are peptides that are sensed by transmembrane receptor components that activate an intracellular response pathway.

Examples of QS-induced processes in Gram-positive bacteria include virulence, genetic competence, and production of antimicrobial peptides. Virulence is induced in *Staphylococcus aureus* and *Lactobacillus plantarum* by autoinducing peptides (AIPs)—a 7- to 9- and a 5-residue cyclic peptide, respectively,—and in *E. faecalis* and *Bacillus cereus* by gelatinase biosynthesis activating pheromone (GBAP)—an 11 residue cyclic peptide—and PapR (a heptapeptide with the sequence ADLPFEF[29]), respectively. Genetic competence is induced in *Streptococcus pneumoniae* and *Bacillus subtilis* by competence-stimulating peptides CSP and competence-stimulating factor (CSF), which are 17 amino acid peptides with the sequence EMRLSKFFRDFILQRKK and a pentapeptide with the sequence ERGMT, respectively.[29] *B. subtilis* 168-type strain produces another competence pheromone: a posttranslation modified 10 residue linear peptide containing a farnesyl group, termed Com-X (ADPITRQWGD).[29]

Production of antimicrobial peptides, known as bacteriocins, also involves a QS mode of regulation. Bacteriocins are divided into Class I posttranslationally modified peptides, often referred to as lantibiotics, and Class II, which are not posttranslationally modified; their production can be regulated in a cell-density-dependent manner by the antimicrobial peptides themselves, as with nisin and subtilin production in *Lactococcus lactis* and *B. subtilis*, respectively, or by signaling molecules that are distinct from the antimicrobial peptides and which include the plantaricin A (PlnA) or BlpC peptides—also termed SpiP peptides—that regulate bacteriocin production in *L. plantarum* and *S. pneumoniae*, respectively.[11,23] Another example of QS is the regulation of cytolysin production in *E. faecalis*, in which a subunit of the bacteriocin, $CylL_s$ regulates the transcription of the toxin.[26] The mechanisms regulating each of the above QS systems are very complex and differ from one another with respect to secretion and sensing of the autoinducer, and in the regulatory cascade that results from its perception. Detailed reviews on QS peptides in Gram-positive bacteria and their biosynthetic pathways have been published recently (see Refs 11–13, 29 and references therein).

In Gram-negative bacteria, most QS signals are *N*-acyl homoserine lactones, which are internalized by diffusion and bind to an intracellular receptor molecule to activate the response.[29] However, recent studies have revealed the existence of signaling peptides in Gram-negative bacteria too. Studies based on an in silico strategy to screen the Gram-negative bacterial genome for the presence of leader double-glycine sequences, which are conserved leader motif sequences of many Gram-positive pheromone peptides, have revealed the presence of genes coding for putative peptides that contain such motifs and that also show structural similarity to bacteriocins and pheromone peptides of Gram-positive bacteria. The role of such peptides in signal transduction, and the mechanisms by which they might exert their activity in Gram-negative bacteria are unclear at present.

FUNGAL PHEROMONE PEPTIDES

Although diverse fungi generate chemical pheromone gradients during mating, the pheromone peptides of yeasts are among the best documented fungal pheromones. Two pheromone peptides that initiate mating in the yeast *Saccharomyces cerevisiae*—the α-factor and the a-factor, which contain 13 and 12 amino acids, respectively, are currently known. The peptides are secreted by donor cells and act on the recipient via G-protein-coupled receptors (GPCRs). The mating pheromones are absolutely indispensible for triggering the mating cycle, and cells that cannot produce these molecules or that lack their cognate receptors are sterile. The α-factor is a tridecapeptide pheromone (WHWLQLKPGQPMY) synthesized constitutively by *S. cerevisiae* mating type α cells, and it acts on *S. cerevisiae* mating type ***a*** cells. The peptide was isolated and characterized by Stotzler and Duntze[27] and later found to be encoded by two genes: *MFα1* and *MFα2*.[20] The **a**-factor of *S. cerevisiae* is a dodecapeptide pheromone (YIIKGVFWDPAC[farnesyl]-OCH_3)[2] that requires posttranslational modification with a farnesyl isoprenoid and carboxymethyl group to enable the expression of its full biological activity. Biosynthesis of these mating pheromones has been studied extensively and used as a model for posttranslational processing, modification, and secretion of mammalian peptide hormones and proteins. The cellular events and signal transduction pathways stimulated by these pheromones were recently found to affect the cell cycle, and they are currently used as a model to study this complex system in eukaryotic cells (for review see Ref. 7). The SAR studies and the extensive biological, biochemical, molecular, and biophysical analyses of the α-factor peptide provided a model of its structure and of its interaction with its receptor (for an overview see Ref. 24). Recently, GPCRs that bind peptide pheromones that mediate mating in filamentous fungi were identified, and their signaling was characterized.[21] The pheromones, their receptors, the downstream intracellular signal transduction pathway by which the yeast cells respond to the presence of mating peptide pheromone in their vicinity, the importance of chemical gradients in yeast chemotropism, and the peptide's mode of action at the cellular level have been examined thoroughly and are summarized in reviews.[3,7,21]

CILIATES

Ciliates can exhibit both asexual and sexual reproduction. Asexual reproduction occurs by binary fission whereas sexual reproduction involves conjugation, i.e. mating, of two cells that divide to form four new cells. Ciliate sexual mating involves chemical signaling that is mediated by a

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

complex pheromonal system of small protein pheromones, containing 75 and 130–150 amino acid residues: E*r*-1, E*r*-2, E*r*-7, E*r*-10, E*r*-11, E*r*-20, E*r*-21, G3, and G4. Formation of such mating pairs enables some species to avoid mating between siblings, and promotes mating with foreigners, and thereby retains cell-type-specific signals for distinguishing self from nonself. Most ciliates' pheromones were characterized in *Euplotes* spp. and other hypotrechs. Details of the structures of the various polypeptides, their putative receptors, and their possible modes of interaction and function are detailed in Ref. 22

MOLLUSK PHEROMONE PEPTIDES

Pheromone peptides and proteins have also been implicated in the control of a number of behaviors in mollusks—from egg laying to mate attraction—but only a few have been characterized. Most studies of mollusk pheromone peptides were carried out on *Aplysia*, and the two groups of pheromones that were identified so far were mostly found during these studies. These groups comprise a contact pheromone whose nature has not yet been determined, which triggers a synchronous discharge of neuroendocrine bag cells which, in turn, secrete a family of peptides that promote egg release and mate-attracting pheromones. The latter comprise a family of water-borne pheromonal protein attractants, of which the major is attractin, a 58 residue glycosylated protein that is released from the albumen gland during egg laying and that acts in concert with other water-borne protein pheromones—enticin, temptin, and seductin (which are, respectively, 69-, 103-, and 192-residue proteins found in the albumen gland)—to stimulate mate attraction by recruiting other *Aplysia* to the freshly laid eggs, thereby stimulating other *Aplysia* to increase egg laying and to form mating aggregations (for review see Refs. 8, 9). Recently, another protein—Alb-1, a 101 residue protein—has been identified and cloned from the albumen gland; it is believed to play a pheromonal role, together with the above-mentioned four peptides,[8] and has been suspected to be associated with factors from non-laying *Aplysia* that might act in conjunction with attractin to stimulate enhanced mate attraction.[9] Other pheromone peptides are: a tetrapeptide (Ile-Leu-Met-Glu, termed ILME) that is eluted from egg masses of the cephalopod *Sepia*, and that is thought to stimulate the transport of oocytes in the genital tract; and a *Sepia* sperm-attracting peptide, termed SepSAP, that is released from oocytes during egg laying and that facilitates external fertilization by attracting spermatozoa.[28] Evidence for the pheromonal role of the above peptides and proteins in various *Aplysia* and *Sepia* species, their expression and localization, biochemical and molecular characterization, structure and SAR, release, inter-molecular interactions and bioactivity is presented in Refs. 8–10.

ANNELID PHEROMONE PEPTIDES

Females of the ragworm, *Nereis succinea* use a tetrapeptide, cysteinyl-glutathione (CSSG) as a mate-recognition and gamete-release pheromone during reproduction. The tetrapeptide pheromone (termed nereithione) controls reproductive behavior and release of gametes. The pheromone is released into water by swimming ripe females, and it induces males to swim faster and to release sperm. The role of peptide-based pheromones in these worms and the time course of their appearance as related to the worms' sexual maturation have recently been reviewed.[15]

ARTHROPOD PHEROMONE PEPTIDES

Insects

One of the largest and best documented groups of pheromones comprises those of insects. Chemical cues are major sources of information used by most insects to interpret environmental stimuli; they lead to the initiation of gregarious behavior, formation of aggregations at food sites, dispersal behavior during predator attack, synchronized sexual maturity, mating attraction, etc. However, none of the pheromones that elicit these functions is of a peptidic nature. There are only two examples of peptides (and proteins) being related to pheromonal activity in insects. One involves *Drosophila melanogaster*, in which the peptides act as primer pheromones that cause physiological changes associated with reproductive activity in the fly. The other involves peptides that originate in the central nervous system (CNS) of Lepidopteran species and that stimulate sex-pheromone biosynthesis in female moths.

The first system involves proteins and peptides that are transferred, together with sperm and seminal fluid, by males; they act within and outside the reproductive tract of their female targets, and elicit a wide variety of short-term and long-term responses such as increased oogenesis and ovulation, decreased female receptivity, enhanced sperm storage, and formation of the mating plug.[33] The very first seminal fluid peptide to be identified was the "sex peptide" (SP) or accessory gland peptide (Acp70A). From the 1960s through the 1980s, the nature of Acp70A was gradually revealed, and the *Acp70A* gene that encodes the 36 amino acid Acp70A peptide was identified (for an overview see Ref. 6 and references therein). In around 2000, another closely related peptide (DUP99B)—a homolog of SP—was revealed.[19] Within females, SP and its closely related homolog DUP99B are thought to elicit postmating responses through a specific GPCR, termed SPR,[34] which triggers these responses mainly by modulating neuronal activity in the subsets of the *fruitless* and ventral nerve cord neurons.[19] Detailed SAR studies have associated some of the SP functions with specific parts of the molecules,[19] and

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

detailed cellular studies uncovered a neuronal mechanism by which SP exerts its control over reproductive behavior.[33] The ongoing study of seminal fluid molecules is revealing that they have an unexpected variety of functions and, furthermore, that some of the genes that encode these molecules show evidence of extremely rapid evolutionary change. These findings suggest that seminal fluid molecules might be strong targets for natural or sexual selection. At present, homologous recombination and RNA interference, along with microarrays and yeast two-hybrid systems, are being used to gain better insight into the functions of these molecules and their receptors. Information on the currently known functions of the seminal fluid proteins and peptides of *D. melanogaster*, and the approaches used to study their role in the fruit fly's reproductive and postmating functions have been published.[33] Interestingly, numerous attempts to identify SP orthologs in other insects revealed their presence in the mosquito *Anopheles gambiae*.

The second system involves a sub-esophageal ganglion neuropeptide—pheromone biosynthesis activating neuropeptide (PBAN)—that acts via a GPCR mechanism to initiate sex-pheromone biosynthesis in the pheromone glands of female moths. Studies of the regulation of sex-pheromone biosynthesis in moths have revealed that this function can be elicited by additional neuropeptides, all of which share the common C-terminal pentapeptide FXPRL-amide (in which X = S, T, G, or V) and belong to a large family of peptides: the pyrokinin (PK)/PBAN family. In the past two decades extensive studies were carried out on the chemical, cellular, and molecular aspects of PBAN and the other peptides of the PK/PBAN family, aiming to understand the mode of their action on sex-pheromone biosynthesis (for an overview see Ref. 1 and references therein). A detailed review of some of the above topics is presented in the chapter on "The FXPRL-amide Pyrokinin/PBAN Family" by Altstein et al. in the Invertebrate Peptide section of this book.

Crustaceans

Another group of pheromone peptides in arthropods comprises those of the crustaceans. Crustacean pheromone peptides have been implicated in two different behavioral patterns: gregarious settlement of barnacles, which involves "settlement pheromones"; and synchronization of larval release, which involves larval-release pheromones—also termed "pumping pheromones"—which are released from newly hatched embryos and induce stereotypical larval-release behavior in crab (*Rhithropanopeus harrisii*) or lobster (*Panulirus argus*) females. This larval-release behavior involves rapid abdominal extensions and pleopod pumping, which help to break open the egg membrane and results in synchronous release of the larvae. The settlement pheromones are peptides released from intact living barnacles, whereas the larval-release pheromones are released from the brood. Knowledge of the biological activity and SAR of synthetic settlement pheromones and of larval-release pheromones is quite elusive at present, and most studies were carried out with crude extracts or synthetic analogous peptides, because the natural pheromone peptides have not yet been fully identified. In light of current knowledge, it is well accepted that all known crustacean release pheromone peptides are based on serine protease degradation products that have basic carboxyl termini, which are essential for bioactivity. Recent studies have revealed that the released peptide pheromones are dipeptides and tripeptides that have a neutral amino acid, i.e. Gly, at the amino terminus, a basic amino acid, i.e. Arg, at the carboxy terminus, and a basic-basic dipeptide (Lys-Arg). The current state of knowledge has recently been summarized.[14,35]

VERTEBRATE PHEROMONE PEPTIDES

Amphibians

In recent years, it has became apparent that although communication among amphibians depends primarily on auditory signals, pheromonal signaling is used by both males and females for mating attraction; it is widespread in salamanders and newts, and may also be important in some frogs and toads. These pheromones are typically peptides and proteins, and several of them have been behaviorally, biochemically and molecularly identified. The best-characterized amphibian pheromones are those that influence male–female interaction. The first pheromone identified in amphibians was the female attractant sex pheromone—sodefrin—of the newt, *Cynops pyrrhogaster*, and a cDNA comparable with the cDNA encoding *Cynops* sodefrin was also isolated from another newt, *Triturus carnifex*. In 2000, a second sex pheromone was isolated from another *Cynops* species, *C. ensicauda* and was termed silefrin. *Cynops* sodefrin and silefrin are decapeptides with amino acid sequences SIPSKDALLK and SILSKDAQLK, respectively, they are secreted from the abdominal glands of males via the cloacae, their synthesis is regulated by prolactin and androgens, and each pheromone attracts only conspecific females. In 2007, a third decapeptide—aonirin—was isolated from the abdominal gland of the male *C. pyrrhogaster*, which is found in the Nara region of Japan (for review see Ref. 32). Another sex pheromone, isolated from the frog, *Litoria splendida*, is a 25-residue peptide—splendipherin[32]—which is produced by a gland in the head of the male during the mating season. Splendipherin attracts conspecific females and has no effect on males or on other species.

In recent years, many studies focused on the courtship pheromones of the salamander. Currently, it is well established that the salamander pheromone is a complex blend of compounds secreted by the male submandibular (mental)

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

gland. Several such pheromones—plethodontid receptivity factor (PRF), plethodontid modulating factor (PMF), and sodefrin precursor-like factor (SPLF)—have been isolated, molecularly and biochemically characterized, and tested for effects on female behavior. During courtship, salamanders transfer mental-gland pheromones via two main modes: the olfactory mode, in which pheromones from the mental gland of the male reach the female's nasal cavity; and the transdermal mode, in which the male pheromone is deposited directly onto the skin of the female and diffuses into the peripheral vasculature.

Male–male pheromonal signaling has also been reported in amphibians. In 2005, an amphibian pheromonal peptide—leptodactylus aggression-stimulating peptide (LASP)—has been characterized and isolated from male norepinephrine-stimulated skin secretions.[17] LASP exhibited a chemoattractive effect on males, in which it stimulated aggressive behaviors that resulted in the emergence of dominant animals that subsequently attracted females to nesting sites.

Most amphibian pheromones are detected by the vomeronasal organ (VNO) and the main olfactory epithelium (MOE), which form a unique chemosensory system. Chemosensory neurons present in those organs express VNO receptors or olfactory receptors. In recent years, detailed studies were carried out on these pheromones, on the anatomy of the receptive organs, and on the molecular, genomic and physiological characteristics of the chemosensory receptors. To date, no chemosensory ligands have been matched to VNO receptors or olfactory receptors; this indicates the need for further examination of the issue, which could also provide an insight into the nature and evolution of vertebrate pheromonal communication (for detailed review on amphibian pheromones, their receptors and the chemosensory organs, please refer to the review in Ref. 32 and references therein, and to the chapter by Kikuyama in the Amphibian Peptides section of this book).

Mammals: Rodents

Needless to say, the most complex, interesting, but as yet unidentified signaling molecules are those of mammals. All mammals emit chemical cues into the environment, via urine, saliva, and/or divers secreted fluids. So far, only a few mammalian pheromones, especially those of rodents, have been identified, and examination of their chemical nature has revealed a wide diversity of compounds, that range from small organic molecules to large proteins. Several proteinaceous pheromonotropic families are described below; they all play essential roles in sex discrimination and attraction between males and females, and thereby promote mate choice and successful reproduction. Among them are: aphrodisin (for review, see Ref. 5); mouse urinary proteins (MUPs); major histocompatibility complex (MHC) class I peptides; and the tear exocrine-gland-secreting peptide 1 (ESP1) (for a detailed review, see Ref. 30 and references therein).

Aphrodisin is a protein that belongs to the lipocalin family; it is found in hamster vaginal secretions, and when it is detected by the male accessory olfactory system copulatory behavior is induced. At present, it is not clear whether aphrodisin itself performs the pheromonal function or whether it is simply a carrier for hydrophobic small pheromone molecules that have not yet been identified. Studies on this topic focus on the aphrodisin structure, its biological properties, and the associated signal transduction processes in the VNO.[5]

Other members of the lipocalin family are the MUPs, of 19 kD, found in sexually mature male mice, rats, and some other rodents. These proteins are believed to be responsible for the binding and release of low-molecular-weight pheromones, thereby providing a slow-release mechanism for volatile components of scent marks. However, the proteins may function as chemosignaling molecules in their own right, filling one or more roles in communication of individual identity, territorial behavior, and ownership. Male MUPs seem to promote, among other actions, aggressive behavior between males. Other pheromonotropic compounds present in male mouse urine are the MHC class I peptides—SYFPEITHI and AAPDNRETF—which have also been shown to convey information about individual identity and to mediate pregnancy blockage or spontaneous abortion, i.e. the Bruce effect. Recently, a male-specific peptide—ESP1—has been found to be secreted in the tears of the extraorbital lacrimal gland of male mice. This peptide is a member of the ESP gene family and seems to be involved in sexual behavior associated with the conveyance of information on strain and species, similar to the function of MUPs. A few recent reviews[25,30] summarize the current understanding of the structure and function of urinary and other proteins, and speculate on their roles as supporters or as key participants in the elaboration of the complex chemosensory properties of a rodent scent mark.

As in amphibians, peptide and protein pheromones in rodents—MPUs, MHC peptides, and ESPs——are believed to be recognized by specific transmembrane receptors—members of the VIR and V2R family—that are expressed in the VNO on sensory neurons; however, this issue is still somewhat controversial. Some chemosensory peptidic pheromonal signals, i.e. MHC peptides in rodents are conveyed via MOE. Much of the research on the molecular mechanisms underlying vomeronasal and MOE sensing of peptide pheromones has been conducted with mice and has focused on the structure of the two areas and their receptors, the search for natural ligands, signal processing and signal transduction from the chemosensory organs to the CNS (for review see Refs 25, 30 and references therein).

The VNO in mammals has received a lot of attention within a broader aspect in the past few years, and studies of

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

this secondary olfactory system yield much new information such as the existence of a large number of VNO receptor genes. This unexpected receptor diversity indicates that there probably is a wide variety of chemosensory signals sensed by these receptors, about which little is known at present and which needs to be further explored. Although peptide pheromones and VNO play a most important role in communication between individuals of mammalian—rodent—and amphibian species, it seems that there was a tendency toward loss of VNO function and elimination of peptide pheromones at this point in evolution, as indicated by the absence of peptide or protein pheromones, and also of the VNO receptor gene families that mediate these cues, in primates, including humans.[30] The current consensus is that the VNO is not functional in adult humans. It is possible, however, that pheromone communication does exist in humans and is processed by the receptor neurons in the MOE. This issue also needs further exploration.

Last but not least are the neurohypophysial peptides—vasopressin (AVP) and oxytocin (OT)—that do not serve directly as pheromonal cues in mammalian species, but are rather critical to the mammalian ability to process such cues appropriately in the olfactory circuit and throughout the brain. In a recent review by Higashisa et al.[16] and an earlier review by Bielsky and Young,[4] the roles of OT and AVP in rodent social interaction, social recognition, pair bonding, and maternal behavior are discussed.

SUMMARY

There is no doubt that the wide variety of pheromone peptides described above highlight their crucial role in many and varied behavioral patterns that are associated mostly, but not exclusively, with courtship and mating, or transfer of genetic material. Despite the vast amount of information that is already available to us, and the immense progress that was made in the past few years the study of pheromone peptides still requires further exploration, and it seems that we have only just begun to understand some of the languages of a few of the "inhabitants" of this fascinating world. As our studies advance along the evolutionary tree we find that the chemical cues responsible for mating become more and more complex, and it is reasonable to assume that social and sexual behavior in vertebrates is too complicated to be controlled solely by the few components or mechanisms so far identified, and that it requires the integration of multiple sensory cues within the neural network of the brain, all of which are still to be explored. Further, comparison among the peptide or protein pheromones that are used for sociosexual communication by the various species reveals no homology, which suggests that each peptide has undergone an independent molecular evolutionary process, and hints at the possibility that there are many more novel peptide pheromones, associated with many and varied species, that need to be discovered in the future. Understanding of the interplay between behavioral and biochemical factors in the deposition and reception of scents, identification of key signal molecules and elucidation of their chemical nature, and exploitation of their modes of action and regulation in donor and recipient organisms present a challenge that is currently being evaluated in depth, and, as peptide signaling systems continue to be discovered, there is a growing need to understand the details of these communication mechanisms.

In light of current knowledge, it is already obvious that pheromones of a peptidic nature play an important role in species-specific communication, either directly or via neural processing of the olfactory signal. Their high solubility, specificity, and variability, which are achieved through the existence of multiple genes encoding for peptide variants, ensure their highly efficient pheromonal activity. The currently available novel biochemical, molecular and chemical analytical methods and approaches will enable us further to identify new peptide pheromones, to study their biosynthetic pathways, to dissect their sequences of behavioral events, and to study their mechanisms of action in the donors and recipients at the cellular and molecular levels. It is anticipated that such studies will widen our understanding of the extraordinary diversity that surrounds us, and will stimulate further studies that may lead to the unraveling of the chemical signaling mediated by peptides, and thereby lead to practical applications, such as development of new therapies against bacterial infections or of behavior-modifying compounds for agrochemical, aquacultural, and medical applications.

Chapter 259

Prebiotic Peptides

Bernd M. Rode and Kristof Plankensteiner

ABSTRACT

Based on modern geochemistry view of the atmospheric and geological conditions on the primordial earth ~3.8–4 billion years ago, the most realistic scenario for the formation of amino acids and peptides in chemical evolution is discussed, including possible reasons for sequence preferences in early proteins and for biohomochirality. Arguments for a "peptide/protein world" as primary origin of life, preceding RNA/DNA-based evolution, are presented.

INTRODUCTION

Looking at the astonishing variety and complexity of peptides and proteins in today's living organisms, the question about their origin and subsequent evolution is one of the most fundamental ones for chemists and biologists. Providing the pathways to these compounds long before life in its modern form developed, chemical evolution has become a most challenging research topic after Oparin's hypothesis[23] of a "primordial soup," containing numerous organic compounds synthesized by nature under the conditions of the primitive earth some 3.8 billion years ago, when the earth had cooled down sufficiently to allow the existence of liquid water. As the key role of peptides for the origin of life[21,23] is increasingly better understood, the question of how amino acids and their first polymers came into being became crucial. Was the formation of the first prebiotic peptides a matter of chance with arbitrary results, or did chemistry and the given scenario point the way to specific, almost compulsory syntheses? The main difficulty of "prebiotic research" is our limited knowledge about this scenario, i.e. the conditions prevailing on the primitive earth. Fifty years ago, these conditions were, in the literal sense, still mostly "*terra incognita*," but since then, specific and interdisciplinary research in physics, chemistry, and earth sciences has widely improved our knowledge.

With this knowledge, it has become possible to achieve quite trustworthy reconstructions of the processes forming amino acids and subsequently linking them to peptides, almost ubiquitously and within a relatively wide variation of environmental conditions. As we cannot get any direct access to remnants of that time, the only chance to obtain conclusive results is the attempt to experimentally "repeat" the evolutionary processes under laboratory conditions mimicking the primordial scenario. Any of these experiments can be scrutinized, therefore, by challenging the availability of necessary components, environmental conditions and stability of products in the most likely scenario predicted by geochemical sciences for the primitive earth.

THE PRIMITIVE EARTH SCENARIO

According to present geochemical knowledge, Terra should have cooled down below the boiling point of water about 4 billion years ago, forming the first stable hydrosphere in its history. At that time, because of the weak gravitational field, the earth had already lost its primary atmosphere of hydrogen and helium, and a secondary atmosphere was formed by gases of volcanic origin,[9,13,14,18,19,23,28] which were stable enough to withstand the constant UV radiation of the sun and thus mainly consisted of CO_2, N_2, and water vapor, with smaller amounts of SO_2, possibly also some CO and H_2S and traces of noble gases.[12,23,30] Even certain amounts of oxygen, formed by decomposition of CO_2 and water, should have been present.[3,8,11,23,28,29] Because of the high temperature, weather phenomena such as thunderstorms and rain must have been much more violent than today. For the same reason, evaporation and recondensation in coastal regions of the primitive ocean and lakes must have been common and frequent processes. Many minerals—partly still identifiable in precambrian rocks—could have served as reactants and catalysts for chemical reaction, together with inorganic salts dissolved in the sea and lakes, where they could reach considerable concentrations.

THE FORMATION OF AMINO ACIDS

In 1953, Stanley Miller initiated the quickly expanding field of experimental simulations of prebiotic chemistry by his famous experiment investigating the possible formation of organic molecules in an assumed primitive atmosphere consisting of methane, hydrogen, ammonia, and water, under

the influence of electric discharges.[23] Soon some amino acids were identified among the products. However, after it had been realized that this reducing atmosphere could not have existed on the primordial earth, the experiment had to be repeated varying atmospheric composition and sources of energy.[6,20,23] It was shown only more recently[21,23] that amino acids can readily be formed in a neutral or even mildly oxidizing atmosphere of the type previously outlined as the most probable geochemical scenario of the primitive earth. Up to now numerous amino acids, such as Gly, Val, Ala, Ser, Pro, His, and Lys have been identified as products,[23] and the fragments found by means of Proton Transfer Reaction Mass Spectroscopy in the plasma of the artificial "lightning" in these experiments[22] point at a variety of synthetic pathways to these and other types of precursor molecules of today's biochemistry.

THE FORMATION OF PEPTIDES

As the synthesis of a variety of amino acids on the primitive earth thus seems to have been an easy and common process, the subsequent major evolution problem is the synthesis of peptides from these amino acids in aqueous solution. To form a peptide bond, water has to be removed, which makes the process thermodynamically very unfavorable. A second problem for peptide synthesis in water is the kinetic barrier, because amino acids are rather unreactive concerning a nucleophilic substitution by an amino nitrogen at the carbonyl carbon. Therefore, the reaction partners would have to be activated somehow to lower the activation energy of the reaction.[23]

When prebiotic chemistry research aimed at the formation of peptides, the main concern, therefore, was to find ways to overcome both thermodynamic and kinetic obstacles. Evaporation of water, condensation reagents, and catalysts were the main tracks along which solutions were searched. Fox and Harada proposed melts of dried amino acids to form peptides.[8,21,23] At the melting temperatures of amino acid mixtures, all formed water evaporates and is thus removed from the reaction. However, a large excess of acidic and/or basic amino acids is necessary to allow polymerization and to avoid decomposition. As these amino acids are rarely synthesized in atmospheric processes and the temperature range between melting and decomposition is very narrow, the prebiotic feasibility of this reaction seems highly questionable. Further, a more thorough analysis of the resulting polymers (initially termed "proteinoids") showed that they are polymers that only occasionally contained peptide bonds.[23]

Another approach to prebiotic peptide formation was the use of condensation agents to facilitate the reactions between amino acids.[21,23] Substances used in these experiments included cyanamides, cyanates, trimetaphosphate, ATP, GTP, CTP, UTP, linear and cyclic inorganic polyphosphates, and imidazoles, all of which must have been rather scarce or unstable in a primordial earth setting, because of rapid hydrolytic decomposition and/or precipitation as insoluble salts. There is, therefore, only a very minor probability that these types of peptide synthesis have contributed to chemical evolution.

Under assumed hydrothermal vent conditions,[23] amino acids can also condense to peptides, but this scenario would be restricted to specific locations in the deep sea and especially high partial pressures of carbon monoxide, and thus its relevance for large-scale prebiotic peptide formation is rather questionable.

A further possibility is peptide formation on the surface of minerals like clays, silica, or alumina.[21,23] In principle, it is possible to form peptides from adsorbed amino acids, but the yields are very low and the applicability apparently restricted to very few amino acids such as Gly and Ala. However, these adsorption processes are of great importance for prebiotic peptide formation since peptides formed in other processes can be protected from decomposition[1] on the surface of such minerals, and further, short peptides can be elongated to longer chains by this mechanism.[21,23] For example, the Salt-induced peptide formation (SIPF) reaction[23] discussed in detail below, which efficiently forms peptides, perfectly harmonizes with clay catalyzed peptide elongation in a one-pot reaction.[21,23]

This SIPF reaction is a special case among the many proposals for peptide formation under primordial earth conditions.[23] It allows for peptide formation in aqueous solution directly from amino acids or amino acids and short peptides, as long as sodium chloride, Cu(II) ions, and thermal energy are available. Sodium chloride has always been ubiquitously present[9,23] in the oceans, in salt lakes, and in lagoons and puddles along the sea shore. In concentrations >3 M that can be reached either in large volume salt lakes or lagoons (simulated by the constant volume type[21,23] of SIPF reaction with constantly high sodium chloride concentrations) or in evaporating small puddles and small lagoons (simulated by evaporation cycle experiments[21,23] where the active concentration is reached by evaporation and subsequent redilution), sodium ions do not have a saturated first hydration shell and can, therefore, act as a dehydrating agent to overcome the thermodynamical barrier of peptide formation in aqueous solution.[23] Computational investigations of sodium chloride solutions,[21,23] showing this effect in detail, were the basis for the discovery of the SIPF reaction. Subsequent simulations and experiments showed that complexation of amino acids to metal ions, in particular to Cu(II),[23] can activate them and thus lower the activation energy for the peptide formation process. As precambrian rock formations contain large amounts of Cu(II)-containing minerals,[17,23] the availability of these ions on the primitive earth seems secured,

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

and the proper oxidation state could have been reached easily under the assumed atmospheric conditions.[23] Since the late 1980s the SIPF reaction has been and still is being investigated in many areas,[21,23] continuously revealing new favorable aspects and proving its very general applicability for prebiotic peptide formation under the conditions of the primordial earth scenario outlined above.[21]

The ideal temperature for the SIPF reaction is between 60 and 90 °C,[21,23] a very realistic condition for recently condensed oceans on the cooling surface of the earth. The reaction prefers the biologically relevant α-amino acids compared with amino acids containing a more distant amino group.[21,23] Amino acids such as glycine and histidine and also small linear or cyclic peptides like diglycine and diketopiperazine show a yield-increasing catalytic effect in the reaction,[21,23] which can produce peptides even with otherwise almost nonreactive amino acids, thus resulting in peptide formation with all amino acids investigated so far. The catalytic mechanism[23] apparently involves intermediary formation of a peptide with the catalyst, followed by condensation with another educt amino acid and the release of the catalyst by hydrolysis to the product peptide and the catalyst.

Quite striking evidence for the prebiotic relevance of the SIPF reaction resulted from a comparison of the specific dipeptide yields of the reaction to the frequency of the respective peptide linkages in membrane proteins of archaea and procaryonta, some of the oldest still existing organisms on earth: a correlation of the preferred sequences was observed that could hardly have occurred only by chance,[21,23] indicating an evolutionary pathway from the SIPF process to the proteins of the first living organisms. It is interesting that the (in)famous protein-like prions show an even higher degree of similarity with the most preferred SIPF sequences (Gly-Gly > Gly-Leu > Ala-Ala > Ala-Gly > Ala-Val > Pro-Pro > Pro-Gly > Val-Val > Gly-Ala > Val-Gly > Leu-Gly > His-Gly > Leu-Leu > Val-Ala > Gly-His > Val-Lys > Lys-Val), in particular the characteristic dominance of the Gly-Gly linkage, thus indicating an origin of the prions at a very early stage of evolution.[24]

As mentioned previously, the oligopeptides formed in the SIPF reaction could have been stabilized and elongated to longer chains with the help of clay minerals such as montmorillonite or hectorite in the same environment.[21,23] Thus the role of clay minerals in peptide evolution could have been a quite significant one, not so much for the primary formation of peptides from amino acids, but for the further development of larger and more complex peptides and for their "survival" against hydrolytic attack.

Another quite important feature of the SIPF reaction refers to chirality-related aspects; during the reaction, optical purity of the amino acids is almost fully conserved,[21,23]

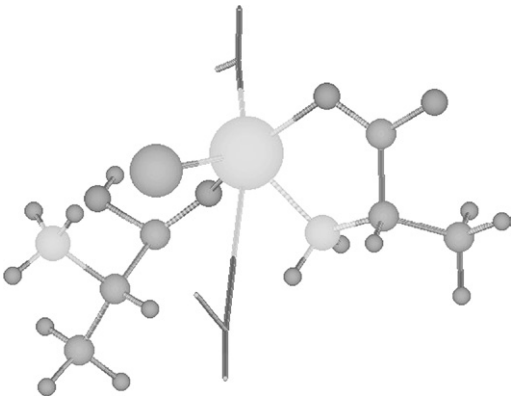

FIGURE 1 Ab initio geometry optimized structure of the tetrahedrally distorted SIPF complex $[CuCl(alaH_2)(H_2O)_2]^+$.[21,23]

especially at low concentrations as would be expected in a very dilute prebiotic "soup." This preservation of chirality, albeit quite important, is not the only characteristic of the reaction with respect to optical activity. The active complex in the SIPF reaction[21,23] is a copper(II) complex with one amino acid coordinated as a chelate, another amino acid or oligopeptide bound end-on via its carboxylic group, a chloride ion, and two water molecules at elongated distance (Fig. 1).

Quantum chemical calculations have predicted a pseudotetrahedral arrangement of the amino acid and chloride ligands,[21] thus leading to a central chirality at the Cu(II) ion that seems to amplify the small inherent chirality of copper due to the parity violating effect, which because of its Z^5 to Z^6-dependence (Z being the atomic number), is considerably larger than in organic compounds. This chirality effect can lead in some cases, especially with simple aliphatic amino acids such as Ala and Val, to a preference of L-amino acids over D-amino acids in the SIPF reaction[4,21,23] and might be, together with yet unknown amplification mechanisms, a basis for the processes having led to the phenomenon of biohomochirality. Yield differences according to the chirality of the educt amino acids, differences in the complex formation constants of L- and D-alanine, and CD spectroscopy have supplied independent indications toward this particular stereoselectivity in the SIPF reaction in favor of L-amino acids.[4,23]

A 'PEPTIDE WORLD' AS THE ORIGIN OF LIFE?

Any discussion on the "origin" of life naturally involves a definition of a "living system." It has become a kind of convention to characterize "life" by the essential properties metabolism, replication, propagation of information, and the possibility of mutation, allowing evolution to adapted

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

and more complex forms. Although a kind of metabolism can be assigned to many chemical systems, the other characteristics can be achieved according to our contemporary chemical knowledge by two types of "biomolecules" only, namely, peptides/proteins and nucleic acids, which are the key players in all of today's living organisms. Nucleic acids are the "modern" information carrying molecules and replicators, but peptides and proteins could have preceded them in that task, as peptides can also work as carriers of information and can replicate,[23] albeit not as efficiently as nucleic acids. Under the harsh conditions of the primordial earth, however, evolution of life-like processes based on peptides would have had many favorable aspects. Besides various problems with the formation of nucleic acids under primordial earth conditions[5,7,26] the first argument to support this statement is the chemical and physical (in)stability of nucleic acids; in a hot salty ocean, irradiated by the UV light of the sun, nucleic acids, and their building blocks decompose very rapidly[10,16,23,27] and thus would not have had time to pass on their information and to chemically evolve. Peptides, however, could be formed much more efficiently[21,23] and, once formed, would be much more stable[2,15,23] and well protected from UV damage by dissolved ions and other organic molecules in the prebiotic "soup" that absorbed a great part of UV radiation in the wavelength region below 220 nm that would have been harmful to them.[23] Further, peptides are far less prone to errors caused by mutations, since their informational content and their functionality are less harmed by an exchange of amino acids in the sequence. For example, a hydrophobic amino acid would mainly be replaced by another hydrophobic amino acid, which in most cases would not have a strong influence on the characteristics of the peptide, while the replacement of one or several nucleobases by another of the four possibilities can have dramatic effects, even leading to a total loss of function. Without the help of sophisticated enzymatic repair mechanisms (which demands the existence of sophisticated proteins!) nucleic acid evolution would quickly reach a dead end. Peptides can deal with many more errors by themselves. Based on information theory, Freeman Dyson's model of chemical evolution[23] has predicted that, given the low autocatalytic efficiency of the first prebiomolecules, four basic building blocks, as in the case of nucleic acids, would be too few to reach a state where the development of autocatalytic biochemical cycles would be possible; at least 8–10 would be required. This figure is realistic for early peptides, even considering a still limited number of amino acids formed during prebiotic chemical evolution. Finally, follow-up investigations on Eigen's RNA hypercycles[23] quickly showed through computational simulations[23] that such cycles would quickly be terminated by various catastrophic conditions, thus not providing a possible development of living systems.

Therefore, an initial "Peptide/Protein World,"[21] as opposed to an "RNA World" scenario, seems a much more probable starting point on the way to life on earth. Amino acids and peptides would have been formed first and then have chemically evolved to assume the function of primary information carriers and replicators. Nucleic acids could probably only have been synthesized and have chemically evolved after some kind of protection against environmental influences had become available, most probably in the form of peptide/protein membranes or shells.[25] Inside this protected environment, further evolution of the nucleic acids to nucleosides and nucleotides and the necessary enzymatic repair mechanisms could take place, passing over the functions of the first peptides and proteins to RNA and DNA and ultimately leading to the genetic apparatus of today's organisms. This later involvement of RNA/DNA in evolution has actually been anticipated by numerous scientists in the past 3 decades,[21,23] but only the recent development in peptide research has shown a plausible and more convincing alternative for the evolution of life on our planet.

Chapter 260

Viral Fusion Peptides

Avraham Ashkenazi and Yechiel Shai

ABSTRACT

A viral fusion peptide is a segment of a viral fusion protein partly responsible for the ability of the protein to induce virus–cell membrane fusion. Despite its importance, there is no precise definition for a fusion peptide. Generally, it is hydrophobic, rich in Gly and Ala residues, and located at the N-terminus of the fusion protein. Studies using synthetic fusion peptide reveal that it binds and inserts into membranes, disrupts membranes, induces vesicle aggregation, creates pores, and mixes lipids between various populations of vesicles. Importantly, synthetic fusion peptides inhibit virus–cell fusion possibly because of their interaction with the native fusion peptide. Emerging studies on distal virus families suggest that this segment is not the sole factor in promoting fusion. Other regions within the fusion protein synergize with the fusion peptide to induce fusion, thus drawing a more complex picture for the mechanism of virus–cell membrane fusion.

INTRODUCTION

Mechanism of Membrane Fusion

Membrane fusion is a fundamental event that is critical to many biological systems such as entry of enveloped viruses to their host cells, intracellular vesicle fusion, and cell-to-cell fusion in fertilization and development. These processes are mediated by many transmembrane proteins that remarkably share similar motifs.[6,27,30]

The fusion of two stable biological membrane bilayers into one is a complex event that requires physical forces. In many biological systems, membrane merger can be divided into two steps: the formation of a hemifusion intermediate and the fusion pore.[13,30] Both steps are governed by the membrane lipids and proteins. First, the contacting "cis" monolayer leaflets are merged, but the "trans" distal leaflets remain intact. The structures of these intermediates are often called the ''stalks'' that further progress to form a hemifusion diaphragm. At this stage, lipid mixing occurs only between the cis monolayer leaflets with no content mixing. The hemifusion state is a key step because a productive fusion requires transformation of the hemifusion intermediate into an expanding fusion pore. Posthemifusion is the rate-limiting step of the fusion reaction, and theoretical analysis confirms that fusion pore expansion is more energetically demanding than hemifusion.[5] Overcoming the energy barriers is related to the membrane lipids and proteins that effect the tensions and stresses of the membranes by mechanisms that are not yet fully understood.[10]

Viral Membrane Fusion

A basic phenotypic distinction for animal viruses is whether or not they are sheathed in a membrane envelope. Progeny envelope viruses acquire a cell-derived membrane following budding from infected cells.[29,30] As expected, these membranes are enriched in viral fusion proteins, which are virally encoded. It is these fusion proteins that are responsible for carrying out the task of merging the viral envelope with the target cell plasma membrane to transfer the genome-containing nucleocapsid into the host cytosol. Viral fusion proteins can be further categorized into two classes, I and II. Signature features of class I fusion proteins include (i) trimeric organization in a metastable state on the virion surface, which is retained while folding to a more stable conformation during fusion, (ii) predominantly α-helical six-helix bundle (SHB) low-energy conformation with hallmark internal trimeric parallel coiled coil, (iii) membrane active fusion peptide usually located at the N-terminus, and buried in the trimer interface in the metastable state.[1,3,4,9,31] Examples include Influenza, Parainfluenza, HIV, SIV, Ebola, SARS, Measles, and Sendai.

Class II fusion proteins have a somewhat different organization, with the following key features: (i) dimeric organization in the metastable state, which reassembles to a low-energy trimer during fusion, (ii) predominantly β-sheet structural organization of both dimeric and trimeric states, (iii) an internal loop fusion peptide, which is sequestered in the metastable dimer. Enveloped viruses characterized as class II, based on their fusion protein, include Tick-Borne Encephalitis, Dengue, and Semliki Forest viruses. Despite their obvious structural differences, it is evident that both Class I and II viruses share a similar fusion mechanism based on target membrane insertion of the hydrophobic

fusion peptide, followed by refolding of the fusion protein to a low-energy conformation which directs fusion.[6]

Structural Organization of Class I Fusion Proteins

The essential commonality is the mechanism by which the transmembrane (TM) subunit directs membrane merger via a set of conformational changes. It is precisely at this level that Influenza sets the stage for our mechanistic understanding of Class I viral fusion, based on both precedent and the fact that there is a more complete set of high-resolution structures of its fusion protein in different conformations associated with different stages of fusion.[5,6] However, although high-resolution structures of fusion proteins serve as the basis for models describing viral fusion, these structures are of soluble fragments in solution environments. The most interesting information lies at the membrane–protein–water interface, an environment that is technically challenging to reproduce, especially for studies at the atomic level.

Being a single pass TM protein, the Class I fusion protein consists of Ecto-, TM-, and Endo-domains. Widely held models identify the ectodomains as being primarily responsible for fusion based on both conformational changes as well as direct membrane interactions.[4,6] For many Class I fusion proteins, the ectodomain is organized in a conserved manner (Fig. 1). The membrane active and hydrophobic fusion peptide is located at the N-terminus and is abutted by a N-terminal heptad repeat (NHR). A loop region separates the NHR from a C-terminal heptad repeat (CHR), which sits adjacent to the TM domain. Remarkably, different Class I fusion proteins, with decidedly different sequences, fold into a conserved low-energy SHB conformation through their cognate NHR and CHR regions. These SHB's are characterized by three NHR regions forming a parallel trimeric coiled coil, with three cognate α-helical CHR regions packing against the coiled coil in an antiparallel manner (Fig. 2C). Their highly helical character is a hallmark of Class I fusion proteins, and the low-energy SHB conformation is believed to represent a final, end-state fusion conformation. SHBs can form in solution from free cognate NHR and CHR peptides, and high-resolution crystal structures have been determined for Class I viral fusion proteins, including Influenza,[31] HIV-1,[3,28] SIV, Ebola, SARS, and Parainfluenza.

The Definition of Viral Fusion Peptides

There are many parameters that characterize fusion peptide segments from viral fusion proteins. There is no general rule that allows identification of a fusion peptide. Some of the following parameters can match one family of peptides and not the other. The fusion peptide is often hydrophobic, rich in Gly residues and located at the N-terminal end of the fusion protein. In some cases mutations in the fusion peptide region leads to loss of activity. Many viral fusion peptides adopt an α-helical structure when inserted into a

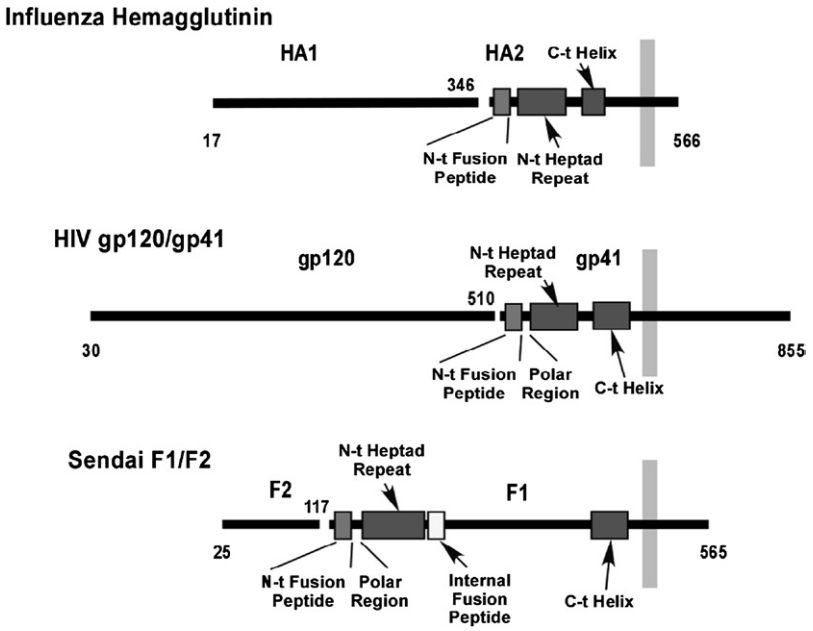

FIGURE 1 Schematic representation of the ectodomain organization of several class I fusion proteins: Influenza, HIV, and Sendai viruses. The boxes represent: the N-terminal fusion peptide; the N-terminal heptad repeat; and the C-terminal helix (heptad repeat). The bright vertical strip represents the viral envelope. In Sendai F1, the additional bright box represents the putative internal fusion peptide. Note that the residue numbers in the three proteins correspond to the mature polypeptides, after processing of the signal sequences.

membrane. The insertion is often at an oblique angle. Some of them favor a β-sheet in the membrane, and as for internal fusion peptides, they do not have stable secondary structures. A common property of a number of fusion peptides is that they lower the bilayer of phosphatidylethanolamine to hexagonal phase transition temperature, indicating that they promote negative curvature. This property is well correlated with conditions that lead to membrane fusion. Additionally, lowering membrane rupture tension is another important characteristic that is attributed to several fusion peptides. The fusion peptide does not function as an isolated unit, but is rather assembled into an organized complex in which several fusion peptide segments can act in a coordinated fashion. In addition, there are other regions of the fusion protein outside of the fusion peptide that can also participate in accelerating fusion.[10]

METHODS TO ANALYZE FUSION PEPTIDE STRUCTURE AND FUNCTION

Conformation of Fusion Peptides within the Membrane

A detailed X-ray or nuclear magnetic resonance (NMR) structure of a segment of the ectodomain of a viral fusion protein can be obtained as a crystal in the absence of membranes. In addition, NMR spectroscopy can be used to obtain the conformation of a small synthetic fusion peptide, either in the presence or absence of membranes. A general assessment of the secondary structure of a fusion peptide can be made using less specific spectroscopic techniques, based on the properties of the amide chromophores, such as circular dichroism (CD) or infrared spectroscopy. In addition to the secondary structure, polarized attenuated total

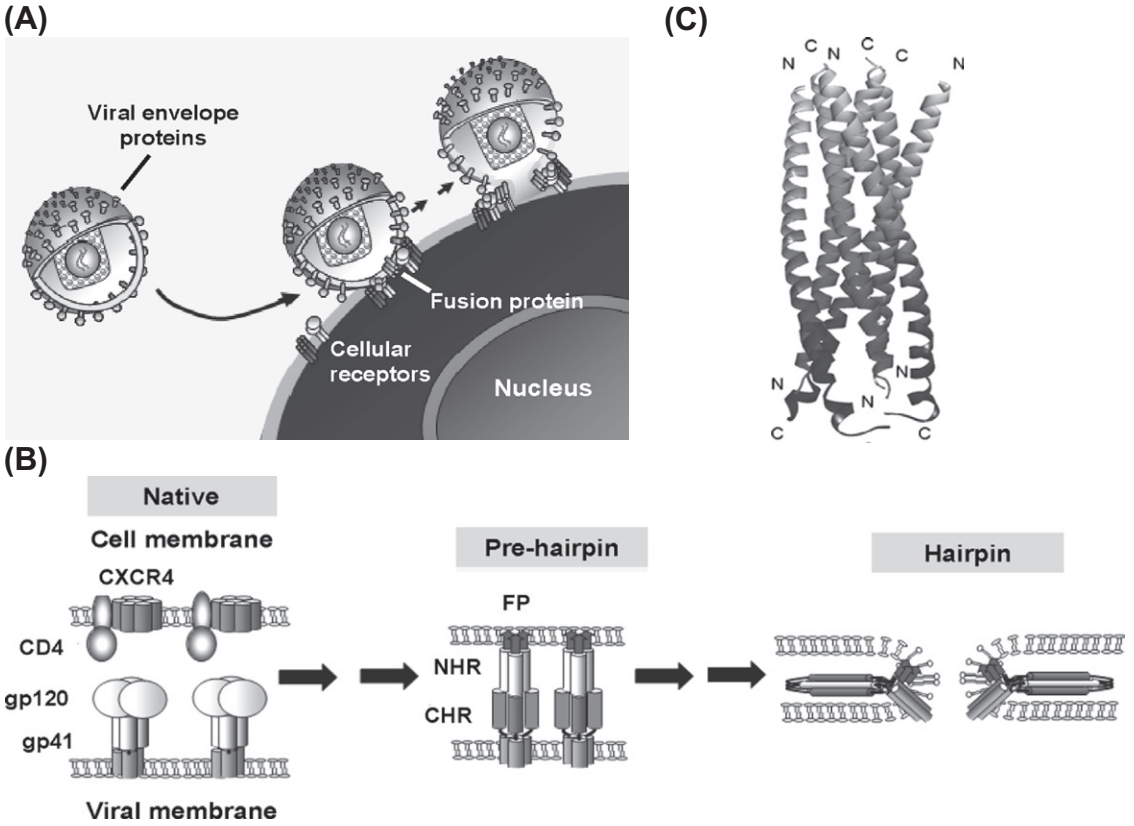

FIGURE 2 (A) Illustration of entry of an enveloped virus into its host cell. The first step in viral infection (e.g. HIV or Sendai) is fusion between the membranes of the virus and the host cell, leading to the insertion of the viral genetic material. The surface subunit of the envelope protein facilitates the interaction with cellular receptors. This interaction induces conformational changes that lead to the exposure of the transmembrane fusion protein. Additional conformations of the fusion protein subsequently lead to membrane fusion. (B) The proposed model of HIV fusion mediated by gp41, its transmembrane fusion protein. First, the envelope protein is in its metastable native state on the virion surface. In this state gp41 is considered to be sheltered by gp120. Second, binding of gp120 to CD4 and coreceptor (such as CXCR4) involves conformational changes in both gp120 and gp41 resulting in the prehairpin conformation. At this point, gp41 is exposed and extended leading to the insertion of the fusion peptide (FP) into the host cell membrane. Third, additional conformational changes generate the hairpin conformation. This conformation comprises a SHB that is created by three NHR regions into which three CHR regions pack in an antiparallel manner. (C) A side view of the recent hairpin structure of HIV-1 gp41[2] (PDB ID: 2x7r) comprising the trimeric inner coiled coil of the N-helices and the three packing C-helices. C, carboxyl terminus; N amino terminus. Note that the structure lacks the fusion peptide and the transmembrane domain.

reflectance Fourier transform infrared spectroscopy (ATR-FTIR) can be used to determine the orientation of a helical peptide in a membrane.[14,25]

Functional Role of a Fusion Peptide in Membrane Fusion

Mutations in the Fusion Protein and Hydrophobic Affinity

Various experimental approaches have been used to study the functional role of fusion peptides in the membrane fusion process. For example, the interaction between fusion proteins and membranes has been studied using hydrophobic photoaffinity labeling. This technique was used to show that the fusion peptide of Influenza hemagglutinin (HA) penetrates deeply into the target membrane. Mutational studies reveal that substitution of critical residues in fusion peptides of, for example, Influenza HA, SIV gp32, HIV gp41,[12] and VSV G protein, abolish membrane fusion. Nevertheless, in addition to the local effects on the fusion peptide, single mutations may sometimes affect the overall folding of the fusion protein and thus make the analysis difficult.

Using Synthetic Fusion Peptides

Because membrane fusion is a complex process and involves a wide range of biochemical and biophysical interactions, it is difficult to address the specific role of fusion peptides in the context of the full-length envelope proteins. In an attempt to overcome this, researchers have studied the interactions between liposomes or cells and synthetic peptides, corresponding to regions of the intact protein. The relevance of this approach was demonstrated by (i) effects of mutations in synthetic peptides, corresponding to segments of the fusion protein, are mostly similar to those in the full-length protein,[12,17–19,23] and (ii) factors, such as pH or the addition of inhibitory agents, which affect the infectivity of the virus *in vivo*, also affect the activity of the synthetic peptides *in vitro*.

Measurement of the interactions between synthetic fusion peptides and the membrane is commonly achieved by fluorescent studies. For example, (i) the binding affinity constant of a fusion peptide to a membrane with specific lipid composition is calculated from a titration curve of liposomes to a solution of peptide, labeled with a fluorescent probe which is known to be quenched inside the membrane (such as NBD), and (ii) the lipid mixing activity of a fusion peptide is often determined by introducing the peptide to a solution which comprises two populations of liposomes: the first one is fluorescently labeled with two probes that are quenched in close proximity (such as rhodamine and NBD), and the second one is unlabeled liposomes at 10-fold higher concentration. The induction of lipid mixing by the peptide would induce fusion between the unlabeled and labeled liposome populations, leading to dequenching of the fluorescent signal.

The use of peptidic fragments from a membrane protein that interfere with its function is an emerging approach for understanding protein function. Synthetic fusion peptides in some cases inhibit viral fusion, and models have been suggested to describe where they interact with the fusion protein and at which stage during the fusion event.[9,17]

FUSION PEPTIDES IN RETROVIRUSES

HIV-Mediated Membrane Fusion

Human immunodeficiency virus (HIV) is the most known membrane enveloped retrovirus, which mainly infects cells from the immune system: T-cells and macrophages. It is the cause of acquired immunodeficiency syndrome (AIDS). The first step in HIV infection is fusion between the membranes of the virus and the host cell, leading to the insertion of the viral genetic material into the cytoplasm (Fig. 2A). After reverse transcription, the viral cDNA is integrated into the chromosomes of the cell. The membrane fusion step is mediated by the viral envelope glycoprotein. Like other class I fusion proteins, the HIV envelope protein adopts trimeric organization on the viral surface. It consists of two noncovalently associated subunits (Fig. 1): The gp120 subunit enables cell receptors and coreceptors binding, whereas the gp41 TM subunit endows the physical membrane fusion.[13]

The model of HIV membrane fusion asserts the conversion between at least three major envelope protein conformations (Fig. 2B). First, the envelope is in its metastable native state on the virion surface.[9] In this state, gp41 is considered to be sheltered by gp120. Second, binding of gp120 to CD4 and a coreceptor (such as CXCR4 and CCR5) involves conformational changes in both gp120 and gp41 resulting in the prehairpin conformation.[9,11] At this point, gp41 is exposed and extended leading to the insertion of the fusion peptide into the host cell membrane.[10] Third, additional conformational changes generate the hairpin conformation.[6,13] This conformation comprises a trimeric central coiled coil that is created by three NHR regions, into which three CHR regions pack in an antiparallel manner (Fig. 2C). This structure is usually referred to as the SHB or "core" structure, and it is suggested to be essential for complete membrane merger and pore formation.

The HIV Fusion Peptide

Functional Role

The assumptions that the fusion peptide serves as a membrane anchor, whereas folding between NHR and CHR regions draws together the virion and cell are straightforward

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

enough. Yet, they fail to describe how fusion occurs. This brings us to an interesting though little understood aspect of the gp41 fusion protein; its ability to directly destabilize membranes. The tendency for peptides or regions of a protein to bind or otherwise interact with membranes is based on their regions of hydrophobicity.[32] Early on, the fusion peptide was believed to be membrane active based on high hydrophobocity in its 16 N-terminal residues.[30] In addition, the heptad repeats with leucine/isoleucine zippers, which create amphipathic helices, were also purported to be membrane active through their hydrophobic interfaces.[25] Although HIV undergoes extensive mutation because of the low fidelity of its polymerase and rapid turnover, the sequences comprising the hydrophobic fusion peptide and the hydrophobic leucine zipper residues involved in both coiled coil and SHB formation are highly conserved.[8] Indeed, studies with free peptide fragments reveal that the fusion peptide binds and inserts into membranes and disrupts membrane vesicles.[17,24,33] In addition, it disrupts membranes causing vesicle aggregation, pore formation, mixing of lipids between populations of vesicles, as well as vesicle fusion.[7,17,19,20,24,33,34]

A polar amino acid substitution at position 2 of the fusion peptide of HIV-1 gp41 (V2E) results in an envelope glycoprotein that dominantly interferes infection mediated by the wild-type HIV-1 envelope glycoprotein. This mutant elicits a dominant interfering effect even in the presence of excess wild-type glycoprotein, which suggests that a higher order envelope glycoprotein complex is involved in membrane fusion.[12] The fusogenic properties of the intact gp41 and its V2E mutant could be further modeled with synthetic peptides. This synthetic peptide model was used to explore the mechanism in which the V2E mutant interferes with the fusion peptide activity. The dominant form of both peptides is a dimer but the wild-type peptide also forms higher order oligomers. The inability of the V2E mutant to form higher order oligomers may be correlated with its loss of activity. Further, the coassembly of the two peptides in their membrane-bound state suggests that the inhibition of membrane fusion exhibited by the V2E mutant occurs via its association with the wild type. This inhibition may occur either because the V2E mutant decreases the portion of higher order oligomers of wild type or because the V2E mutant forms nonfunctional higher order oligomers with the wild-type peptide. Because the V2E mutant gp41 elicits a dominant interfering effect even in the presence of excess wild-type glycoprotein, the second possibility is a more probable mechanism.[17]

Structural Dilemma

Despite more than a decade of effort put in by many research groups, the structural organization of the HIV fusion peptide region remains debated. Class I fusion peptides are somewhat loosely defined, but it is generally accepted that they include the following traits: (i) high hydrophobicity, (ii) membrane interacting; free fragments disrupt model membranes, (iii) N-terminus of fusion protein, (iv) rich in Ala and Gly residues, and (v) conserved sequences with mutations leading to loss of function.[10,29] For HIV, the N-terminal 16 residues fit these criteria. The HIV fusion protein, gp41, is expressed along with the gp120 surface subunit as the gp160 precursor, which is posttranslationally cleaved to generate the free gp41 N-terminus. This free N-terminus is probably immediately sequestered at the gp41 trimer interface as in Influenza.[31] Hence, the membrane disrupting fusion peptide region is held like an attack dog on a leash, away from membranes until specific activation and release. Toxicity is directly linked to the fusion peptide at the free, exposed N-terminus, and probably results from membrane disruption effects on expressing cells. Given the absence of biophysical data describing the fusion peptide in context of gp41, a wealth of results exists concerning fusion peptide fragments amenable to chemical synthesis. It must be kept in mind that when using such a reductionist approach to study a specific region of a protein, the probability of artifact increases. From the outset, and continuing until the present, structural characterization of free fusion peptide fragments in membrane and membrane-mimetic environments shows that the fusion peptide is structurally plastic. Inherent structural plasticity in the fusion peptide may result from enrichment in Gly and Ala residues. Reports of predominantly α-helical conformation[15,18] contend with those of those predominantly β-sheet structure,[20,24,33] and share space in the database with reports of helical or β-structure, which is dependent on environment. Caution must be exercised on extrapolation to *in vivo* structure in function because these studies are of fragments representing specifically the fusion peptide.

During the different stages of fusion, the fusion peptide is expected to interact with the gp41/gp120 trimer in the metastable state,[31] probably is solvent exposed at least briefly after triggering or activation, and then is expected to interact with and insert into the target cell membrane.[30] The fusion proteins of Influenza and Sendai have been crystallized in both their metastable[31] and fusion active (SHB) conformations,[35] with their N-terminal regions included for both. In each case, the fusion peptide is a helical extension of the helical coiled coil NHR in the fusion active conformation.[35] However, because crystallization and data acquisition conditions lack the presence of a membrane or otherwise membrane-mimetic environment, the α-helical fusion peptide conformation in both cases may represent a transient solvent exposed interaction. All current high-resolution structures of the HIV fusion protein lack the fusion peptide region.[3,28] A clear understanding of the structure of the HIV fusion peptide, in the context of its gp41 fusion protein in both solution and a membrane environment, promises to illuminate the poorly understood process of membrane merger directed by gp41. If the HIV fusion

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

peptide is helical, is it continuous with the adjacent NHR? If it is β-structured, what is the organization and how does this transition to the parallel trimeric coiled coil NHR? The structural analysis and membrane activity of the N-terminal fusion peptide in context with its adjacent coiled coil provided insights into these questions.[25] The results suggest that the HIV fusion peptide structure differs from that of Influenza and Parainfluenza in the fusion active conformation. A β-structured fusion peptide may be unique to HIV as a Class I fusion protein.

FUSION PEPTIDES IN PARAMYXOVIRUSES

Paramyxoviruses-Mediated Membrane Fusion

The family of paramyxoviruses includes the causing agents of several common childhood diseases, such as mumps, measles, and respiratory infections, as well as more serious pathogens that attack the central nervous system. One of the two common envelope proteins, named HN, N, or G, depending on the genus, plays the role of "docking" during the fusion process, most commonly by binding to sialic acid-containing receptors in the target cell.[1,22] F, the other protein common to all paramyxoviruses, is responsible for mediating the actual membrane fusion step. After protease activation, F is formed by two disulfide-linked subunits, F1 (the TM subunit) and F2, the surface (SU) subunit. Binding of HN to the cell receptors has been postulated to trigger a conformational change in F1–F2 that starts the fusion process.[16] The way in which HN modifies F1–F2 conformation is still not clearly known, although it has been proposed to involve direct contacts between both proteins. Indeed, HN interacts with F1–F2, either in the endoplasmic reticulum or on the surface of infected cells.[1,16]

As in other class I fusion proteins (and as described above for HIV gp41), the F1 subunit contains two heptad repeat regions, one (named NHR) is located close to the N-terminal fusion peptide, whereas the other (named CHR) precedes the TM domain (Fig. 1). Also common to other class I fusion proteins, peptides derived from the NHR and CHR regions form a stable complex in solution, in which three NHR peptides fold into an internal trimeric coiled coil, surrounded by three CHR helices, a structure presumably formed at a late stage during the fusion process.[4,22]

Paramyxovirus F1 Protein Has Two Fusion Peptides

The fusion peptide located at the N-terminus of F1 was initially believed to be solely responsible for the actual merging of the viral and cell membranes. However, it is unlikely that the whole membrane fusion process is mediated by such a short segment in a protein consisting of >560 residues. Additionally, it has been shown in Influenza virus, HIV-1 and Sendai virus that regions other than the N-terminal fusion peptide bind to membranes, suggesting that these regions have possible roles during the fusion process. Accordingly, screening of the Sendai F1 ectodomain for regions homologous to previously known fusion peptides renders, in addition to F1 N-terminus, a segment (corresponding to amino acids 214–226) that is strikingly similar to HIV-1 and Respiratory Syncytial virus (RSV) fusion peptides (Fig. 3). Experimental evidence for the participation of this internal region in Sendai virus cell entry comes from protein dissection studies in which short peptides encompassing this region induce membrane fusion of large unilamellar vesicles.[14,21] Elongation of the peptide results in higher fusion activity, strongly supporting a similar role for this sequence in the full-length protein. Further, the peptides are potent inhibitors of Sendai virus infection of red blood cells, presumably by blocking conformational changes in the F protein. Interestingly, mutations that abolish this inhibitory activity also reduce the ability of the peptides to induce fusion of vesicles. Further, peptides from the same region of the Measles virus F1 protein behave similarly, despite having low-sequence similarity at their C-terminus, a region poorly conserved among paramyxovirus F proteins.[26] This suggests that the presence of two fusogenic regions might be a general feature of paramyxovirus F proteins.[22,26]

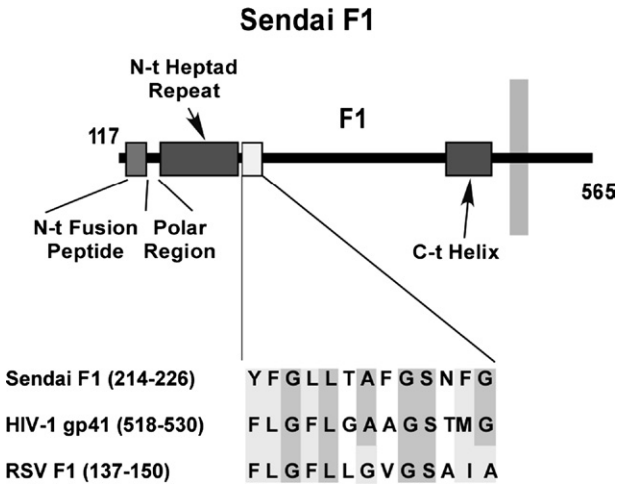

FIGURE 3 Schematic representation of Sendai F1 protein indicating the region that corresponds to the putative internal fusion peptide. As observed, this segment is highly similar to the N-terminal fusion peptides of HIV-1 gp41 (a retroviral protein) and Respiratory Syncytial virus (RSV) F1 (a paramyxoviral protein).

CONCLUSIONS AND PROSPECTS

A major segment within the fusion protein, which is important to its function, is the fusion peptide. The assumptions that the fusion peptide serves as a membrane anchor,

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

whereas folding between NHR and CHR regions draws together the virion and cell membranes, are too simple to describe how fusion occurs.

Early studies predicted that a coiled coil structure adjacent to the N-terminal fusion peptide is a common theme in viral fusion protein architecture. The fusogenic interplay between these two subdomains is consistent among different viral families. The HA2 and F-protein subunits of Influenza and Sendai virus fusion proteins, respectively, function similarly to the gp41 subunit of the HIV fusion protein. The NHR of HA2, F protein, and gp41 bind membranes. The NHR acts synergistically with the fusion peptide in inducing membrane fusion for the Sendai F protein and the HIV-1 gp41. In recent years, a more complex picture is emerging for membrane fusion in which multiple regions from the viral fusion protein interact with membranes and synergize with the fusion peptide to induce membrane fusion. Future experiments are needed to determine the role of each region within the fusion protein in facilitating the membrane fusion reaction.

sequences of, 197, 198t
Triatoma infestans, 200
Allototropin-receptor (ATR), 201
Allototropin-related peptide (ATRP), 200–201, 278–279
Alpha-melanocyte–stimulating hormone (α-MSH), 735
Altered peptide ligands (APL), 703
Alytidae family, 476
Alzheimer's disease (AD), 675, 772, 941, 948–949, 1637, 1652
β-amyloid peptide, 1668–1669
EFRH phage elicits antibodies, 591–592
in vitro modulation, 590–591, 591f
APP, 590
AβP antibodies, 593–594
clinical trials, 593
transgenic mice
amyloid plaques, 592
hAPP gene, 593
AM. *See* Adrenomedullin (AM)
δ-Amaurobitoxins (δ-AMATX-Pl1), 467–468
Amidating enzyme, 740
AMP-activated kinase (AMPK), 1045–1046, 1092, 1381–1382
Amphibian alimentary tract, 1341
Amphibian opioid peptides
δ-agonists, 379
cDNA library screening, 377
D-Ala^2-deltorphin II, 379–380
deltorphins, 379
dermorphin, 378, 379t
nonmammalian prodynorphin-derived peptide, 376
origin of, 376–377, 377t
Phyllomedusinae, 376
"sapo," screen secretion, 376
structure and conformation, 377–378
Amphibian tachykinins
actions
in mammals, 396–397
NK1 receptor agonist, 395
PHYS, RTKs and BFK, 395–396
amino acid sequence
of brain/gut, 393, 393t
of skin, 391, 392t
aromatic and aliphatic TKs, 391
history of, 391
Kassina senegalensis, 393–394
Odorrana grahami, 393–394
pathological implications, 397–398
PHYS, RTKs and BFK, 395–396
in *Rana catesbeiana*, 394
in *Rana pipiens*, 394
in *Rana ridibunda*, 394
receptors and signaling cascades, 394–395
Amphiporine activity, 483
AMPK. *See* AMP-activated kinase (AMPK)
AMRNALVRFamide, 292
Amylin
acute and chronic eating-inhibitory effects, 1049
adiposity signal, 1050–1051
anorectic effects, 1052–1053
AP, 1053
CCK, 1054
CL-R protein, 1049
CT-R, 1049
diabetes mellitus, 1055
eating/body weight overexpression, 1051
energy expenditure, 1051
energy metabolism, 1052
and estradiol, 1054
features, 1049
forebrain effects, 1053
in knockout animals, 1051
in lean and obese individuals, 1052
and leptin, 1054
and metabolites, 1054
satiating hormone, 1050
site of action, 1053
VMH, 1054
Amyloid beta-protein precursor (APP), 590, 1759–1760
Amyloid β (Abeta) protein efflux, 1668–1669
AN. *See* Anorexia nervosa (AN)
Anaphylatoxins
anaphylatoxic effect, 628
C3A and C5A generations, 626–627, 626f
C3aR and C5aR, 627–628, 628f
chemotactic effect, 628
genome, synthesis and processing of, 625, 626f
hepatocytes, C3 and C5 synthesis, 625–626
history of, 625
immunoregulatory effect, 629
pathophysiological implications, 629
phagocyte-activating effect, 628
structure of, 627, 627f
Androgenic gland hormone (AGH), 209–210
Androgen receptor (AR), 507–508
Ang II. *See* Angiotensin II (Ang II)
Angiogenic growth factors
chronic GI ulcers. *See also* Gastrointestinal (GI) ulcer healing
granulation tissue formation, 1172–1173
physiologic angiogenesis, 1173
peptic ulcers, 1172
Angiotensin-converting enzyme (ACE), 494, 1388, 1444, 1488, 1501–1502, 1760–1761
Angiotensin II (Ang II)
Ang-(1–7)
clinical trials, 499–500
interstitial fibrosis, 499
tumor growth attenuation, 498–499
VEGF-A reduction, 499
AT_1R, 498, 1371, 1371f
cardiac remodeling, 1372–1373
vascular remodeling, 1373–1374

pathological cardiac hypertrophy, 1371–1372
protein kinase B, 498
RAS
component of, 1369–1370, 1370f
plasma and pulmonary endothelial ACE, 1370
serine proteases, 1370
receptor subtypes, 1370–1371
tumor angiogenesis
CDDP, 496–497
cell migration and invasion, 497–498
COX-2, 497
MAPK, 497
VEGF, 496–497
in tumor tissue and cancer cell lines, 495–496
Angiotensinogen (AGT)
ACE, 1501–1502
formation and metabolism of, 1499–1500, 1500f
intrarenal Ang II receptors, 1502–1503, 1502f
JAK-STAT pathway, 1499–1500
mRNA and protein, 1499–1500
renin and (pro)renin receptor, 1500–1501
Animal Toxin Annotation Program of UniProt, 424
Animal toxins
biotechnological applications, 408–409
as candidate drugs, 407–408, 408f
maurocalcine
calcin toxins, sequence alignment, 409–410, 409f
channel activity, 409–410
CPPs. *See* Cell-penetrating peptides (CPPs)
macropinocytosis, 411

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

nanoSPECT/CT imaging, *in vivo*, 412–413, 414f
origin, 409–410
pharmacological activity, 410–411
Annelid antibacterial peptide toxins, 485–486
Annelid *(glycera)* neurotoxin, 485
Annexin-A1/acetyl (Anx-A1/Ac2–26) peptide
acute rodent inflammation, 631–632
antiflammins, 631
anti-inflammatory action, 631–632, 632f
biochemistry of, 632–634
biological actions of, 631, 632t
"Boc" antagonists, 634
FPR, 634
Fpr2/3 null mouse strain, 634–635
history of, 631
homology of, 637t, 638
in vitro systems, 635–636, 635t
in vivo systems, 635–636, 635t
structure–activity relationships, 636–638, 637t
structure of, 632–634, 633t
"type 2" calcium-binding sites, 631
Anorexia nervosa (AN), 782, 1280, 1311
ANP. *See* Atrial natriuretic peptide (ANP)
Antiadhesin peptide-based vaccines. *See Pseudomonas aeruginosa (Pa)*
Antibacterial peptides, 160
amino acid sequences of, 157, 158t
peptaibols with, 157–158
Anticholinesterases, 452–453
Antidiuretic factors (ADFs), 230–232
Antidiuretic hormones, 1674. *See also* Diuretic hormones (DHs)
Antifungal peptides, 160
AFPNN5353 protein, 159
amino acid sequences of, 157, 158t
cyclic peptide, 158–159
D-Phe-L-Val-D-Val-L-Tyr tetrapeptide, 159
HIV-1 RT inhibitory peptide, 160
hybrid peptide polyketides, 159
mushroom proteins, 160
PAF, 159
peptaibols with, 157–158
thermostable 5773-Da, 159
Antigen presenting cells (APCs), 572
Antimalarial toxins, 471
Antimicrobial peptides (AMPs), 273, 331–332
ant venoms, 476
centipede, 477
frog and toad venoms, 475–476
IBP5, 1778
nosocomial infections, 475
scorpion venoms, 476–477
sea squirt, 477
snake venoms, 477
spider venoms, 477
wasp, hornet and bee venoms, 477
Antiopioid peptides
CCK. *See* Cholecystokinin (CCK) receptors
MIF-1, 1547
N/OFQ, 1546–1547
NPFF, 1546
TYR-MIF-1, 1547
TYR-W-MIF-1, 1547
Antitumor peptides
marine source venoms, 478–479
scorpion venoms, 478
snake venoms, 478
toad venoms, 478
Ant venoms
ectatomin, 421
Myr p peptides and pilosulin, 420
poneratoxin, 420
ponericins, 420–421
Apamin, 417–418
Apelin (APL)
amino acid sequences of, 715, 716f
aqueous diuresis, 721–722
and atherosclerosis, 1381
in cancer, 503–504, 503f
angiogenesis and lymphangiogenesis, 503
EMT, 502
carcinogenesis pathway, characteristics, 502
"deorphanization" approach, 721–722
and drinking behavior, 720
forskolin-induced cAMP production, 1377–1378
fragments of, 715, 716f
GI tract
expression, 1182, 1183f
and pancreatic actions, 1183–1184
heart effects
cardiomyogenesis, 1381
contractility, 1379–1380, 1380f
electrophysiology, 1380–1381
heart failure
cardiac expression and plasma levels, 1382
cardiac function effect, 1382–1383
cardiac hypertrophy, 1383
fibrosis, 1383
history of, 502, 715
HPA axis, 721
hypothalamic oxytocin neurons, lactating rats, 720–721
immunofluorescence detection, 1182, 1183f
intestinal inflammation
colonic apelin mRNA and peptide levels, 1184, 1185f
HIF-1α- and HIF-1β overexpression, 1184–1185, 1185f
hypoxia-induced elevation, 1184–1185
Jak/Stat signaling pathway, 1185
putative Stat3 binding site, 1185, 1186f
ischemia and reperfusion, 1381–1382
and metabolic disorders, 1186
milk-borne apelin, 1182–1183
neuroanatomical distribution of, 715–716, 717f
ontogeny of, 1182, 1184f
pathological cardiovascular conditions, 1383–1384, 1384f
peripheral cardiovascular actions, 721
polyclonal antibody development, 715–716
preproapelin and APJ mRNA, 1377
and RAS, 1379
receptor distribution, 716
"reverse pharmacology" approach, 1182
sequence analysis, 1377
signaling cascades, 716–717, 1183
USF-1/-2, 1182
vasculature effects
angiogenesis, 1379
vascular tone, 1378–1379, 1378f
water balance regulation
AVP neuronal activity, blood circulation and diuresis, 717–718, 719f
vasopressin, kidney, 718–720
vasopressin opposite regulation, 718
Aphrodisin, 1896
Apis mellifera. *See* Honey bee venom

Arginine vasopressin (AVP) *(Continued)*
primary function of, 1451
in septic shock, 1452
stimulation of, 1452
structures of, 1450–1451, 1450f
V1aR-stimulated Gq, 1451
Arginine vasotocin/mesotocin (AVT/MT)
in amphibians, 371, 372t
behavioral effects, 373
cardiovascular effects, 373
chromaffin cells, 373
distribution of, 371–372
hepatic glycogenolysis, 373
hydrins, structure and function, 374
osmoregulatory effects, 372–373
peptide structure and processing, 371
receptor structure, 372
reproductive tract effects, 373
Ascaris FMRFamide-like precursor proteins (afp-X proteins), 288–289
Asthma, 1514
Atherosclerosis, 1412
*At*PEPR1 and *At*PEPR2 receptors, 10
AT_1 receptor subtype blockade (ARB), 1488
Atrial natriuretic peptide (ANP), 456, 1853. *See also* Brain and C-type natriuretic peptide (BNP and CNP); Natriuretic peptide (NP)
in kidney, 1467
tubular transport systems
amino acid sequence, 1467, 1468f
angiotensin II, 1467
CCD cells, 1470, 1470f
collecting duct system, 1469
Henle's loop, 1468–1469
IMCD, 1470–1471
late distal tubule, 1469
organic cation transporter, 1468
transport regulation, 1468, 1469f
ATRP. *See* Allatotropin-related peptide (ATRP)
Augurin and *Ecrg4*-derived neuropeptides
amino acid sequences, 1656, 1657t
autocrine *vs.* endocrine homeostatic mechanisms, 1664–1665, 1664f
blood–CSF barrier *vs.* blood–brain barrier, 1659–1660
circulatory link, CSF, 1658–1659
CP–CSF–ependyma-SVZ, 1662–1664, 1663t
CSF-peptide-mediated homeostatic responses, 1660, 1661f
degree of conservation, 1656, 1658t
discovery of, 1655
ECRG4 ORF, 1656, 1660f
gene products, 1656, 1656f
HMM, 1655
injury response feedback loop, 1661–1662
neural and nonneural tissues, 1656, 1659f
physiologic roles, 1658
TBI, NPC mitosis, 1662
Autocrine growth factor, 514–515
AVP. *See* Arginine vasopressin (AVP)
AVPGVLRFamide, 292
AVT/MT. *See* Arginine vasotocin/mesotocin (AVT/MT)

Boiga irregularis, 1736
Bombesin (BN), 478
BRS-3, 1064–1065, 1068
energy homeostasis, 1068–1069
food intake
central effects, 1066
neural pathways, 1066–1067
peripheral effects, 1065–1066
history of, 1064
Bombesin (Bn)-related peptides
Bombina bombina, European frog, 1188
GI tract
and cancer, 1193
in esophagus, 1191
in gallbladder, 1193
in large intestine, 1192
in pancreas, 1192–1193
peristalsis, 1191
in small intestine, 1192
in stomach, 1192
GPCR, 506
growth promoting activities, 508–509
image tumor extent/location, 509
induced growth effects, 507–508
mRNA/gene structure, 1188
nonneoplastic diseases, 1195
NSCLC, 506
overexpression/ectopic expression, 1194
prognostic agents, 508
ProGRP isoforms, 1189
radiolabeled compounds/cytotoxic agents, 509–510
receptor activation, cancer growth/proliferation, 506–507
receptors for, 1190–1191
receptors growth effects, on tumors, 1193–1194
RNA/peptide distribution, 1189–1190
SCLC, 506
serum levels, tumor markers, 1194
signal cascades for, 1191
Bombinin-like peptides (BLPs)
amphibian bombesins
prohormones, 328
structures of, 326–327, 327f
amphibian phyllolitorins, 328
AMPs, 331–332
antimicrobial and cytolytic activity, 331–332, 333t
B. maxima, 332
bombinins H. *See* Bombinins H
BRS-3 receptor, 329–330
cytotoxic effect, 334
gastrin-releasing peptide, 329, 329f
gene-encoded L-isoleucine, 331–332
gene structure, 333
GRP and NMB, 326

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

MIC, 331–332, 334t
mRNA expression, 326, 327f
opioid dermorphin and deltorphins, 331–332
peptidyl-aminoacyl-L/D-isomerase, 331–332
primary structure, 331–332, 332t
ranatensin-like peptides, 328–329
solution structure, 332–333
Bombinins H
antimicrobial activity, 333–334
Leishmania promastigotes, 334–335, 336f
membrane perturbation activity, 334–335
PE/PG and PG/CL liposomes, 334–335, 335f
Gly residue, 333
Bombolitins, 418
Bombyx mori, 257–258
Bone marrow erythroid progenitor cells, 1622
Bone marrow mesenchymal stem cells (BMSC), 652
Botrocetin®, 474–475
Bovine pancreatic trypsin inhibitor (BPTI), 455
Bradykinin (BK) peptides, 1519–1520
ACE, 1388
B_1 and B_2 receptors, 1388–1389
biosynthesis of, 321–322, 322f–323f
BK-(1-5), 1389
blood kinin peptide levels, 1388, 1388t
bombinakinin M, 323–324
'contact system,' 1389–1390, 1390f
HMWK and LMWK, 1386, 1387f
tissue kallikrein, 1387, 1387f
kallidin, 1386
kinin peptide metabolism, 1388, 1388f
KKS, 1386
components of, 1390–1391
molecular variants of, 323, 324f
myotropic activities, 323–324
occurrence of, 321
pathophysiological implications, 1392
plasma kallikrein, 1387
plasma prekallikrein mRNA, 1388
probradykinin, posttranslational processing, 322–323
structures of, 322–323, 323f
Bradykinin-potentiating peptides, 457
Brain and C-type natriuretic peptide (BNP and CNP)
amino acid sequences of, 724, 725f, 1415f, 1416
γ-ANP and α-ANP, 1417
brain and pituitary, biological actions, 729–730
in cardiovascular system
blood pressure reduction, 1418
hormone-sensitive lipase, 1419
intracerebroventricular infusion of, 1419
TGF-β, 1418
tissue concentrations, 1417
ventricular tissue, 1417
VSMC migration and proliferation, 1419–1420
cDNAs encoding of, 725, 726t
furin, 725–727
heart failure, 1420–1421
history of, 724, 1415–1416
in situ hybridization histochemistry, 727
mammalian NP genes, 1416, 1416f
mapping of, 727, 728f
nonmammalian species, 727
NPR-A, NPR-B and NPR-C, 1418, 1419f
NRSF, 1416–1417
pathophysiological implications, 730
phylogenetic distribution of, 724, 726f
precursor proteins, 1417
proBNP, 1417
receptors and signaling cascades, 727–728
teleost CNP4, 727

Expressed sequence tags (ESTs), 431
Extracellular loop 1 (EC1) deletions, 557
Extracellular matrix (ECM) proteins, 1647
Extracellular signal-regulated kinase (ERK) phosphorylation, 558, 1372

F

Feeding circuit-activating peptides (FCAPs), 278
FGLa-related allatostatins (FGLa/ASTs)
amidation, 194
Diploptera precursor, 192
Dippu-AST 5, 193
distribution and expression, 192–193
GPCRs, 191–192, 192f
JHs, 191
MIP, 191
PISCF/AST family, 194
prohormone convertases, 193
receptors, 193–194
sequences of, 191, 192t
$W(X)_6Wa$/MIP family, 194
Fibroblast activation protein (FAP), 664
Fibrolase, 474
FMRFamide-like peptides (FLPs)
afp-X proteins, 288–289
arbitrary *C. elegans*, 247–248, 249t–250t
in arthropods, 237, 238t–239t
Ascaridia galli and *Haemonchus contortus* body wall muscle, 292
Ascaris suum, 287–288, 288t

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY
Copyright Elsevier 2024

body wall muscle, 291–292
dorsal inhibitory, 293
ovijector, 292
pharynx, 292
ventral inhibitory, 293
BLAST survey, 288–289
cAMP and cGMP, 293–294
expression of, 248
extended FMRFamides and FL/IRFamides, 237
Aplysia californica, 239–240
biological actions, 244
D. melanogaster, 240–241, 243
GPCRs, 242–243
Helix aspersa, 239–240
Lymnaea stagnalis, 239–241
mRNA/peptide distribution, 242
Procambarus clarkii, 240
glycine residue, 247–248
G. pallida, 288–289, 290t
immunocytochemistry and *in situ* hybridization, 289
KHEYLRF, 248
Meloidogyne incognita and *Bursaphelenchus xylophilus* Genome Sequences, 289, 290t
in molluscs, 237, 238t
myosuppressins, 237, 240–241
biological actions, 244
GPCRs, 243
mRNA/peptide distribution, 242
NPF, 238, 240–241
A. gambiae, 244
biological actions, 245
D. melanogaster, 243–244
mRNA/peptide distribution, 242
parasite behavior, body length and phenotype, 292–293
peptide signaling, 241
receptors, 290–291
RFG pattern, 247–248
SADPNFLRF and SDPNFLRF, 248
sNPFs, 238–239, 241
biological actions, 245
GPCR, 244
mRNA/peptide distribution, 242
FMRFamide-related peptides (FaRPs), 214, 276–277
Formyl peptide receptors (FPRs), 634
agonists of, 672–676, 672t–673t
host-derived nonpeptide, LXA4, 676–677
peptide libraries, 676
small compound library, 677
antagonists, 677, 678t
Boc1 and Boc2, 677–678
COX-inhibitor, 678
CsH, 677
deoxycholic and chenodeoxycholic acid, 677
LDLLDL, 677
NSDAID, 678
PD168368 and PD176252, 677
biological roles, 678–679
DCs, 671
FPRL1 and FPRL2, 671
Fprrs1 and *Fpr-rs2*, 671–672
GPCRs, 671
host-derived peptides
with amyloidogenic diseases, 674–675
Anx A1 and N-terminal peptides, 675–676
FPR3 and F2L, 676
frog skin peptides, 676
inflammatory and antibacterial responses, 675
leukocytes migration, 671
microbial peptides, 674
nonformylated peptides, 674
Free-living nematodes
antimicrobial peptides, 252–253, 253f
FLPS, 247–250, 249t–250t
gene encoding, 253, 253t
INSs, 251–252, 252f
nervous system, 247
NLPS, 250–251
Fungal peptides
mushroom
Aspergillus niger RNase, 163
non-Pleurotus species, 162
Pleurotus species, 162
Saccharomyces cerevisiae RNase, 163
ubiquitin-like peptides, 162
ribonucleolytic toxins, 163
RIPs, 164, 164t
Fungal toxins
amatoxins and phallotoxins, 166–167
antidotes to, 167
CODSs, 167
mycotoxins and mushroom toxins, 166
protease/protease-like enzyme, 167
use of, 167
Furin
history of, 1803
in vitro properties, 1805
in vivo mouse knockout models, 1804–1805
pathophysiological implications, 1806–1807
precursor protein cleavage, 1806
substrate types, 1805–1806, 1806f
zymogen activation and cellular trafficking, 1803–1804, 1804f
FXPRLamide family. *See* Pyrokinin (PK)

G

GAHKNYLRFamide, 214–215
Galanin (GAL)
alanine amide, 1210, 1211f
clinical trails, 1101
DA synthesis, 1100
dietary fat intake, 1098
distributions of, 1211, 1212f
ENK analogs, 1100
esophageal cancers, 1216–1217
GAL 3 receptor antagonist, 1097–1098
GalR1, GalR2 and GalR3, 1098–1099, 1210–1211, 1212t
amino acid sequences, 1211, 1213f
signaling pathways, 1212–1214, 1215f
gene expression and, 1098
genetic manipulation, 1098
GI tract
motility regulation, 1214
secretion regulation, 1214
sphincters regulation, 1214–1216
vagal afferent mechanosensation modulation, 1214
GLAP. *See* Galanin-like peptide (GALP)
GMAP, 1210–1211. *See also* Galanin message-associated peptide (GMAP)
G protein–coupled receptors, 766
hormone effects, 1099
IBD, 1216
infectious diarrhea, 1216
inflammation role, 1101
MAPK activation, 1212–1214
mRNA expression, 1217
NPY, 1099
orexigenic effects, 1097
pathophysiological implications
AD, 772
addiction, 773
depression, 773
multiple sclerosis, 773–774
neuropeptide dysregulation, 774
seizures and epilepsy, 771–772
stress and anxiety, 772–773
stroke, 774
psychological process, 1097
PVN expression, 1098–1099
receptors and signaling cascades, 768–769
triglylcerides, 1100–1101
Galanin-like peptide (GALP)
feeding and metabolism, 771
LHRH, 768
precursor peptide, 767
reproduction, 771
structural organization, 766–767
Galanin message-associated peptide (GMAP), 1210–1211
arousal and sleep, 770
feeding and metabolism, 769
galanin-positive fibers, 768
galanin precursor mRNA expression, 767, 767f
memory and cognition, 770
modulatory functions, 769
neuronal growth and regeneration, 771
nociception, 770
pituitary hormones, 769–770
'preprogalanin' gene structure, 766
serine residue, 767
GALP. *See* Galanin-like peptide (GALP)
Gastric inhibitory peptide (GIP), 1295
Gastric inhibitory polypeptide, 1227
Gastric ulcer (GU), 1173–1174, 1174f

Gastrin
acidic polyGlu sequence, 1220
apoptosis, 1224
bacterial artificial chromosomes, 1219
CCK, 1220
CCK1R and CCK2R gene, 1222, 1222t
dibasic sequences, prohormone convertases, 1220, 1221f
gastric acid secretion, 1223–1224
gastrimmune, 1225
Helicobacter pylori infection, 1221, 1224–1225
history of, 1219
hypergastrinemia, 1224–1225
iron homeostasis, 1224
mRNA, structure of, 1219, 1220f
PAK1, 1223
PKC, 1222–1223
progastrin, 1220–1221
proliferative effects, 1224
receptors
acid-stimulatory peptides, 519–520
CCK, 519–520
in normal tissue, 519, 520t
origin, 519
as tumor growth factor, 521–522
in tumors, 520–521, 521t
U2AF35 ribonudeoprotein particle splicing factor, 520
Zollinger–Ellison syndrome, 1221
Gastrin-releasing peptide (GRP), 326, 668. *See also* Bombesin (BN)
Gastroenteric peptide hormones, 1200–1201
Gastrointestinal tract (GIT) motor, 396
Gastrointestinal (GI) ulcer healing
bFGF. *See* Basic fibroblast growth factor (bFGF)
PDGF. *See* Platelet growth factor (PDGF)
PlGF, 1178–1179
Rac1, 1179
small molecular mediators and modulators, 1173
VEGF. *See* Vascular endothelial growth factor (VEGF)
GDVPGVLRFamide, 292
Ghrelin
"acylated ghrelin," 1236
acylation type, 776
acyl modification, 779
adrenal gland, 1002
amino-acid sequences of, 778, 778f, 1236–1237
AN, 782
anti-inflammatory action, 1411
appetite-promoting effect, 1410
appetite stimulation, 779–780
AMP-K, 780
free-radical production, 781
lipid metabolism, 780
UCP2, 780, 780f
atherosclerosis, 1412
autocrine/paracrine actions, 1002–1003, 1003f
blood glucose, 1238–1239
cardiac cachexia, 1410
cardiac sympathetic efferent pathway, 1410–1411
cardiac vagal afferent pathway, 1411, 1411f
in cardiopulmonary diseases, 1411
central nervous system, 777–778
definition, 776
des-Gln 14–ghrelin, 776–777
direct cardiovascular actions, 1410
distribution of, 1237
emotional behavior, dopaminergic neurons, 781
endocrine cell types, 1408
expression of, 998
extra-hypothalamic areas, 1107
feeding behavior, 1104
female gonads, 1000
gastric acid secretion, 1237
gastrointestinal motility, 1238
stimulating effects, 1239
gastrointestinal pathophysiology plasma, 1239
gastroprotection, 1237
genome structure of, 776, 778f
GH release, 779, 1410
GHRH and somatostatin, 997–998
GHS, 1408
GH secretion, 999
GHS-R, 779
GHS-R1a expression, 996, 997f, 1105
GOAT, 779, 1236, 1408–1409. *See also* Ghrelin *O*-acyltransferase (GOAT)
GPCRs, 1408
GPR39, 1237
in heart failure, 1411
history of, 996, 1236
hypothalamus
intracellular fuel sensing pathways, 1106–1107
orexigenic NPY/AgRP and anorexigenic POMC neurons, 1105–1106
POMC neurons, 1106
IGF-1, 1408
intestinal inflammation, 1238
lactotroph and corticotroph response, 998–999
learning and memory processes, serotonin system, 781
male gonads, 1000–1001
mammalian ghrelins, 776, 777f
MBOAT4, 779
motilin associated peptide, 1236
mRNA distribution, 1409
in myocardial infarction, 1411–1412
on myocardial ischemia/reperfusion injury, 1412
neuroprotective effects, 781–782
nonmammalian ghrelins, 776, 777f
OB, 996–997
pancreatic islets, 1001–1002
parathyroid gland, 999–1000
plasma concentration, 1409
peripheral ghrelin levels, 1107–1109
porcine ghrelin cDNA, 777
posttranslational mechanism, 996, 998f
in pulmonary hypertension, 1412
PWS, 782
signal pathway, 781
and sleep regulation, 782
structure of, 776, 777f, 1412–1413, 1413f
and thyroid gland, 999
UAG, 996
ulimorelin, 1239
vagal nervous system, 997
visceral afferents, 1107
Ghrelin *O*-acyltransferase (GOAT), 1108, 1236, 1408–1409
acyl donors, 1733
bisubstrate inhibitor, 1731, 1733f
blood glucose and plasma GH levels, 1734–1735, 1734f
Des-acyl ghrelin, 1730, 1731f
detergent effects, 1731
functions of, 1730–1731
history of, 1730
ions activity, 1733
long-chain fatty acids, 1731
mammalian and nonmammalian species, 1730
molecular weight, 1731
multiple acyl-modified forms, 1733
n-octanoyl modification, 1731
optimal pH activity, 1733–1734, 1734f
optimal temperature, 1734, 1734f
peptide substrates, 1731–1733
properties of, 1731
structure, 1731, 1732f
thyroid medulla carcinoma cell line, 1730
tissue distribution of, 1734
Ghrelin receptor (GHSR), 646
Gila monster venom, 480
GIP. *See* Glucose-dependent insulinotropic polypeptide (GIP)

Glucagon-like peptide (7–36) amide (GLP-1)
central nervous system, 1114–1115
endogenous peripheral, 1112–1114, 1113f
obesity therapy
DPP-IV inhibitors, 1115
and GLP-1 analogs, 1115
new co-agonists, 1116
RYGB, 1115
peripheral GLP-1
GLP-1R activation, 1111–1112
site and mode of action, 1111–1112
synergistic satiating effect, 1111–1112
proglucagon, 1111
Glucagon-like peptides 1/2 (GLP-1/2)
appetite and food intake, 1246
cardiovascular effects of, 1247
conformation and metabolism, 1243–1244
DPP-IV, 1248–1249
gastric acid secretion, 1245
gastrointestinal tract, 1246
gene expression regulation, 1242–1243
gene secretion, 1243
GLP-2R, 1244–1245
glucagon receptor, 1244
glucose-induced insulin secretion, 1245
GRPP, 1241–1242
HbA1c, 1248
immunoreactivity, 1241–1242
islets effects, 1245–1246
L-cell secretion, 1247–1248
mucosal hypertrophy, 1247
mutagenesis based screening studies, 1244
PC-1/3, 1241–1242
proglucagon process, 1241–1242, 1242f
subepithelial myofibroblasts, 1244–1245
type 2 diabetes, 1248
Glucose-dependent insulinotropic polypeptide (GIP)
adrenal glands, GIP-Rs, 1229
amino terminal flanking region, 1228
and bone, 1233
and brain, 1233
and diabetes, 1232–1233
enteroinsular axis, 1227
food-dependent Cushing's syndrome, 1229, 1232
gastric inhibitory polypeptide, 1227
gastrointestinal tract, biological tract, 1230–1232
GPRs, 1230
insulinotropic properties, 1228
and obesity, 1233
PKA, 1229
proGIP hormone, 1227–1228
prohormone convertase, 1228
secretin-vasoactive intestinal polypeptide family, 1229
signaling pathways, 1230, 1231f, 1233–1234
structural organization of, 1228, 1228f
β-Glucuronidase (GUS) reporter gene, 72–73
Glutaminyl cyclases
amyloid peptides, 1738–1739
iso-glutaminyl cyclase, 1740–1741, 1740f
mammalian QC, 1739
peptide modification
of invertebrates, 1736, 1737t
of plants, 1736, 1737t
of vertebrates, 1737–1738, 1738t
terminal glutaminyl and glutamyl residues, 1739, 1739f
Glutamate receptors/transporters, 471
Glycoaminoglycans (GAG), 412
Glycogen synthase kinase-3β (GSK-3β) expression, 954
GMAP. *See* Galanin message-associated peptide (GMAP)
GMC. *See* Guard mother cell (GMC)
*Gm*Pep914/890, 11
*Gm*SubPep, 10–11
Gonadotropin-inhibitory hormone (GnIH)
LPXRFamide peptides, 802–805
mRNA precursor expression, 805–806, 807f
origin, 802
pathophysiological implications, 809–810
physiological functions, 808–809, 808t
receptors and signaling cascades, 807
RFamide peptide, 804, 805f
and RFRP-3, 809
RFRP precursor polypeptide, 804, 806f
SIKPSAYLPLRFamide, 802, 803t
Gonadotropin-releasing hormone (GnRH), 282–284, 1737
biological actions, 799
clinical applications, 799–800, 800f
C-terminal glycine, NH2 donor, 794–795, 795f
desensitization, 798
gonadotropin gene expression, 798
history of, 792
intracellular signaling pathways, 797–798, 797f
neuronal systems, 794, 795f
nonribosomal biosynthesis, 794–795
primary amino acid sequences of, 792, 793f
putative ligand interaction sites, 796–797
receptor function, 795, 796f
receptor genes, 798–799
structure–activity relations and molecular modeling, 799
tertiary structure of, 796
three dimensional structures, 792–794, 794f
Gram-positive bacteria, 119, 127
Granulocyte macrophage–colony stimulating factor (GM-CSF), 1685
Growth hormone-releasing hormone (GHRH) precursor, 1408, 1793–1794, 1864–1865
amino acid sequence, 786, 787f
GHRH-R variants, 787–789, 788f
history of, 784
human and rat genomes, 785
mRNA peptide distribution, 785–786, 786f
organization of, 784, 785f
pathophysiological implications, 789–790
pituitary and brain, biological actions, 789
precursor processing, 785
structure of, 784
Growth hormone secretagogue receptor (GHSR-1A), 1105, 1236
Growth hormone secretagogues (GHS), 1408
GsMTx-4 peptide, 480
GU. *See* Gastric ulcer (GU)
Guard mother cell (GMC), 20–21
Gut leptin
intestinal inflammation process, 1254
jejunal absorption
of amino acids, 1254
dietary proteins, 1253
of fats, 1253
of sugars, 1253–1254

H

Head/neck squamous cell cancer (HNSCC), 507–508
Helicoverpa/Heliothis moths, 257–258

Natriuretic peptide (NP) *(Continued)*
estrus cycle-dependent gene expression, 1016–1017
gastrointestinal tract, 1014–1015
heart, 1014
Leydig cells, 1017
pituitary gland, 1015
PTH, 1016
TSH secretion, 1016
BNP and CNP genes, 1011
DNP, 1011
history of, 1011
NP family structure, 1011, 1012f
pathophysiological implications, 1017
proANP encoding gene, 1011, 1012f
prohormones, 1011–1012
release of, 1013
signal peptide sequence, 1012
subtypes and signaling pathways, 1013, 1013f
Necrotizing enterocolitis (NEC), 1305
NEFA, 1271
Nematode and platyhelminth peptide cytolysins, 486
Nemertine neurotoxins, 483–484
Nemertine peptide cytolysins, 485
Neprilysin. *See* Neutral endopeptidase (NEP)
NERPs. *See* Neuroendocrine regulatory peptides (NERPs)
Nerve growth factor (NGF), 1650
clinical trials, 1644–1645
cysteine knot motif, 1640–1641
history of, 1639
inflammatory pain, 1644
in situ hybridization and northern blot analysis, 1639–1640
ligand–receptor interface, 1641
neurodegenerative diseases, 1644
Neurotrophic Factor Hypothesis, 1639
noncovalent homodimer, 1640
physiological roles, 1639
p75 receptors
signaling pathways, 1642–1643, 1643f
structure, 1641–1642, 1642f
precursor protein, 1640
receptors–binding sites, 1641
retrograde transport, 1643
structure of, 1639, 1640f
sympathetic and sensory neurons development, 1643
TrkA receptors
extracellular signal-related kinases 1 and 2, 1642
phosphorylation of, 1642
Nervous system
analgesia
frog venoms, 479
marine cone snail venoms, 479
scorpion venoms, 479
snake venoms, 479
spider venoms, 479–480
anticonvulsants, 480
spinal cord injury, 480
Nesfatin-1, 1271
acute intracerebroventricular injection, 1271
amino acid sequences, 850, 851f
anorexigenic effect, 853
cardiac function, 1273
ELISA, 1273
expression of, 850–852, 852f
food intake, 853
gastrointestinal motility, 853
in GI tract, 1272–1273
history of, 850
intraperitoneal injection, 1272
NUCB2, 1271
pathophysiological implications, 854
POMC/CART, 852–853
precursor structure of, 1271, 1272f
puberty onset, 854
stress response, 854
structure of, 850
systemic energy balance, 1273, 1274f
Neural apoptosis-regulated convertase (NARC-1), 1824
Neuregulins (NRGs)
EGF ligand family, 1634–1635
ErbB4 expression, 1635, 1635f
ErbB receptors, 1634
glial cell mitogens, 1635
mRNA expression, 1633–1634
multiple neurotransmitter receptors, 1636
and neurological disorders, 1637
nigrostriatal dopaminergic neurons, 1636–1637
NRG-1 types, 1633
peptide growth factors, 1633
synaptogenesis, 1636
transmemembrane domains, 1634
Neuroendocrine regulatory peptides (NERPs)
FMRFamide, 1773–1774
MS/MS identification of, 1774, 1774f
NERP-2 immunoreactivity, 1775
posttranslational modification, 1773–1774
Vgf gene, 1774–1775
Neurohypophyseal peptides
body fluid homeostasis, 1481–1482
history of, 1481
OTR expression, kidney, 1482–1483
VP. *See* Vasopressin (VP)
Neuroimmune peptides
AVP, 681–684
CRH, 681–685
GHSR, 684–685
HPA axis, 681
immunological effects, 681, 682t–683t
Met-enkephalin, 681
substance P and CGRP, 684
VIP, 684–685
Neurokinin-B (NKB) neuropeptide, 824
Neuromedin B (NMB), 326. *See also* Bombesin (BN)
Neuromedin N (NMN)
mRNA expression, 875–876, 878f
structure of, 875, 877f
Neuromedin S (NMS)
adrenal gland, 1022
hypothalamus, 1019–1021
NMUR1 and NMUR2 receptors, 1019
ovary, 1022
pancreatic islets, 1021
pituitary gland, 1021
Q-PCR analysis, 1019, 1020f
testis, 1022
thyroid gland, 1021
Neuromedin U (NMU). *See also* Neuromedin S (NMS)
energy balance regulation, 858–859
expression of, 856–857, 857f–858f
gastric acid secretion and emptying, 859
GPCR, 857
history of, 856
HPA axis and stress response, 859–860
immunoreactivity, 856, 860f
NMS, 860–861
NMU1R, 858
NMU2R, 858
pathophysiological implications, 861
precursor peptide, 856, 857f
Neuromedin U receptor (NmU-R), 260
Neuron-restrictive silencer factor (NRSF), 1416–1417
Neuropeptide B (NPB)
antihyperalgesic effect, 1029–1030
cDNAs, 863
distribution and localization of, 863–864, 865f
endocrine function, 1026–1027
N- and C-terminals, 863, 864f
neuroendocrine function, 1025–1026, 1027f
pharmacological effects, 1029, 1029f
Neuropeptide F (NPF), 238, 240–241, 277–278
A. gambiae, 244
biological actions, 245
D. melanogaster, 243–244
mRNA/peptide distribution, 242
Neuropeptide F–related peptides, 216–217
Neuropeptide-like peptides (NLPs), 250–251
biological actions, 296
mass spectrometry/nucleotide sequence resources, 294–295, 294t–295t
non-RFamide peptides, 295
PCR, 296
WNamides, 295
Neuropeptide proctolin (RYLPT)
agonistic property, 306
Arg–Tyr bond, 306–307
biological actions, 307–308
Ca^{2+} activity, 306
Drosophila melanogaster genome, 304
GPCR, 305–306
immunohistochemistry, 305–306
microarray analyses, 305–306
Northern blot analyses, 305–306
predicted protein sequence, 304, 305f
proctolin biosynthesis and processing, 304–305
Tyr–Leu bond, 306–307
Neuropeptides
cell-to-cell signaling peptides, 1749
discovery of, 1836

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

features, 1839
at Karolinska, 1836
mass spectroscopy
characteristics, 1749
label-free measurements, 1754–1755
in vitro sampling method, 1750–1751
localization and distribution studies, 1752–1753, 1752f
microdialysis, 1751–1752, 1752f
quantitative peptidomic approach, 1754, 1754f
single cell analysis, 1753–1754, 1753f
SPE material, 1750–1751, 1751f
transport studies, 1750
peptidome measurement, 1750
plasticity in, 1837–1838, 1838f
receptors, 1838
and drug development, 1837f, 1838–1839, 1839t
Neuropeptide S (NPS), 1868, 1878–1879
alignment of, 869, 870f
biological actions, 872–873
history of, 869
Kölliker-Fuse nucleus, 871
NPSR1 transcript distribution, 870–871, 871f
pathophysiological implications, 873
precursor protein process, 869–870
receptors and signaling cascades, 871–872
structure of, 869, 870f
Neuropeptide W (NPW)
antihyperalgesic effect, 1029–1030
CHO cells, 863
distribution and localization of, 864–865
endocrine function, 1026–1027
feeding and energy metabolism, 1028–1029, 1028f–1029f
GPCRs, 863, 1025
in hypothalamus, 867
N- and C-terminals, 863, 864f
neuroendocrine function, 1025–1026, 1027f
NPB. *See* Neuropeptide B (NPB)
NPBWR1
expression of, 866, 866f
ROB cell function, 866–867
RT-PCR analysis, 865–866
NPBWR2, 867
Neuropeptide Y (NPY), 667, 779–780, 1859, 1868, 1874–1875
ARC
food intake, 1144
NPY receptors, 1144–1145
nucleus, 1144
biological actions, 887
cancer and receptors, 548, 549t, 552
clinical applications of, 552
functional effects, 554
intratumoral blood vessels, 553
subtypes, 553
tumoral NPY receptors, 553–554
in tumor cells, 552–553, 553f
CPON, 883–884
DMN, 1145
and feeding behavior, 1143–1144, 1146–1147
food intake, central regulation, 1143
gene sequence, 883, 884f
genetic models, 1146
history of, 548, 883
hydrophobic signal peptide, 883–884, 885f
hypothalamus, 884–885
in vivo target, 554
LHA, 1146
NPY-ergic neurons distribution, 884–885, 886f
pancreatic polypeptide, 552
pathophysiological implications, 887
PVN, 1145
receptor subtypes, 886
structure of, 886
VMN, 1145–1146
Neurotensin (NT)
appetite control, 880
cerebrospinal fluid, 881
and colonic stress responses, 1269
conformation, 878
discovery of, 1265
and dopamine, 878–879
and endogenous antipsychotic, 879
exon–intron and pro-peptide organization, 1265, 1266f
fat absorption, 1267
gastric acid secretion, colon, 1267
GI cancers, 1268–1269
liposomal ceramide, 876–877
MAPK pathway, 1266
motility, colon, 1267
mucosal healing phase, 1268
mucosal hypoplasia, 1268
neuromedin N, 1265
NMN
mRNA expression, 875–876, 878f
structure of, 875, 877f
NTR-2 and NTR-3 expression, 1266
NTR-1 expression, 877, 1266
intestinal inflammation, 1267–1268
origin, 875
and pain, 880
PCs, 876
peptides of, 875, 876t
prohormone convertase and endopeptidases, 1265–1266
and psychostimulant sensitization, 879
and reproductive functions, 881
and stress responses, 880
7-transmembrane G protein-coupled receptors, 876
ultrastructural analysis, 1266
α-Neurotoxins, 451–452
Neurotransmitters
ACh, 1835
"one-neuron-one transmitter" concept, 1837
storage–synaptic *vs.* dense core vesicles, 1836–1837
types, 1835–1836, 1836t
VGLUTs, 1837
Neurotrophic peptides
acidic FGF, 1684
adsorptive endocytosis and chemical modifications, 1684
binding proteins, intravenous delivery *vs.* in situ brain perfusion, 1684
EGFR, 1684
exocytosis, 1685
functions of, 1682
intracellular trafficking, 1684–1685
in vivo and *in vitro* method, 1683
neuroregeneration, 1686
pharmacokinetics, 1685
receptor mediated transport, 1684
transport system regulation, 1685–1686
vasoactive peptides, 1682
Neurotrophins. *See* Nerve growth factor (NGF)

drug abuse and, 1600
Dyn A(1–17), 1598
dynorphins, history of, 1596
immunocytochemical distribution of, 1598
KOR-mediated inhibitory effect, 1598–1599
neurodegenerative diseases, 1600–1601
neuropeptide gene expression, 1597
pathophysiological implications, 1599–1600
in peripheral tissues, 1600
physiological parameters, 1598
processing signal sequences, 1597
radioimmunoassay analysis, 1597–1598
radioreceptor-binding assays, 1598
Proenkephalin-derived peptides. *See* Enkephalins
Progestin and AdipoQ receptor (PAQR) family, 984–985
Programmed cell death 4 (PDCD4), 1649–1650
Prohormone convertase 1/3 (PC 1/3)
features of, 1789
GHRH precursor, 1793–1794
Northern blot analysis, 1793
peptide biosynthesis and processing, 1789–1790, 1790f
properties
activity regulation, 1792–1793
cDNA sequence of, 1792
domains of, 1790–1791, 1791f
Golgi apparatus, 1791–1792
substrate specificity, 1792
SAAS, 1794
Prohormone convertase 2 (PC2)
activity regulation, 1799–1800
7B2
furin consensus cleavage site, 1798, 1799f
and null animals, 1800
CHO cells, 1799
enzymatic activity, 1798–1799
features of, 1797–1798, 1797f
neuroendocrine cells, 1800
peptide biosynthesis and processing, 1798
proPC2 maturation, 1798, 1798f
substrate specificity, 1799
Prohormone convertases (PCs), 876, 1765
Prolactin (PRL)
"hallmark" action, 1494
and osmoregulation, 1495
receptors, 1494–1495
in mammalian kidney, 1495
renal actions of, 1496
glycosylated PRL/16-kDa isoform, 1497
potential renotropic agent, 1496
renal production of, 1495–1496
Prolactin-releasing peptide (PrRP)
amino acid sequences, 899–900, 900f
cross reaction, mammalian RFaminde peptides with receptors, 904–905, 904t
food intake suppression, 904
functions of, 904–905
genomic structure of, 899, 899f
GPCRs, 898–899
GPR10 ligand, 901–902
history of, 898
human RFamide peptides, 898, 899f
immunoreactive elements distribution, 900–901, 901f
mature PrRP production, 899–900, 900f
NPFF-1 and NFFF-2 receptors, 902
pathophysiological implications, 905
PRL-releasing activity, 902
stress responses, 902–904
tissue distribution of, 902, 903t
Proline-directed peptidases, 1762–1763
Prolyl oligopeptidase (POP), 1762–1763
Promoter trap T-DNA, 40–41
Proopiomelanocortin (POMC), 867
and AgRP neuronal systems, 840, 840f
glycosylation, 839–840
PAM, 839–840
structure of, 838–839, 839f
Proopiomelanocortin (POMC)-derived opioid peptides. *See* β-Endorphin
Proprotein convertase 5/6 (PC5/6)
history of, 1803
in vitro properties, 1808–1809
in vivo KO models, 1808
pathophysiological implications, 1809–1810
substrates, 1806–1807
zymogen activation and cellular trafficking, 1807–1808
Proprotein convertase furin. *See* Furin

catalytic domain structure, 1812
discovery of, 1812
intrauterine fetal growth restriction, 1813–1814
in vivo mouse KO models, 1813
RT-PCR, 1812
substrates, 1813
zymogen activation and cellular trafficking, 1812–1813
PC7
discovery of, 1812
ex vivo substrates, 1817–1818
in vitro properties, 1816–1817
in vivo models, 1818
pathophysiological implications, 1818
zymogen activation and cellular trafficking, 1816, 1817f
PCSK9
β-cell function and diabetes, 1827
clinical trials, 1827
crystal structure, 1825
discovery of, 1824
ELISA assay, 1824–1825
extracellular *vs.* intracellular pathways, 1825, 1826f
HR-CHRD of, 1825–1826
in vivo mouse model, 1826
LDLR, 1824–1825
NARC-1, 1824
partial hepatectomy, 1826–1827
prosegment of, 1825
transgenic expression, kidney, 1826
VLDLR, 1825
SKI-1/S1P. *See* Subtilisin kexin-isozyme-1/site-1 protease (SKI-1/S1P)
Prostaglandin D(2) (PG(D)2), 1143–1144
Prostate cancer, 535
agonists and antagonists, LHRH, 535–536
AN-152 (AEZS-108), men, 536
Prostate specific antigen (PSA), 535
Protein Data Bank, 154
Protein disulfide isomerase (PDI). *See* Disulfide bond formation
Protein kinase A (PKA), 1229
Protein kinase C (PKC), 512, 1222–1223
Protein tyrosine kinase (PYK) 2B, 559
Proteolysis, 1757
Prothoracicotropic hormone (PTTHs), 226–227
processing sites for, 223, 223f
Proton-coupled oligopeptide transporter (POT)
basolateral transporter, 1691
intracellular transporters, 1691
molecular basis for, 1690
Oatp gene family, 1691
prokaryotic homolog structure, 1690–1691
tissue distribution, 1690
Proximal convolutes tubule (PCT), 1496
PrRP. *See* Prolactin-releasing peptide (PrRP)
Psalmotoxin 1, 479
Pseudomonas aeruginosa (Pa)
antibiotics, 563
ESKAPE, 563
exoproducts, 563
MDR, 563
pili, vaccine target
advantages, 564–565

amino acid sequence, 565, 565f
Dichelobacter nodosus, type-IV, 564
PAK pilin protein monomer, 564–565, 564f–565f
synthetic consensus sequence peptide
amino acid sequence, 567, 567f
competitive ELISA, 567, 568f
Cs1 peptide, 566–567, 567f
PAK (ADN) mutant, 567–568
PAO peptide, 566–567
surface-exposed residues, 568, 569f
Pseudomonas aeruginosa strain K (PAK)
amino acid sequences, 565, 565f
pilin protein monomer, 564–565, 564f–565f
PSK. *See* Phytosulfokine (PSK)
PSK/PSP. *See* Polysaccaride krestin/polysaccharopeptide (PSK/PSP)
PTTHs. *See* Prothoracicotropic hormone (PTTHs)
Pulmonary arterial hypertension (PAH), 1509–1510, 1515, 1539
Pulmonary disease
ALI, 1539, 1540t
bronchial asthma, 1538–1539
lung cancer, 1539
NFAT transcription factor, 1540, 1541f
PAH, 1539, 1539f
Pulmonary hypertension (PH), 1515
Purinergic (P2X) receptors, 471
Pyroglutamyl (pGlu)-residue. *See* Glutaminyl cyclases
Pyrokinin (PK), 217–218
amino acid sequence, 255–257, 256t
biological actions, 263–264
capa gene
Np preprohormones, 258
PVK-1 and PVK-2, 258
trans-Golgi network, 258
evolutionary trace analysis, 260
FXPRLa sequence, 255, 257–258
GPCRs, 260
H. peltigera, pheromone gland cells, 260
LPK, 255–257
myotropic peptides, 257–258
pban gene
DH, β-SGNP and γ-SGNP, 258
gene-derived peptides. *See* Lepidoptera
Np preprohormones, 258
pest management, 264
PK-1/DH
cloned receptors, 260, 261t–262t
in lepidopterans, 262
in non-lepidopterans, 263
PK-2/PBAN
cloned receptors, 260, 261t–262t
in lepidopterans, 262
in non-lepidopterans, 262
PYY. *See* Peptide YY (PYY)

Q

Quantitative structure–activity relationships (QSAR) approach, 81
Quiescin–sulfhydryl oxidase (QSOX), 1724
Quorum-sensing (QS) systems, 1892–1893

R

RALF peptides. *See* Rapid alkalinization factor (RALF) peptides
RAMPs. *See* Receptor-activity modifying proteins (RAMPs)
Ranidae family, 476
Raniseptins, 350–354, 356t, 361
Rapid alkalinization factor (RALF) peptides
amino acid sequences, 47, 47f
brassinolide, 48
cDNA library, 47–48
cysteine residues, 46
definition, 46
preproRALF precursor protein, 46, 47f
receptors and signaling cascades, 48–49
SacRALFs, 48
soybean pollen transcriptome survey, 47–48
tissue-specific expression, 47, 48f
RAS. *See* Renin–angiotensin system (RAS)
Rat calvaria osteoblastlike (ROB) cells, 866–867
Raynaud's phenomenon, 1398–1399
RCC. *See* Renal cell carcinoma (RCC)
RCP. *See* Receptor component protein (RCP)
Reactive oxygen species (ROS), 174–175, 1373
Receptor-activity modifying proteins (RAMPs), 1168, 1395
Receptor binding domain (RBD). *See* *Pseudomonas aeruginosa (Pa)*
Receptor component protein (RCP), 1205, 1205f
Receptor coupling protein (RCP), 1396
Receptor-mediated transcytosis (RMT), 1699
Receptor tyrosine kinsases (RTK), 558
Red pigment-concentrating hormone (RPCH), 218
Bombyx mori, 187–188
distal retinal pigment retraction, 188
Drosophila melanogaster, 187–189
GPCRs, 188
immunocytochemistry, 186
precursor structure and processing, 187
Relaxin peptide
INSL3 gene, 907, 915
feeding and metabolism, 913
learning and emotional memory, 914
mRNA, 909
osmotic homeostasis, 913
precursor peptide, 908
RLN1 and *RLN2*, 908
somatosensory and motor behavior, 914
water drinking behavior and pregnancy, 913–914
receptors and signaling cascades, 909–910
relaxin-3
arousal, circadian rhythm and sleep, 912
feeding and metabolism, 911, 914
GABAergic, 908–909
hypothalamic and pituitary hormones, 911–912
mood, reward, depression and addiction, 915
motivation and reward pathway, 912
mRNA- and peptide-positive neuronal cell bodies, 908
nucleus incertus, 910
precursor peptide, 908
spatial and emotional memory, 912–913
stress, anxiety and fear, 914
stress responses and behavioral activation, 913
structure/sequence of, 907–908
water drinking, icv injection, 911
RXFP1, RXFP2 and RXFP3, 910
signaling molecule release, 914
tyrosine kinase, 907
Renal cell carcinoma (RCC), 534, 538
Renin–angiotensin system (RAS), 1885
ACE, 494
AGT. *See* Angiotensinogen (AGT)
Ang II. *See* Angiotensin II (Ang II)
apelin, 1379
AT_1 and AT_2 receptor, 494
biological actions, 494
components of, 1499
component of, 1369–1370, 1370f
intrarenal Ang II
biological actions of, 1504, 1505f
interstitial, 1503
intracellular, 1503–1504
tubular, 1503, 1503f
plasma and pulmonary endothelial ACE, 1370
proteolytic process, 494, 495f
serine proteases, 1370
Resistin
and energy homeostasis, 1047
rodent *vs.* human resistin, 1046–1047
Reverse pharmacology process, 1577
26RFa peptide
bioinformatics approach, 917
biological actions, 921–922
GPR103, 920f
characteristic features, 918
GPR103A, 918–922
GPR103B, 918–921
in peripheral organs, 921
high-performance liquid chromatography analysis, 917–918
localization of, 918, 920f
prohormone convertases, 917–918
Rana esculenta, 917
vs. 43RFa-immunoreactive peptides, 917–918, 919f
structure of, 917, 918f
three-dimensional NMR structure, 921, 921f
RGF. *See* Root meristem growth factor (RGF)
Rheumatic heart disease (RHD), 573
Rhodnius prolixus, 237, 304, 305f
Rho GTPase family, 1179
Ribosome inactivating proteins (RIPs), 164, 164t
Ribulose bisphosphate carboxylase/oxygenase (Rubisco), 1571
RIPs. *See* Ribosome inactivating proteins (RIPs)

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY Copyright Elsevier 2024

Root meristem growth factor (RGF), 36–37
AtTPST *(tpst-1)*, 50, 50f
expression levels and patterns, 51, 52f
multiple sequence alignments, 51, 51f
PIN auxin efflux facilitator network, 52
PLT transcription factors, 51–52
PSK and PSY1, 50
RGF1 effect, 51, 51f
wild-type seedlings, 52
ROS. *See* Reactive oxygen species (ROS)
ROT-FOUR-LIKE/DEVIL (RTFL/DVL) protein, 53–54, 54f
ROTUNDIFOLIA4 (ROT4) gene
cell proliferation rate, 55
FUL /AGL8, 56–57
in situ hybridization analysis, 55
leaf and pleiotropic phenotype, 55, 56f
MtDVL1, 53
rot4-1D mutants, 53, 54f
RTFL/DVL protein and intracellular localization, 53–54, 54f
loss-of-function phenotypes, 55
posttranslational proteolytic process, 54–55
T-DNA insertion, 53
Roux-en-Y Gastric Bypass (RYGB) effects, 1115
RTFL/DVL protein. *See* ROT-FOUR-LIKE/DEVIL (RTFL/DVL) protein

S

SacRALFs, 48
Salt-induced peptide formation (SIPF), 1900–1901
Salusins
ACAT1 expression, 1426
dibasic amino acid residues, 1423–1424
history of, 1423
mRNA distribution, 1425
pathophysiological implications, 1426
preprosalusin, 1424–1425
receptors and signaling cascades, 1425
salusin-α and salusin-β, 1423–1424
systemic bioactivities, 1425–1426
TOR2a, 1424, 1424f
SAMP8 model, 1668–1669
Sarafotoxins, 455
Sarcoma growth factor (SGF), 1647
Schistocerca gregaria, 257–258
Scorpion peptides
cDNA library, 424
CS-α/β peptide, 425
documented molecular diversity, 424–425
α-helical peptides, 425, 426f
ICK structural motif, 425
K^+ and Na^+ channels, 423
L. australasiae venom, 425
potassium channel blockers, 427–428, 427f
Protein Data Bank, 425–427
proteomic and transcriptomic analyses, 424
sodium channels, 427–428
venom proteomes, 423–424
SCR. *See* S-locus cysteine-rich protein (SCR)
Sea anemone peptides
Anemonia erythraea, 432–433
APETx1, 433
APHC1 modulator, 434
BcIV, 433
CgNa, solution structure, 434
cytolysins, 430
ESTs, 431
Kunitz-type protease inhibitors, 432
Nematostella vectensis, 430–431
posttranslational modification, 431
SHTX I and II, 432
Thalassianthidae, 433
therapeutic applications, 434–435
VGSCs, 430–431
Secapin, 418
Secretin, 1295
amino acid sequence alignments, 924, 924f, 1315, 1315f
autism, 931
biochemical regulatory mechanism, 1318
brain (and pituitary)
amygdala, 929–930
cerebellum, 929
Fos activation, 930–931
hippocampus, 929
hypothalamus, 930
lamina terminalis, 930
chromosomal locations, 924, 925f
discovery of, 1314
distribution of, 926–927, 927f
gastric hypersecretory syndromes, 1318
genomic organization of, 1314–1315, 1315f
GI tract, 1318
Gly-Lys-Arg amidation sequence, 924–926
GPCRs, 1316–1317
history of, 924
immunoreactivity, 926
N-terminal flanking sequence, 924–926
ontogeny of, 926
receptor amino terminus, 1316, 1317f
receptor dimerization, 928–929
receptor signaling and regulation, 928
schizophrenia, 931
secretin-like immunoreactivity, 1316
structure of, 928
superfamily genes, 924, 925f
Secretogranins II (SgII). *See* Chromogranin A and Chromogranin B (CgA and CgB)
Secretogranin V and Sgne1, 1798
Self assembling amphiphilic block copolymers (SAABCs), 1699–1700
Sepia officinalis, 281–282
Serine–threonine receptor kinases, 33
Serum amyloid A (SAA), 674–675
Sex peptides (SP)
biological actions, 206–207
Drosophila SPR, 205–206, 205f
DUP99B, 203–204
signal sequence, 203
SP peptides, 204
SGMRNALVRFamide, 292
Shoot apical meristem (SAM). *See* CLAVATA3 (CLV3)
Short chain fatty acids (SCFA), 1162, 1254
Short neuropeptide F (sNPF), 238–239, 241
biological actions, 245
GPCR, 244
mRNA/peptide distribution, 242
SIFamide, 218
Single residue distribution analysis (SRDA), 431
Skin peptides
adaptive immunity, 1842
Agnatha, 1843
amphibia, 1847–1848
archaeobatrachia, 1843, 1844t
chromatin and "extranuclear" histones, 1843
Elasmobranchii, 1843–1845
neobatrachia, 1843, 1845t
nontetrapod vertebrates, secretions/extraction, 1843, 1844t
Schiffer–Edmundson wheel, 1842–1843, 1843f
Teleostei
hipposin, 1846–1847
histones, 1846–1847
Oncorhynchus mykiss, 1847
pardaxin, 1846
piscidins, 1845–1846
pleurocidin gene, 1846
vertebrate host-defense peptides, 1842
Sleep electroencephalogram
characteristics, 1864
DSIP, 1868
galanin, 1868
HPA system. *See* Hypothalamic pituitary adrenocortical (HPA) system
HPS system. *See* Hypothalamic-pituitary-somatotropic (HPS) system
hypothalamic–pituitary–thyroid system, 1868
NPS, 1868
NPY, 1868
orexins/hypocretins, 1869
PACAP, 1868
substance P, 1868–1869
VIP, 1869
S-locus cysteine-rich protein (SCR)
ARC1, 63
biological actions and and SI signaling, 62–63
"chromosome walking," 59–60
mRNA gene
heterozygotes, allelic dominance, 60–61
structure of, 60
multiple sequence alignment, 58–59, 59f
pseudogenes, self-fertile brassicaceae, 60
SCRL gene family, 63, 64f
self-incompatibility system, 58
S haplotypes, 59–60
SRK gene, 58, 61
stigma and pollen specificity determinant, 58
structure of, 61–62, 62f
S-locus glycoprotein *(SLG)* gene, 61
S-locus receptor kinase *(SRK)* gene, 58, 61

Smad proteins, 1648–1649, 1648f
Small cardioactive peptide (SCP) gene, 278
Small-cell lung cancer (SCLC), 506
Snail peptides
augerpeptides, Terebridae family, 445
biological effects, 444
clathurellipeptides, minute venomous conoideans, 448
conotoxins, 439
characteristics, 440
cone snail species, 442–444
Conoidea, 439
α-conotoxins, 444
Cys pattern, 440–441
ligand-gated ion channels, 441, 442t
posttranslationally modified amino acids, 440, 441t
purification and characterization of, 442–444
voltage-gated ion channels, 441, 443t
crassipeptides, Crassispirid snails, 447–448
molecular targets, 444, 444t
nicotinic acetylcholine receptors and sodium channels, 448
"toxin cabals," 445
toxoglossan marine snails, 445, 446t–447t
transcriptomic analysis, venom ducts, 439
turripeptides, Conopeptide-like gene superfamilies, 445–447
venomous molluscs
cone snails and turrids, 437
Conus venoms, 437–439
marine snail shells, 437, 438f–439f
toxoglossates, 437
Snake peptides
AVIT peptides, 457–458
bradykinin-potentiating peptides, 457
cathelicidins, 458
CRISPs, 455–456
crotamine-like myotoxins, 455
C-type lectins and lectin-like proteins, 456–457
cystatins, 458
disintegrins, 456
natriuretic peptides, 456
protease inhibitor homologs
Ca^{2+}-channel blockers, 455
dendrotoxins, 454–455
enzyme inhibitors, 454
sarafotoxins, 455
three-finger toxins
adrenoceptor antagonists, 454
anticholinesterases, 452–453
Ca^{2+}-channel blockers, 453
cardiotoxins, 453–454
cobra venom toxins, 451
disintegrin-like peptides, mamba venoms, 453
muscarinic toxins, 452
α-neurotoxins, 451–452
protein isolation and cDNA cloning, 454
synergistic toxins, 454
vascular endothelial growth factors, 459
waglerins, 457
waprins, 458
Social wasps venoms
amphipathic polycationic peptides, Vespide venoms, 420
chemotactic peptides, 419–420
crabrolin, 419
mastoparans, 418–419
short peptides, 420
wasp kinins, 420
Sodefrin and related pheromones
biological actions, 388–389
cDNA, 385–387
dibasic amino acids, 387
electro-olfactogram, 387–388
epithelial cells, 384, 385f
lateral nasal cell types, 388
molecular mass and nucleotide sequence, 385, 386f
Northern blot analysis, 387
physiological implications, 389
radioimmunoassay system, 384–385
reversed-phase HPLC, 384
SKDALLK and DALLK, 388
Solenopsis invicta, 259
Solidphase extraction (SPE) material, 1750–1751, 1751f
Soluble secreted endopeptidase (SEP), 1760
Somatostatin (SST), 1021
agonist-triggered events, 1323–1324
antiangiogenic effects, 550
cancer
direct and indirect antiproliferative effects, 548–549
hormone release, 548
neoplasia, 548
and receptors, 548, 549t, 550–552, 551f–552f
cortistatin, 1320–1321
receptors, 1325
GI tract, 1321–1322
in colon, 1327
gastric acid secretion, 1326, 1326f
by gut regulatory peptides, 1323, 1326
Helicobacter pylori infection, 1327
by intraluminal stimuli, 1322
in neoplastic disease, 1328
by neural mechanism, 1322–1323
neuroendocrine tumors, 1327
in pancreas, 1327
receptor localization, 1324–1325
receptor selectivity, 1325, 1325t
in small intestine, 1327
somatostatin-like peptides, 1322
in vivo and *in vitro* studies, 1326
history of, 548, 1320
molecular signaling of, 550
nonallelic genes, 1323
nonradioactive noncytotoxic somatostatin analogs, 1328
pharmacokinetics and oral bioavailability, 1328
preprosomatostatin, 1321
radioactively labeled somatostatin, 1328
receptor subtypes characteristics, 1323, 1324t
sequence homology, 1323
somatostatin-14 and somatostatin-28, 1320–1321
thrittene, 1321
tumor therapy, somatostatin analogs, 1328
in vertebrates, 1321
Somatotropin-release inhibiting factor/cortistatin (SRIF/CST)
Alzheimer's disease, 941
amino acid sequence, 939
biological functions, 936
brain and pituitary, biological actions, 939, 940t–941t
characteristics of, 937–938, 938t
distribution of, 934, 935f
history of, 933
immunolocalization of, 936, 936f
long-projecting neuronal somatostatinergic systems, 934
MgrX2, 937
neuronostatin, 933
peptide degradation, 935
receptor-multidomain protein complexes, 938
and receptors, 933, 934f
sst2A receptor, 936–937
SST gene regulation, 933–934
TLE, 941
tumor imaging, 939–941
South American hylid antimicrobial peptides. *See* Dermaseptins
κ-Sparatoxins-1 toxins (κ-SPRTX-1), 469
SPE material. *See* Solidphase extraction (SPE) material
Spider venom peptides
acute toxicity testing, 463–464
ArachnoServer database, 461
aranemorph and mygalomorph spiders, 461, 462f
biological activity and targets, 461–462, 463f
cytolytic peptides, 464–466
disulfide-rich peptides
ancestral fold, 466, 467f
antimalarial toxins, 471
ASIC, 470
blockers and gating modifiers. *See* Voltage-activated sodium channels
glutamate receptors/transporters, 471
MSCs, 470
P2X receptors, 471
TRP channels, 471
voltage-activated calcium channels, 469–470
voltage-activated potassium channels, 469
HXTXs and TRTXs, 463–464
insect-selective toxins, 461–462
MAMPs, 464–466
molecular mass, 461
precursor structure, 464, 465f

Color Plates

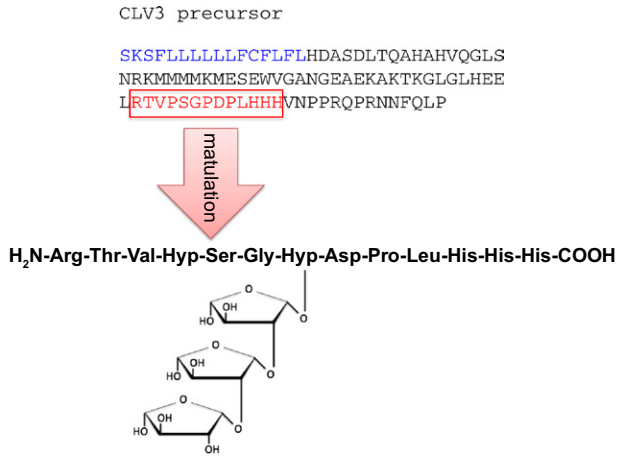

PLATE 1. Structure of CLV3 preprotein and matured peptide. ***(Chapter 1, see page 2).***

PLATE 2. Phenotypes of the ida mutant. (A) In wildtype Arabidopsis plants, the floral organs (petals, sepals, and filaments) abscise shortly after the flower is pollinated (arrow head). (B) In the inflorescence deficient in abscission (ida) mutant, the floral organs remain attached indefinitely to the receptacle of the growing fertilized silique (arrow). ***(Chapter 5, see page 24).***

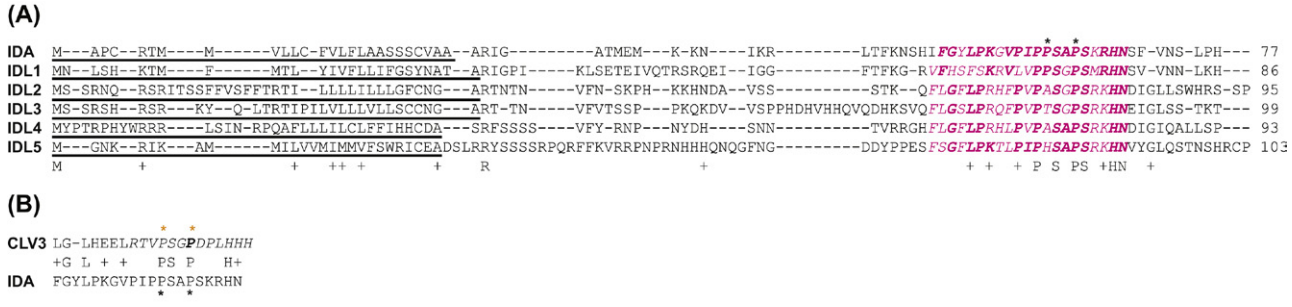

PLATE 3. Alignment of IDA and IDL proteins and similarities to the mature CLV3 Peptide. (A) The IDA and IDL proteins have predicted N-terminal signal peptides (underlined) and a conserved C-terminal EPIP domain (italics in magenta). Amino acids (aa) in the EPIP domains of the IDL proteins identical to the IDA-EPIP domain are in bold italics, asterisks indicate prolines, which are probably hydroxyprolinated in IDA. Identical aa are indicated by letters and conserved aa by (+). (B) The mature CLV3 (MCLV3) peptide, indicated in italics, and some of the upstream aa have similarities to the EPIP domain of IDA. Identical aa are indicated by letters and conserved aa by (+). The MCLV3 peptide has two hydroxyprolines, indicated by orange asterisks, where one is posttranslationally modified with triarabinoside (bold italics). The predicted hydroxyprolines of the IDA-EPIP domain are indicated with black asterisks. ***(Chapter 5, see page 25).***

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY

Copyright Elsevier 2024

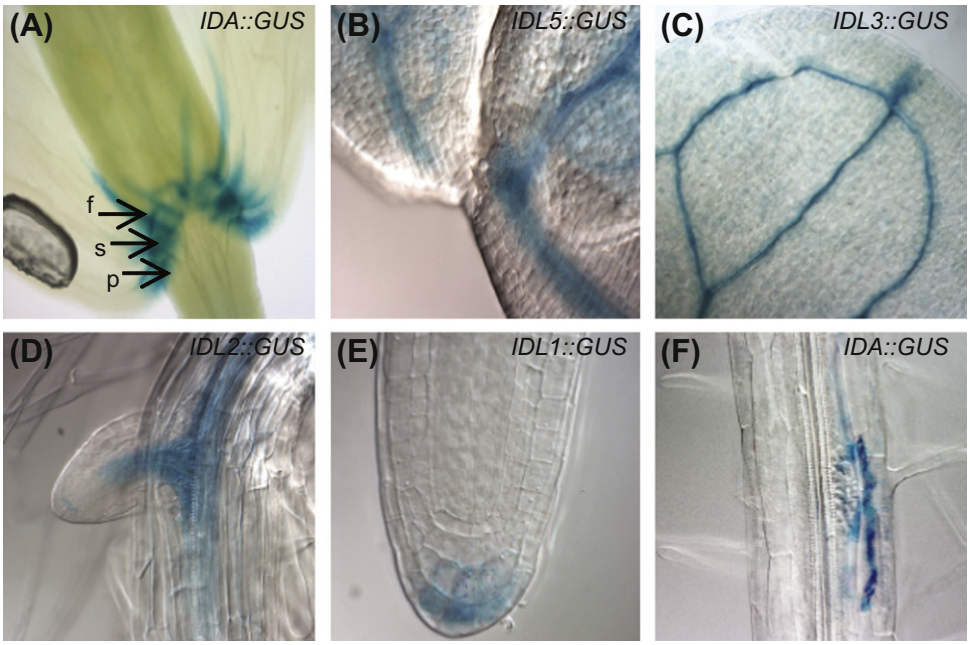

PLATE 4. Promoter:GUS expression of IDA and IDL genes. (A) IDA is expressed in the filament (f), sepal (s), and petal (p) abscission zones during the abscission process. (B) IDL5 expression in the vascular tissue shortly after germination. (C) IDL1, IDL2, IDL3, and IDL4 are all expressed in the vascular tissue of the expanding cotyledon, here IDL3 is shown as a representative example. (D) IDL2, IDL3, and IDL4 are all expressed in the vascular tissue of the main root, and the expression accumulates around the lateral root; here, IDL2 is shown as a representative example. (E) IDL1 expression in the columella cells at tip of the main root. (F) IDA is also expressed in the cortex and epidermal cells of the main root during lateral root emergence. ***(Chapter 5, see page 27).***

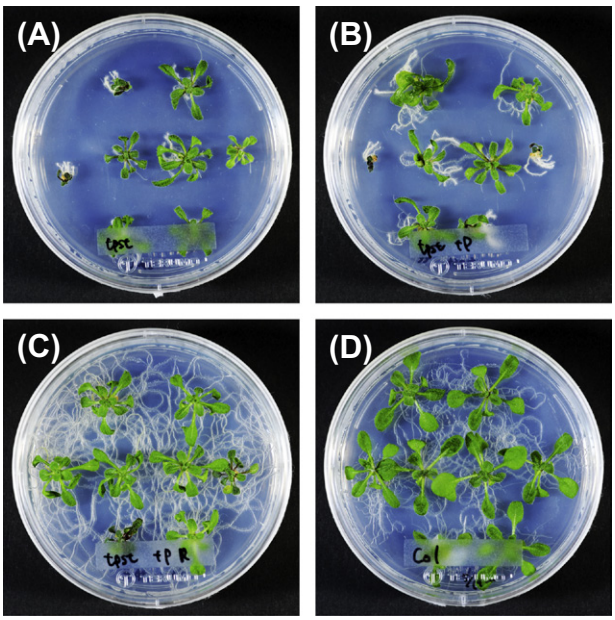

PLATE 5. Effect of RGF1 on root phenotypes of tpst-1. Photographs of tpst-1 seedlings grown in the absence (A) or the presence of PSK (100 nM) (B) or both PSK (100 nM) and RGF1 (100 nM) (C) 16 days after germination. PSK is required for full activity of RGF1. (D) Wild-type seedlings as a control. ***(Chapter 10, see page 51).***

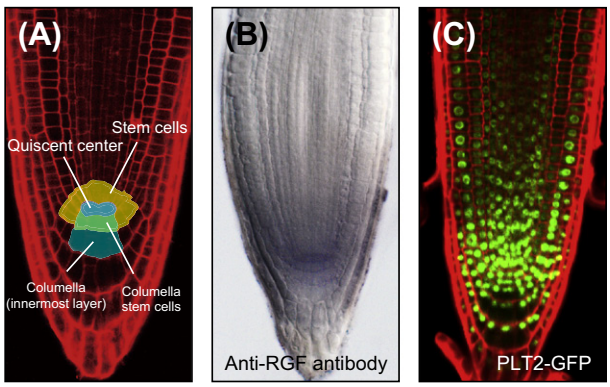

PLATE 6. RGF peptides define expression levels and patterns of PLTs. (A) Schematic representation of the representative cell types present in the Arabidopsis root meristem. (B) Distribution of RGF peptides in the root meristem visualized by whole-mount immunostaining using anti-RGF antibody. (C) Expression pattern of PLT2-GFP protein showing gradient distribution with maxima in the stem cell area. ***(Chapter 10, see page 52).***

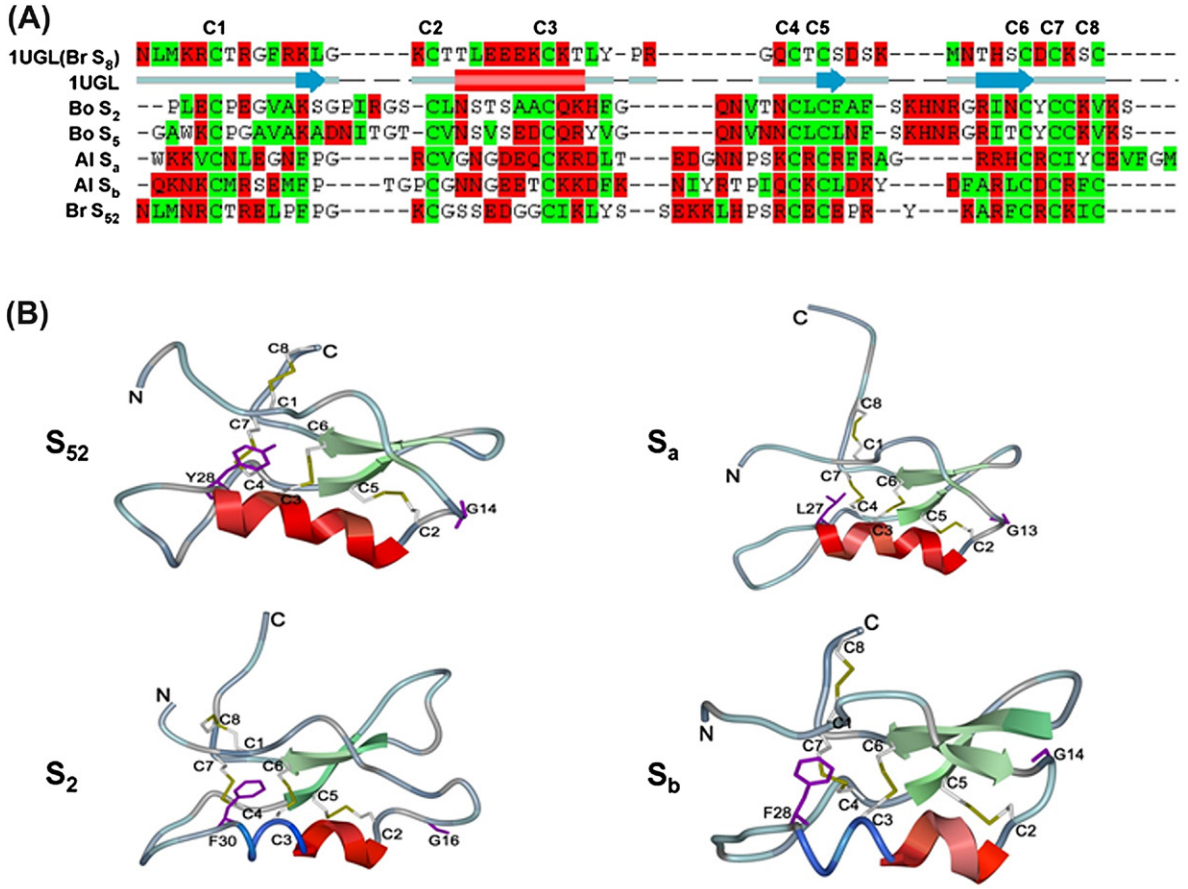

PLATE 7. Predicted conservation of secondary structure in SCR variants. (**A**) Structure-based sequence alignment of SCR variants from B. rapa (Br) S52, B. oleracea (Bo) S2 and S5, and A. lyrata (Al) Sa and Sb. The NMR structure (model 1) of the B. rapa S8 variant13 (PDB code: 1UGL) was used as template. The secondary structure of the experimental model was computed by the method of Kabasch and Sanders.5 The rectangle in the "1UGL" line depicts the α-helix and the arrows show the β-strands. Hydrophilic residues are shaded in dark gray and hydrophobic residues are shaded in light gray. The conserved C1–C8 residues are shown above the alignment. (**B**) Three-dimensional (3D) models of the SCR variants encoded by the Brassica S52 and S2 and the A. lyrata Sa, and Sb haplotypes. These predicted models were generated with the program MODELLER5 based on the S8 SCR NMR structure (PDB code: 1UGL) determined by Mishima et al.13 and the alignments given in A. The 3D models show the N/C termini and the location of the conserved cysteine residues (C1–C8) and glycine (G) in the G x C2 motif. Lines connecting pairs of cysteines depict the disulfide bridges. The α-helix is shown as a dark gray coiled ribbon and β-sheets are depicted by light gray arrows. The aromatic residue in the C3xxxY/F motif found in most SCRs is shown in stick representation for SCR variants of S52 (Y28), S2 (F30), and Sb (F28). SCRa contains a lysine (L27) at the corresponding position. ***(Chapter 12, see page 62).***

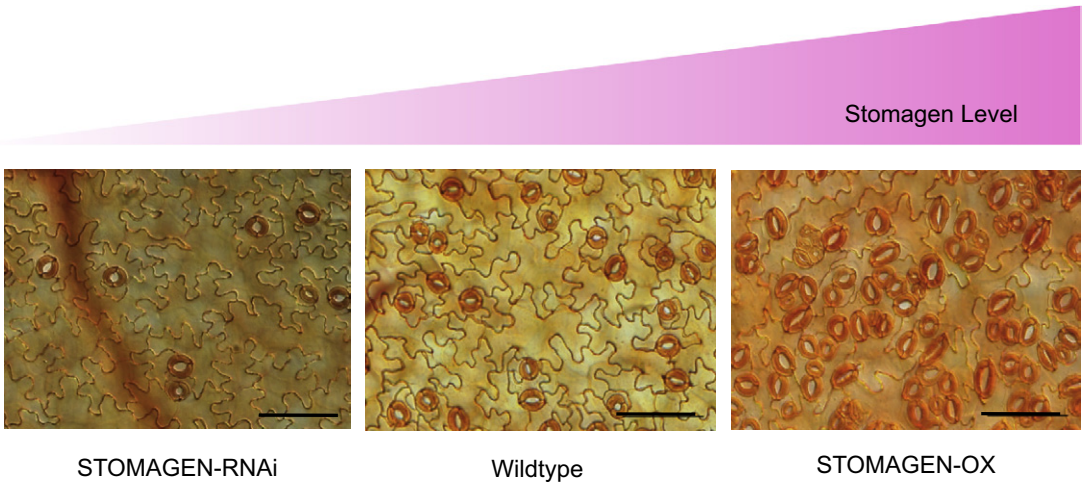

PLATE 8. Stomagen/EPFL9 positively regulates stomatal density. Differential interference contrast (DIC) images of the abaxial epidermis of mature leaves of wild-type Arabidopsis, a STOMAGEN-silenced line (STOMAGEN-RNAi), and a STOMAGEN-overexpressing line (STOMAGEN-OX). The expected accumulation level of stomagen is illustrated above panels. Stomata were stained with Safranin-O. Scale bars = 100μm. ***(Chapter 13, see page 69).***

Copyright Elsevier 2024

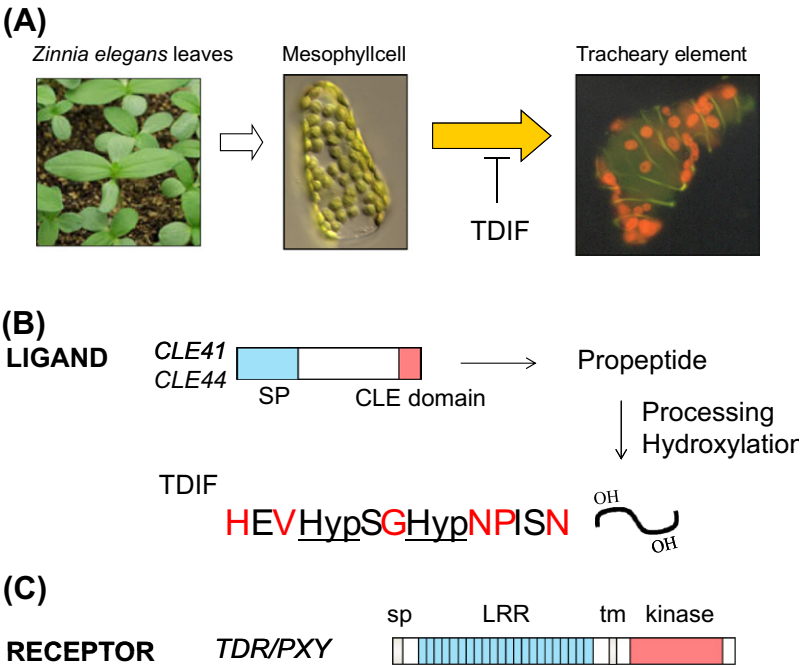

PLATE 9. Identification and characterization of TDIF. (A) TDIF was isolated as a factor inhibiting TE differentiation from the Zinnia xylogenic culture. (B) Maturation of TDIF peptide through translation as a propeptide, processing, and hydroxylation. TDIF is produced as a 12-amino acid peptide with two hydroxyproline residues. Bold characters indicate indispensable amino acids for TDIF activity. (C) Structure of TDR/PXY encoding a TDIF receptor, which consists of a signal peptide (sp), leucine-rich-repeat domains (LRR), a transmembrane domain (tm), and a kinase domain. ***(Chapter 14, see page 72).***

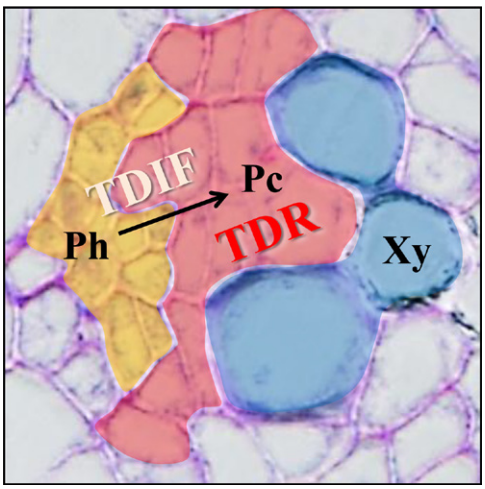

PLATE 10. Non-cell-autonomous function of the TDIF signal TDIF is secreted from phloem cells and functions in procambial cells in a non-cell-autonomous fashion. Ph, Pc, and Xy indicate phloem, procambium, and xylem, respectively. ***(Chapter 14, see page 72).***

This book belongs to Central Library BADJI Mokhtar-ANNABA UNIVERSITY

Copyright Elsevier 2024

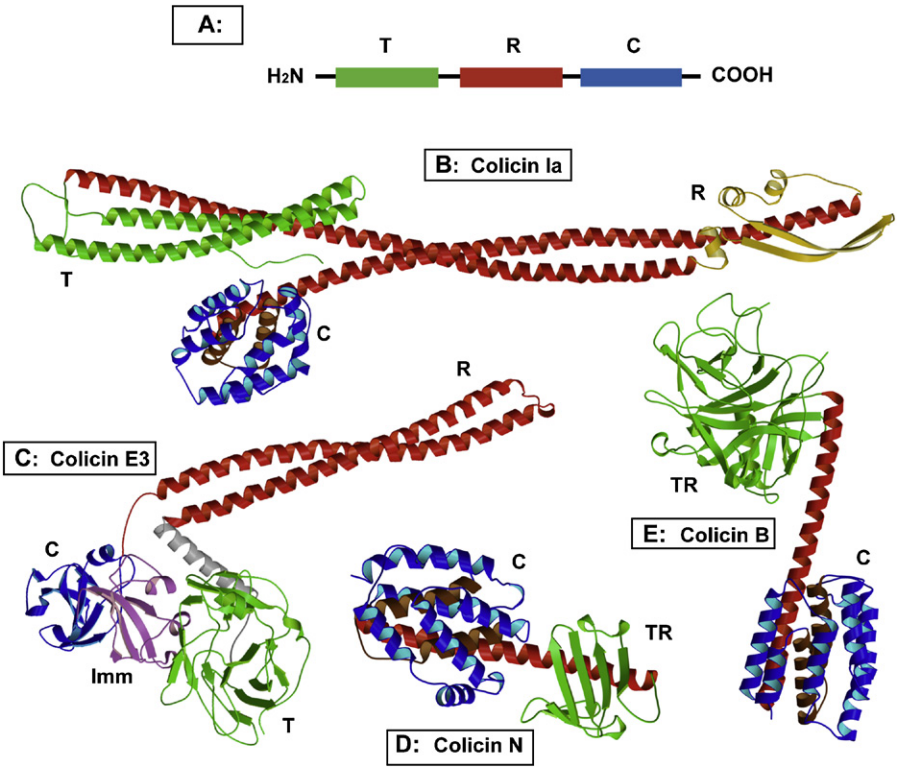

PLATE 11. (A) Generic domain structure of colicin polypeptides (top): T, translocation; R, receptor binding; C, catalytic or activity containing domain (B – E). Ribbon diagrams of structures of pore-forming colicins, Ia **(B)** , B **(E)** , and N **(D)** , and of rRNase colicin E3 **(C)** . Note the prominent long (210 and 100 Å in colicins Ia and E3) coiled-coil structure of the R-domain. Structures, predominantly a-helical, have also been obtained of the C-domains of (i) colicins A and E1 by X-ray diffraction and (ii) of E7 and E9 by solution NMR. The structures of E3 and E7 contain bound immunity protein, as is characteristic of the nuclease colicins. ***(Chapter 17, see page 94).***

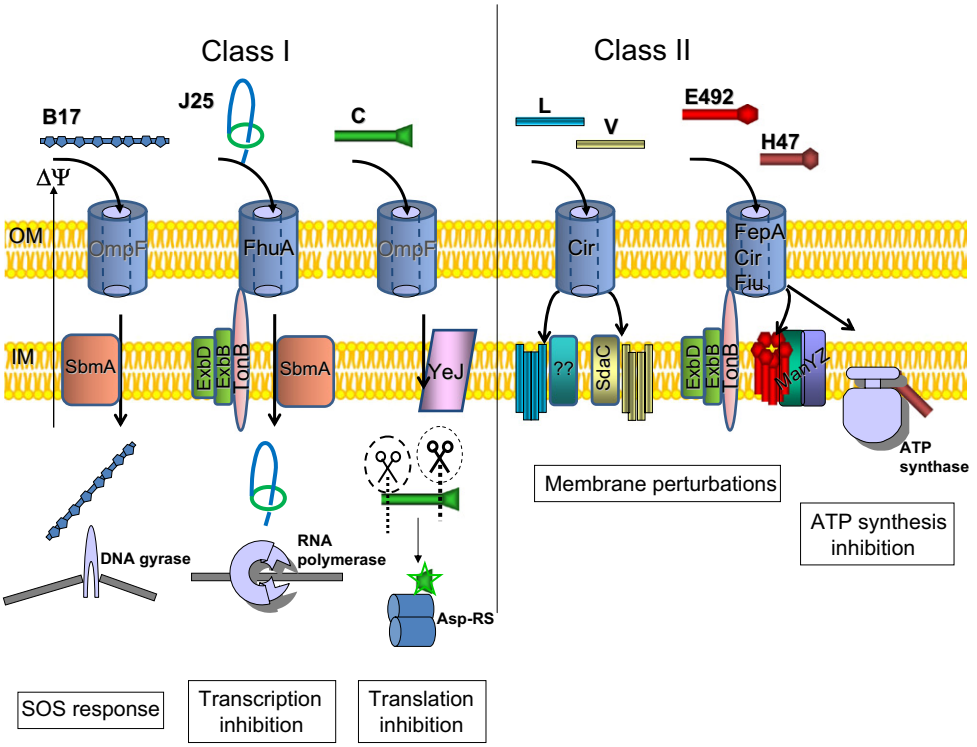

PLATE 12. Synthetic scheme of the mechanisms of action of microcins of classes I and II. ***(Chapter 20, see page 133).***

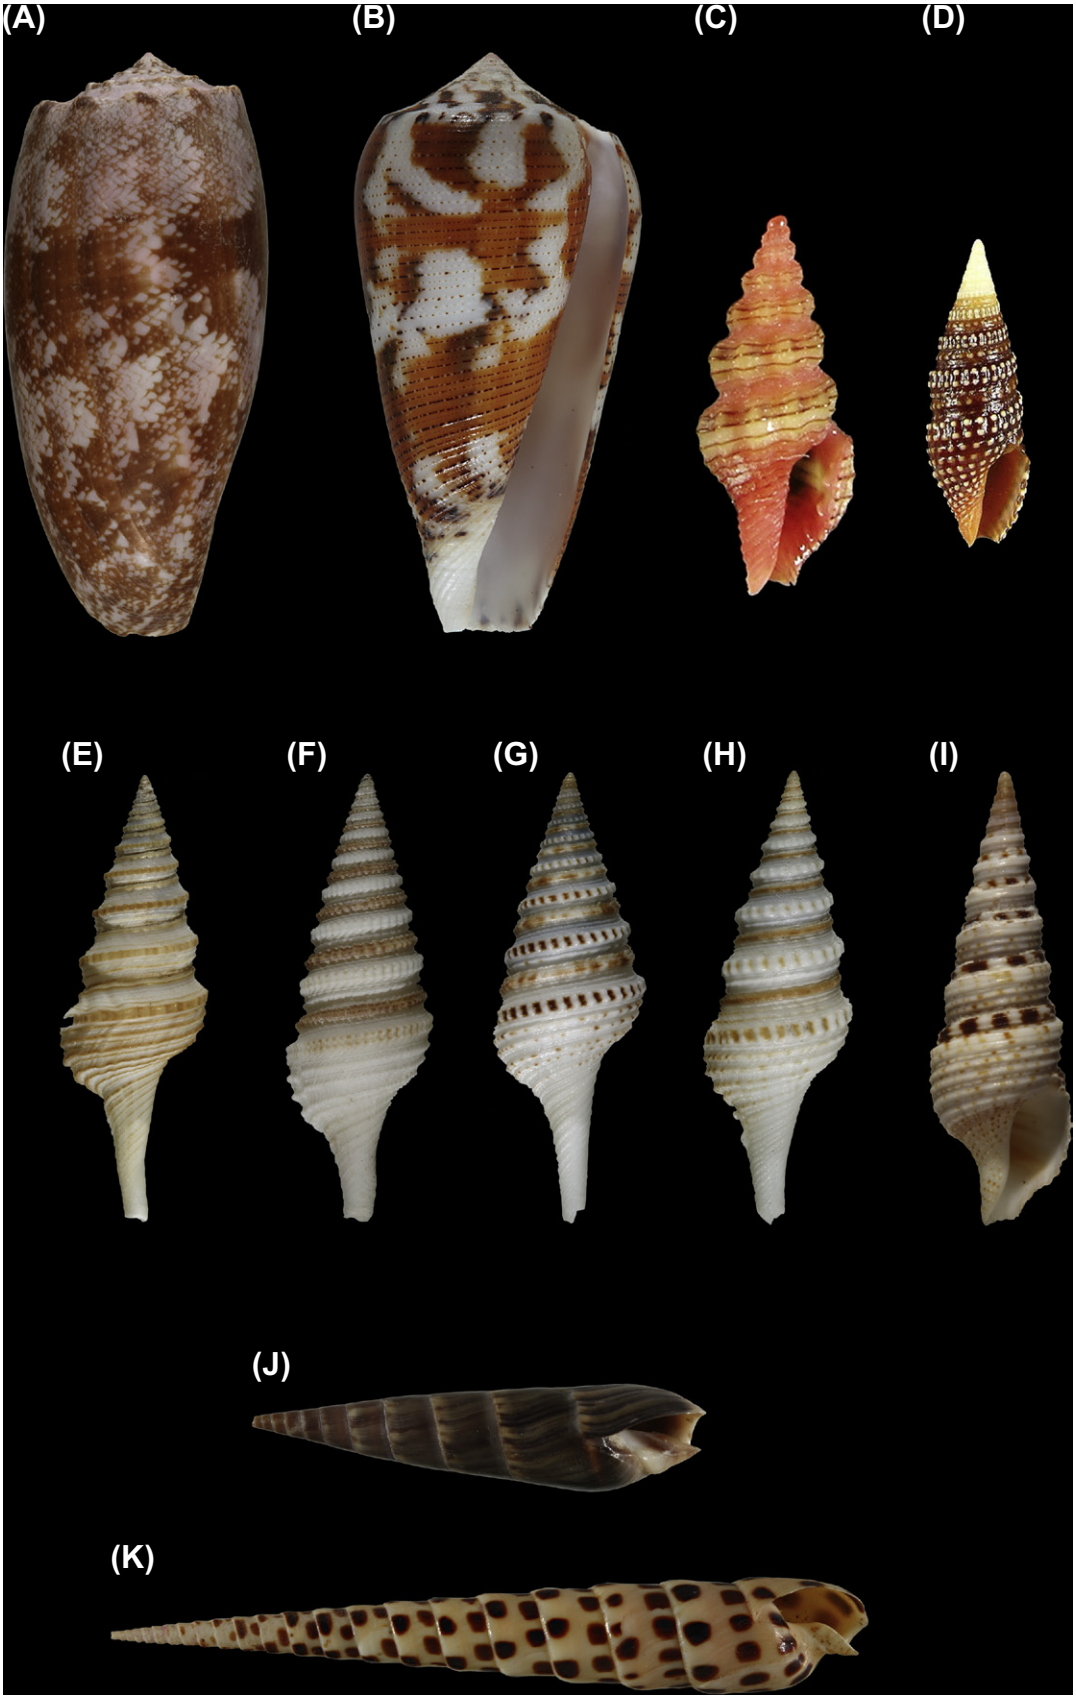

PLATE 17. Shells of venomous marine snails from which peptides have been characterized. As described in the text, four classes of venom peptides have been characterized. Best known are **conopeptides** ("conotoxins") that come from the venoms of cone snails such as the geography cone, Conus geographus (A) and the magician's cone, Conus magus (B). Other classes of venom peptides include **clathurellipeptides** from clathurellid conoideans such as the recently described Lienardia totopotens, Rosenberg, 2011(C); **crassipeptides** from crassispirid snails such as Crassispira cerithina (D); **turripeptides**, from the family Turridae such as Gemmula speciosa (E), Gemmula diomedea (F); Gemmula kieneri (G), Gemmula sogodensis (H), and Lophiotoma olangoensis (I), **augerpeptides** from species in the family Terebridae such as Hastula impages (J), and Terebra subulata (K). ***(Chapter 61, see page 438).***

PLATE 18. The gigantic Antarctic heteronemertine Parbolasia corrugatus and several adult starfish with diameters of approximately 30cm. ***(Chapter 65, see page 485).***

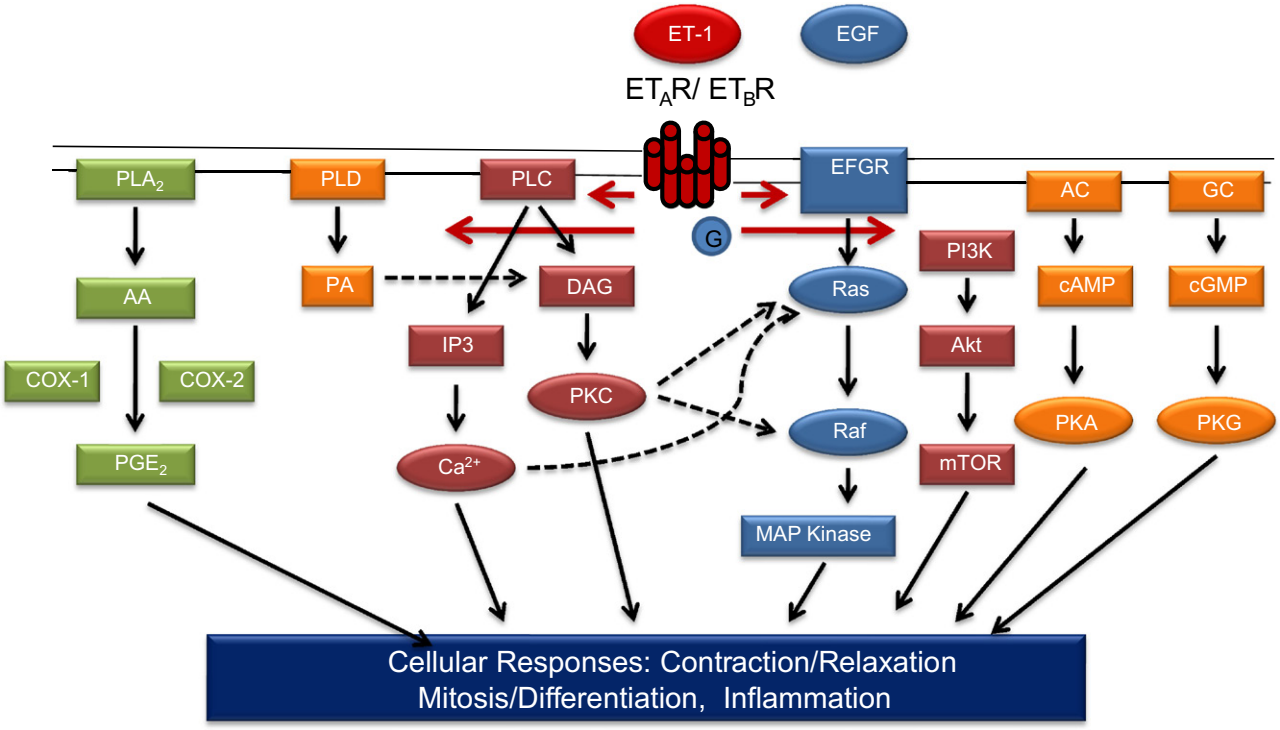

PLATE 19. Schematic representation of the signal transduction pathways associated with stimulation of the Endothelin receptors. Upstream transduction molecules activated (phosphorylated) by the G-protein are shown at the top of each pathway and include the Epidermal Growth Factor Receptor (EGFR), Phospholipase A2, C, D (PLA2, PLC, PLD), Adenylate Cyclase (AC), Guanylate Cyclase (GC), and Phosphoinositide 3-Kinase (PI3K). Downstream effectors include phosphatidyl inositol 3 kinase (IP3), diacylglycerol (DAG), phospholipase A (PA), cyclic GMP (cGMP), protein kinase A, C, G (PKA, PKC, PKG), Akt, mTOR, cyclooxygenase 1, 2 (COX-1, COX-2), and prostaglandin E2 (PGE2). ***(Chapter 70, see page 513).***

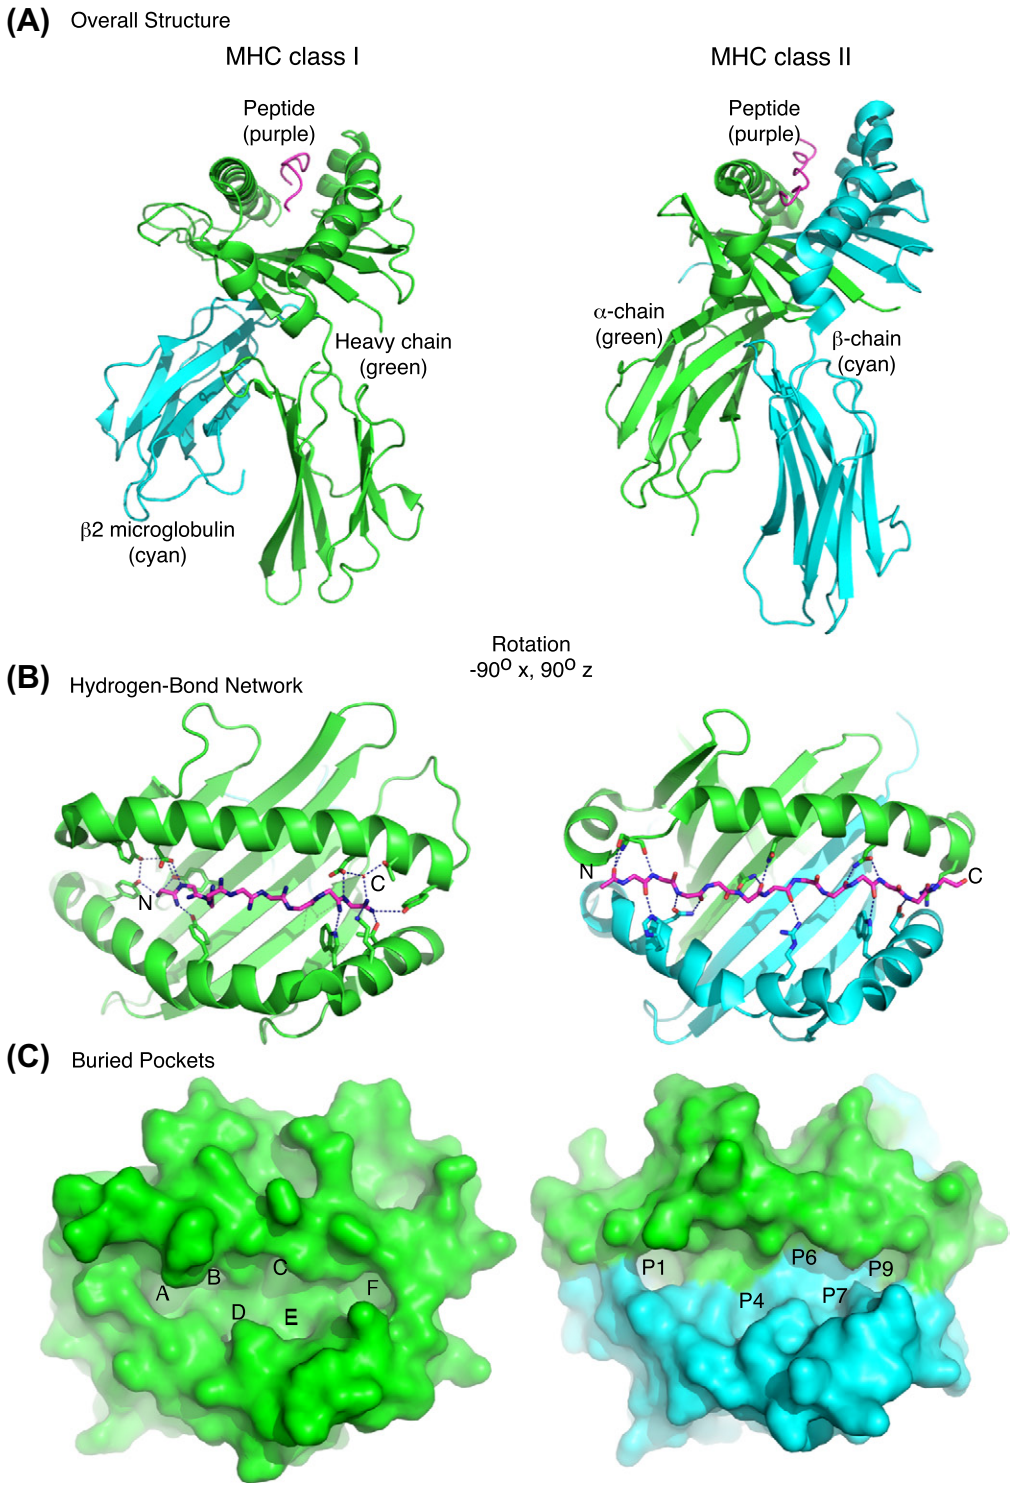

PLATE 23. (A) Side view of MHC-class I (left) and MHC-class II (right) showing the peptide-binding site at the top and the membrane proximal immunoglobulin domains at the bottom. (B) Looking down on the peptide-binding site, which is formed by α-helices that flank the peptide and supported by an eight-strand β-sheet. Conserved hydrogen bonds that stabilize the peptide backbone are indicated as dashed lines in each structure. Note that in MHC-class II, the α- and β-chains together combine to form the groove, and peptide extends out of the peptide-binding site. The peptide N- and C-termini are indicated with N and C respectively. (C) The same view as (B), but in surface rendering with the peptide removed. The pockets that serve as anchor points for peptide side chains are labeled A–F for MHC-class I and P1–P9 for MHC-class II. PBD files 1S9Y and 1DLH were used to generate this figure. ***(Chapter 93, see page 689).***

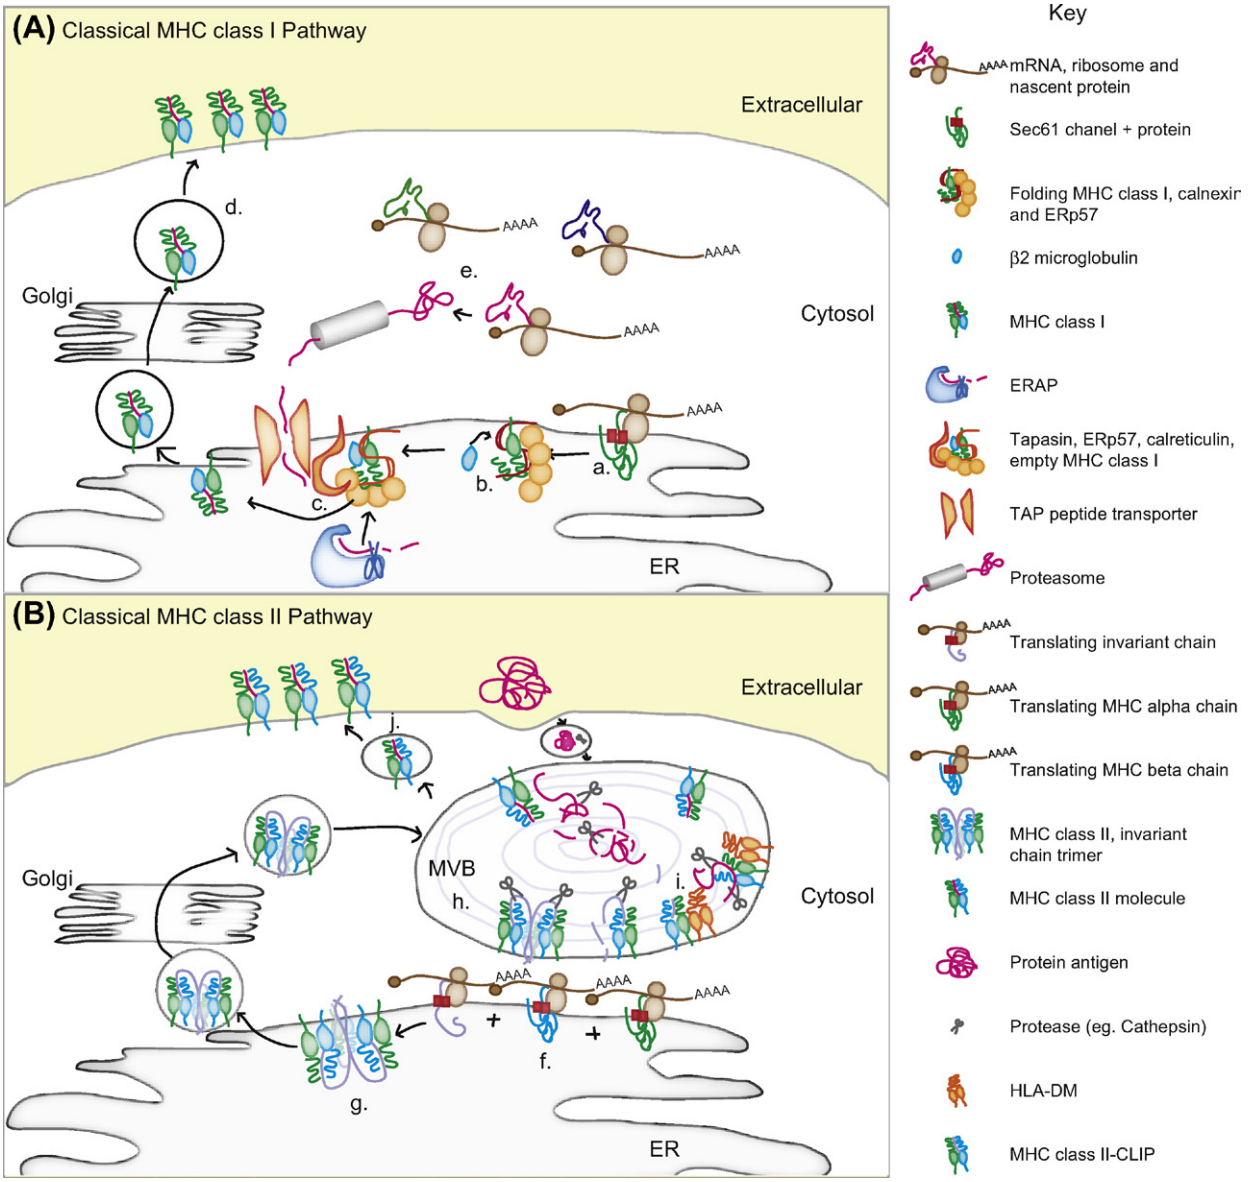

PLATE 24. (A) MHC-class I heavy chains are synthesized in the ER (a) and then partially folded with assistance from calnexin and ERp57 (b). After β2 microglobulin joins the MHC-class I heavy chain the heterodimer is incorporated into the peptide-loading complex and loaded with peptides transported from the cytoplasm to the ER lumen by TAP and trimmed to the correct size by ERAP family proteases (c). Peptide-loaded MHC-class I is then transported via the Golgi to the cell surface (d). Proteasomes cleave proteins in to peptides, which can be selected by TAP for transport into the ER (e). (B) MHC-class II chains and invariant chain are synthesized in the ER (f) and fold together into a nonameric complex with 3 invariant chains, and 3 MHC-class II molecules (g). A region of the invariant chain (CLIP) occupies the peptide-binding groove of MHC-class II. This complex is exported via the Golgi to multivesicular bodies in the endocytic compartment (h). Proteolytic cleavage of invariant chain occurs to release MHC-class II molecules and allow HLA-DM mediated release of CLIP and replacement with peptides from endocytozed proteins (i). MHC-class II molecules are transported to the cell surface for display to $CD4^+$ T-cells (j). ***(Chapter 93, see page 690).***

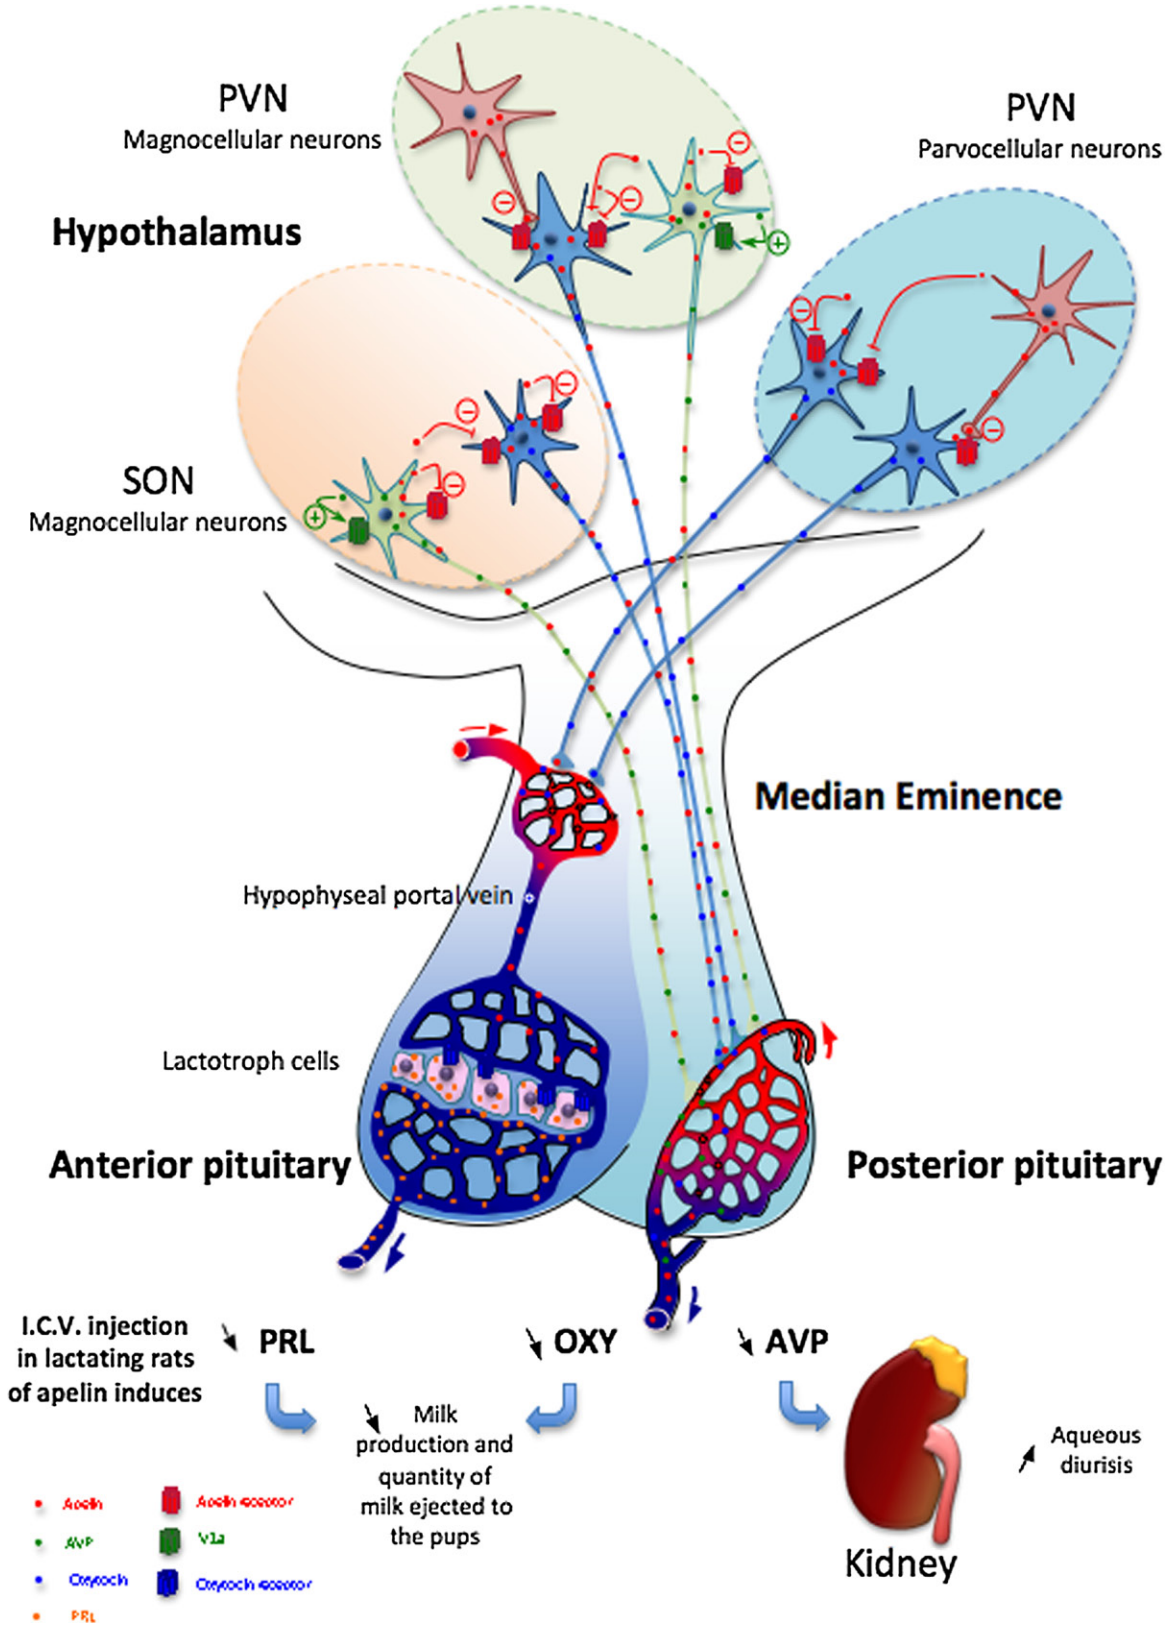

PLATE 25. Putative schema of apelin of the interactions with AVP and oxytocin. In lactating rats, apelin and its receptor are colocalized with AVP and oxytocin in the SON and PVN magnocellular neurons. Apelin and its receptor are also colocalized with oxytocin in parvocellular neurons. ICV administration of apelin inhibits the phasic electrical activity of AVP and oxytocin neurons. The decrease of AVP neuron activity results in a decrease of AVP secretion into the bloodstream and thereby the increase of aqueous diuresis at the kidney level. In contrast, the decrease of oxytocin neuron activity in magnocellular neurons and in parvocellular neurons would certainly decrease the secretion of oxytocin and PRL in the bloodstream in the anterior pituitary respectively. Adapted from De Mota et al.[7] and Bodineau et al.[2] ***(Chapter 96, see page 719).***

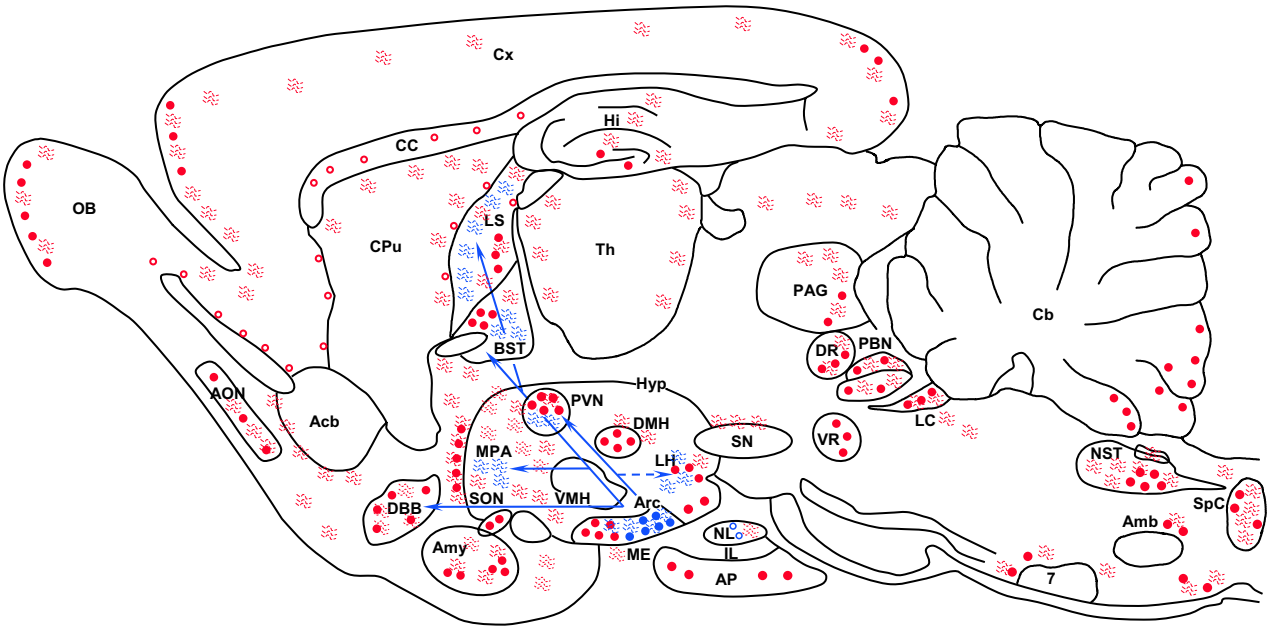

PLATE 26. Schematic illustration of the contrasting distribution of galanin and GALP positive neurons and their innervations in rat brain. Cells that express mRNA (and immunoreactivity) for galanin (black dots) and GALP (grey dots) are illustrated, along with the approximate localization of their immunoreactive nerve fibers/terminals (small black and grey lines). Non-neuronal GALP expression in astrocytes (pituicytes; grey circles) and galanin expression in oligodendrocyte and other progenitors (black circles) is also illustrated. The two major GALP pathways proposed from the arcuate nucleus to the paraventricular nucleus and to other hypothalamic and limbic regions are indicated by grey arrows. The relative topography of the many, widespread galanin pathways has been omitted for clarity. ***(Chapter 103, see page 767).***

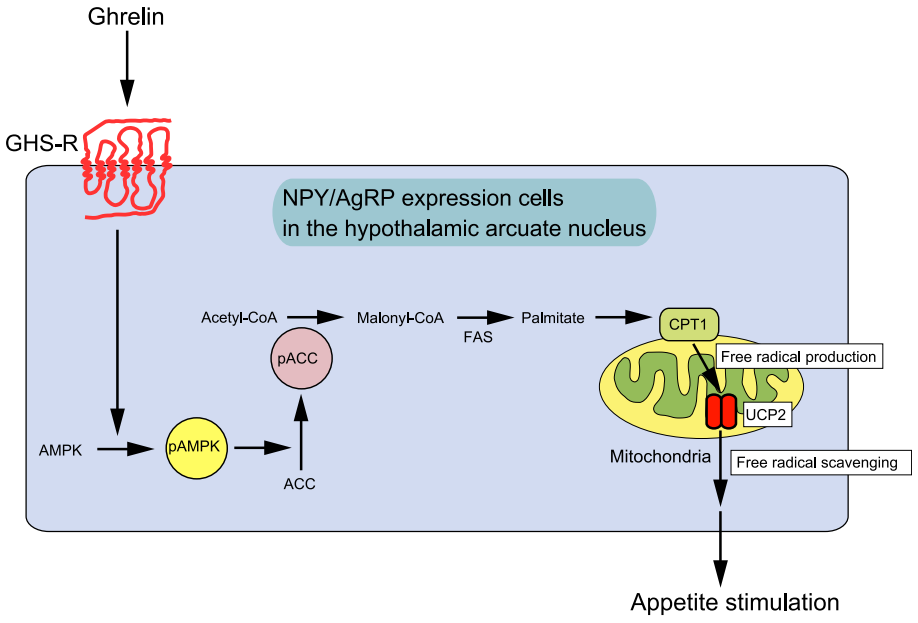

PLATE 27. Intracellular action of ghrelin in NPY/AgRP-expression cells in the hypothalamic arcuate nucleus. In NPY/AgRP-expression cells in the hypothalamic arcuate nucleus, ghrelin stimulates AMP-K and regulates fatty acid metabolism, leading to CPT1 activation. Ghrelin's effects on mitochondrial respiration are dependent on the function of UCP2 and hence result in an increase of food intake. ***(Chapter 104, see page 780).***

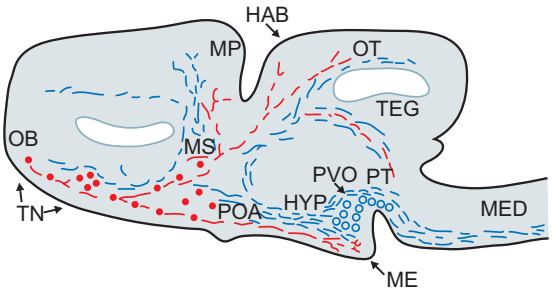

PLATE 28. GnRH-immunoreactive neuronal systems in an amphibian Taricha granulosa. Mammalian GnRH antiserum labeled cell bodies (red circles) in the anterior forebrain, including terminal nerve, medial septum, and anterior preoptic area, and a restricted set of projections to the medial pallium, habenula, and median eminence (red lines). GnRH II antiserum-labeled cell bodies (blue circles) in the paraventricular organ and posterior tubercle and a diffuse system of fibers to most brain area (blue lines). Abbreviations: HAB, habenula; HYP, hypothalamus; ME, median eminence; MED, medulla; MP, medial pallium; MS, medial septum; OB, olfactory bulb; OT, optic tectum; POA, preoptic area; PT, posterior tubercle; PVO, paraventricular organ; TEG, midbrain tegmentum; TN, terminal nerve. Adapted from Muske.[17] ***(Chapter 106, see page 795).***

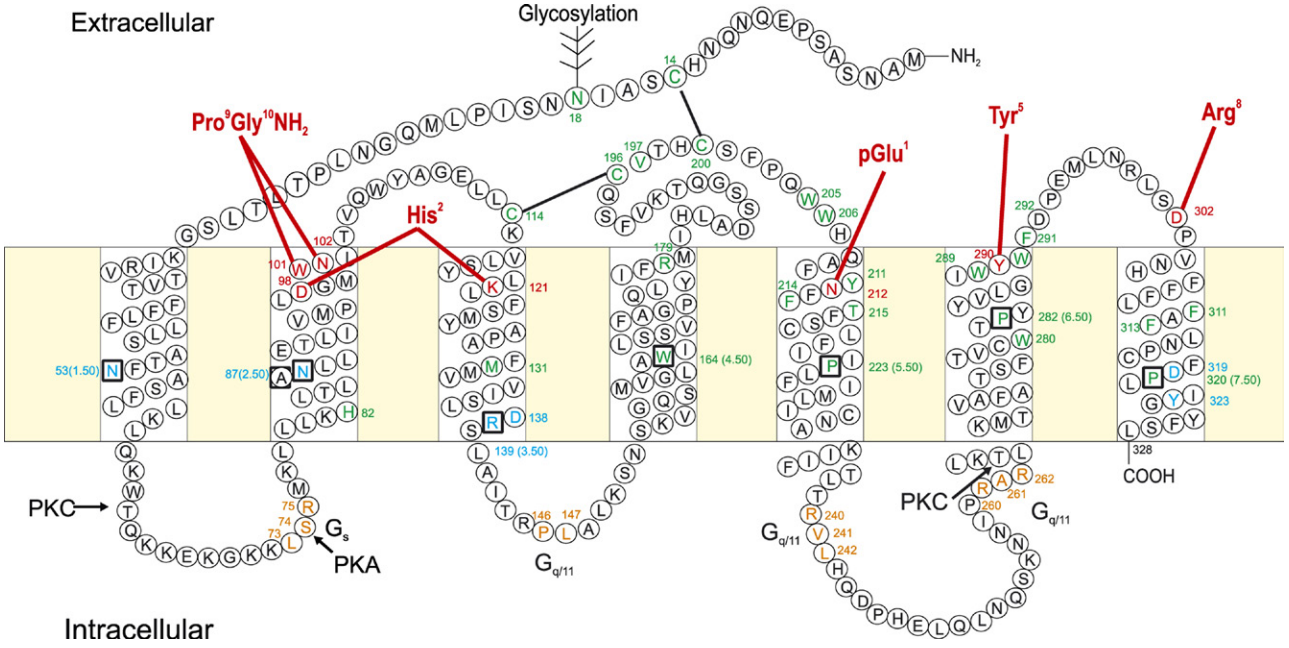

PLATE 29. Two-dimensional representation of the human GnRH receptor: the 7-(TM) α-helical domains (boxed) are connected by three extracellular loops (ECLs) and three intracellular loops (ICLs). Residues in squares are ones that are highly conserved throughout the rhodopsin family of GPCRs. Ligand-binding residues (red) and residues believed to be important in receptor structure or binding pocket configuration (green) are shown. These include residues involved in disulfide bond formation (black lines) and a glycosylation site. Residues involved in receptor activation are shown in blue. Residues involved in coupling to G proteins are shown in orange. Putative PKC and protein kinase A (PKA) phosphorylation sites are indicated. The intermolecular interactions between GnRH I residues and the receptor are indicated with red lines. Residues shown to alter selectivity for relative binding affinities of GnRH I and GnRH II are shown in bold circles. Figure modified from Ref. 12 with permission. ***(Chapter 106, see page 796).***

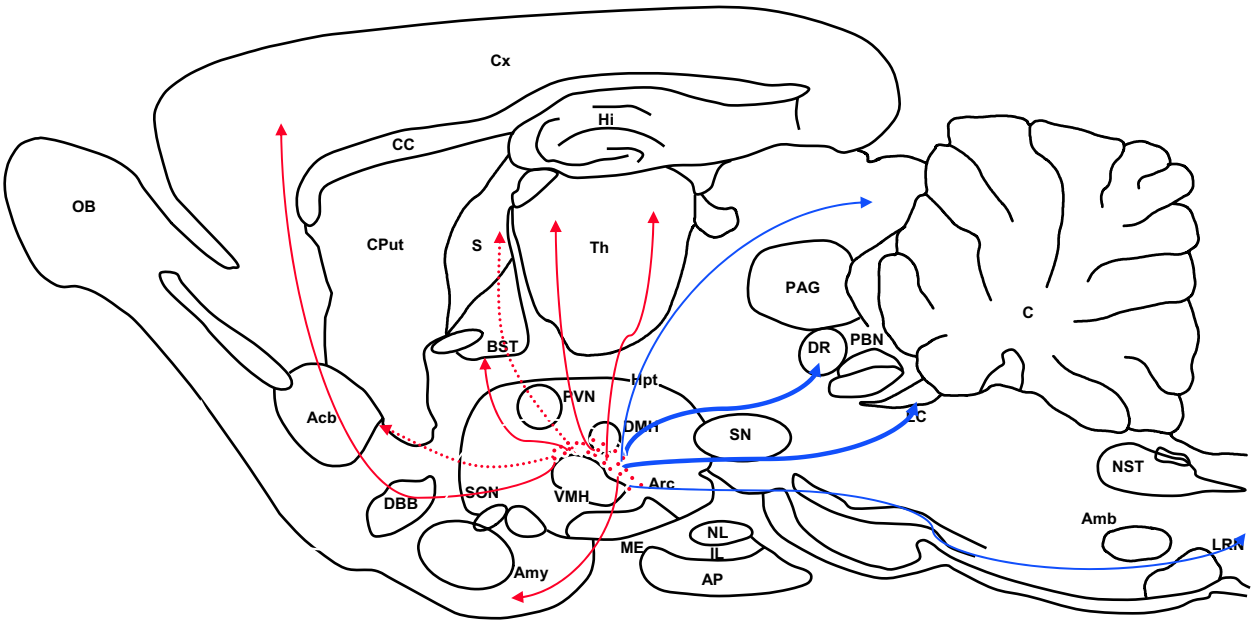

PLATE 30. Schematic of the distribution of Hcrt projections originating in the lateral hypothalamus. A very dense intrahypothalamic network of Hcrt fibers can be detected by immunohistochemistry in the DMH, VMH, Arc and PVN. Another set of fibers can be followed along the medial thalamus (Th). An ascending projection connects Hcrt with the ventral forebrain and amygdalar structures (Amy) and diffuse sparse innervation of neocortical areas (Cx). Descending efferent areas include the main monoaminergic nuclei such as the noradrenergic locus coeruleus (LC), serotonergic median and dorsal raphe (DR) and dopaminergic fibers passing through the ventral tegmental area. A direct monosynaptic connection to the spinal cord has also been described. DMH-dorsomedial hypothalamus; VMH- ventromedial hypothalamus; Arc- Arcuate nucleus; PVN- Paraventricular hypothalamic nucleus. ***(Chapter 108, see page 813).***

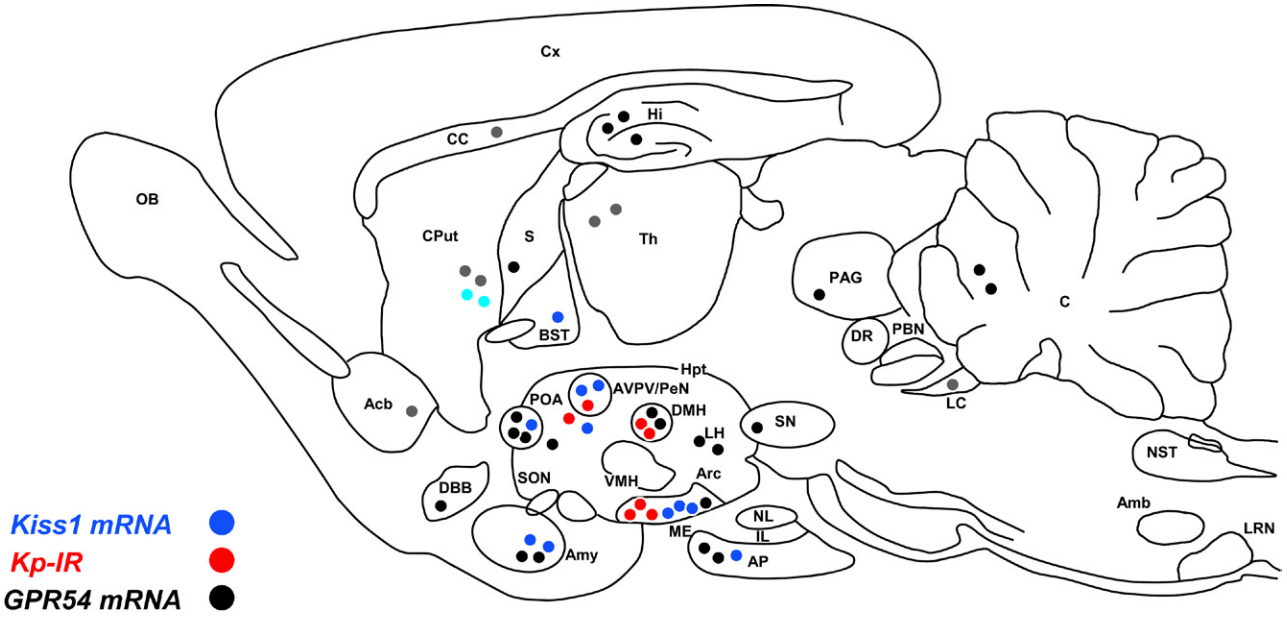

PLATE 31. Anatomical distribution of Kiss1 mRNA (blue dots), kisspeptin immunoreactivity –Kp-IR- (red dots) and GPR54 mRNA (black dots) in the different brain areas of rodent brain. In the mouse and rat, Kiss1 mRNA expression has been detected in the hypothalamus, mostly in the arcuate nucleus (Arc) as well as in the anteroventral periventricular area (AVPV) and the adjacent periventricular nucleus (PeN). In addition, the presence of Kiss1 mRNA has been reported in the preoptic area (POA), amygdala (Amy) and bed nucleus of stria terminalis (BST). In addition, the expression of KISS1 gene has been detected in the basal ganglia in humans (as detected by RT-PCR; denoted by light blue dots). In the rat brain, Kp-IR has been identified mainly in neurons in the Arc and the AVPV/PeN (the latter, especially in the female), with additional signals being detected in the dorsomedial hypothalamic nucleus (DMH), among other CNS areas. In addition, multiple Kp-IR fibers, originating from the Arc and AVPV/PeN populations and projecting to various hypothalamic and extrahypothalamic areas, have been mapped; yet, for the sake of simplicity, these are not specifically depicted in the scheme. Finally, in the rat, Gpr54 mRNA has been detected in different forebrain areas, including the diagonal band of Broca (DBB), septum, POA, anterior and lateral hypothalamus (LH), and DMH. Likewise, prominent expression of GPR54 has been observed in the hippocampus (Hpt), locus coeruleus (LC), Amy and periaqueductal gray (PAG), among others. The functional relevance of such expression sites remains to be elucidated, except for the POA, where the expression of GPR54 in GnRH neurons has been thoroughly documented. In addition, in the human brain, scattered expression of GPR54 mRNA has been reported, including basal ganglia –CPut-, Hpt, substantia nigra (SN-) and, at low levels, thalamus (Th-), cerebellum (C-) and corpus callosum. These are denoted by light gray dots. ***(Chapter 109, see page 821).***

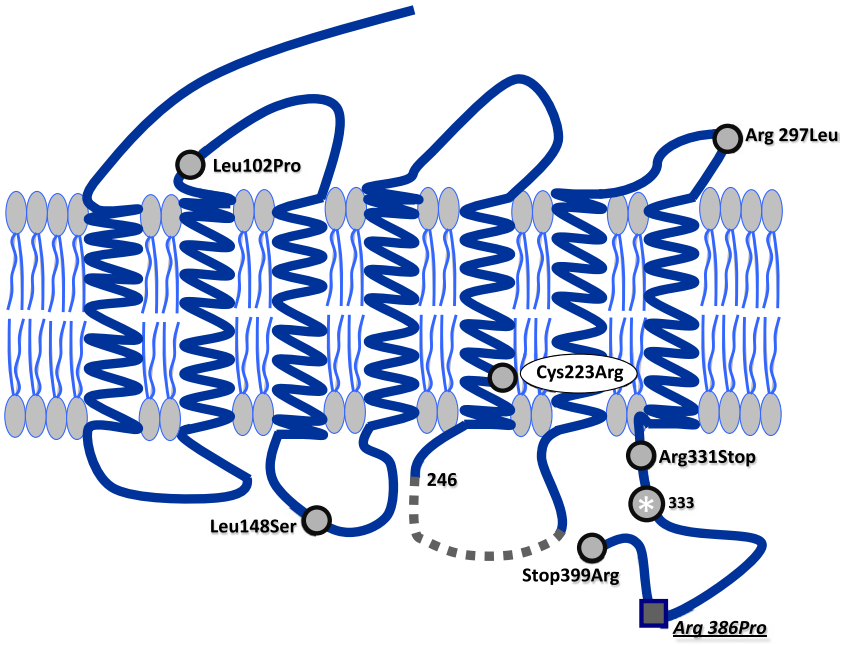

PLATE 32. Schematic representation of deletions and disease-causing mutations of GPR54 gene reported so far in humans. Inactivating mutations are indicated as black dots, with reference to the reported amino acid substitution. In addition, the location of the predicted deletion reported by de Roux et al. is marked as gray dots, while the position of the predicted insertion (1001_1002insC), which results in a shift of the open-reading frame is denoted by an asterisk. Finally, the only activating mutation of GPR54 described so far in humans, as potential cause for precocious puberty, is denoted as an open square. ***(Chapter 109, see page 825).***

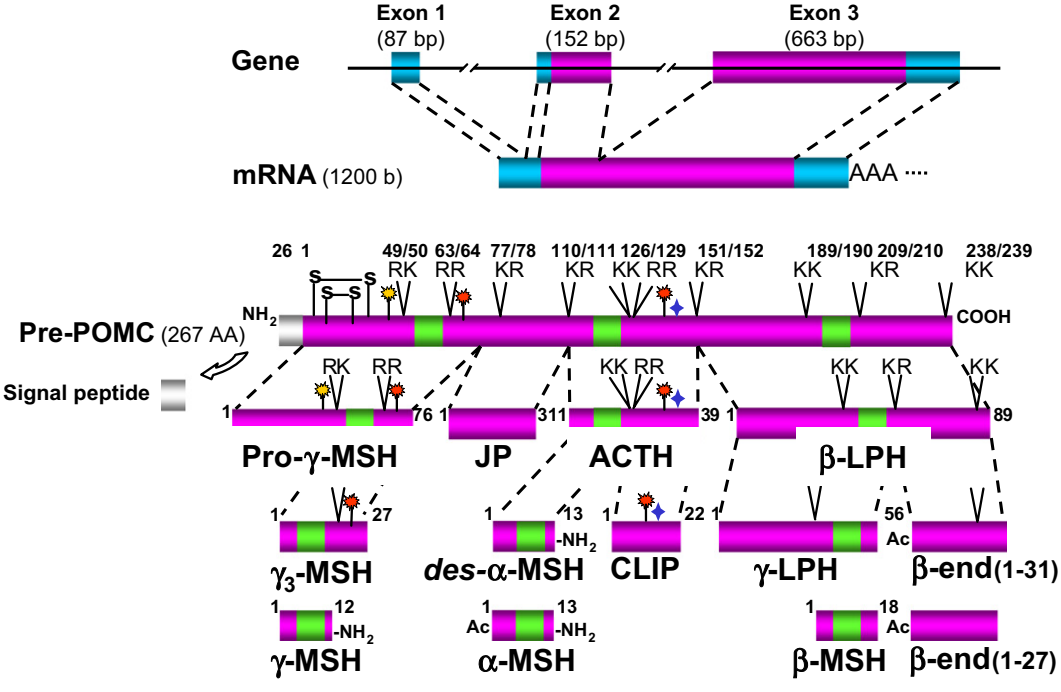

PLATE 33. Structural organization of the human POMC gene and processing of the precursor in neurons. : paired basic residue cleavage sites where processsing of POMC occurs to yield various peptide products. The numbers of the amino acid residues contributing to the cleavage site are indicated. K = Lys ; R = Arg, : MSH core sequence, : site of N-glycosylation, : site of O-glycosylation, : site of phosphorylation, CLIP : corticotropin-like intermediate lobe peptide, JP : joining peptide. ***(Chapter 111, see page 839).***

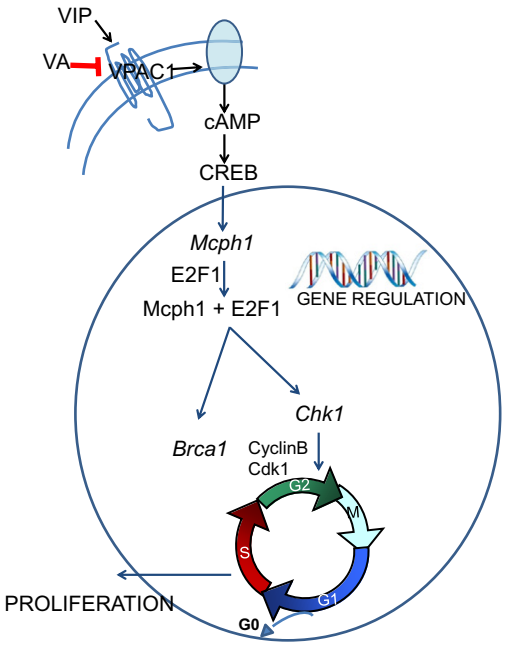

PLATE 36. Current hypothesis depicting how VIP can induce mouse neural stem cell progenitor proliferation through VPAC1–PKA–Mcph1–Chk1 signaling pathway. VIP proliferative effects are mediated by VPAC1 coupled to the cAMPc–PKA pathway, and this action is blocked by VA. PKA can phosphorylate CREB that potentially binds to one of the 3 cAMP-responsive element sequences on *Mcph1* gene. VIP blockade induces a decrease of *Mcph1* gene expression. *Mcph1* in turn regulates *Chk1* and *Brca1*, two key check points of the cell cycle, through its interaction with E2F1 on the promoter of both genes. VIP blockade then induces a decrease of neural stem cell proliferation through VPAC1–cAMP–PKA–Mcph1–Chk1 signaling pathway. ***(Chapter 128, see page 970).***

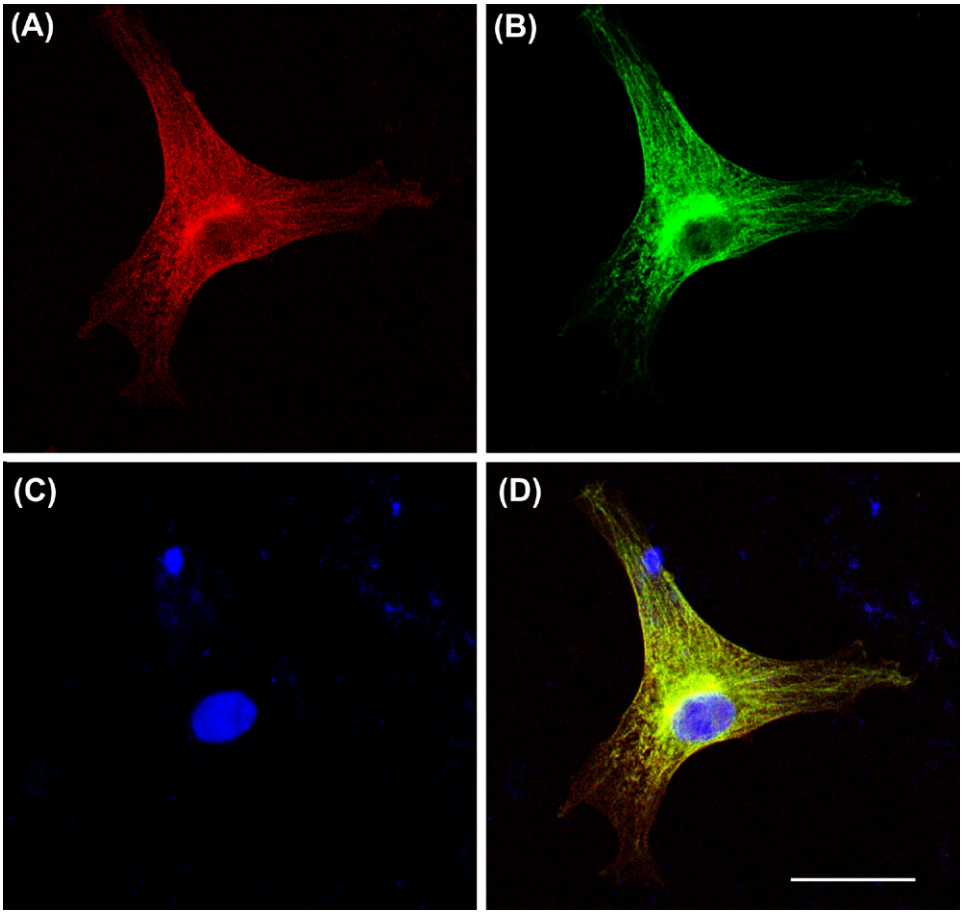

PLATE 37. Confocal images of Cos7 cells in culture stained for AM (A), tubulin (B), DAPI (C), and the combination of the 3 colors (D). Note that AM decorates all the microtubules of the cell. Bar = 20 μm. ***(Chapter 131, see page 991).***

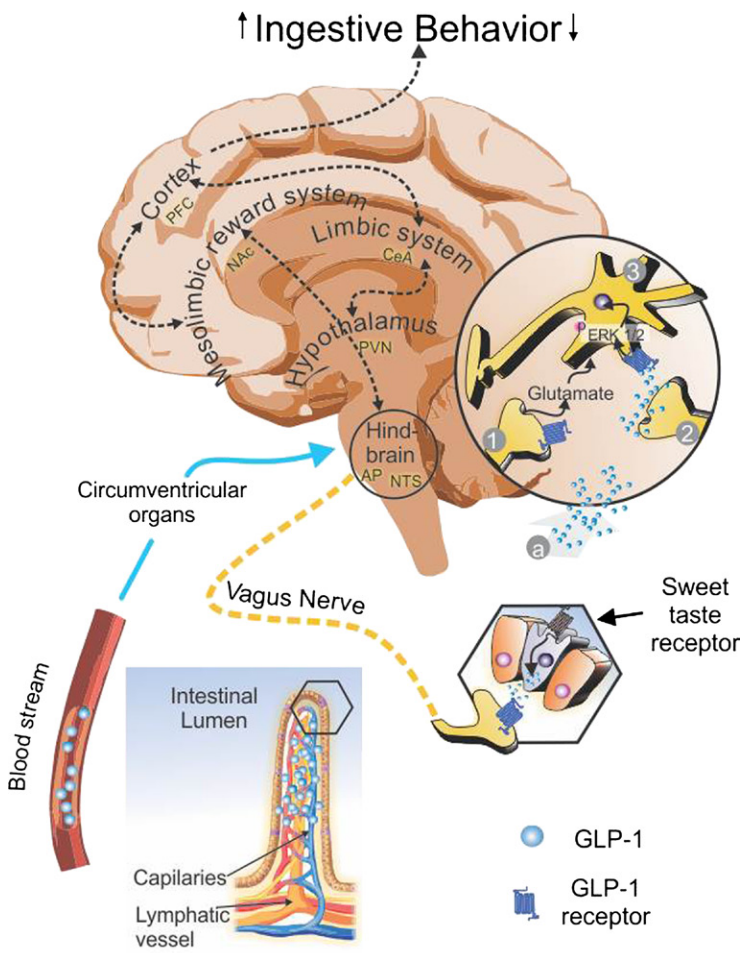

PLATE 41. Scheme of GLP-1 satiation intestinal luminal nutrients trigger GLP-1 release through taste receptor mechanisms present in enteroendocrine L-cells. GLP-1 can inhibit eating (1) through a paracrine action on GLP-1 receptors (GLP-1Rs) on intestinal vagal afferents that connect the gut to the nucleus tractus solitarii (NTS) in the hindbrain; and (2) through an endocrine action on the brain, provided that sufficient GLP-1 escapes inactivation by dipeptidyl peptidase-4 to act through circumventricular organs such as the area postrema (AP) and perhaps elsewhere. Although hindbrain processing of the GLP-1 signal seems to be sufficient to inhibit eating, rostral brain areas such as the hypothalamic paraventricular nucleus (PVN), the nucleus accumbens (NAc) and the central nucleus of the amygdala (CeA) may also be involved. See the text for further details. ***(Chapter 149, see page 1113).***

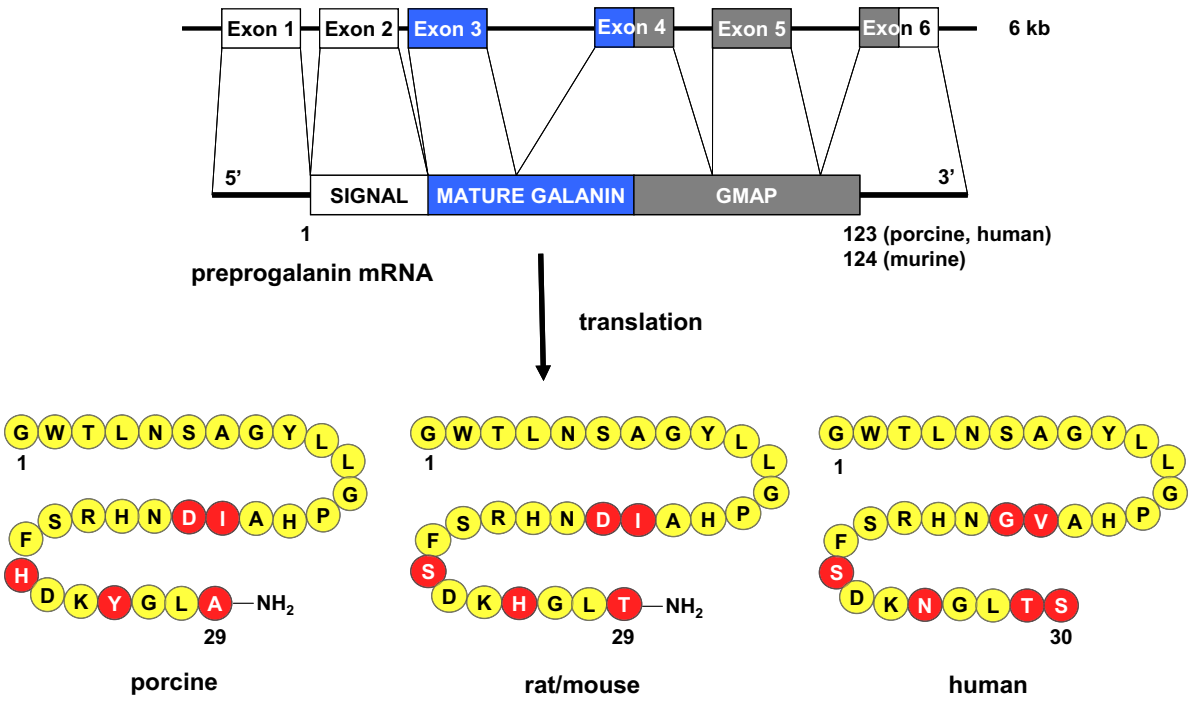

PLATE 44. Schematic diagrams showing the predicted transcription of galanin gene and the translation of preprogalanin mRNA to produce the mature peptide galanin in porcine, rat, mouse, and human. The first exon encodes the 5′-untranslated region of preprogalanin mRNA. Exon 2 starts with a translation initiation codon of the signal peptide and terminates before the proteolytic site preceding the mature galanin peptide. The first 13 amino acids of galanin are encoded by exon 3; the remaining 16 amino acids and most of galanin message associated peptide (GMAP) by exons 4 and 5. The remaining portion of GMAP and the polyadenylation site are located in exon 6. Note: 29 amino acids with C-terminal amidation in the pig, rat, and mouse, but 30 amino acids without C-terminal amidation in humans, and gray circles indicate residues that are different from human. ***(Chapter 164, see page 1211).***

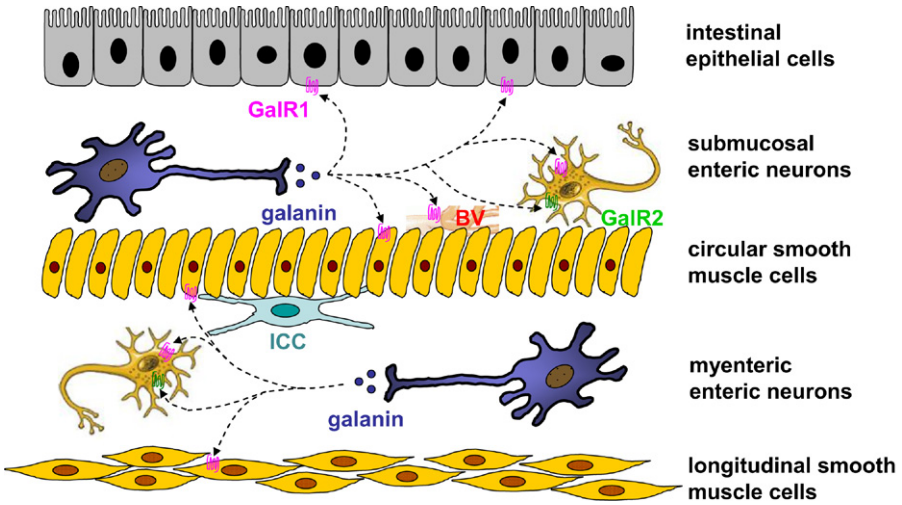

PLATE 45. Schematic diagrams showing the distributions of galanin-containing nerve cell bodies and nerve fibers, galanin receptors (GalR1, GalR2, not yet GalR3), and acting sites of galanin (indicated by dashed arrows) in the gut. PLATE 58. VIP corrects pulmonary vascular and RV pathology in monocrotaline (MCT)-induced PAH in rats: (A) H&E section of normal control lung, showing alveoli, bronchus, and small PA. No evidence of inflammation or vascular thickening. (B) Lung section 3 weeks after injection of MCT, showing vascular thickening and inflammatory cell infiltrates. (C) 3 weeks after VIP treatment, almost complete reversal of MCT-induced pathology. ***(Chapter 209, see page 1539).***

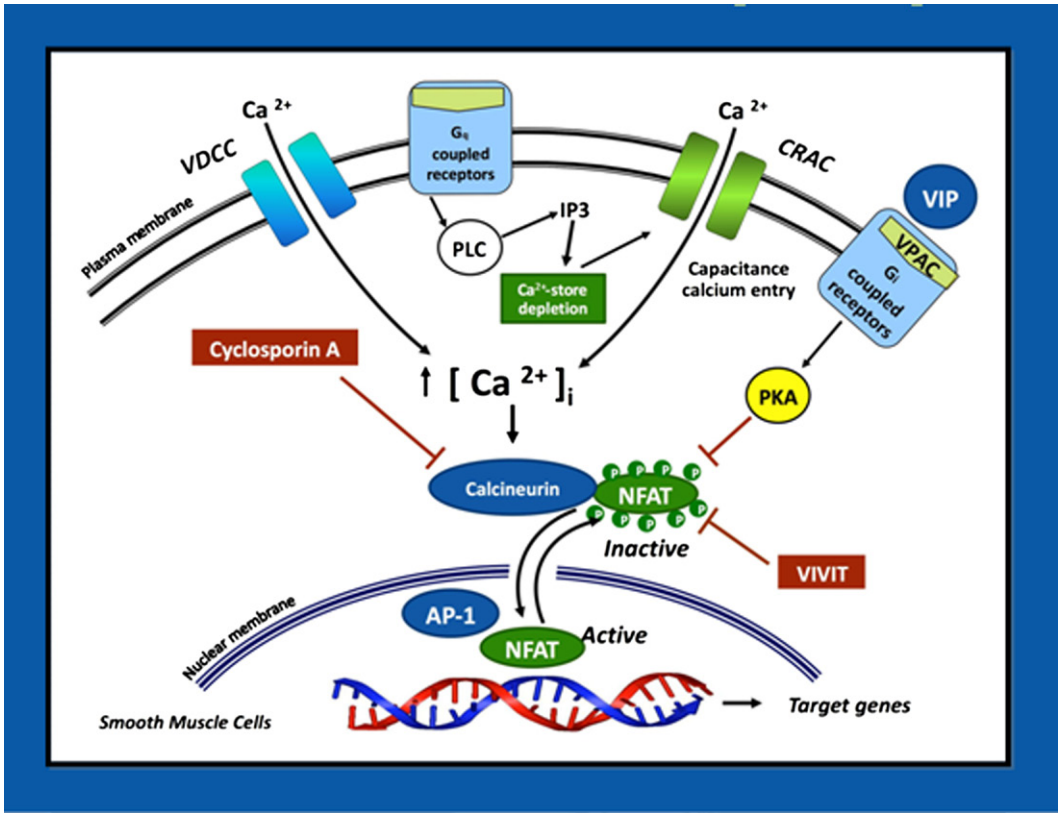

PLATE 59. Calcineurin–NFAT signaling and its inhibition by VIP. In resting cells, NFAT resides in the cytoplasm, where it is maintained in a phosphorylated, inactive state. Stimulation of cell-surface receptors coupled to phospholipase C (PLC) results in calcium mobilization, initially from intracellular stores, followed by influx of Ca^{2+} through specialized voltage-dependent Ca^{2+} channels (VDCC) and Ca^{2+} release-activated Ca^{2+} channels (CRAC). On activation by Ca^{2+}, the phosphatase calcineurin dephosphorylates NFAT, triggering its activation and nuclear translocation. In the nucleus, NFAT interacts with other transcription factors, including activator protein (AP)-1, to stimulate gene expression. When NFAT is rephosphorylated, it is exported back to the cytoplasm. The immunosuppressive drug cyclosporin A inhibits calcineurin interactions with all its substrates, whereas VIVIT selectively inhibits NFAT activation. VIP seems to inhibit this pathway, but its mechanism of action is yet to be determined. IP3: inositol-1,4,5-triphosphate. ***(Chapter 209, see page 1541).***

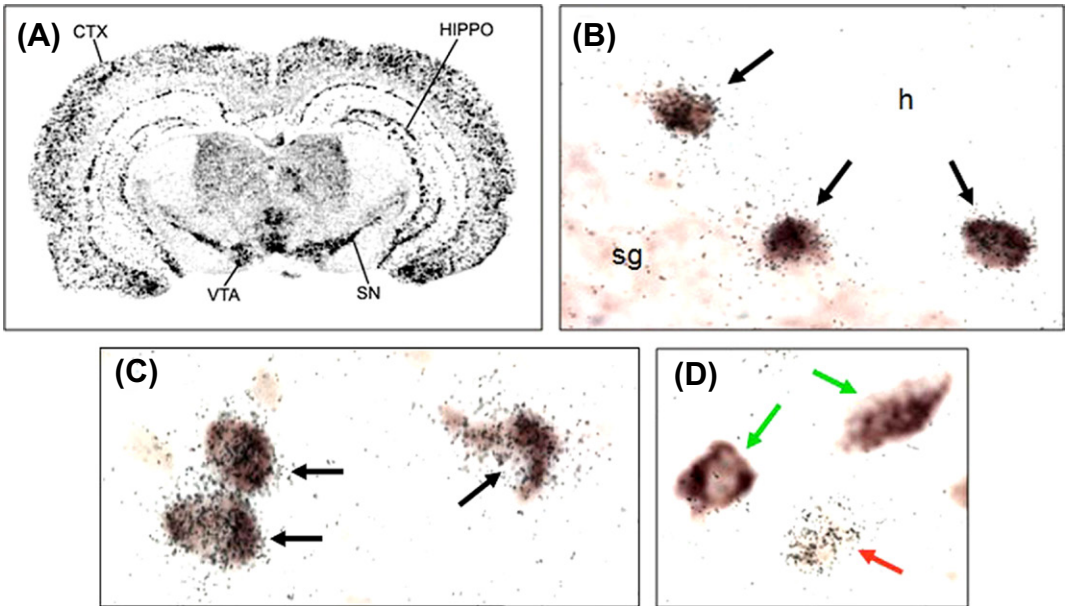

PLATE 60. (A) Distribution of ErbB4 mRNA-expressing neurons in rat cortex and midbrain as revealed by in situ hybridization. The vast majority of the scattered ErbB4 mRNA-labeled cells in the cerebral cortex (CTX) and hippocampal formation (HIPPO) represent GABAergic interneurons. In the substantia nigra (SN) and ventral tegmental area (VTA) of the midbrain, ErbB4 is expressed by virtually all of the dopaminergic mesotelencephalic neurons. (B,C) Double-labeling in situ hybridization demonstration of the extensive coexistence of ^{35}S-labeled ErbB4 mRNA and digoxygenin-labeled glutamic acid decarboxylase (GAD, the biosynthetic enzyme for GABA) mRNA in neurons of the rat hippocampal dentate gyrus (B) and primary motor cortex (C). Black arrows denote double-labeled cells. (D) Demonstration of the *non-coexistence* of ^{35}S-labeled ErbB4 mRNA (red arrow) and digoxygenin-labeled GAD mRNA (green arrows) in the rat substantia nigra. h, hilus; sg, stratum granulosum. ***(Chapter 223, see page 1635).***

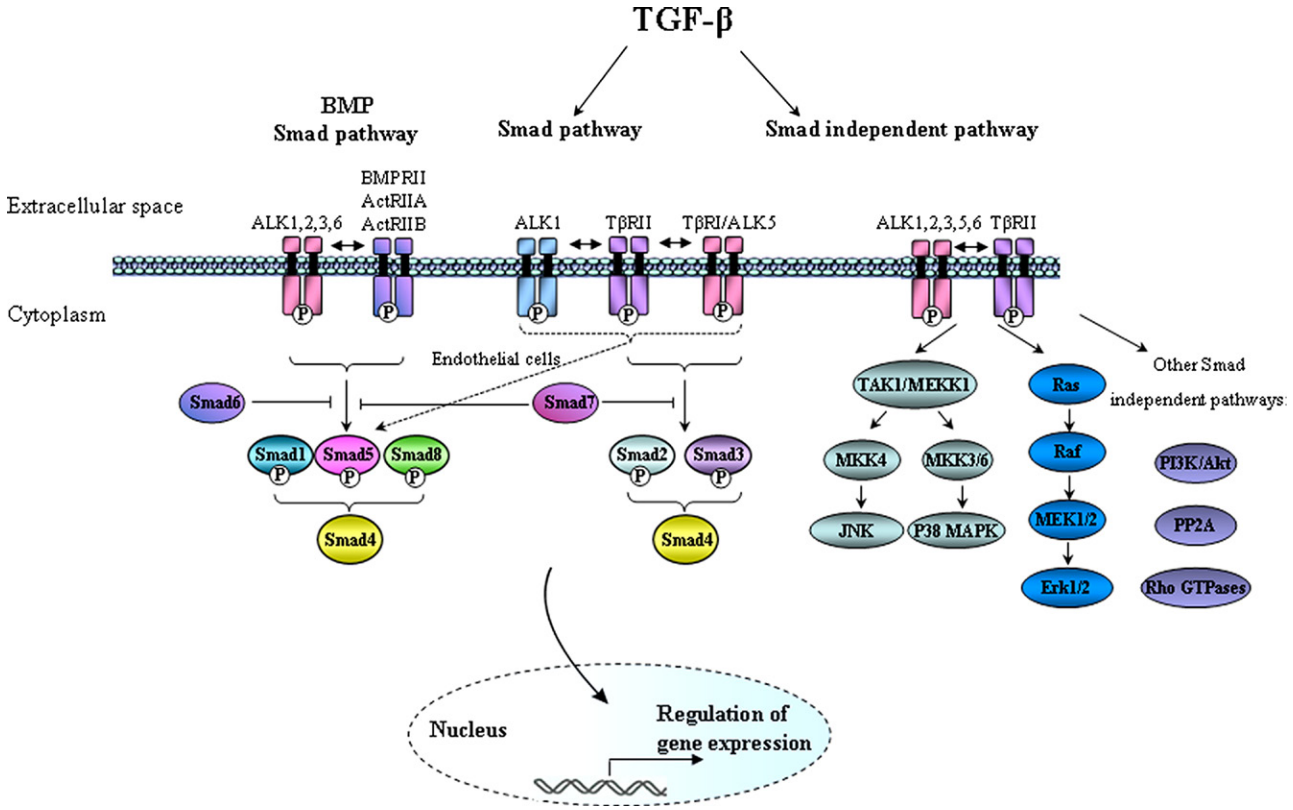

PLATE 61. TGF-β signaling through Smad-dependent and Smad-independent pathways. TGF-β binds a complex of transmembrane receptor serine/threonine kinases (TβRII and TβRI) and induces phosphorylation and activation TβRI by TβRII. In most cells, TGF-β interacts with TβRII and ALK5, but in endothelial cells, it can also signal via ALK1. BMPs signal via BMPRII, ActRIIA, and ActRIIB, and type I receptors ALK1, 2, 3, and 6. Activated type I receptors induce the phosphorylation of specific receptor regulated Smads (R-Smads: Smad1, 2, 3, 5, and 8). ALK5 induces phosphorylation of Smad2 and Smad3, and ALK1, 2, 3, and 6 mediate phosphorylation of Smad1, Smad5, and Smad8. Activated R-Smads form heteromeric complexes with common mediator Smad4, which accumulate in the nucleus, where they can act as transcription factor complexes and regulate the expression of specific target genes. Inhibitory Smads, such as Smad6 and Smad7, can antagonize TGF-β signaling by inhibiting the activation of R-Smads. TGF-β activated receptor complex (TβRI and TβRII) can activates Smad-independent signaling pathways, such as extracellular-signal regulated kinase (Erk), p38 mitogen-activated protein kinase (p38 MAPK), c-Jun N-terminal kinase (JNK), phosphatidylinositol-3-kinase (PI3 K/Akt), Src, and pathways involving Rho GTPases. ***(Chapter 225, see page 1648).***

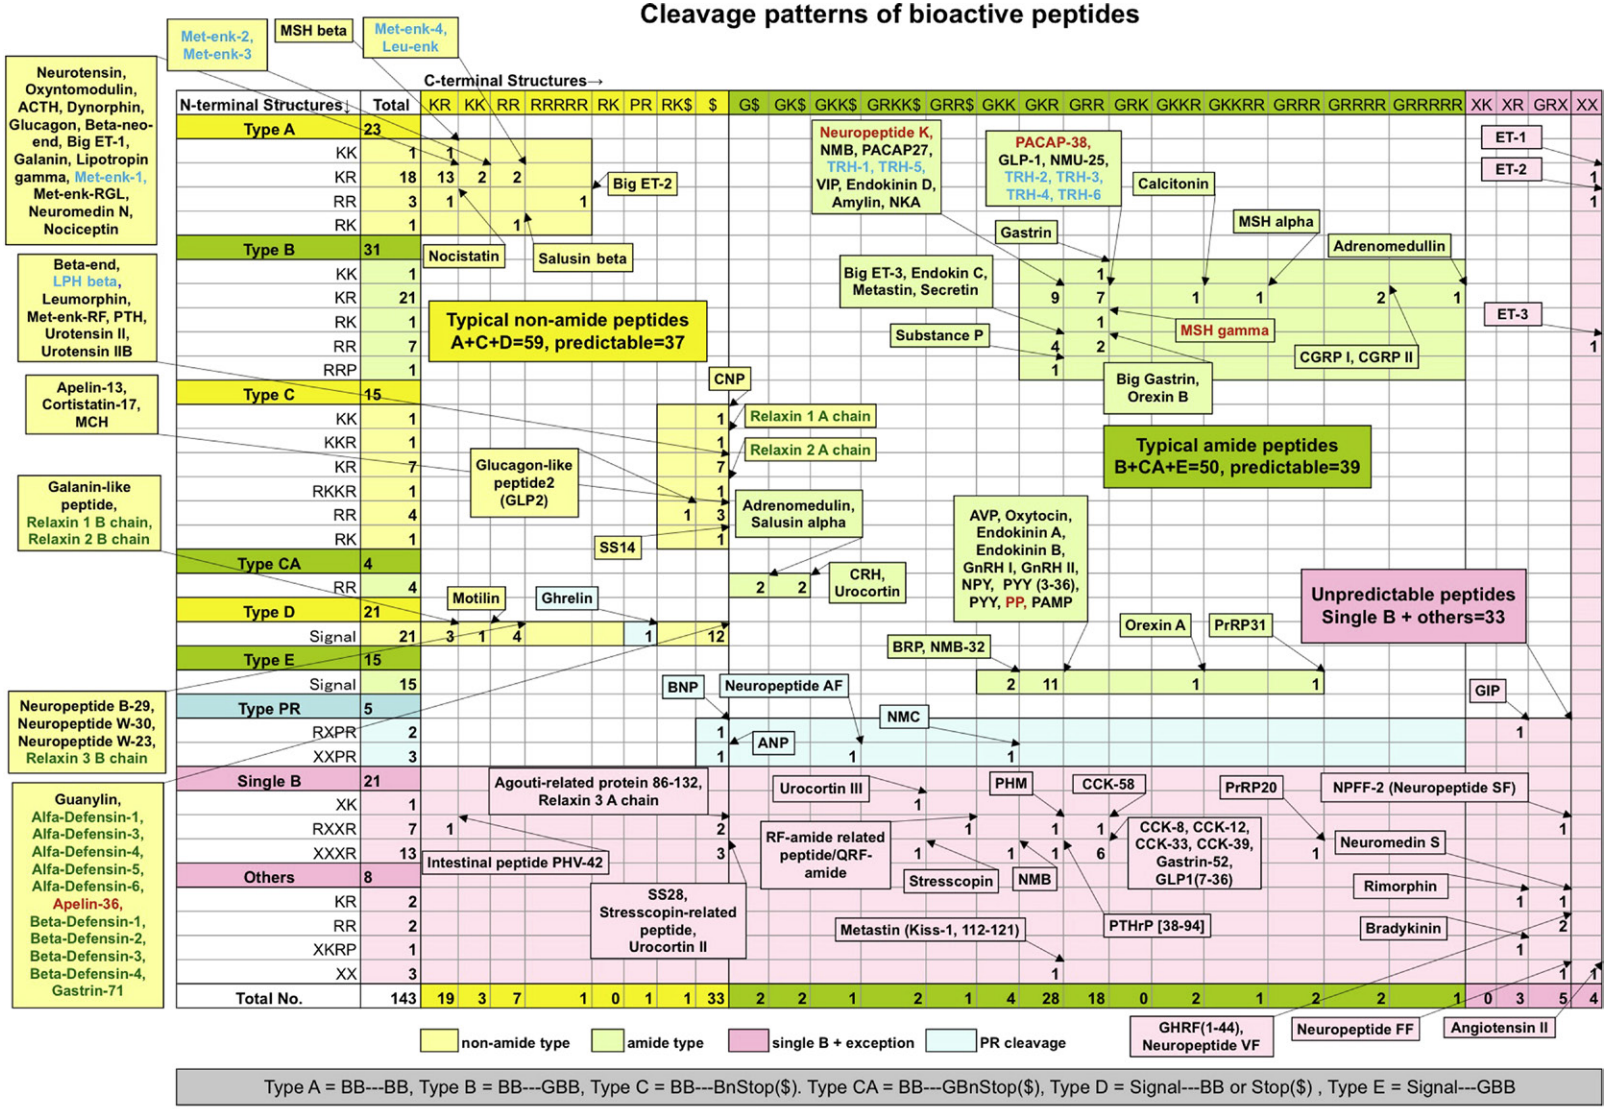
Cleavage patterns of bioactive peptides



Peptides written in red, blue, or green are difficult to predict, because those written in red contain KR and RR in the molecule, those written in blue are ≤5 or ≥61 amino acids in length, and those written in green contain more than 6 cysteine residues.

PLATE 62. Processing Patterns of Known Bioactive Peptides ***(Chapter 239, see page 1745).***

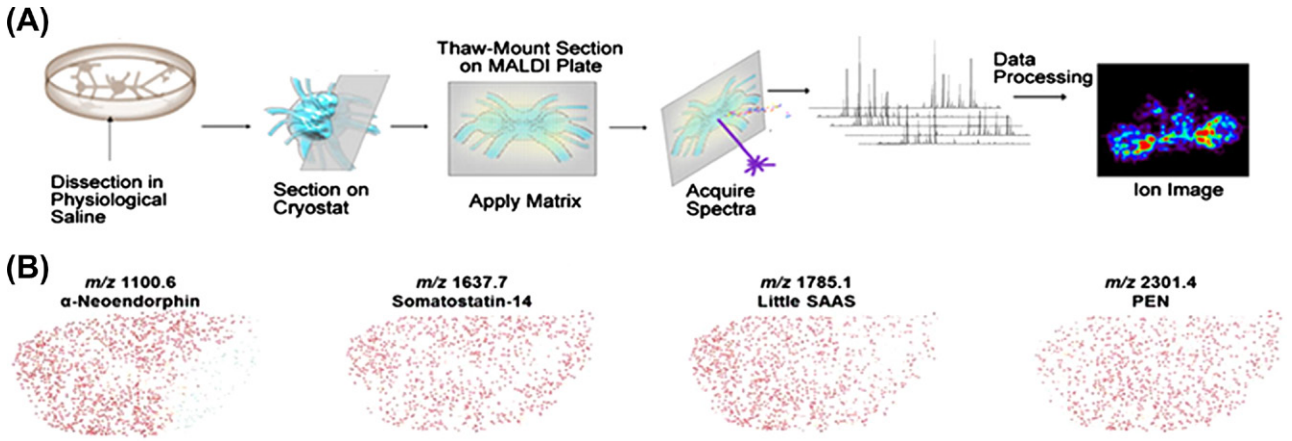

PLATE 63. Schematic of MS imaging protocols with representative ion images. (A) Typical procedures for MSI. Figure adapted and modified from Ref. 9 with permission. (B) Molecular distribution maps of four endogenous peptides detected in spinal cord using the stretched sampling approach and MS imaging. Figure adapted and modified from Ref. 34. ***(Chapter 240, see page 1752).***

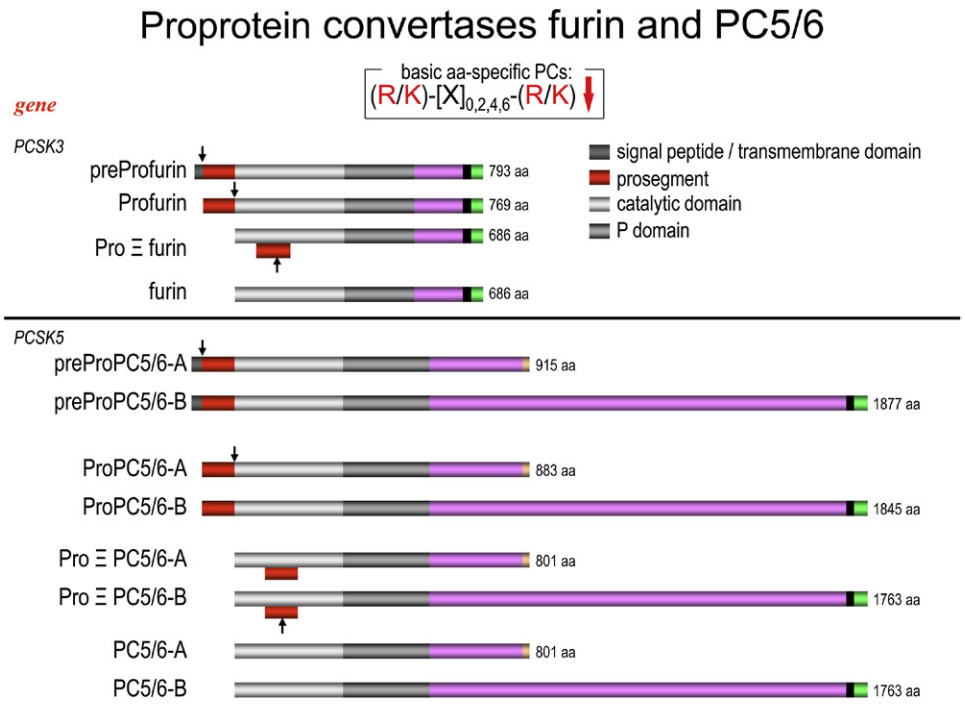

PLATE 64. Schematic representation of the processing of preProfurin and preProPC5/6. The number of aas in each form is emphasized, as well as the gene symbol, and the different domains. The arrows point to sites of either signal peptidase cleavage or autocatalytic cleavages. ***(Chapter 247, see page 1804).***
